Title: Plastic changes of the early spinal cord in mice with the genetic absence of corticospinal tract

Authors: ***J. DUAN**, L. HUANG, Y. QU, L. ZHOU;
Guangdong-Hongkong-Macau Inst. of CNS Regeneration, Jinan Univ., Jinan Univ., Guangdong, China

Abstract: Spinal cord maturation is followed with the corticospinal inputs. In order to understand how much the early events in the spinal cord are influenced by the arrival of corticopsinal axons, we studied the monosynaptic elimination, the expression of activity-related genes, neurotrophins and their receptors from postnatal day (P) 0 to 21, using Celsr3|Emx1 mice, in which corticospinal axons never reach the spinal cord. The corticospinal tract was specifically labeled by anti-PKCγ antibody in the dorsal funiculus, showing gradually increased from P0 to P21 in the control, but never visible in the mutant. Using anti-parvalbumin and ChAT double immunostaining, close contacts of proprioceptive fibers and spinal motoneurons appeared at P0 and were gradually eliminated thereafter, showing no difference between control and mutant mice. The number of parvalbumin-positive interneurons behaved an increased trend from P7 to P21 and an elevation of c-Jun protein was seen at P7, but there was no significant difference at each time-point between two groups. In control samples, CNTF protein was increased at P7 and gradually decreased after P14, which fluctuation from P0 to P14 was not found in mutant samples, and reached comparable levels at P14 and P21 between two groups. The expression patterns of NT3, truncated and full-length TrkC were similar in the control: increasing at P7 and decreasing after P14. In contrast, a significant increase of these neurotrophins was not found at P7 in the mutant. The similar fluctuation of BDNF, TrkB , GDNF and p75NTR proteins was present in two genotypes, such as BDNF increased at P7 and decreased at P14, the ratio of truncated to full-length TrkB increased after P14, GDNF increased at P14, and p75NTR gradually decreased after P7. In conclusion, the elimination of monosynaptic contacts and the changes of the expression of activity-related genes, neurotrophins and their receptors happen during the critical period, but these events are not highly dependent on the corticospinal inputs, except for the expression of CNTF, NT3 and TrkC.

Title: Incorporation of parvalbumin expressing neurons in the caudomedial nidopallium (NCM) of juvenile zebra finches is affected by song tutor availability

Authors: ***K. ASIK**, J. R. KIRN;
Biol. Dept., Wesleyan Univ., Middletown, CT

Abstract: The songbird telencephalon continually receives new neurons throughout life. Peak levels of new neuron incorporation in HVC (proper name) have been associated with a critical period for vocal learning (Nordeen & Nordeen, 1988.). A subsequent, age-related drop in the rate of new neuron incorporation is accompanied by song crystallization and the end of the critical period for song learning. The caudomedial nidopallium (NCM), analogous to mammalian auditory association cortex, is a crucial brain region for acquiring tutor song memory (Bolhuis & Gahr, 2006). Additionally, NCM contains a high number of inhibitory interneurons, including parvalbumin-expressing (PV) interneurons, which are known to be important for proper development of many critical period processes across several organisms (Pinaud et al., 2004, Phan et al., 2006, Hensch, 2005). The extents to which levels of NCM neuron addition relate to learning have not been explored. We injected male zebra finches with the cell birth marker Bromodeoxyuridine (BrdU) during song learning to quantify new NCM neurons including those expressing parvalbumin. We found a peak rate of incorporation of both new PV and new non-PV neurons around 40 days-post-hatch (dph) in normally raised males, which is consistent with the timeline of tutor song memory acquisition. For both types of new neurons, this peak was followed by a decline at around 60 dph and a further decline in adulthood. Another group of zebra finches was raised without tutors, a procedure that delays the normal end of the critical period (Eales, 1985). We found elevated levels of both PV and non-PV new neurons at around 60 dph, compared to normally raised birds. These findings suggest a relationship between levels of new neuron incorporation and the timing of song learning, a crucial process for mating success in male zebra finches.

Title: Odorant receptor expression is perturbed in mice following recovery from genetically-mediated lesion

Authors: *J. H. BRANN[1], X. ZHANG[2], E. F. SPINAZZI[3], C. FRANKLIN[1], P. LIS[1], N. KHARAS[3], C. ALTOMARE[3], S. J. FIRESTEIN[3];

Abstract: Several repositories of neural stem cells are resident in the nervous system. One population, residing in the olfactory epithelium (OE) lining the nasal cavity, generates excitatory projection neurons that extend a long axon from the neuroepithelium to the olfactory bulb. Each sensory neuron expresses a single odorant receptor (OR), a single gene choice out of ~1200 OR genes in mice, conferring an identity required for odorant detection and appropriate targeting of its axon to the olfactory bulb. Basal stem cells have been known for more than 30 years to generate sensory neurons in the young adult OE, but the ability of their counterparts in aged tissue to recapitulate the OE is relatively unexplored. In particular, aging may alter OR expression, implying receptor gene choice in newborn neurons may become restricted. Here we probe the ability of the stem cell to generate a diverse array of sensory neurons expressing the appropriate repertoire of odorant receptors in aged animals. To this end we generated a line of mice, iDTR+OMPCre/+, whereby a Cre-mediated excision of a STOP cassette renders mature neurons sensitive to diphtheria toxin (DT) via activation of the DT receptor. This method permits a specific and reversible ablation of mature (OMP-expressing) neurons upon DT administration but without damage to potential synaptic targets in the OB or to other cell types found in the OE. We administered either DT or saline to male mice of several age groups (2-18 months) for six days. RNAs were harvested 30 days following ablation, to allow for complete degeneration and subsequent recovery of the OE. Results reveal that age does not affect the cohort of OR genes expressed following recovery from lesion in DT injected mice. In addition we observe that age does not affect OR expression in saline injected mice. However, the OR repertoire does significantly change following ablation and these effects are observed at all ages tested. These results provide evidence that the regenerative potential of the neuronal stem cell is not altered by age per se, as a wide array of sensory neurons are generated. However, lesion induced ablation of a large number of sensory neurons disrupts the typical OR expression patterns observed in intact mice.

Title: A novel postnatal population of cortical projection neurons characterized by the co-expression of Ctip2 and Satb2 in the mouse neocortex

Authors: ***M. C. STUDER**[1], K. HARB[1], E. MAGRINELLI[1], C. NICOLAS[1], N. LUKIANETS[1], G. SANDOZ[1], F. GRAMMONT[2], C. ALFANO[1];

Abstract: The mammalian neocortex is tangentially subdivided into several functional areas and radially organized into six neuronal layers showing prominent diversities in features and functions despite similarities in their laminar organization. Differences in the molecular identity, morphology and long-range connectivity of residing neurons allow neuronal diversity of the mature cortex. The specification and differentiation of long-distance neocortical projection neurons are first controlled by the expression of transcription factors, which become gradually restricted and mutually exclusive during development. However, little is known on the mechanisms by which area-specific projection neurons acquire their subtype identity and final connectivity after birth. In this study, we show that neurons co-expressing Ctip2 and Satb2, respectively involved in the early specification of subcerebral (SCPN) and callosal projection neurons (CPN), progressively increase in numbers between P0 and P21 in the mouse somatosensory cortex. This neuron population displays unique connectivity and morphology features, distinct molecular codes and electrophysiological properties. Since it is known that Satb2 inhibits the expression of Ctip2 during development, we also investigated the molecular mechanisms allowing their co-expression at postnatal stages and in different neocortical areas. Our study thus demonstrates that co-expression of mutually exclusive CPN- and SCPN-specific

determinants enhances heterogeneity of distinct neuronal subpopulations and thereby subsequent complexity of the postnatal mammalian neocortex.

Title: Differential effects on ventricular zone cell genesis following deafferentation or direct injury to the olfactory bulb in adult zebrafish

Authors: *D. M. TRIMPE, C. A. BYRD-JACOBS;
Western Michigan Univ., Kalamazoo, MI

Abstract: Stem cells in the telencephalic ventricular zone generate neural precursor cells for the olfactory bulb that are involved in maintenance and repair following injury. We have previously shown that the adult zebrafish olfactory bulb is able to regenerate following deafferentation and direct injury. Here, we examine the potential differential effects of injury type on cell genesis in the ventricular zone. The hypothesis of this study was that the ventricular zone will exhibit a similar injury response to various forms of damage in which cell genesis will increase in the ventricular zone ipsilateral to the injury site, with an incremental return of cell genesis to control levels following recovery. Temporary, partial deafferentation of the olfactory bulb was achieved by single or repeated intranasal irrigation with Triton X-100; complete, permanent deafferentation was accomplished with cautery ablation of the olfactory organ; and direct injury involved a stab wound to the bulb. The potential effects on cell proliferation were examined using intraperitoneal injection of bromodeoxyuridine (BrdU). A single application of Triton X-100 caused a significant bilateral increase in proliferating cells in deafferented fish. Three weeks of deafferentation with Triton X-100 significantly increased the number of anti-BrdU labeled profiles in the treated side, whereas the untreated side had returned to control levels. With 4 weeks of Triton X-100 deafferentation, both sides appeared to exhibit reduced cell genesis but were not significantly different from control levels. Similarly, ventricular zone proliferation following complete, permanent deafferentation exhibited a bilateral increase anti-BrdU staining intensity suggesting enhanced proliferation. Fish examined 4h following direct injury showed a significant increase in anti-BrdU labeled profiles on the treated side only, while at 24h post-lesion, anti-BrdU labeled profiles remained significantly increased on the treated side but were

significantly reduced on both sides compared to control fish. Ventricular zone response during recovery from temporary deafferentation was then examined at 1 week and 3 weeks following 3 weeks of Triton X-100 deafferentation. One week of recovery resulted in a significant bilateral decrease in anti-BrdU labeled profiles, while 3 weeks of recovery allowed both sides to return to control levels. Thus, contrary to our hypothesis, these findings suggest that cell genesis in the ventricular zone exhibits an injury-specific response where deafferentation results in bilateral changes and direct injury causes primarily ipsilateral effects in cell proliferation.

Title: Spatiotemporal dynamics of adult-born granule cell mossy fiber terminal development in aged hippocampus

Authors: K. D. MURRAY[1], X.-B. LIU[3], L. P. CAMERON[1], M. YOSHIHARA[1], *H.-J. CHENG[2];

Abstract: The constitutive generation of new neurons is now a well-established feature of the adult mammalian brain. A central question regarding adult neurogenesis is how new neurons integrate into existing circuitry particularly in aged brains where neurogenesis has been reported to significantly decline. To address this we combined a cellular morphometric analyses with serial immune-EM ultra-structural analysis in a conditional transgenic mouse line to measure the spatiotemporal dynamics of adult-born hippocampal mossy fiber (MF) synaptic development in young adult (3 months, 3M) and aged (18 month, 18M) brains. We used the Gli1CreER tamoxifen (TM) inducible reporter line to fate map newborn granule cells and their processes in young as well as aged brains. We found that while proliferation and survival of newborn neurons decreases with age in the short term (4 weeks (W) post TM), in the long term (16W post TM) no difference was observed between young adult and aged brains. This suggests robust long term integration in newborn neurons in aged brain. However, differences in spatiotemporal dynamics of newborn MF development were observed. In 3M hippocampus between 4W and 16W post TM the density of newly formed MF terminals decreased while the average size of their boutons increased. In contrast, in the 18M hippocampus MF bouton density steadily increased during development, while average bouton size decreased. EM analysis confirmed these developmental trajectories and revealed differences in the pattern of structural maturation in young adult and

aged brains. In particular, in young adult hippocampus newborn MF boutons initially form nascent synaptic contacts that mature from 4W to 16W post TM while in aged hippocampus newborn MF boutons were fully mature from the first times examined (4W post TM). We also observed a significant amount of terminal "sharing" between newborn MF terminals and pre-existing terminals in young adult brain during the entire developmental period examined (4-16W post TM), but could only observed similar sharing at young developmental times (4W post TM) in aged hippocampus. Together these data suggest that the mechanism by which newborn hippocampal GCs integrate their axons into mature circuits is fundamentally different in young adult brains and aged hippocampi. In young adult brains new MF terminals are added which compete with pre-existing terminals for target space in mature circuits while in aged brain they replace existing circuits. Therefore the cognitive impact of adult neurogenesis could be profoundly different in young adult versus aged brain.

Title: Preferential targeting of lateral perforant path inputs to newly-generated dentate granule cells

Authors: N. I. WOODS, C. CHATZI, J. PEREDERIY, K. TOVAR, *G. L. WESTBROOK; Vollum Inst., Portland, OR

Abstract: Primary and associative sensory information converge in the entorhinal cortex before entering the hippocampus via the perforant path. Lateral and medial entorhinal neurons project axons to the dentate gyrus as discrete laminae, providing segregated functional and anatomic innervation of granule cell dendrites in the molecular layer. To examine the distribution of perforant path inputs onto adult-generated newborn granule cells, we selectively activated or silenced inputs from the entorhinal cortex. Following labeling of lateral or entorhinal cortex in young adult mice with AAV9-CAG- channelrhodopsin2-GFP, we optogenetically stimulated either lateral or medial entorhinal axons in brain slices, and verified laminar-specific activation

of mature dentate granule cells. We then labeled newly-generated granule cells with a retrovirus to determine the distribution of perforant path inputs onto newborn neurons. At 21 days post-injection, optogenetic stimulation revealed that excitatory inputs onto newborn neurons were almost exclusively associated with lateral perforant path axons that target dendrites in the outer molecular layer. Although the medial perforant path contributed only a minor component to the excitatory input to newborn neurons, chronic silencing of the medial perforant path with AAV9-expressing tetanus toxin, disrupted the development of excitatory inputs onto newborn neurons (but not mature dentate granule cells) as measured by EPSC amplitude and dendritic spine number. Our results indicate that newborn neurons are preferentially targeted by perforant path axons from the lateral entorhinal cortex, which carry associative (contextual) information - a distribution pattern consistent with a role for newborn neurons in pattern separation during memory formation.

Title: Combining Ki-67 and the thymidine analogue 5-chloro-2-deoxyuridine (CldU) to monitor cell proliferation in the dentate gyrus of the adult rat

Authors: *R. E. KALIL, M. L. HENDRICKSON, L. R. STIPPICH;
Univ. of Wisconsin-Madison, Madison, WI

Abstract: The protein Ki-67 is widely used as a marker of cell proliferation. Despite its frequent use, the *in-vivo* half-life of Ki-67 is still unknown, although most agree that it is probably brief. If the half-life of Ki-67 were known, Ki-67 could be used accurately as a marker for cell proliferation in studies of neurogenesis in the adult mammalian hippocampus to determine whether individual dividing cells continue to proliferate. To investigate the half-life of Ki-67 we analyzed cell proliferation in the subgranular zone (SGZ) of the dentate gyrus in adult male Sprague Dawley rats. In addition, in order to monitor the temporal distribution of proliferating cells, one injection of CldU (42.5 mg/kg) was administered and the animals then were permitted to survive for 30 minutes, 4 hours, 8 hours, 24 hours, 48 hours, 1 week, and 3 weeks before being deeply anesthetized and perfused with 4% paraformaldehyde in phosphate buffer. Following perfusion, brains were sectioned through the dentate gyrus at 40 μm and stained with

antibodies for Ki-67 and CldU. A rabbit monoclonal anti-Ki-67 primary antibody and a donkey anti-rabbit secondary antibody conjugated to the fluorophore Cy-2 were used to resolve cells expressing Ki-67. Similarly, a sheep polyclonal anti-BrdU primary antibody and a donkey anti-sheep secondary antibody conjugated to the fluorophore Cy-3 were used to resolve cells positive for CldU. DAPI was used to stain all cell nuclei in order to clearly delineate cells in the SGZ stained for Ki-67 and CldU. Cells expressing Ki-67 were regularly seen in clusters of 2 to 5 cells. Cells that had incorporated CldU were typically observed in groups of 2 to 3 cells at survival periods that ranged from 30 minutes to 48 hours and as isolated cells at 1 and 3 week intervals. At survival periods of 30 minutes, 4 hours, and 8 hours we observed a near-complete overlap of staining for CldU and Ki-67 in SGZ cells. At survival periods greater than 8 hours, the overlap in staining is still observed, albeit decreased, suggesting that the half-life of Ki-67 may be longer than results from *in vitro* experiments indicate.

Title: Adult peripheral nervous system stem cells: from their identification towards their role and fate in pathological conditions

Authors: *M. MANIGLIER[1], M. VIDAL[2], C. BACHELIN[2], C. DEBOUX[2], A. BARON VAN EVERCOOREN[2];
[1]ICM (institut Du Cerveau Et De La Moelle Epiniere, Paris, France; [2]ICM, INSERM U1127, UPMC Univ. Paris 06 UM 75, CNRS UMR 7225, Paris, France

Abstract: Neuropathic pain (NP) is a major public health problem caused by a primary lesion or dysfunction in the nervous system, with no effective therapy available. Since dorsal root ganglion (DRG) is considered as an active player in the development and maintenance of NP, elucidate DRG cellular pain partners is crucial to find new molecular targets. Prior to the conception of these new strategies, it is necessary to identify and characterize the different DRG cells to understand their involvement in pain. Recent publications suggested the presence of stem cells in the adult DRG. So far, these cells were not examined in NP studies due to the lack of tools to correctly identify and track them *in situ*. Using newly developed powerful transgenic mice combined with 5-ethynyl-2'-deoxyuridine incorporation assay, immunohistochemistry or

electron microscopy, we were able to identify different subset of cells with fast proliferating rate and one type of slowly proliferating stem cells. These adult DRG stem cells were purified to study specifically their properties *in vitro*. FACS sorted positive stem cells had a slower expansion rate, generated spheres over time with neurogenic and gliogenic potentials. Finally, using lineage tracing with an inducible mouse line to activate YFP expression in adult DRG stem cells and their progeny, we are able to investigate their fate and role in a DRG neurotoxic model. By combining multiple approaches, we succeeded to identify DRG stem cells, highlight their specific properties by comparing them to adult central nervous system stem cells and test their participation to DRG neurogenesis in pathophysiological conditions. This fundamental knowledge on adult PNS stem cells will open new avenues to therapeutic strategies in NP. Support by ARSEP and ELA.

Title: Effects of cholinergic manipulations on adult neurogenesis

Authors: ***S. L. OTTO**, J. L. YAKEL;
Neurobio. Lab. - Ion Channel Physiol. Group, NIEHS, Research Triangle Park, NC

Abstract: Adult neurogenesis is a life-long process whereby neural stem cells located in the subgranular zone of the dentate gyrus in both humans and rodents, as well as in the subventricular zone in rodents, divide, differentiate, mature and integrate in the local circuitry. While the signaling important in each of these stages is still poorly understood, it is known that local cholinergic signaling plays a role in the subventricular zone. The dentate gyrus receives cholinergic input from the basal forebrain, a potential source of signaling that may impact adult neurogenesis. Both metabotropic and ionotropic cholinergic receptors could contribute a counterbalanced set of signals to modulate neurogenesis. For example, α7 nicotinic acetylcholine receptors (nAChRs) are considered important in maturation of granular cells in the dentate gyrus and have been shown to be expressed on cells in the subgranular zone. α7 nAChRs are highly expressed in neonates and then see declining levels of expression until reaching adult levels at 3 weeks in mice. Though environmental factors as diverse as exercise and solitude have been shown to have an effect on adult neurogenesis, extant literature conflicts as to possible

cholinergic effects. Little is known of the possible mechanism(s) through which cholinergic signaling may act. To better understand adult neurogenesis in the dentate gyrus, we use a NestinCrERT2 mouse that permits the labeling of Nestin+ neural stem cells. Using this model we show that expression of Nestin+ neural stem cells in juvenile mice (p21-23) is unaffected by exposure to nicotine during gestation and nursing, however is significantly decreased by exposure to high levels of choline, which is known to bind to α7 nAChRs. On the other hand intermediate precursor cells are unaffected. By contrast in adults (8-10 weeks), exposure to the choline diet during gestation and nursing had no lasting effect, but chronic nicotine exposure significantly reduced levels of Nestin+ neural stem cells. In addition, a subset (approximately 50%) of all animals exposed to nicotine at any age showed an increased level of granular cells that were Nestin+, possibly indicating that nicotine exposure is increasing the rate at which stem cells mature. While preliminary, these studies show that the effects on neurogenesis of cholinergic signaling may vary with the age of the animal. Ongoing research is attempting to envision cholinergic signaling in organotypic culture, correlate changes in numbers of Nestin+ cells with neurogenesis, quantitate the effect of α7 nAChR knockout on adult neurogenesis, and study the Nestin+ granular cells seen after exposure to nicotine.

Title: Survival of adult born hippocampal neurons

Authors: P.-J. WU[1], H.-H. LIN[1], *G.-J. LAI[1,2];
[1]Natl. Chengchi Univ., Taipei City, Taiwan; [2]Res. center for mind,brain & learning, Natl. Chengchi Univ., Taipei, Taiwan

Abstract: The hippocampus is a brain region critical to learning and memory and is a frequent target of many neurological diseases such as Alzheimer's, other forms of dementia, and chronic stress that have dramatic cognitive consequences. The Subgranular zone (SGZ) of the hippocampus is one of the mammalian brain regions where new neurons are generated continuously throughout adult life. Previously, we have successfully promoted adult neurogenesis and demonstrated functional recovery after hippocampal granule cell degeneration in a rat model. We used adrenalectomy (ADX) to induce gradual hippocampal granule cell death in a rat model. This model leads to a gradual loss of neurons, a feature more in line with neural

degenerative diseases. Treatment of ADX animals with sonic hedgehog (shh) can promote a significant amount of short term granule cell regeneration. However animals housed in enriched environment were capable of maintaining the survival of new neurons for longer term. The ability of the dentate gyrus to produce adult born neurons in both ADX and sham animals were examined. The number of new born neurons in the DG area of ADX animals was comparable to those observed in sham animals. These results suggest that environmental enrichment is critical for the survival of new born neurons in this experimental paradigm. Animals kept in regular cages without environmental enrichment were capable of producing adult born neurons, but the new born neurons cannot survival for long term(months).

Title: Impact of muscular overexpression of PGC-1α on photothrombotic stroke in the mouse neocortex

Authors: *L. KARLSSON[1], N. GONZÁLEZ-ALVARADO[1], A. OSMAN[2], K. BLOMGREN[2], G. KUHN[1];
[1]Inst. for Neurosci. and Physiol., Univ. of Gothenburg, Gothenburg, Sweden; [2]Dept. of Women's and Children's Hlth., Karolinska Insitute, Stockholm, Sweden

Abstract: OBJECTIVE: To determine if overexpression of the exercise-induced transcription factor PGC-1α in skeletal muscle improves morphological stroke outcomes. METHODS: Male transgenic mice overexpressing PGC-1α under the muscle creatinine kinase (MCK) promoter were subjected to a photothrombotic stroke in the sensory-motor cortex area. Ischemic lesions were induced using Bengal rose and an infrared laser beam aimed at the exposed skull of 3-

month-old mice. Animals were perfused 4 weeks post-lesion for morphological analysis of lesion size, inflammatory response and neural progenitor migration. RESULTS: Muscular overexpression of PGC-1α resulted in increased infarct size (0.97 ± 0.07 mm3, n=5) compared to wild type controls (0.58 ± 0.10 mm3, n=7; t-test, p=0.017). No differences could be detected in the peri-lesional size, defined as an area with a distinct reduction in neuronal density. We measured the inflammatory response by quantifying microglial and astrocytic markers. Total and activated numbers of microglial cells (IBA1/CD68) within the peri-lesional area were similar for the transgenic and wild type groups. As a measure of reactive astrocytosis, the radial intensity profile of the astrocytic marker (GFAP) was quantified up to a distance of 1.6 mm from the infarct border. We were unable to detect any differences in the intensity profile between the two groups in neither stroke nor control conditions. Furthermore, no difference could be detected in the migration of neural progenitor cells (DCX) from the sub-ventricular zone to the lesioned neocortex. CONCLUSION: Contrary to our expectations, we found that overexpression of PGC-1α does not seem to have beneficial effects on morphological stroke outcomes in mice, but rather displays detrimental effects, resulting in increased infarct size. This suggests that muscular expression of PGC-1α has an impact on recovery and rescue of penumbral tissue through mechanisms that need to be analyzed in further studies.

Title: Effects of reduced adult neurogenesis on cognition and emotional behavior of mice and environmental strategies as possible rescue

Authors: *M. E. SAKALEM[1], T. SEIDENBECHER[3], R. SAFFARI[2], M. ZHANG[2], K. DIEDERICH[4], J. C. SCHWAMBORN[5], W. ZHANG[2], O. AMBRÉE[2];

Abstract: Although it is now accepted that newborn neural cells are continuously integrated into distinct areas of the adult mammalian brain throughout life (a process referred to as adult

neurogenesis), its functional role remains rather unclear. Much has been speculated and investigated; nevertheless there is controversy on how adult neurogenesis contributes to memory processes and emotional behavior. The aim of this study was to investigate the influence of adult newborn neural progenitors on anxiety-related behavior as well as recognition and emotional memory. For this purpose, dividing progenitor cells were depleted by ganciclovir treatment in GFAP-tk transgenic mice. After the pharmacological depletion, a two-week rest was presented prior to behavioral testing in order to allow the new differentiating neurons to be functional and start integrating into the neural circuitry. The behavioral tests used were Open Field, Object Recognition and Contextual Fear Conditioning. After testing, the brains were collected for immunohistochemistry. BrdU and Doublecortin stainings confirmed a clear reduction in the number of proliferating neural progenitor cells in transgenic mice in comparison with wild types, as well as in the number of immature neurons, respectively. With regard to the behavior, transgenic animals presented no deficit in general locomotion; also no anxiety-related changes were observed. Nevertheless, recognition memory was evidently impaired in the animals with reduced neurogenesis, in addition to an increased freezing response in the Fear Conditioning Test. In order to investigate a possible rescue effect on these transgenic mice, a combination of two neurogenesis-stimulant factors is currently carried out. For this study, after the pharmacological depletion, animals undergo a 3-week protocol with enriched environment combined with physical exercise in running wheels, for 1 hour a day. By manipulating the environment this way, it is expected that not only the remaining neural progenitor cells will be stimulated to proliferate, but their survival rate will also be supported. The results of this manipulation on recognition and emotional memory as well as adult neurogenesis will be presented.

Title: Extended intermittent access to palatable food decreases hippocampal neurogenesis and impairs hippocampal function

Authors: *A. FERRAGUD, C. VELÁZQUEZ-SÁNCHEZ, A. AL ABDULLATIF, V. SABINO, P. COTTONE;
Pharmacol. and Psychiatry, Boston Univ., Boston, MA

Abstract: Development of compulsive eating in eating disorders and obesity is promoted by cycles of access to and deprivation from highly palatable food, and resembles that of addiction to drugs. Epidemiological studies have shown that forms of compulsive eating in obesity and eating disorders are also accompanied by cognitive deficits, which have been proposed to result from a diet-induced reduction in hippocampal plasticity. Here, we studied the effects of intermittent access to palatable food on hippocampal neurogenesis, a pivotal mechanism of plasticity, and on hippocampal function. Male Wistar rats were either fed chow continuously for 7 days/week (Chow/Chow group), or fed chow intermittently 5 days/week, followed by a high-sucrose, palatable diet 2 days/week (Chow/Palatable group). Following diet cycling, hippocampal function was assessed either during acute withdrawal or following renewed access to palatable food. Our results show that animals withdrawn from palatable food displayed deficits in the ability to recognize a novel location of a familiar object, as well as a bias in their preference of a "novel cue" over a "novel place", compared to Chow/Chow animals. Furthermore, diet cycled rats showed reduced expression of immature neurons in the dentate gyrus of the hippocampus as well as a withdrawal-dependent decrease of proliferating cells. In summary, our results suggest that intermittent access to highly palatable food impairs hippocampal function and reduces hippocampal neurogenesis.

Title: Cytokine regulation of adult neurogenesis: The immune system provides neuronal precursors for adult neurogenesis

Authors: *B. S. BELTZ, E. COCKEY, J. LI, J. L. BENTON;
Neurosci. Program, Wellesley Col., Wellesley, MA

Abstract: Adult neurogenesis, the creation of new neurons in the adult brain, is an evolutionarily conserved process that occurs in both vertebrate and invertebrate species. In the crayfish Procambarus clarkii, the 1st-generation neuronal precursors are not self-renewing, however the pool of neuronal precursors in the niche is never depleted over the long lives of these animals. Thus, neuronal precursors in the crayfish must be added to the neurogenic niche from an extrinsic source. *In vitro* and *in vivo* findings have shown that hemocytes generated by the immune system are the likely neuronal precursors. In the current studies, three protocols are used to extend these findings and to further characterize the relationship between the immune system and adult neurogenesis in P. clarkii. Cells labeled with 5-bromo-2'-deoxyuridine (BrdU) were quantified in the neurogenic niche and immune system tissues (the anterior proliferation center [APC] and posterior hematopoietic tissue [HPT]) at standardized time points over a 21 day period. The dynamics within the immune system were then altered with recombinant astakine 1 (r-AST1), a cytokine in the prokineticin family that promotes the release of hemocytes into the circulation. The effects on precursors in the neurogenic niche were determined. The resulting data show that manipulating the immune system of P. clarkii with r-AST1 alters the timeline by which neuronal precursors arrive in the neurogenic niche, confirming that neuronal precursors in the crayfish are indeed derived from the innate immune system.

Title: Bipolar cell death precedes retinal ganglion neuron loss in a complex 1 deficiency mouse model

Authors: *L. SONG;
Univ. of California-Davis, Davis, CA

Abstract: Mitochondrial complex 1 deficiency is associated with a wide spectrum of neurodegenerative diseases such as Leber hereditary optic neuropathy and Parkinson's disease. The molecular basis of neuronal death mediated by defective complex 1 activity remains unclear. Ndufs4 is an important subunit of complex 1, and its loss causes complex 1 deficiency. Ndufs4-/- mice have acute vision loss between p20 and p30 days. Here we explore the retinal pathology occurring between p20 and p30 in the Ndufs4-/- mice. Our results showed that Ndufs4-/- retinas exhibited significant reduction in bipolar cells and postsynaptic density protein 95 accompanied

by retinal ganglion cell dendritic atrophy, but retinal ganglion cell counts were similar at this point between Ndufs4-/- and wildtype mice. Our previous published data indicated that there is loss of retinal ganglion cells in retinas of Ndufs4-/- mice at around p42 days. In addition, we found that apoptosis was significantly increased in optic nerve, inner and outer nuclear layer of Ndufs4 -/- mice at p20-21 days, and this result was confirmed by Western blot and QRT-PCR. Ndufs4-/- retinas also exhibited increased oxidative stress as manifested by increased 4HNE, HO1 and Cuzn-SOD at p20 days. Our results cast light onto the mechanism of retinal ganglion cell death induced by complex 1 deficiency and may have implications for the development of new therapies and early detection for blinding mitochondrial disease.

Title: Maturation of postural sway is not influenced by body mass index or gender

Authors: *C. FRENCHIK, S. M. SORIA, S. SCHULMAN, D. PICARDI, D. J. GOBLE, H. S. BAWEJA;
San Diego State Univ., San Diego, CA

Abstract: The purpose of this study was to determine the age by which children attain and exhibit adult like postural sway characteristics during quiet unperturbed standing. In addition, we examined whether development of postural sway control was influenced by gender and body mass index (BMI). 50 children between the ages of 7-12 years (19 females), 39 children between the ages of 13-17 (17 females) and 70 young adults between the ages of 18-24 years (30 females) volunteered to participate in the study. The Balance Tracking System (BTrackS, San Diego, CA) force plate was used to assess the postural sway during quiet standing for all trial. Testing consisted of 3 trials of quiet standing with eyes closed with feet shoulder width apart and hands on the hips. Each trial lasted 20 seconds during which the total center of pressure (COP) sway, COP antero-posterior sway, COP medio-lateral sway path-lengths were calculated. A principle component analysis was used to calculate the 95 and 99% confidence intervals of the area within which the COP would lie. Overall, Children from 7-12 years of age exhibited greater postural

sway when compared with 13-17 year olds and young adults. However, 13-17 year old children exhibited similar postural sway characteristics to those of young adults. There were no differences in postural sway between males and females irrespective of the age and BMI. As expected the BMI increased significantly with age, but only accounted for ~ 18% of the variability in total COP sway path-length. Our tests relied heavily on vestibular and proprioceptive integration as they were performed only with eyes-closed. Therefore, our findings are indicative of an inefficient multisensory integration in children up to the age of 12 years. Our findings support and extend previous findings suggesting that children do not exhibit adult-like sensory integration prior to the age of 12 years.

Title: Changes in ankle joint proprioception resulting from robotic training of ankle mobility rehabilitation in cerebral palsy children

Authors: *Y. LEE, D. XU, Y. REN, K. CHEN, D. GAEBLER-SPIRA, L.-Q. ZHANG; Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Cerebral palsy (CP) is the leading cause of childhood motor disability. Although brain lesions in CP are not progressive, children with CP continue to experience the motor difficulties caused by the secondary impairments, such as spasticity, muscle weakness, reduced selective motor control and sensory deficits. Furthermore, although sensory function plays an important role in functional activities, sensory deficit has not been well studied in the children with CP. The objectives of this study were to 1) investigate proprioception deficit at the ankle in CP; 2) improvement in proprioception through robotic ankle stretching and active movement training. Seven children with CP participated in the combined passive stretching and active movement training using an ankle rehabilitation robot. Eight healthy children were recruited for one-time assessment of ankle proprioception. Children with CP received robotic training 45 minutes/session, 3 sessions/week for a total of 18 sessions. Each session consisted of 10 min intelligent stretching followed by 20 min active movement training and ended with 10 min stretching. Proprioception was measured as the plantar or dorsi-flexion movement (at 0.5°/sec

controlled by the ankle rehabilitation robot) when the children felt the movement. The evaluation was done at two time points: pre-treatment and post-treatment. First, children with CP had impaired proprioception. Their ankle proprioception acuity was 3.90±2.40° (mean±SD) in dorsiflexion and from 3.96±2.46° in plantar flexion, as compared to that of the healthy controls' 0.94±0.43° in dorsiflexion ($p<0.01$) and 0.86±0.48° in plantar flexion ($p<0.01$). Furthermore, children with CP sometimes detected the movement in wrong direction. For children with CP gone through multiple sessions of the robot-guided therapy, the results showed an ankle sensory improvement after the robotic training. The proprioception angle threshold reduced from 3.90±2.40° to 3.28±2.15° in dorsiflexion ($p=0.01$) and from 3.96±2.46° to 2.72±2.05° in plantar flexion ($p=0.18$). Result suggests ankle proprioception deficit in CP. Furthermore, the use of robotic training for CP children reduced the ankle sensory deficit, suggesting sensory impairment in CP can be improved through controlled stretching and active movement training.

Title: Twitches drive neural activity in the deep cerebellar nuclei of sleeping newborn rats: Implications for sensorimotor development

Authors: ***A. M. PLUMEAU**[1,2], C. DEL RIO-BERMUDEZ[1], G. SOKOLOFF[1], M. BLUMBERG[1,2];
[1]Psychological and Brain Sci., [2]Interdisciplinary Grad. Program in Neurosci., Univ. of Iowa, Iowa City, IA

Abstract: Spontaneous muscle twitches during active sleep drive robust neural responses in the developing brain that are thought to be critical for the development of sensorimotor systems. The cerebellum is one structure that likely serves as a comparator of sensory and motor signals. In

rats, the cerebellar circuit undergoes extensive postnatal reorganization, with many transient synapses appearing and disappearing over the first few postnatal weeks. Recent work from our lab has shown that twitching drives activity in the cerebellar cortex during this period. However, little is known about twitch-related activity in the deep cerebellar nuclei, the primary output of the cerebellum. In this study, we recorded multiunit activity and local field potentials from the anterior interpositus and dentate nuclei of unanesthetized, headfixed 8- and 12-day-old rats as they cycled between sleep and wake. Forelimb, hindlimb, and nuchal EMGs were also recorded and an experimenter simultaneously scored behavior. The majority of neurons from both the interpositus and the dentate showed increased activity approximately 70 ms after twitches of the forelimb or hindlimb. Additionally, we observed rhythmic unit firing at both ages at a frequency of 8-10 Hz. Finally, at 12 days of age some cells exhibited a slow activity rhythm of 3-5 Hz that occurred during behavioral quiescence. Together with recent findings of twitch-related activity in other associated structures_including the red nucleus and inferior olive_these results provide further support for the hypothesis that twitching, as a substantial contributor to neural activity in the infant brain, promotes plasticity and somatotopy in the developing sensorimotor system.

Title: The inferior olive processes twitch-related information during active sleep in newborn rats: evidence of corollary discharge

Authors: *D. MUKHERJEE, G. SOKOLOFF, M. S. BLUMBERG;
Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: The inferior olivary nucleus (IO) plays an important role in modulating motor activity in mammalian species, including rats. Located within the brainstem, climbing fibers from the IO project to Purkinje cells in the cerebellar cortex where they trigger complex spikes. Various functions for IO activity have been proposed. For example, the IO is thought to provide teaching signals for the execution of skilled motor movements or error signals regarding inappropriately performed movements. The applicability of such notions to the early expression of IO activity is not known. We have shown that during the first two postnatal weeks in rats, active (or REM)

sleep-related twitches trigger complex spikes, suggesting a role for twitching in activity-dependent development of cerebellar Purkinje cells. Based on these findings, we hypothesized that the IO would exhibit twitch-related activity. To test this hypothesis, we recorded extracellular multiunit activity and local field potentials from the IO of head-fixed unanesthetized 8- and 12-day-old rats that were cycling normally between sleep and wake. IO neurons exhibited phasic activity that was particularly pronounced immediately after twitches of the nuchal and forelimb muscles. This twitch-related IO activity was remarkably precise and pronounced, reaching a peak in firing rate within 0-10 ms after a twitch. Moreover, some IO neurons exhibited rhythmic firing with a frequency of 8-10 Hz. Importantly, IO neurons exhibited little or no activity during wake movements or in response to exaffarent stimulation of the limbs. Also, local field potentials exhibited a prominent 2-Hz rhythm primarily during periods of quiescence, likely reflecting subthreshold oscillations of IO neurons as has been reported in adults. These findings confirm that twitch-related information is processed by the IO during early infancy. Moreover, the timing of IO activation suggests that this nucleus is receiving a motor copy or corollary discharge signal, perhaps from the red nucleus that is known to contribute to the production of twitches. Processing of this information by the IO during development could play an important role in motor learning and sensorimotor integration.

Title: Sensorimotor integration in the red nucleus of infant rats during active sleep

Authors: *C. DEL RIO BERMUDEZ, G. SOKOLOFF, M. BLUMBERG;
Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: Sensorimotor integration of self-generated movements and their associated sensory feedback (i.e., reafference) is necessary for the early development of somatotopic maps and coordinated motor skills. During infancy, self-generated movements are not restricted to periods of wakefulness. On the contrary, sensory feedback from myoclonic twitching during active (or REM) sleep is thought to drive activity-dependent development of the perinatal nervous system.

We hypothesized that the red nucleus (RN), source of the rubrospinal tract (RST), is not only a major source of motor output for twitching early in development, but also processes twitch-related reafference in a somatotopic fashion. We recorded extracellular neural activity in the RN during sleep and wakefulness in 8- and 12-day-old unanesthetized rats. Neuronal activity in the RN significantly increased before twitching of the contralateral forelimb, consistent with a role of the RN in the production of twitches. In fact, unilateral inactivation of the RN using a cocktail comprising GABAA, GABAB, and glycine receptor agonists markedly decreased twitching. In addition, a subpopulation of neurons exhibited significant increases in activity after twitches, suggesting reafferent sensory processing. Analysis of local field potentials and multiunit activity in the RN revealed distinct state-dependent and age-related patterns of activity. Overall firing rates increased substantially by the end of the second postnatal week as rhythmic activity patterns emerged. These developmental changes in firing properties of RN neurons suggest the emergence of new functional connections with other related structures, such as the deep cerebellar nuclei. We propose that twitches, which are characterized by discrete motor output and reafferent input, provide an opportunity for the activity-dependent development of sensorimotor integration and somatotopy within the newborn RN and associated neural networks.

Title: Mosaic regulation of placodal and neural crest-derived cranial sensory neurons establishes distinct developmental states during early neuronal differentiation and axon outgrowth

Authors: B. A. KARPINSKI[1,2], C. BRYAN[1,3], A. HORVATH[1,4], A. FERNANDEZ[1,3], J. L. BAKER[1,5], T. M. MAYNARD[1,3], S. A. MOODY[1,2], *A.-S. LA MANTIA[1,3];
[1]Inst. for Neurosci., [2]Dept. of Anat. & Regenerative Biol., [3]Dept. of Pharmacol. and Physiol., [4]McCormick Genomic and Proteomic Ctr., The George Washington Univ. Sch. of Med., Washington, DC; [5]Ctr. for the Advanced Study of Human Paleobiology, The George Washington Univ., Washington, DC

Abstract: We assessed transcriptional, signaling, and cellular mechanisms that regulate initial differentiation of placodal and neural crest-derived cranial sensory neurons. We asked whether quantitative expression of 21 transcription factors associated with these cells defined an anterior-posterior gradient of sensory neuron identity. With few exceptions we found that a mosaic of transcription factors, rather than consistent gradients, identifies cranial sensory neurons or precursors in the olfactory placode, trigeminal ganglion, geniculate/vestibular/acoustic ganglia, otic placode, and petrosal/nodose ganglia. There is a similar quantitative mosaic of cell lineages for placodal or neural crest-derived sensory neurons. Disrupting the activity of two signaling pathways, via Fgfs or RA, believed to be essential determinants of cranial A-P identity modified this transcriptional and cellular mosaic; however, these changes did not follow an A-P gradient. Instead, expression levels of key factors and proportions of distinct lineage cohorts are locally sensitive to diminished Fgf and RA signaling. The primary consequence of disrupting Fgf signaling was to shift proportions of placodal and neural crest-derived populations and in parallel arrest cranial sensory axon outgrowth. The primary consequence of disrupting RA signaling was to alter axon trajectories of cranial sensory neurons. In each instance, local changes of transcription factor expression accompanied locally distinct altered sensory axon growth. Together our data show that there is not a graded transcriptional code in the A-P axis for cranial sensory neuron differentiation. Instead, there is a transcriptional mosaic, locally modulated by morphogenetic signals, that parallels lineage contributions from cranial placodes and neural crest. This mosaic is associated with the developmental state of diverse cranial sensory neurons, likely insuring appropriate axon growth and targeting.

Abstract: We recently found that the area of the compound action potential (CAP) evoked in sensory sural nerves (SU n.) of adult male rats that were total maternal deprived and artificial reared (AR) was smaller than the CAP provoked in SU n. from mother reared (MR) and AR social rats (reared with two same-age foster pups). In order to determinate at what age such effects appears, during isolation, male pups rats of 4 postnatal days (PND) were reared artificially (AR group) until 14 or 21 PND. At such ages, the electrophysiological properties of the SU n. were recorded. As control groups, we recorded the CAP of SU n. from pups reared with their mother (MR group), or that were AR but received five bouts of perineal+body tactile stimulation a day (AR-Tactile group) with a paint brush. We found that the electrical threshold necessary to generate the CAP of SU n. from AR pups at 14, but not at 21PND, was significant higher than that determined for SU n. from MR pups ($p<0.05$, all comparisons). Furthermore, the amplitude and area of the maximal CAP response provoked in SU n. from AR pups with 14 and 21PND were significant shorter than that of SU n. from MR pups ($p<0.05$, all comparisons). The conduction velocity of the CAP was similar among groups. The replacement of the tactile stimuli during isolation prevented most of the effects, i.e., the CAP evoked in SU n. from AR-Tactile pups showed no significant differences with respect to that of MR nerves. These results suggest that AR provokes disturbances in the electrophysiological properties of SU nerves at early stages of postnatal development (14 and 21 PND) which can be prevented by perineal+body tactile stimulation.

Title: Elucidating the role of spinal cord Atoh1-lineage neurons in proprioception

Authors: *H. C. LAI;
UT Southwestern Med., Dallas, TX

Abstract: ATOH1, a basic helix-loop-helix (bHLH) transcription factor, is transiently expressed in the dorsal-most part of the developing neural tube. Atoh1-lineage neurons in the spinal cord have been implicated in forming cerebellar-projecting neurons of the dorsal spinocerebellar tract (DSCT); however, it is unknown precisely how they contribute to the DSCT. We find that Atoh1-lineage neurons reside outside Clarke's column, a major contributor of neurons to the DSCT. In addition, elimination of caudal Atoh1-lineage neurons results in mice that are unable to perform coordinated motor tasks. Altogether, our findings suggest that DSCT neurons derive from more than one developmental source, which can be used to distinguish subsets of the proprioceptive system.

Abstract: Previously, our laboratory has examined the effects bilateral enucleations that occur at extremely early stages of development, before the arrival of retinal ganglion cell axons to their targets. Because opossums are altricial at birth, enucleations at very early stages of development can be made ex utero, at postnatal day 4 (P4). We demonstrated that neurons in the caudal pole of cortex (primary visual cortex in sighted animals) become responsive to somatosensory and auditory stimuli following early visual loss. These results were corroborated by connectional studies, indicating that large-scale changes in thalamocortical as well as cortico-cortical connectivity were also observed for cortex that would normally develop into V1. Additionally, we have shown that early loss of vision also affects the connectivity of the spared sensory systems, with numerous exuberant cortical projections to primary somatosensory cortex (S1).

However, whether this very early visual loss alters thalamic projections to S1 has yet to be determined. In these studies we utilized neuroanatomical tracing techniques to examine thalamocortical connections of S1 in opossums that were bilaterally enucleated at P4, before thalamocortical connections innervate the neocortex. Following injections of anatomical tracers in S1, we quantified the proportion of labeled neurons in different, architectonically defined nuclei of the thalamus. Unlike cortical connections of S1 in bilaterally enucleated opossums, thalamic projections to S1 maintained the same modality-specific pattern of connectivity to S1 as in normal animals. However, there were differences in the composition of thalamic projections to S1 in enucleates, with fewer neurons (as a percent of the total number of labeled neurons in the thalamus) originating from the ventral posterior nucleus, and a greater number originating from both the posterior and ventral medial nuclei. These results suggest that while early enucleation does not induce aberrant projections to S1 from nuclei traditionally associated with the visual and auditory processing (e.g. MG, LGN), differences in the thalamic connectivity of S1 are still present in these animals suggesting that cross-modal plasticity is restricted to cortico-cortical connections of S1.

Title: PRDM12 is a novel, evolutionarily conserved transcription factor that controls sensory neuron specification and nociception

Authors: *V. NAGY[1], T. COLE[2,3], C. VAN CAMPENHOUT[4], T. M. KHOUNG[2,3], C. LEUNG[2,5], S. VERMEIREN[4], M. NOVATCHKOVA[1], D. WENZEL[1], D. CIKES[1], A. A. POLYANSKY[6], I. KOZIERADZKI[1], A. MEIXNER[1], E. J. BELLEFROID[4], G. G. NEELY[2,3], J. M. PENNINGER[1];

Abstract: PR homology domain-containing member 12 (PRDM12) is a transcription factor belonging to a conserved family implicated in cell fate decisions. PRDM12 plays an important role in the development of the neural crest in several species and plays a potential role in pathogenesis of chronic myeloid leukaemia in humans. PRDM12 is almost exclusively expressed in the central and peripheral nervous system, however, very little is known of its downstream targets or the potential role it might play in neuronal cell fate decisions and functions. We found

that PRDM12 is a key regulator of sensory neuronal specification in Xenopus. Further, we modeled PRDM12 mutations that cause hereditary sensory and autonomic neuropathy (HSAN) and show remarkable conservation of the mutated residues in evolution. Expression of wild-type human PRDM12 in Xenopus induced the expression of sensory neuronal markers, which were reduced using various disease-causing human PRDM12 mutants. In *Drosophila*, we identified Hamlet as the functional PRDM12 homologue that controls nociceptive behavior in sensory neurons. Furthermore, expression analysis of human patient fibroblasts with PRDM12 mutations uncovered possible downstream target genes. Knockdown of several of these target genes including thyrotropin-releasing hormone degrading enzyme (TRHDE) in *Drosophila* sensory neurons resulted in altered cellular morphology and impaired nociception. These data show that PRDM12 and its functional fly homologue Hamlet are evolutionary conserved master regulators of sensory neuronal specification and play a critical role in pain perception. Our data also uncover novel pathways in multiple species that regulate evolutionary conserved nociception. In addition, we are investigating the role PRDM12 and its downstream targets plays in development and sensory neuronal function in conditional mutant mouse models.

Title: A detailed Golgi-Cox morphological analysis of the auditory cortex and inferior colliculus in rats exposed to an acoustically enriched environment

Authors: ***J. BURIANOVA**, L. OUDA, J. SYKA;
Inst. of Exptl. Medicine, CAS CZ, Prague, Czech Republic

Abstract: Evidence has accumulated that various kinds of acoustic exposures during the critical period of development can have either a positive or negative impact on the morphology of the central auditory system. In our previous study (Ouda et al., 2014), we demonstrated that early postnatal short noise exposure (8 min, 125 dB, day 14) resulted in the remodeling of neuronal trees in the central auditory system, comprising of a longer mean total length of neuronal trees in the inferior colliculus (IC) and medial geniculate body (MGB), a shorter mean total length of

apical dendrites in pyramidal cortical neurons of the auditory cortex (AC), and a higher numerical density of spines on branches of the pyramidal AC neurons. In the present study, we analyzed, using the Golgi-Cox method, the morphology of neurons in the IC and AC of 4-month-old Long-Evans rats exposed to an acoustically enriched environment (AEE) during the third and fourth weeks of life. In AEE exposed rats, the mean total length of the neuronal tree was found to be greater than in control animals in the external cortex and the central nucleus of the IC. In the AC, the mean total length of the basal dendritic segments of pyramidal neurons was significantly longer in AEE exposed rats, however, only slight differences with respect to controls were observed in the length of apical dendrites of pyramidal cells. These findings demonstrate that early AEE exposure can induce permanent changes in the development of neurons in the central auditory system, which apparently represent morphological correlates of functional plasticity.

Title: Lack of muscle spindles in infant ErbB2 knockout mice is associated with deficits in functional and anatomical cerebellar development

Authors: N. J. SATTLER[1], A. J. YONK[1], C. M. COLEMAN[1], *G. SOKOLOFF[2], M. S. BLUMBERG[1];

Abstract: The cerebellum, which exhibits protracted postnatal development, is important for sensorimotor integration. Previous studies in infant rats have shown that sensory feedback from myoclonic twitches, which occur exclusively during active (or REM) sleep, is a substantial driver of Purkinje cell activity. To further examine the contributions of proprioceptive feedback to twitch-related cerebellar activity and assess its role in cerebellar development, we investigated the neurophysiology, anatomy, and behavior of ErbB2 conditional knockout mice_which fail to develop functional muscle spindles_over the first two postnatal weeks. Because both climbing fibers and mossy fibers convey proprioceptive information to Purkinje cells, we hypothesized that knockout mice would exhibit fewer complex and simple spikes than wild-type mice. We further hypothesized that knockout mice would exhibit twitch-dependent Purkinje cell activity. Next, we assessed climbing fiber innervation of Purkinje cells as evidenced by the distribution of the vesicular glutamate 2 transporter (VGLUT2). Finally, we tested knockout and wild-type mice

on a cerebellar-dependent balance beam task. At 8 days of age, knockout mice exhibited reduced Purkinje cell activity, weaker twitch-related neural activity, and altered neural rhythmicity. VGLUT2 labeling differed between knockouts and wild types with respect to translocation of climbing fibers as well as distribution of vesicles across the Purkinje cell and molecular layers. At 15 days of age, knockout mice exhibited pronounced deficits on the balance beam task; at narrow widths, footslips increased significantly and latencies to traverse the beam increased. Taken together, these results support the hypothesis that proprioceptive input from muscle spindles contributes substantially to the functional and anatomical development of the cerebellum.

Title: Highly patterned spontaneous activity in the developing mammalian auditory system *in vivo*

Authors: *A. P. LOMBROSO[1], A. GRIBIZIS[1], H. C. WANG[2], W. ZHANG[2], T. BABOLA[2], D. BERGLES[2,3], M. CRAIR[1];

Abstract: Spontaneous activity is a common feature of developing sensory systems. In the visual system, waves of spontaneous activity generated in the retina propagate to the thalamus and cortex before the retina is visually responsive. This patterned spontaneous activity helps to define neuronal pathways in the ascending visual system. In the developing auditory system, bursts of activity initiated within the cochlea before hearing onset may play a similar role in refining auditory system neural circuits. However, relatively little is known about the spatial and temporal patterns of this spontaneous activity in the ascending mammalian auditory system, and its role in development remains to be defined. To examine developmental changes in this sensory-independent activity and determine the mechanisms responsible, we imaged global changes in neuronal activity in the developing inferior colliculus (IC) and auditory cortex (A1) in awake neonatal mice using genetically encoded calcium indicators (GECIs). The IC plays a central role in the ascending auditory system, receiving input from auditory brainstem nuclei and relaying this activity to the MGN and eventually A1. We observed bands of activity in neonatal IC that were highly correlated between hemispheres and with activity in the ipsilateral auditory

cortex. These activity bands were stationary (they did not propagate across the IC), their orientation was consistent with tonotopic bands previously observed using anatomic and functional (electrophysiological) techniques, and they depend on input from the cochlea. Spontaneous bands of activity become more frequent, more refined, and of shorter duration as animals aged. By examining the source of this spontaneous activity and changes in its spatial and temporal properties during development, we hope to understand the role this early activity plays in preparing the auditory system for the onset of hearing.

Title: Anatomical study of transient commissural projections between the vestibular ganglia in neonatal opossums (Monodelphis domestica)

Authors: *F. LANTHIER, A. LALONDE-LARUE, T. CABANA, J.-F. PFLIEGER;
Sci. Biologiques, Univ. De Montréal, Montreal, QC, Canada

Abstract: The opossum is born in a very immature state. It nevertheless has to crawl, unaided by the mother, from the urogenital opening to a nipple where it attaches to pursue its development. Sensory information must guide the newborn to a nipple and trigger its attachment to it. In a previous study, the possible involvement of the vestibular system, which acts on spinal motor networks in response to gravitational cues, was investigated by anatomical tracing. This study showed the existence of vestibular afferents to the utricle and to the vestibular complex of the brainstem as well as of vestibulospinal projections in the newborn opossums. An unexpected finding was the presence of vestibular afferents crossing to the contralateral vestibular ganglion. To investigate the development of these projections, Texas Red conjugated Dextran-Amine crystals were placed in a longitudinal section in the brainstem midline, from the level of the trigeminal ganglia to the level of the obex, in *in vitro* preparations of the head taken from opossums aged postnatal day 5 (P5) to P15. A 4.5 h period was allowed for transport of the tracer, in the dark. The tissue was then fixed, cryosectioned and the slides were observed under a fluorescence microscope. Labeling of cells and nerve fibers was abundant in the brainstem at all ages studied. More specifically, labeled cells in the vestibular ganglion and labeled fibers which

entered or exited the ganglion were observed, bilaterally. To examine the temporal evolution of this commissural projection, the labeled cells in the vestibular ganglia were counted. The number of labelled cells per ganglion increased from about 16 at P5 to a maximum of around 43 at P11, and then decreased to around 7 by P15, the oldest age available. These results confirm the existence of commissural projections between the left and right vestibular ganglia in early postnatal opossums and show their subsequent decrease by the end of the second postnatal week. The period of increase of the commissural vestibular projections corresponds to a period just before neurons in the vestibular nuclei start to express c-Fos, a marker of neuronal activity, in response to vestibular stimulation. This raises the question of a link between the vestibular ganglia commissural projections and vestibular function in neonatal opossums. We must further investigate if commissural projections are functional and if they totally disappear past P15.

Title: Alcohol-sensitive period during early octavolateral organ development in Zebrafish (Danio rerio)

Authors: *L. ZAMORA[1,2], K. C. MIGUEL[2], Z. LU[1,2,3];
[1]Biol., [2]Neurosci. Program, Univ. of Miami, Coral Gables, FL; [3]Intl. Ctr. for Marine Studies, Shanghai Ocean Univ., Shanghai, China

Abstract: It is well known that fetal alcohol exposure can cause Fetal Alcohol Spectrum Disorders (FASD), a completely preventable developmental disability that is characterized by permanent birth defects. However, it is unclear whether or not there is a specific time window during gestation that fetuses are most sensitive to alcohol exposure. In this study, we used the zebrafish (*Danio rerio*) as a model to determine the alcohol-sensitive period in the first 24 hours post fertilization (hpf). Zebrafish's octavolateral organs, including inner ears and lateral line neuromasts, function in hearing, balance, and hydrodynamic detection, respectively. *SeqET4* zebrafish that express green fluorescent protein in all sensory hair cells were treated in 2% alcohol for 5-hour time windows from 2-7, 7-12, 12-17, and 17-22 hpf. Octavolateral organs of

control and alcohol-exposed larvae were morphologically examined at 3, 5, and 7 days post fertilization (dpf). Using confocal and light microscopy, we found all alcohol-exposed larvae had significantly smaller otic vesicles and saccular otoliths at 3 dpf. Only alcohol-exposed larvae from 12-17 hpf had smaller otic vesicles at 5 dpf and smaller saccular otoliths at 7 dpf. Number of saccular hair cells, number of neuromasts, and hair cells per neuromast were also decreased only for alcohol-exposed larvae from 12-17 hpf. Auditory function was also assessed at 3 dpf by inner ear recordings of extracellular microphonic potential responses to 200-Hz stimulation. Hearing sensitivity was significantly diminished only for larvae exposed to alcohol from 7-12 and 12-17 hpf. To determine if fewer hours of alcohol exposure between 12-17 hpf also caused detrimental defects of octavolateral organ morphology and function, embryos were alcohol-exposed from 12-14 and 14-17 hpf. Significantly smaller otic vesicles and saccular otoliths were observed after 2 and 3 hours of alcohol exposure, similar to all 5-hour alcohol-exposed larvae. Fewer number of neuromasts were also found at 3 dpf, similar to larvae alcohol-treated from 12-17 hpf. Saccular otoliths were also smaller at 5 dpf for 2-hour alcohol-exposed larvae. Although, neither number of hair cells per neuromasts nor hearing sensitivity was significantly affected for larvae alcohol-treated for 2 or 3 hours. Our results show that 12-17 hpf is an alcohol-sensitive time window when morphology and function of octavolateral organs in zebrafish are most vulnerable to embryonic alcohol exposure. This study demonstrates that precise timing of maternal alcohol consumption during fetal development can cause specific FASD symptoms, such as hearing deficits.

Title: Brief developmental hearing loss leads to a deficit in inhibitory synaptic transmission in the adult auditory striatum

Authors: ***T. M. MOWERY**, V. KOTAK, D. SANES;
New York Univ., New York, NY

Abstract: Background Critical periods have been studied almost exclusively in the primary sensory pathways, including auditory cortex (Mowery et al. 2014). However, deprived animals often display behavioral deficits that are not solely attributable to sensory processing. Here, using a cortico-striatal brain slice preparation, we explored whether transient hearing loss affects synaptic inhibition recorded from regions of adult striatum that receives input from auditory cortex (ACx) . Methods Whole-cell voltage-clamp recordings were obtained from ACx-recipient

putative medium spiny neurons (MSN) in cortico-striatal brain slices from gerbils (Meriones unguiculatus) that experienced transient mild hearing loss. Earplugs were inserted bilaterally on postnatal day (P) 11 and removed on P35; thus the animals experienced hearing from P35 until the day of recording (P86). MSNs from earplugged animals (n=12) were compared to those recorded from age-matched controls (n= 15). Results In transiently earplugged animals, spontaneous postsynaptic inhibitory current (sIPSC) was significantly smaller [mean ± SEM: control; -25.1 ± 3.6 pA vs. transient earplug: -12.7 ± 1.0 pA; $p < .05$). The sIPSC time constant was also significantly longer [control: 22.2 ± 2.7 ms vs. transient earplug: 30.1 ± 3.3 ms, $p < .05$). Finally, the sIPSC rate was significantly lower [control: 15.2 ± 2.7 Hz vs. transient earplug 3.77 ± 1.3 Hz, $p < .01$]. Conclusion: These results suggest that the striatum, a major non-sensory region downstream from sensory cortex, is sensitive to a brief period of acoustic deprivation. Furthermore, these effects persisted until adulthood, and this has implications concerning recovery from hearing loss in children.

Title: Mapping of pain circuitry in early post-natal development using manganese-enhanced MRI

Authors: ***M. M. SPERRY**[1], B. M. KANDEL[1], K. E. BASS[2], S. R. DAS[1], P. S. DHILLON[1], J. C. GEE[1], G. A. BARR[2];
[1]Bioengineering, Univ. of Pennsylvania, Philadelphia, PA; [2]Anesthesiol. and Critical Care Med., Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Approximately 400,000 human infants are admitted to the neonatal intensive care unit in the United States every year, and undergo 10-20 or more medically essential but potentially painful procedures each day, often without analgesics. We know that the number of painful procedures in the human neonate is related to poorer outcomes but not how these painful procedures change brain function. Thus we have virtually no detailed understanding of the mechanisms by which the brain is engaged during pain early in life. Based on similarities in brain development between rat and human neonates, the goal of this study was to use MEMRI to map brain circuits that are activated following peripheral tissue injury in infant rats, at an age

roughly equivalent to that of a human neonate. To characterize this circuitry, 12-day old rat pups were systemically injected with manganese chloride (75 mg/kg), a calcium analog able to pass through the blood brain barrier at this stage in development. Twenty-four hours later, half of the pups (n=19) were treated with formalin injected into the hindpaw and half were not (n=19). This injury model engages supraspinal pathways and has been used extensively in both developmental and adult studies as a model of inflammatory pain. To allow activation of multiple structures, pups survived for 7 hours prior to perfusion and brains were imaged for 8-10 hours *ex vivo*. T1 weighted 3D spin echo images were used to visualize the Mn uptake in the brain (Bruker Biospin). Images were normalized and smoothed to a previously established group template space (Advanced Normalization Tools) and intensity normalized to the visual cortex, a region unlikely to be affected by pain stimuli. Two methods of analysis were implemented to elucidate the pain circuits. Voxel and region-wise morphometric analysis showed statistically significant differences in several brain regions between the control and formalin-treated groups ($p < 0.001$, uncorrected for multiple comparisons). Using structural equation modeling (SEM) of anatomically defined circuits, and iterative addition and subtraction of anatomical components known to be involved in pain processing, two possible models that accounted for the maximum variance (comparative fit index, CRI > 0.90 and standardized root mean square residual, SRMR < 0.08) were identified. In these models the formalin-treated group exhibited a significant fit to the SEM, whereas the control group did not, suggesting that these pathways are involved in the pain perception circuitry, as activated by the formalin stimulus. These findings suggest that as young as 12 days of age, a painful injury activates both the sensory and affective components of pain.

Abstract: The auditory perceptual abilities of newborn human infants develop rapidly as they are exposed to a rich acoustic environment that includes spoken language, but little is known about how the cortical auditory system - the substrate of these abilities - changes during this time of critical development. Functional neuroimaging studies have shown that it possible to measure brain responses to sounds in neonates and very young infants, but there have been no controlled studies to investigate what aspect of sounds auditory cortex (AC) is sensitive to, and there are no studies that examine how sensitivity to complex auditory features changes with age. In this study, we used functional magnetic resonance imaging (fMRI) to measure brain responses evoked by rich and naturalistic sounds at two time points during the first 12 months. 3-month (N=9) and 9-month old (N=11) infants, and adult control subjects (N=16), were scanned in two 8 minute blocks while listening to a series of lullabies. Vocal recordings were re-synthesized to create stimulus classes that varied in high-level auditory features (high vs. low phonemic content, and more vs. less human sounding), and importantly, were matched in basic acoustic properties (pitch, amplitude envelope, and frequency spectrum). Infants were a mixed group of term-born healthy infants (N=3 and N=4, 3- and 9-month olds) and NICU graduates. Univariate fMRI analysis showed reliable sound-evoked activity in AC in 3- and 9-month old subjects, but only adult AC was sensitive to the different classes of sounds. Inter-subject correlation (ISC) was used to measure the degree to which individuals within a group showed a similar response when listening to the same songs; unlike block-averaged comparisons between conditions, ISC can detect modulations of brain activity during stimulus presentation, and is therefore sensitive to differences in responses between individual songs, or even between different parts of the same song. We found that 3-month old listeners had significantly correlated responses in bilateral AC, cerebellum, and the supplementary motor area. Importantly, ISCs persisted when the neural responses were adjusted to control for the simple response to the presence of sound. This shows that at three months of age, AC is sensitive to the differences in features between sounds. Interestingly, no such inter-subject correlations were found at 9-months of age, despite the presence of auditory-evoked activity, which might reflect different feature sensitivity, attention, or developmental trajectories between individuals.

Title: Long and short term effects of the mother's presence during noxious stimulation in the infant rat

Authors: *G. A. BARR[1], R. PERRY[2], R. M. SULLIVAN[2];
[1]Anesthesiol. and CCM, Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Dept. of Child and Adolescent Psychiatry, New York Univ. Langone Med. Ctr., New York, NY

Abstract: Modern medical treatment allows very low birth weight premature infants to survive and hundreds of thousands of newborn infants are admitted to the neonatal intensive care unit in the United States yearly. Each infant is subjected to up to 10-20 daily medically essential painful procedures with analgesia used in fewer than half of these procedures. Increasingly, non-pharmacologic interventions are being utilized, where the caregiver provides physical comfort during procedures to reduce pain and stress, including kangaroo care and facilitated tucking. Although effective in reducing pain in these infants, limited clinical and basic science data suggest these well-intentioned interventions likely have long term consequences. As non-pharmacologic treatments continue to be implemented, it is important to understand the long term effects of caregiver comfort during painful procedures early in life. To test the long-term effects of maternal comfort on adult pain responses, we presented mild electric shocks (0.5mA) over a 45 minute period daily to the hindquarters of rat pups aged PN5-9 or PN10-14 with or without the mother present. We included a no-shock, no-mom control group. PN5-9 includes the pain sensitive period when infant inflammatory injury has long term effects on adult pain responses and the infant attachment period when pups learn preferences to odors associated with the shock. PN10-14 is outside the pain sensitive period and includes the attachment transitional period when pups learn aversions to odors paired with the shock if tested without their mother but preferences if tested with the mother. At both ages, escape behavior to the shock and ultrasonic vocalizations were reduced when the mother was present. Pups grew up and were regularly handled to reduce stress. At 50-60 days of age, adults were tested in the plantar thermal test for baseline latencies and on the next day, one hour following carrageenan inflammation of the hindpaw. There was a slight but statistically significant elevated withdrawal threshold (longer latency) in the adults who experienced pain with the mother present at PN10-14 compared to shock without the mother or the no-shock controls. There were no differences in the PN5-9 group. Following inflammation, withdrawal latencies were reduced in all groups at both ages and there was a significant decrease in the hyperalgesia induced by carrageenan in pups shocked with the mother at PN5-9 compared to the two other groups. No differences were found in the PN10-14 in the carrageenan test. The results show short and long-term reductions in inflammatory pain by the mother’s presence that is age specific during a painful experience.

Title: Analysis of proprioceptive sensory afferent inputs on populations of spinal interneurons in neonatal mice

Authors: ***D. R. LADLE**, B. GOSKY, T. RAPETTI, P. PAINTER, Y. DAI;
Neurosci, Cell Bio, Physiol, Wright State Univ., Dayton, OH

Abstract: A key step in the development of neural circuits is formation of synaptic connections with restricted subsets of neurons such that circuits with behaviorally appropriate output are produced. Synaptogenesis between primary afferents of the somatosensory system and neuronal targets in the spinal cord provides an attractive model system for such studies. Analysis of synaptic connections made by muscle spindle afferents on defined interneuron populations in the deep ventral horn may be particularly instructive. Among the interneurons in the ventral horn, two classes of inhibitory neurons, Ia inhibitory interneurons (IaINs) and Renshaw cells (RCs) have been reasonably well described in terms of morphology and function. Glycinergic IaINs mediate reciprocal inhibition whereby activation of muscle spindle afferents in a given muscle, an extensor muscle, for example, leads to inhibition of motor neurons that antagonize movement at the same joint (i.e. flexor muscles). RCs are primarily driven by motor axon collaterals and mediate recurrent inhibition. While monosynaptic connections between muscle spindle afferents and IaINs have long been demonstrated, monosynaptic connections between afferents and RCs have only recently been described in postnatal animals. To date, no studies have analyzed the selectivity of afferent connections with IaINs or RCs during development. Therefore, we mapped the connections of afferents of the quadriceps (Q; knee extensor) and obturator (Obt; supplying adductor muscles) nerves onto immunohistochemically defined IaINs and RCs, using retrograde tracing with fluorescent dextrans in an isolated spinal cord/muscle nerve preparation from neonatal mice (P0/P1). The percentage of identified interneurons in lumbar segments 3 and 4 contacted by either or both muscle afferent sources were quantified by analysis of high-magnification confocal image stacks. Similar percentages of IaINs received contacts from either Q (34 ± 4%; n = 3 animals) or Obt (36 ± 4%) afferents. A significant portion of IaINs, however, received converging contacts from both afferent sources (30 ± 5%). We observed half of RCs (56 ± 5%; n = 5 animals) do not receive contacts from Q or Obt afferents at this early stage. Among RCs contacted by Q or Obt afferents in these animals, 45 ± 2% received contacts from only Obt

afferents, while only 28 ± 3% were exclusively contacted by Q afferents. The remaining 26 ± 3% of RCs received convergent contacts from both muscle afferent sources. These results reveal a previously unappreciated degree of convergence of sensory input from disparate afferent populations on spinal interneurons in early postnatal animals.

Title: Larval mutant ninja zebrafish: an axon initial segment *in vivo* imaging project

Authors: *A. S. DUMITRESCU, M. P. MEYER, M. S. GRUBB;
Kings Col. London, London, United Kingdom

Abstract: The axon initial segment (AIS) is a specialised neuronal compartment involved in the maintenance of axo-dendritic polarity and in the generation of action potentials. The AIS has also been shown to be a novel site for neuronal plasticity, as changes in ongoing activity levels *in vitro* and *in vivo* result in significant alterations in the structure's position or size thus regulating a cell's intrinsic excitability. However, all findings so far have been based on experiments carried out on mammalian fixed samples that offer only a snapshot view of this newly described plasticity mechanism. This approach is limited as it always compares and contrasts findings of AIS plasticity based on group averages and it doesn't allow us to follow individual cell dynamics. We are aiming to address this significant gap in knowledge and pursue the first AIS live imaging experiments making use of the zebrafish larvae for *in vivo* imaging, pioneering research at a time when there is almost nothing known regarding the AIS in this animal model. We have started by developing techniques to visualise the AIS in both fixed samples and live zebrafish. At the moment we have established protocols to confirm and describe AIS morphologies in zebrafish wholemount fixed tissue in retinal ganglion cells, tectal and cerebellar neurons. In parallel we have created and are now in the process of testing several zebrafish specific fluorescently tagged AIS live-imaging constructs. To further probe AIS function *in vivo* we have made use of the TALEN genome editing system to generate both a mutant Ankyrin-G knockout zebrafish line and a transgenic Ankyrin-G:EGFP insertion line. Using our newly developed tools we will fully exploit the power of this model organism to watch the AIS develop

and adapt, live and *in vivo* focusing on retinal ganglion cells during controlled manipulations of sensory experience.

Title: Disabled-1 expression identifies a subset of Lmx1b superficial dorsal horn neurons involved in nociceptive circuits

Authors: *G. METTA YVONE, H. ZHAO, J. C. UDEOCHU, P. E. PHELPS;
Integrative Biol. and Physiol., UCLA, Los Angeles, CA

Abstract: Neuronal positioning defects are found in the dorsal horn of the spinal cord in the absence of Reelin, the two lipoprotein Reelin receptors (Vldlr and ApoER2), or the intracellular adaptor protein Disabled-1 (Dab1). These mispositioned neurons cause distinct sensory abnormalities: thermal (heat) hyperalgesia and a reduction in mechanical sensitivity. In this study we used mice with the *lacZ* reporter gene inserted into the *dab1* locus to identify correctly positioned Dab1 neurons in heterozygous ($dab1^{lacZ/+}$) mice and mispositioned neurons in mutant ($dab1^{lacZ/lacZ}$) mice. Initially we used sensory testing and cFos expression to verify that $dab1^{lacZ/+}$ mice replicate the sensory behavior of the $dab1^{+/+}$ mice and $dab1^{lacZ/lacZ}$ mice display the same nociceptive abnormalities as other Reelin-signaling pathway mutants. To identify the Dab1-labeled cells in laminae I-II (superficial dorsal horn), lateral lamina V, and the lateral spinal nucleus (LSN) in the lumbar enlargement, we combined β-galactosidase histochemistry with immunofluorescence. In the superficial dorsal horn, Dab1 rarely or never co-localizes with GAD67, Calbindin, Calretinin, or PKCgamma. However, about 70% of these Dab1-positive neurons co-express Lmx1b, a transcription factor that marks excitatory glutamatergic neurons in the dorsal horn. Many Dab1 cells in lateral lamina V and the LSN also co-localize with Lmx1b. The Dab1-Lmx1b neurons in the superficial dorsal horn appear subtly mispositioned, whereas those in lateral lamina V and LSN have extensive positioning errors. We then asked if neurons in the combined lateral cervical nucleus (LCN) and LSN, an area in high cervical segments that relays pain information from the spinal cord to the brainstem and thalamus, sustain positioning errors in Reelin-signaling pathway mutants. On average, there were 50% more neurons in $dab1^{+/+}$ than $dab1^{lacZ/lacZ}$ LCN/LSN. Taken together, these results suggest that migratory errors of

Dab1-expressing neurons in lumbar dorsal horn and the high cervical LCN/LSN likely contribute to the nociceptive defects found in Reelin-signaling pathway mutants.

Title: Potency and neurogenesis in the basal stem cells of the olfactory and respiratory epithelia

Authors: ***J. N. PETERSON**, J. SCHWOB;
Dept. of Cell, Mol. and Developmental Biol., Tufts Univ. Sackler Sch. of Grad. Biomed, Boston, MA

Abstract: The mammalian olfactory epithelium (OE) and neighboring respiratory epithelium (RE) both possess a remarkable capacity for repair and regeneration in response to injury. This regeneration is made possible in part through the action of two resident stem cell populations that closely resemble each other but are fated to give rise to different types of cell and exhibit different levels of activity. In the RE, these basal cells will give rise to ciliated columnar epithelium and mucous-producing goblet cells and are active and proliferative under normal physiological conditions. In the OE, the most basal stem cells are termed horizontal basal cells (HBCs) and will give rise to the olfactory sensory neurons and supporting sustentacular cells, but remain quiescent until activated by severe tissue injury. This project seeks to understand the differences in activity and plasticity between these two histologically and morphologically similar stem cell populations with an emphasis on what gives HBCs their unique neurogenic potential. To approach this question we utilize transgenic mice, a novel xeno-free *in vitro* system, an olfactotoxic lesion system and transplantation studies. We have identified the first unique histological marker that is expressed differentially between the two stem cell populations. Our *in vivo* and *in vitro* results indicate that this marker is functionally important in defining their relative plasticity and may be regulated by the physiological microenvironment. By exploring the differences between these two stem cell populations we hope to gain a better understanding of the nature of the regulation of tissue stem cell plasticity and potency.

Abstract: Mature olfactory sensory neurons (OSNs) express olfactory receptors (ORs) in specific zones along the dorsal/ventral axis of the olfactory epithelium (OE). In addition to the spatial patterning of OR expression, dorsomedial OSNs express the enzyme NQO1 exclusively while ventrolateral OSNs express the mammalian homologue of fasciclin II (mamFasII, or OCAM) exclusively; the dorsomedial and ventrolateral territories are sharply bounded and strictly complementary. During the reconstitution of the neuronal population following injury, the spatial patterning of OR expression is restored as is the boundary and complementarity between NQO1 and mamFasII/OCAM expression. The re-emergence of spatial organization across the OE may reflect positional “memory” in the spared, residual stem cells, or, alternatively, cues from surrounding tissues that do not suffer direct injury. As a test of these two alternatives, we tested whether neurons derived from transplanted stem/progenitor cells would retain the markers (OCAM/NQO1) and receptors (ORs) that characterize the region from which they were harvested, or adopt the phenotype of neurons that typify where they engrafted. Specifically, progenitors were harvested from both the dorsal and ventral OE of CAG-TdTomato transgenic mice and transplanted separately into regenerating epithelium of host male mice that had been exposed to the selective olfactotoxin methyl bromide the previous day. After recovering for three weeks, which provides adequate time for OSN regeneration, the OE was harvested. Immunohistochemical analysis indicated that progenitors transplanted from dorsal OE that engraft in ventral OE give rise to neurons that much more often express the ventral marker OCAM/mamFasII than the dorsal marker NQO1; 81% of all neurons that are born following dorsal into ventral transplant assume a ventral identity (n = 3 transplants; 1473 OSNs). Likewise, OR expression was determined by single cell RT-PCR on transplant-derived neurons isolated by FACS, and the spatial distribution of the harvested OR was assayed by *in situ* hybridization; 75% of the transplant-derived neurons express a ventrally located OR (n = 2 transplants; 4 neurons). These data suggest that most transplant-derived OSNs are instructed by cues that derive from the local environment rather than a memory of place. These data also raise the question as to why a

significant proportion of the OSNs do not demonstrate this plasticity. Follow-up studies will assess if stem cells at later stages of neuronal commitment are less spatially plastic during transplantation experiments.

Title: Estrogen signaling is necessary for the exercise-mediated increase in motoneuron participation in axon regeneration after peripheral nerve injury in mice

Authors: *J. C. WILHELM, P. A. COPLEY, M. C. ACOSTA, J. R. HARRELL;
Col. of Charleston, Charleston, SC

Abstract: Thousands of people each year suffer from peripheral nerve injury. Treatment options are limited, and recovery is often incomplete. Treadmill exercise can enhance nerve regeneration; however, this appears to occur in a sex-dependent manner. Females respond best to short duration, high speed interval training; whereas, males respond best to slower, continuous training. Previous studies have shown a role for testosterone in this exercise-mediated enhancement, but the role of estrogen is unknown. To evaluate the role of estrogen signaling in treadmill exercise, we treated male and female wild type mice with an estrogen receptor antagonist, ICI 182,780 during exercise. The right common fibular branch of the sciatic nerve was cut and repaired with fibrin glue. Estrogen-filled or blank capsules were implanted subcutaneously at the time of nerve transection. Starting three days post-transection, exercised mice received treadmill training using the paradigm appropriate to their sex 5 days a week for 2 weeks. Fourteen days after the initial sciatic nerve transection, motoneurons whose axons had regenerated at least 1500 μm distal to the original cut sites were labeled with a retrograde tracer. Regeneration was quantified by counting the number of fluorescent labeled motoneurons in the lumbar region of the spinal cord. Both treadmill training and estrogen administration increased the number of motoneurons participating in axon regeneration, but this effect was blocked by estrogen receptor antagonist treatment. Estrogen signaling is important for the enhancing effects of treadmill exercise on motoneuron participation after peripheral nerve cut.

Title: Neuropeptide Y induces hematopoietic stem cell mobilization and improves bone loss

Authors: ***H. JIN**[1], N. KIM[1], M. PARK[2], J.-S. BAE[2];
[2]Sch. of Med., [1]Kyungpook Natl. Univ., Daegu, Korea, Republic of

Abstract: Hematopoietic stem cell (HSC) mobilization is an essential homeostatic process regulated by the interaction of cellular and molecular components in bone marrow niches. It has been shown by others that neurotransmitters released from the sympathetic nervous system regulate HSC egress from bone marrow to peripheral blood. In this study we investigate the functional role of neuropeptide Y (NPY) on this process. NPY deficient mice had significantly impaired HSC mobilization due to increased expression of HSC maintenance factors by reduction of matrix metalloproteinase-9 (MMP-9) activity in bone marrow. Pharmacological or endogenous elevation of NPY led to decrease of HSC maintenance factors expression by activating MMP-9 in osteoblasts, resulting in HSC mobilization. Mice in which the Y1 receptor was deleted in osteoblasts did not exhibit HSC mobilization by NPY. Furthermore, NPY treatment in ovariectomized mice caused reduction of bone loss due to HSC mobilization. These results suggest a new role of NPY on HSC mobilization, as well as the potential therapeutic application of this neuropeptide for stem cell-based therapy.

Title: AlphaB-crystallin does not alter the immune response after sciatic nerve crush injury

Authors: *E.-M. F. LIM[1], V. HOGHOOGHI[1], S. S. OUSMAN[2];
[1]Neurosci., [2]Clin. Neurosciences, Univ. of Calgary, Calgary, AB, Canada

Abstract: During Wallerian degeneration (WD) in the injured peripheral nervous system (PNS), immune cells play a critical role in creating a supportive environment for regrowing axons. Dedifferentiated Schwann cells secrete cytokines and chemokines such as TNFα, IL-1α, IL-1β, MCP-1 and MIP-1α that promote the recruitment of monocytes to the injured site. These monocytes differentiate into macrophages and produce TNFα, IL-1α and IL-1β, which contribute to further recruitment of hematogenous macrophages and the breakdown of myelin. Importantly, these hematogenously derived macrophages phagocytose axonal and myelin debris that are inhibitory to axon growth. The beneficial aspects of cytokines and immune cells are evident, but a prolonged inflammatory response after injury has been implicated in the pathogenesis of negative symptoms after peripheral nerve injury, specifically neuropathic pain, and therefore must be carefully controlled to prevent damage and allow for subsequent regeneration. AlphaB-crystallin (αBC) is a small heat shock protein that has been shown to have chaperone properties, promote survival of various peripheral cells undergoing stress and, decrease inflammation. Further, αBC is expressed in the PNS and we have previously shown its beneficial role in peripheral nerve regeneration where mice null for the crystallin have thinner myelin sheaths, decreased conduction velocity, and impaired motor and sensory functions. Due to the extensively reported immunomodulatory role of αBC, we investigated whether the heat shock protein influenced PNS regeneration by modulating the immune response during WD. The *in vivo* cytokine profiles of TNFα, IL-1β, and IL-6 in the distal nerve segment of 1-28d post-crushed WT and αBC-/- mice were found to be similar between the two groups. Further, the number of CD45 and Iba1 positive profiles was also not altered between WT and αBC-/- mice at 1-7 days post-injury. To determine whether αBC can affect the level of cytokines secreted by macrophages, we stimulated these cells *in vitro* with LPS in the presence or absence of recombinant human αBC and evaluated the levels of IL-12p40, IL-1β, TNFα, IL-6 and IL-10. We observed a decrease in levels of IL-12, IL-1β, and TNFα and an augmentation of IL-10 secretion following treatment with αBC. In this study, we show for the first time that treating macrophages with αBC can decrease the secretion of pro-inflammatory cytokines and increase the secretion of anti-inflammatory cytokines *in vitro*. However, in the peripheral nerve crush injury paradigm, αBC does not modulate the immune system to affect regeneration which suggests specificity in the role of the crystallin after PNS injury.

Title: Notch signaling helps maintain reserve neural stem cell quiescence in the setting of neuronal injury

Authors: *D. B. HERRICK[1], J. E. SCHWOB[2];
[2]Developmental Mol. and Chem. Biol., [1]Tufts Univ., Boston, MA

Abstract: The olfactory epithelium (OE) retains the capacity - remarkable for the nervous system - to repair itself structurally and functionally after wholesale or piecemeal loss of olfactory neurons. As such, the OE can regenerate olfactory sensory neurons (OSNs) and all nonsensory cellular constituents, including sustentacular (Sus) cells, throughout adult life by recruiting neurocompetent stem and progenitor cells, particularly in response to epithelial injury. Thus, the OE is an attractive and powerful model for studying adult neurogenesis. Two types of neurocompetent stem cells function within the OE: dormant horizontal basal cells (HBCs), a reserve population, and constitutively active globose basal cells (GBCs). Our lab and others have demonstrated that down-regulation of ΔNp63α, a member of the p53 family of transcription factors, is necessary and sufficient to elicit HBC activation. However, the molecular signaling events upstream of HBC activation remain poorly understood. RNA-seq analysis of purified HBCs following injury demonstrated that the Notch signaling pathway, an evolutionarily conserved cell-cell signaling pathway, is a crucial regulator of HBC activation after injury. Notch receptors and canonical Notch-dependent signaling targets were both down-regulated following injury, which coincides with down-regulation of ΔNp63α mRNA. Genetic deletion of Notch1 in HBCs *in vivo* produces a decrease in ΔNp63α mRNA and increased activation to multipotency as demonstrated by HBC lineage tracing, whereas conditional overexpression of Notch1 intracellular domain (which drives expression of Notch targets) leads to an increase in ΔNp63α expression. Selective death of neurons following olfactory bulb ablation (OBX) causes increased Notch receptor levels by qRT-PCR and immunohistochemistry but was not sufficient to activate HBCs to multipotency. However, OBX in the setting of HBC-specific knockout of Notch1 does activate at least some HBCs to multipotency as shown by tracing the descendants of the recombined HBCs. The resultant clones are similar in composition to those generated in response to MeBr injury, wherein wholesale loss of neurons and Sus cells by MeBr injury results in both decreased Notch signaling and arousal out of dormancy. Thus, Notch1 is required to maintain HBC quiescence in the setting of neuronal injury, suggesting that the undamaged Sus cells play a significant role in maintaining HBC quiescence via Notch signaling. The current results implicate the Notch signaling pathway as a potential target for manipulation in dormant neuronal stem cell populations following injury. Title: MiR-9 inhibits Schwann cell migration by targeting Cthrc1 followingsciatic nerve injury

Authors: S. ZHOU, D. SHEN, Q. ZHANG, H. SHI, X. GU, *F. DING;
Nantong University, China, Jiangsu, China

Abstract: After peripheral nerve injury (PNS), the proximal nerve stump will spontaneously regenerate due to the biological behaviors of Schwann cells, the principal glial cells in the PNS. microRNAs (miRNAs), a class of approximately 22 nucleotide non-coding RNA molecules, negatively regulate the expression of a wide variety of genes mainly through a direct interaction with the 3'-untranslated regions (3'-UTRs) of their corresponding mRNA targets. Collagen triple helix repeat containing protein 1 (Cthrc1) has been shown to be overexpressed in injured arteries of rats, and Cthrc1 increases cellular motility to repair the injury by promoting cell migration. In this study, miR-9 was identified as an important functional regulator of Schwann cell migration that was a crucial regenerative response of Schwann cells to nerve injury. *In vitro*, upregulated expression of miR-9 inhibited Schwann cell migration, whereas silencing of miR-9 promoted Schwann cell migration. Intriguingly, miR-9 exerted this regulative function by directly targeting Cthrc1, which in turn inactivated downstream Rac1 GTPase. Rac1 inhibitor reduced the promotive effects of anti-miR-9 on Schwann cell migration. *In vivo*, high expression of miR-9 reduced Schwann cell migration within a regenerative nerve microenvironment. Collectively, our results confirmed the role of miR-9 in regulating Schwann cell migration after nerve injury, thus offering a new approach to peripheral nerve repair.

Title: Olfactory bulb targeting after recovery from olfactory epithelial injury

Authors: *E. H. HOLBROOK[1,2], A. R. DEZUBE[2], J. E. SCHWOB[2];
[1]Mass Eye & Ear Infirmary, Boston, MA; [2]Developmental, Mol. and Chem. Biol., Tufts Univ. Sch. of Med., Boston, MA

Abstract: In mice, each set of olfactory receptor (OR)-defined olfactory sensory neurons (OSNs) converge their axons and synapse within an average of 2 to 3 glomeruli per olfactory bulb (OB). The maintenance of this map is crucial for normal olfactory function. Although the robust regenerative capacity of the olfactory epithelium (OE)(including spatially-appropriate restoration of OR-defined OSNs) is well-established following injury, evidence suggests that glomerular targeting may be inaccurate and aberrant during reinnervation, thereby causing long-lasting olfactory dysfunction. Thus, disorganization in the projection from the OE to the OB is suggested in humans by the common complaints of phantosmia and parosmia during recovery from head trauma and other epithelial insults. We have previously reported significant errors in glomerular targeting after recovery from MeBr-induced epithelial injury using the P2-ITL mouse line, which genetically labels P2 receptor-expressing OSNs (Holbrook et al., 2014). These abnormalities include both incomplete and multiple innervation of glomeruli. In order to assess the pervasiveness of errors in targeting after recovery from OE lesion, we compared axonal targeting after regeneration vs. control in the additional receptor-tagged mouse lines M72-ITG and I7-ITG as well as P2-ITL. We occluded one naris in mice (n = 3) from each of the three transgenic lines during the 8-hour period of exposure to MeBr gas (175 ppm) to create unilateral epithelial lesions. The nasal plug was removed at completion of exposure, and the mice survived in their usual housing for eight weeks to allow for maximal recovery of the OE and reinnervation of the OB. Coronal cryosections through the olfactory epithelium and OB were immuno-labeled for beta-galactosidase (P2) or GFP (M72 and I7). Reconstructed mosaic images of the OB sections were analyzed for glomerular targeting including number and completeness of glomerular innervation by comparison with olfactory marker protein (OMP)-staining. Our findings indicate a differential capacity for accurate reinnervation depending on the type of OSN that is assessed. The types of targeting errors made by P2 OSNs were not observed to the same degree as M72- or I7 OSNs. The explanation for the results may be due to differences in sensory activation of the different types of OSNs within the laboratory environment. The results are important in extending our understanding of the regenerative capacity of the olfactory system

beyond the OE recovery. In addition, our findings indicate the need to analyze multiple OSN types to achieve a fuller sense of the outcome of the regenerative process.

Title: A transgenic mouse model for accelerated olfactory aging

Authors: *W. JANG[1], E. HOLBROOK[1,2], K. CHILD[1], J. SCHWOB[1];
[1]Tufts Univ. Sch. of Med., Boston, MA; [2]Massachusetts Eye and Ear Infirmary, Harvard Med. Sch., Boston, MA

Abstract: As a consequence of aging, the human olfactory epithelium (OE), which forms a continuous neuroepithelial sheet densely populated by olfactory sensory neurons (OSNs) at birth, becomes interrupted by patches lacking neurons. The aneuronal holes are due either to 1) metaplastic replacement by respiratory epithelium (RE) or 2) neurogenic exhaustion wherein the epithelium consists solely of sustentacular cells and horizontal basal cells (HBCs) and is completely lacking in OSNs and globose basal cells (GBCs). We have identified a transgenic mouse model of enhanced OE aging due to accelerated neuronal turnover as a consequence of which the OE undergoes similar pathological changes as in human OE. Accelerated turnover occurs in the OE of a bigenic mouse line combining an OMP-tTA knock-in mutation ("Tet-Off" tetracycline transactivator) and a TetO-DTA transgene (tet response element-diptheria toxin subunit A). In the absence of Doxycycline, expression of DTA in mature, OMP (+) OSNs abbreviates their lifespan and accelerates their death. Our immunohistochemical analysis demonstrates that the epithelium initially responds by increasing both GBC proliferation and neuron production. However, beginning around 2-4 months of age, neurogenesis declines, GBCs disappear - including the subset of upstream stem cells characterized by the expression of Sox2 and Pax6, and the epithelium becomes progressively aneuronal. On the other hand, HBCs, a population of neurocompetent stem cells that are held in reserve, express high levels of the transcription factor p63, remain dormant, and do not contribute to the repopulation of the epithelium. In addition, areas of the epithelium that were olfactory undergo respiratory metaplasia, a finding that had only been triggered by severe epithelial injury in the past. These areas are often associated with an increased infiltration by inflammatory cells. Analysis of the olfactory bulb (OB), the central target of the OSNs, demonstrates a reduction in glomerular

innervation and a down-regulation of tyrosine hydroxylase in the dopaminergic periglomerular neurons, consistent with their relative denervation. While some of these changes have been noted following other experimental manipulations, epithelial pathology emerges in those models only at a very advanced age. The accelerated aging of the OE in the current model will allow a more in-depth analysis of the age-associated shifts in the GBC population that precede neurogenic collapse and of the potential for ameliorating, preventing, or reversing the pathologies - both in the OE and the OB - that accompany the march of time.

Title: Stimulation of a denervated laryngeal muscle with low frequency promotes selective reinnervation and restores function

Authors: ***Y. LI**[1], S. HUANG[2], D. ZEALEAR[2];
[1]Hearing and Speech Sci., Vanderbilt Univ. Med. Center/Oto, Nashville, TN; [2]Otolaryngology, Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Previously, electrical stimulation of a denervated canine laryngeal muscle was shown to promote reinnervation by original over foreign motoneurons. An implantable nerve stimulation-EMG system was used to index the appropriateness of reinnervation of the vocal fold abductor (posterior cricoarytenoid, PCA) muscle by inspiratory versus foreign reflex glottis closure (RGC) motoneurons following recurrent laryngeal nerve section and repair. In the present study in ten canines, a clinical model was used, where both nerves were sectioned and ventilation compromised due to loss of abduction. The EMG system and a pulse generator were implanted, the latter for electrical conditioning of PCA muscles. After nerve section, animals were randomly assigned to four groups to assess the effect of different muscle stimulus paradigms on reinnervation quality and degree of functional recovery: 1)40 pps train, 2)20 pps train 3)10 pps train and 4)control-no stimulation. One msec pulses were applied with 4 sec on/4 sec off duty cycle during the post neurorrhaphy regeneration period. In bimonthly sessions, spontaneous vocal fold movement was measured endoscopically during induced hypercapnea in the anesthetized animal. Rectified integrated EMG potentials were recorded from abductor muscles and adductor (thyroarytenoid, TA) muscles. Recordings were obtained during

hypercapnic respiration to index reinnervation by inspiratory motoneurons, and during superior laryngeal nerve stimulation to index reinnervation by RGC motoneurons. Exercise tolerance was measured on a treadmill in the awake animal using pulse oximetry. Results demonstrated that nonstimulated controls, 40 pps stimulated and 20 pps stimulated animals had faulty reinnervation (EMG), severe paradoxical closure of the glottis during hypercapnea, and poor tolerance to exercise. In contrast, stimulated 10 pps animals showed a near normal pattern of low PCA and high TA reinnervation by RGC motoneurons, minimal paradoxical glottis closure, and near normal exercise tolerance (12 minutes up to 8 mph). It would appear that low-frequency stimulation of a denervated PCA muscle simulating endogenous activity inhibits reinnervation by foreign RGC motoneurons, leaving receptor sites available for native inspiratory motoneurons. As a consequence, reinnervation of adductor muscles by inspiratory neurons is depressed; paradoxical glottis closure is reduced and exercise tolerance restored.

Title: Injury can induce neuronally committed Neurog1+ progenitors to become multi-potent

Authors: *B. LIN[1], J. HEWITT[2], J. PETERSON[1], J. E. SCHWOB[1];
[1]DMCB, [2]Dept. of Neurosci., Tufts University, Sackler Sch., Boston, MA

Abstract: The mammalian olfactory epithelium (OE) is a powerful model system for studying neural regeneration due to constant turnover and genesis of mature neurons well through adulthood. Two broadly defined basal stem cell populations, globose basal cells (GBCs) and horizontal basal cells (HBCs), participate in regeneration after injury. GBCs are a heterogeneous population that encompasses Sox2/Pax6(+) multipotent cells, neuron-fated Ascl1(+) that are transit-amplifying elements, and Neurogenin1/NeuroD1(+) immediate neuronal progenitors. This hierarchical model of GBC fate is based on the epistatic consequences of gene knockout and temporal correlation during recovery after epithelial injury. As expected, transplantation of Neurog1+ GBCs from an uninjured donor yielded only neurons. Unexpectedly, Neurog1+ GBCs isolated from a setting of constant neuronal death and regeneration (olfactory bulbectomy) revealed a previously unanticipated plasticity as they generated clones containing not only neurons, but also non-neuronal lineage sustentacular cells as well as duct/gland units.

Consequently, we performed a short term lineage trace using the Neurog1-eGFP animal in the context of two independent injury models, showing co-labeling of eGFP with Sox2 and Pax6, which suggests a de-differentiative pathway. Importantly, genetic lineage tracing using both a Neurog1-CreER as well as a more upstream Ascl1-CreER driver has demonstrated a similar plasticity after injury *in situ*, suggesting that this is not due to stresses experienced during the transplantation assay. These results provide an indication that the apparent hierarchy of neuronal differentiation in the OE merely implies differentiative fate-not commitment.

Title: Neuropeptide Y regulates the hematopoietic stem cell microenvironment and prevents nerve injury in the bone marrow

Authors: *J.-S. BAE[1], M. PARK[1], N. KIM[1], H. JIN[2];
[1]Sch. of Med., [2]Col. of Vet. Med., Kyungpook Natl. Univ., Daegu, Korea, Republic of

Abstract: Many reports have revealed the importance of the sympathetic nervous system (SNS) in the control of the bone marrow environment. However, the specific role of neuropeptide Y (NPY) in this process has not been systematically studied. Here we show that NPY deficient mice have significantly reduced hematopoietic stem cell (HSC) numbers and impaired regeneration in bone marrow due to apoptotic destruction of SNS fibers and/or endothelial cells. Furthermore, pharmacological elevation of NPY prevented bone marrow impairments in a mouse model of chemotherapy-induced SNS injury, while NPY injection into conditional knockout mice lacking the Y1 receptor in macrophages did not relieve bone marrow dysfunction. These results indicate that NPY promotes neuroprotection and restores bone marrow dysfunction from chemotherapy-induced SNS injury through the Y1 receptor in macrophages. They also reveal a new role of NPY as a regulator of the bone marrow microenvironment, and highlight the potential therapeutic value of this neuropeptide.

Medicine, Col. of Medicine, Dankook Univ., Cheonan, Korea, Republic of

Abstract: Ursolic acid (UA), a natural pentacyclic triterpene acid, has been reported to possess many biological functions, including anti-oxidant, anti-cancer, anti-inflammatory effects, and neuro-protective effect. However, no studies have been designed to investigate whether UA has an effect on axonal regeneration. Herein, we show here that administration of UA increases neurite outgrowth of rat dorsal root ganglion (DRG) neurons *in vitro* and promotes the regeneration of sciatic nerve *in vivo*. UA (2.5μM) promoted neurite outgrowth from primary cultured adult rat DRG neurons, whereas significantly decreased the number of axon branches. The effect of UA on neurite outgrowth of DRG neurons was similar with PTEN inhibitor bpV(HOpic). Combination of UA and bpV(HOpic) (UA+bpV(HOpic)) showed a synergistic effect on neurite outgrowth than UA only and bpV(HOpic) only, but no difference was found in the number of axon branches. Western blot results showed that phosphorylation level of AKT and S6 ribosomal protein was significantly upregulated in both UA and UA+bpV(HOpic) combination. Sciatic nerve crush injury was performed 5mm distal from the hip joint. The animals were randomly divided into four groups (n=5) : Group I, vehicle (corn oil, 0.25ml/day) ; Group II, UA (10 mg/kg/day); Group III, bpV(HOpic) (0.05 mg/kg/day); and Group IV, UA+bpV(HOpic) combination. Vehicle and drugs were intraperitoneally administered at 0 hr, 24 hr, and 48 hr. Assessment of regeneration using the pinch test 72 h after crush injury revealed that Group II, Group III, and Group IV were more effective compared to Group I in the rate of regeneration after sciatic nerve crush injury, but no significant difference was found among the 3 groups. Our findings indicate that UA can increase neurite outgrowth by upregulating phosphorylation level of AKT and S6 ribosomal protein and promote axonal regeneration following peripheral nerve injury.

Title: Acute intermittent hypoxia promotes regeneration-associated gene expression in axotomized peripheral nerve akin to electrical stimulation

Authors: *J. R. NADEAU[1,2], B. M. ARNOLD[2,1], G. D. MUIR[2], V. M. K. VERGE[1];
[1]Anat. and Cell Biology/CMSNRC, [2]Vet. Biomed. Sciences/WCVM, Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Despite an intrinsic ability for peripheral nerves to regenerate, it is still fraught with challenges often maladaptive in nature. However, the intrinsic repair mechanism can be greatly improved by brief electrical stimulation (ES) at the time of surgical repair resulting in better functional outcomes in both rodents and humans (Al-Majed et al. [2000] J. Neurosci. 20(7):2602-2608); Gordon et al. [2010] Exp. Neurology 223(1):192-202). However, ES is invasive and becomes difficult if the nerve is not readily accessible. An emerging non-invasive therapy, acute intermittent hypoxia (AIH), promotes respiratory and non-respiratory motor function in spinal cord injured rats and humans (reviewed in Dale et al., [2014] Physiology 29(1):39-48). AIH consists of breathing alternating periods of air with half oxygen (11%) and regular air for ten cycles and results in increased phrenic nerve output activity in the rat (reviewed in Mitchell GS, Johnson SM. [2003] J Appl Physiol. 2003;94:358–374). Because the AIH effect is presumably systemic and likely also increases neuronal activity in the peripheral nervous system, we hypothesized that it will impact repair of peripheral nerves and regenerative neuronal reprogramming in a manner akin to that we have observed with ES. To examine the impact of AIH on regeneration-associated gene expression, the tibial nerve in adult male Lewis rats was transected and repaired. AIH (5 min alternating for 10 cycles) was delivered on day 2 and day 3 post-tibial nerve repair, followed by animal perfusion and tissue dissection. Normoxia (continuous regular air) or sciatic nerve ES (1hr; 20Hz) delivered proximally at the time of nerve repair served as controls. Our preliminary results reveal a significant effect of AIH on regeneration associated-gene expression in a manner ressembling that in response to ES. Elevated levels of betaIII-tubulin, brain-derived neurotrophic factor, growth-associated protein-

43, SCG10 in the peripheral nerve neurons at the level of the cell bodies and the growing axon front were observed. Further, behavioral analysis of neuropathic pain states revealed no significant impact of either AIH or ES compared to normoxia for up to 10 weeks post-surgical repair. Impacts on axon regeneration are currently being assessed.

Title: Involvement of c-jun N-terminal kinase in neurite extension of cultured DRG neurons

Authors: **T. H. NGUYEN**, S. MATSUMURA, T. KATANO, *S. ITO;
Kansai Med. Univ., Hirakata Osaka, Japan

Abstract: Peripheral neurons are able to regenerate after axonal injuries. However, the quality of the peripheral nerve regeneration depends on the distance between the injured sites and the target organs. The longer the distance from the injured site to the target organs, the poorer the nerve regeneration. So, the speed of axonal outgrowth is important for the peripheral neurons to reach their target organs timely before these organs become impermissive for nerve regeneration. Neurotrophic factors including NGF, BDNF and GDNF are proved to accelerate peripheral nerve regeneration. We have established the sciatic nerve transection-regeneration model and showed that c-jun N-terminal kinase (JNK), a member of mitogen-activated protein kinase, delayed peripheral nerve regeneration. In an initial approach to clarify which neurotrophic factor is involved in peripheral nerve regeneration *in vivo*, we examined the effect of JNK of neurite extension using mice primary cultured DRG cells. NGF and GDNF at 10 ng/mL increased the percentage of neurons with neurites 3 times higher as compared to the control. Similarly, BDNF at 10 ng/mL increased it 1.5 times. The JNK 600125 inhibitor attenuated the increase in percentage of neurons with neurites by NGF, GDND, and BDNF up to 10 μM in a concentration-dependent manner. The maximum effect of inhibition was 4.4, 2.2 and 2.6 times for NGF, GDNF and BDNF, respectively. These results support the *in vivo* observation that neurotrophic factors may accelerate peripheral nerve regeneration through the JNK pathway.

Ctr. for the Oceans and Human Health, City Univ. of Hong Kong Shenzhen Res. Inst., Shenzhen, China; [5]Dept. of Biol. and Chem., City University of Hong Kong, Tat Chee Avenue, Hong Kong

Abstract: Ciguatera fish poisoning (CFP) is a common foodborne illness causing chronic and persistent neurological effects on peripheral nervous system. It has become a global health issue and its incidence is increasing. The initial symptoms of CFP are gastrointestinal and cardiovascular, which disappear by two weeks' time. However, neurological symptoms, such as muscle fatigue could last for months or years. Proximal peripheral nerve injuries could be potentially devastating and leading to motor function deficit. Restoration of motor function after injury requires not only successful regeneration of damaged axons, but also reinnervation to their target muscles, forming functional neuromuscular junctions (NMJs). Our behavioral studies showed that exposure to pacific ciguatoxin-1 (P-CTX-1) delayed sensory and motor function after sciatic nerve injury significantly. We therefore examined the chronic effect of P-CTX-1 on axonal regrowth and functional NMJ formation in mice after injury following pre-exposure to P-CTX-1. Male adult C57BL/6 mice were administered sub-lethal dose of P-CTX-1 (0.26ng/g, i.p.) twice (day 0 & 3) and sciatic nerve crush was performed on day 14. Animals were provided with food and water ad libitum and maintained under a 12:12 h light/dark cycle for 8 weeks. Sciatic nerve and lateral plantar muscles were harvested after perfusion two months after the injury. Transverse cryosection of sciatic nerve (Ipsilateral and contralateral) were immunostained with anti-NF-200 and total number of axons was quantified. Lateral planter muscle cryosection were immunostained with anti-α-bungarotoxin and anti-NF-200. Sections were quantified into three

categories i.e. fully innervated, partially innervated and denervated. The result of axon quantification showed significant decrease in NF-200 positive axon in the sciatic nerve 5- to 20-mm distal to injury site as compared with vehicle control in ipsilateral side ($P<0.05$). The number of axons in contralateral side reduced suggesting the systemic effect of P-CTX-1 on uninjured axons. NMJ numbers decreased significantly in the ipsilateral ($P<0.05$) and contralateral ($P<0.05$) side to injury in lateral planter muscle. We also performed electromyography (EMG) recording during the course of recovery to assess functional synapse formation following injury. EMG signal was reduced significantly in P-CTX-1 treated mice which in line with our histology and behaviour data.

Title: A peripheral compensatory mechanism of nerve debris clearance after injury in the absence of CCR2+ macrophages

Authors: *J. LINDBORG, R. ZIGMOND;
Neurosciences, Case Western Reserve Univ., Cleveland, OH

Abstract: Wallerian degeneration is the process by which transection or crushing of the axons of peripheral neurons leads to degeneration and clearance of the distal axonal segment. Studies on Wallerian degeneration widely report that monocyte entry into the degenerating distal nerve is necessary for phagocytosis and is required to promote regeneration by the proximal nerve segment. CCR2+ monocytes enter tissues and differentiate into macrophages, which are purported to be the key players in this clearance process. Using a CCR2-/- mouse model, in which the infiltration of CCR2+ monocytes is inhibited, we found that these macrophages may not play as pivotal a role in axonal degeneration as previously believed. Specifically, the disappearances in the distal nerve of myelin (including a specific myelin protein P0) and the axonal light neurofilament protein were similar in CCR2-/- and in wild type (WT) mice 7 days after a sciatic nerve transection, in spite of substantially decreased macrophage accumulation in

the CCR2-/- nerve. Luxol fast blue and toluidine blue-stained nerves were used to assess myelin degeneration and removal after nerve transection. A phagocytosis assay and a time course after injury show that significantly more myelin is removed at 3 days post-injury in the distal nerve segment of CCR2-/- mice, and that an increased amount of myelin is contained within glial fibrillary acidic protein (GFAP)-labeled Schwann cells compared to WT mice. Flow cytometry, western blotting, qPCR, and immunohistochemistry were used to identify the fluctuating patterns of phagocytosis by leukocytes and Schwann cells during degeneration of the sciatic nerve in WT and CCR2-/- animals. We hypothesize that in the absence of infiltrating CCR2+ monocytes in the CCR2-/- mouse, a different phagocyte (or phagocytes) plays a compensatory role in the clearance of degenerating nerve debris and that this role is at least in part played by Schwann cells. Our evidence suggests that this $CCR2^-$ phagocyte may be sufficient for debris clearance in the sciatic nerve, and we propose that CCR2+ macrophages may play a different and less well-known role in Wallerian degeneration.

Title: Reduced induction of injury-induced cytokines and neuropeptides after nerve injury in a mouse model of type 1 diabetes

Authors: *A. R. FILOUS, J. P. NIEMI, A. DEFRANCESCO-LISOWITZ, R. E. ZIGMOND; Neurosciences, Case Western Reserve Univ., Cleveland, OH

Abstract: Neuropathy is a major complication for those suffering from diabetes. It is often associated with numbness, intractable pain, and loss of function. The exact mechanisms underlying diabetic neuropathy are not well-understood, but are believed to partially result from regenerative deficits that accumulate over time, leading to loss of innervation. Previous work from our lab has established that members of the gp130 family of cytokines (or neuropoietic cytokines) are induced after injury and play a role in signaling for regeneration in normal animals (Hyatt Sachs et al., 2010). Here, we explored the possibility that these cytokines may have a reduced induction after injury in diabetic mice, leading to nerve regeneration deficits. We used streptozotocin (STZ) to selectively deplete pancreatic β-islet cells, depleting insulin and ultimately leading to chronic hyperglycemia in these mice. This is the most commonly used chemically-induced model of type 1 diabetes. We injected mice with either multiple low dose

injections of STZ (5x 60mg/kg) or a single high dose injection (1x 200mg/kg) and examined the mice at least four weeks later. At this time, we superimposed nerve injuries [axotomy of the neurons in the superior cervical ganglion (SCG) and axotomy of the sciatic nerve] to study the regenerative response in diabetic mice compared to age-matched controls. Using both the SCG and dorsal root ganglia (DRG), we were able to examine the effects on both sympathetic and sensory neurons. We found that both ganglia have reduced induction of two gp130 cytokines, leukemia inhibitory factor and interleukin-6, after injury. This is accompanied by reduced phosphorylation of signal transducer and activator of transcription 3 (STAT3), a downstream effector of the gp130 signaling pathway. We also found various gp130-dependent regeneration-associated genes (Habecker et al., 2009) including galanin, vasoactive intestinal peptide and pituitary adenylate cyclase activating peptide have reduced induction after injury as well. These changes may lead to deficits in neurite outgrowth of dissociated SCG and DRG neurons. Together, these data suggest a novel mechanism for diabetic neuropathy.

Title: Overexpression of CCL2 in dorsal root ganglia is sufficient for enhanced axonal regeneration

Authors: *J. P. NIEMI, A. DEFRANCESCO-LISOWITZ, M. HOWARTH, R. ZIGMOND; Neurosciences, Case Western Reserve Univ., Cleveland, OH

Abstract: Neuroinflammation plays a critical role in the regeneration of peripheral nerves following axotomy. An injury to the sciatic nerve leads to significant macrophage accumulation in the L5 DRG, an effect not seen when the dorsal root is injured. Recent evidence showed that macrophage accumulation around axotomized cell bodies is necessary for a peripheral conditioning lesion response. In response to an axonal injury, DRG neurons upregulate and release CCL2, a macrophage chemokine which acts on the receptor CCR2. In a CCR2 knockout mouse (CCR2-/-), CD11b+ macrophage accumulation was inhibited in the distal sciatic nerve

and in the axotomized DRG after injury. To ascertain the effect on regeneration, DRGs were placed in explant culture 1 week after a conditioning lesion. Increased outgrowth was seen in previously lesioned DRGs from WT but not CCR2-/- mice. These data suggest a relationship between macrophage accumulation near neuronal cell bodies and the regenerative capacity of neurons as well as highlighting the role CCL2/CCR2 signaling plays in mediating macrophage entry into DRGs after injury. To probe the importance of this signaling, we asked whether overexpression of CCL2 specifically in DRG neurons of uninjured mice would be sufficient to cause macrophage entry and enhanced regeneration, or whether other injury-derived signals are necessary. We found that CCL2 could be significantly overexpressed in DRG neurons by utilizing an adeno-associated virus (AAV) delivered intrathecally. AAV-CCL2 injection led to a time dependent increase in CCL2 mRNA expression compared to AAV-YFP controls, with a maximal response seen at 3 weeks post-injection. Consequently, CCL2 overexpression also led to a time dependent increase in CD11b+ macrophages in the L5 DRG compared to YFP controls, with a maximal response at 3 weeks post-injection, a time point used in all subsequent experiments. CCL2 overexpression and subsequent macrophage accumulation led to a conditioning-like increase in neurite outgrowth of DRG explants from mice injected with AAV-CCL2 compared to AAV-YFP controls. This increase in regeneration was dependent upon CCL2 acting through its primary receptor CCR2. When CCL2 was overexpressed in CCR2-/- mice, macrophage accumulation and enhanced regeneration were not seen. Finally, administration of AAV-CCL2 resulted in increased LIF mRNA and increased neuronal pSTAT3 in L5 DRG. Thus, CCL2 overexpression is sufficient to cause increased macrophage accumulation and increased regenerative capacity of DRG neurons. This likely occurs through the stimulation of signaling pathways critical for regeneration including the activation of the JAK-STAT pathway.

Title: Potential therapeutic applications of chondroitinase C for *in vivo* selective CSPG degradation

Authors: *J. B. GRAHAM, D. MUIR;
Univ. of Florida Col. of Med., Gainesville, FL

Abstract: Chondroitin sulfate proteoglycans (CSPGs) are potent inhibitors of axon regeneration in both the central and peripheral nervous system. CSPGs are constitutively expressed throughout the extracellular matrix and are postulated to maintain homeostasis of inherently sprouting nerve cell appendages through negative interactions of the glycosaminoglycan (GAG) chains. The formation of CSPG rich perineuronal nets that appear during maturation of spinal motor neuron pools are believed to suppress neuronal plasticity through this mechanism. Several laboratories have investigated the application of chondroitinase ABC (ChABC) to degrade the inhibitory CSPG GAG chains of perineuronal nets and induce neuronal plasticity with much success but recent studies within the peripheral nervous system have provided evidence that excessive sprouting may lead to aberrant regeneration. We have successfully enhanced peripheral axon regeneration *in vitro* through selective degradation of CSPG GAG chains using chondroitinase C (ChC), an isozyme of ChABC which is more selective towards chondroitin sulfate C than chondroitin sulfate A or dermatan sulfate. Selective degradation was supported by Alcian Blue and Coomassie Blue stained SDS-PAGE showing complete or partial removal of GAG chains and molecular weight shifts of CSPG core proteins compared to ChABC treatment. Additionally, western analysis confirmed selective degradation with neoepitope labeling of CSPG core proteins at different molecular weight shifts. Furthermore, western analysis has provided evidence that ChC does not degrade GAG chains associated with certain CSPG core proteins. Finally, we applied ChC or ChABC to fixed frozen sections of normal rabbit spinal cord and adult mouse brain and provided evidence that both enzymes have the ability to degrade GAG chains associated with perineuronal nets by producing neoepitope labeling immunoreactive towards C6S antibody. Although the enzymatic activity of ChC has been documented to be inhibited at physiological conditions, we have provided evidence of the contrary by producing C6S immunoreactive neoepitope following microinjection of ChC into the mouse sciatic nerve. Here we provide evidence of potential functional consequences following application of ChC *in vitro* and *in vivo*.

Abstract: Mesoporous silica nanoparticle (MSN) has many advantages as an efficient drug delivery system including a large surface area, high porosity and intrinsic biocompatibility which allow the absorption and release of multiple drugs and biomolecules. We aim to delineate whether PTEN inhibitor-conjugated MSN is more effective on the axonal outgrowth of peripheral nerve than the application of PTEN inhibitor without a delivery system *in vitro* condition and MSN can be loaded into various neurons and glial cells *in vivo* conditions. For *in vitro* study, bisperoxovanadium (BpV) (HOpic) was conjugated to functionalized and rhodamine-labeled MSNs (MSN-BpV) and then applied to primary cultured dorsal root ganglion (DRG) which were dissected from Sprague Dawley (SD) rats. We found that the efficiency of MSN transfection into DRGs were over 95% when the concentration of MSN within culture media was over 20μg/ml. After the application of MSN-BpV to DRGs, the maximal length of outgrowing DRG axons was longer than those only treated with BpV at 20 and 40μg/ml. Western blotting revealed that MSN-BpV treated DRGs showed lower pPTEN/PTEN level and lower pAkt/Akt level than those only treated with BpV at the same concentration and non-treated controls. MSNs were also directly injected into the brain, spinal cord, and DRGs of neonatal or adult SD rats. We found that MSNs were successfully internalized into the cytoplasm of neurons, astrocytes, oligodendrocytes and macrophages. We conclude that MSNs effectively deliver PTEN inhibitor into sensory neurons and enhance axonal outgrowth without cell toxicity *in vitro* and may play an important role in transport of drugs or biomolecules into neurons and glial cells in the central and peripheral nervous systems *in vivo*.

Title: Brief electrical stimulation promotes immune cell clearance and polarizes macrophages toward a pro-repair M2 phenotype in focally demyelinated peripheral nerve

Authors: *N. A. MCLEAN[1,2], V. M. K. VERGE[1,2];
[1]Anat. and Cell Biol., Univ. of Saskatchewan, Saskatoon, SK, Canada; [2]CMSNRC, Saskatoon, SK, Canada

Abstract: Demyelinating diseases are characterized by segmental demyelination of axons and infiltration by cells of the monocyte lineage. We and others have shown that brief electrical stimulation (ES) at the time of peripheral nerve repair enhances regeneration of sensory and motor neurons including axonal remyelination. Recently we have shown that brief ES, 5 days after a focal demyelinating lesion, accelerates removal of myelin debris and myelin repair, promotes axonal protection and is accompanied by the enhanced clearance of ED-1 positive macrophages from the demyelination zone by 5 days post-ES. Macrophages in response to local microenvironment cues can alter their functional polarity, exhibiting either a pro-inflammatory (M1) or a pro-repair (M2) phenotype, with the latter important for the resolution of inflammation and tissue repair. Because ES dramatically impacts remyelination, including macrophage responses, we posited that the ES may be polarizing macrophages toward a pro-repair state. To examine this, the right tibial nerve of adult male Wistar rats was focally demyelinated by 1% lysophosphatidyl choline (LPC) injection just distal to the trifurcation of the sciatic nerve. Five days later, half of the animals were subjected to 1 hour continuous 20 Hz ES proximal to the injection site. At 5, 8, and 10 days post-LPC, animals were perfused and the right and left sciatic nerves removed and processed immunohistochemically to detect the impact of ES on macrophage phenotype. There is robust infiltration of ED-1 positive macrophages into the lesion site, the majority of which are also positive for the M1 phenotype associated markers TNF-α and iNOS by 5 days post LPC. By 8 and 10 days post-LPC (3 and 5 days post-ES) stimulated nerves displayed a significant reduction in the number of M1 phenotype macrophages, coupled with an increase in the percentage of ED-1 positive macrophages expressing the M2 phenotype markers CD206 and Arginase-1. This transition occurs at a time point coincident with an overall reduction in the numbers of ED-1 positive macrophages present within the lesion site. These results suggest that ES may help create an environment permissive for early remyelination by promoting a switch to a pro-repair M2 macrophage phenotype.

Title: Lycium barbarum polysaccharide enhances the intrinsic growth capacity of dorsal root ganglion neurons

Authors: *N. P. B. AU[1], G. KUMAR[1], R. C. C. CHANG[3,5], K. F. SO[4,5], C. H. E. MA[1,2]; [1]Dept. of Biomed. Sci., [2]Ctr. for Biosystems, Neuroscience, and Nanotechnology, City Univ. of Hong Kong, Kowloon, Hong Kong; [3]Lab. of Neurodegenerative Diseases, Dept. of Anat., [4]Dept. of Ophthalmology, LKS Fac. of Medicine, The Univ. of Hong Kong, Pokfulam, Hong Kong; [5]State Key Lab. of Brain and Cognitive Sci., The Univ. of Hong Kong, Pokfulam, Hong Kong

Abstract: Unlike the central nervous system (CNS), the peripheral nervous system (PNS) can regenerate at a slow rate of axonal regrowth (1-2mm/day). Patients with proximal peripheral nerve injury such as brachial plexus injury often result in poor functional recovery largely due to the long distance axonal regrowth. Wolfberry (*Lycium barbarum*) is a well-known traditional Chinese medicine serves as an upper class herb without any known toxicity or side effect. Recent studies showed that one of its major active components *Lycium barbarum* polysaccharides (LBP) exhibit a wide range of beneficial activities including anti-aging, modulation of immune function, protection against liver damage and reduction in blood glucose levels in diabetes. In the CNS, LBP have been shown to promote the survival of retinal ganglion cells in an animal model of glaucoma, and reduce the Aβ-induced neurotoxicity in cortical neurons. However, the beneficial effect of LBP on axonal regeneration in nervous system remains largely unknown. In the present studies, we aim to examine if LBP could enhance the regenerative capacity of injured DRG neurons purified from the adult PNS. The dissociated primary DRG neuron is widely used to assess the intrinsic growth capacity and in gene expression profile studies. Our pilot data showed that LBP induced a marked increase in neurite outgrowth of DRG neurons at all concentrations we tested (0.1-300μg/ml) without any detectable cell survival effect. These data prompted us to examine the promoting effect of LBP on functional recovery after peripheral nerve injury. Further gene expression profile studies will provide insight into the molecular mechanism of LBP in PNS regeneration.

Title: A comparative proteomics analysis of proteins involved in modulating axonal growth in peripheral neurons

Authors: *J. S. VONG, C. H. E. MA;
Dept. of Biomed. Sci., City Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Our previous study showed that the time window for the regenerating axons to re-innervate their target motor endplates was limited to 35 days in mice. We have established an animal model to study critical period by performing repeated sciatic crushes to confine the time in which regenerating axons from reaching the muscle within the critical period (short-crush, <35 days) or outside the critical period (long-crush, >35 days) where functional recovery is limited. Sciatic nerve was crushed 4 times at 2-day intervals (short-crush) and 4 times at 9-day intervals (long-crush). Plantar muscle contralateral and ipsilateral to the sciatic nerve crush was dissected out for proteomic study. Differential protein expression profile after short- and long-crush was resolved by second-dimension gel electrophoresis. Fifteen proteins (spots) were identified and they are differentially regulated after short- and long-crush. We also examined the protein expression profile after chronic muscle denervation. We identified one cytoskeleton protein which was highly upregulated not only in the muscle but also in dorsal root ganglion (DRG) neurons after peripheral nerve injury. We showed that preconditioned primary DRG neurons highly expressed this cytoskeleton protein and its up-regulation result in longer neurite outgrowth. Loss of function assay by siRNA in preconditioned DRG neurons showed a significant reduction in neurite length. Further loss-of-function assay in animals will be performed to assess functional recovery after peripheral nerve injury. **Theme and Topic:** A.07.b. Title: Adult Skin-derived precursor Schwann cells (aSKP-SCs), like acutely injured nerves Schwann cells, exhibit superior myelination and regeneration supportive properties compared to chronically denervated nerve Schwann cells

Authors: *R. KUMAR[1], S. SINHA[2], E. RAHARJO[1], A. HAGNER[1], M. STYKEL[1], K. SINGH[3], R. MIDHA[1], J. BIERNASKIE[1];

Abstract: Despite the innate capacity of peripheral nervous system to regenerate, severe nerve injury patients with chronic nerve denervation never regain full function. Within chronically injured nerve, Schwann cells (SCs) fail to maintain regeneration supporting phenotype, which leads to poor functional recovery in afflicted patients. The goal of this study is to search and evaluate an ideal SC population and provide improved autologous cell transplantation therapy to augment nerve repair. Skin derived precursors (SKPs) are multipotent stem cells, and show phenotypic similarities to neural crest cells. Neonatal SKPs are capable of differentiation into Schwann cells (SCs), which express multiple markers of immature myelinating SCs. Upon transplantation into dysmyelinated or injured peripheral nerves neonatal SKP-SCs not only are capable of survival but also exhibit remarkable myelination. In acute and delayed nerve repair models of severe injuries neonatal SKP-SCs are able to show robust remyelination and restore functional recovery in an array of behavioral tests. We further assessed the potential of adult SKP-SCs (aSKP-SCs) and tested their capacities for promyelinating transcription factor expression, proliferation, neurite outgrowth, and remyelination. Here we show in line with previous literature, following chronic denervation SCs lose the capacity to support axon regeneration and show less robust myelination. We hypothesize that recapitulating the early denervation phenotype; transplanting aSKPSCs in the chronically denervated nerve may restore remyelination and regeneration support capacity. We compared SCs within acute and chronic injured nerves and found that acutely injured nerve SCs exhibit signature marker expression (Oct-6 and Krox-20) of myelinating embryonic SCs during development. Our data suggest that chronically denervated nerve SCs fail to exhibit comparable myelinating phenotype, exhibit retarded proliferation, show diminished neurite outgrowth, and demonstrate inferior *in vitro*/*in vivo* myelination as compared to acutely injured nerve SCs. It is remarkable that aSKP-SCs express the markers of promyelinating SCs such as Sox-10, Oct-6 and Krox-20 and exhibit superior proliferation, neurite outgrowth, and *in vitro*/*in vivo* myelination, which is very similar to acutely or embryonic nerve SCs and superior to chronically denervated nerve SCs. Based on our findings we conclude that aSKP-SCs may serve as a potential source of myelinating SCs to repair injured nerves and can serve as a potential source of autologous cell therapy in patients.

Title: The axonal palmitoyl acyltransferases DHHC5 and DHHC8 are essential for retrograde injury signaling by the gp130/JAK/STAT3 pathway

Authors: *A. MONTERSINO, K. M. COLLURA, S. M. HOLLAND, G. M. THOMAS; Shriners Hosp. Pediatric Res. Ctr., Temple Univ., Philadelphia, PA

Abstract: The protein-lipid modification palmitoylation is an important regulator of protein targeting and trafficking. Interestingly, genetic mutation or loss of a number of palmitoyl acyltransferases (PATs, which catalyze palmitoylation) cause predominantly neuropathological defects, suggesting that palmitoylation plays particularly important roles in neurons. Although there have been several recent advances in the identification of roles and substrates of specific PATs, virtually nothing is known about PAT expression and distribution in peripheral neurons, and the roles of PATs in axons are largely unclear. We therefore sought to identify roles for specific PATs in peripheral axons. One process that is particularly important in peripheral axons is retrograde signaling after a nerve injury, in which proteins are physically transported from distal sites of damage to activate pro-regenerative transcription. One key retrograde signaling pathway involves the transmembrane receptor gp130, its associated kinase JAK, and JAK's substrate STAT3. Here, we report that gp130 is palmitoylated in transfected heterologous cells and endogenously in neurons. To identify potential regulators of gp130 palmitoylation we determined the distribution of all 23 mammalian PATs in sensory neurons. Strikingly, we found that only 2 of 23 PATs, DHHC5 and DHHC8, are enriched in sensory axons and that knockdown of these axonal PATs reduces both palmitoylation and surface targeting of gp130 in sensory neurons. Moreover, consistent with this impaired gp130 targeting, DHHC5 and DHHC8 are essential for retrograde signaling by gp130/JAK/STAT3. Together these findings identify the first axonally enriched PATs and the first axonal substrate for DHHC5/8. We will further discuss how these findings provide new insights into how injury response signals are coordinated and conveyed.

Title: Chemotherapeutics and the taste system: Using cyclophosphamide to study system recovery

Authors: *D. HARRIS[1], D. E. MORGAN[1], E. R. DELAY[2];
[2]Biol., [1]Univ. of Vermont, Burlington, VT

Abstract: Patients undergoing chemotherapy often report disturbances in their ability to taste. These deficits can lead to decreased appetite, malnutrition, and ultimately poorer prognoses. Previous work in this lab has examined the effects of the chemotherapeutic cyclophosphamide (CYP) on the taste system of mice. Initial analyses have shown biphasic (post-injection days 2-3, 9-12) deficits in taste sensitivity and acuity through behavioral measures. These behavioral measures directed immunohistochemical (IHC) assays examining the state of tissue at days 0, 4, 7, 10, 12, 16, and 21 following a single moderate dose of CYP (75 mg/kg). Briefly, mice were perfused using 4% paraformaldehyde, and the tongue was extracted and cryoprotected in 30% sucrose. After being frozen, slides were sectioned and stained for cell type (PLCβ2, SNAP25), proliferation (Ki67, BrdU), and cell death (TUNEL assay and caspase-3). Fungiform papillae showed (1) decreases in Ki67, PLCβ2, and BrdU expression 4 days post injection, (2) maintained deficits in PLCβ2 expression at 7 days post injection, and (3) increased Ki67 expression 10 days post injection. Circumvallate papillae showed decreased expression of (1) Ki67 at day 4 post injection, (2) PLCβ2 at 7 days post injection, and (3) PLCβ2 and BrdU at 10 days post injection. We are expanding upon these initial findings to more fully understand the extent to which the taste system is compromised by CYP. To do this, we are analyzing taste cell populations all days between the time points studied previously. This time-course will be critical for evaluating potential mechanisms underlying recovery of taste function. We are also looking at potential mechanisms involved in the restoration of these taste cell populations. Sox2, for example, is necessary for embryological development of the anterior tongue and taste system and may play a critical role in the recovery of the taste system following injury by CYP. Adult Sox2 expression in the taste system appears to decrease 4 days following CYP injection. Understanding the nature and mechanisms of tissue recovery can provide means to help those undergoing chemotherapy to have better nutritional intake and quality of life.

Title: Sensory neuron involvement in caudal fin regeneration in zebrafish, Danio rerio

Authors: M. YOUNISS[1], *N. W. KLECKNER[2];
[1]Biol., [2]Biology/Neuroscience, Bates Col., Lewiston, ME

Abstract: Most organisms have the ability to regenerate certain body parts. However, some vertebrates have a particularly extensive regenerative capacity. For example, some amphibian limbs and fish tails can be regrown when lost, and both of these processes are well characterized. Amphibian limb regeneration has been found to be dependent on the presence of nerves; once denervated, a limb loses its ability to regenerate following an amputation. This dependence is due to the release of anterior gradient proteins (nAg, in salamanders) by Schwann cells. While zebrafish (*Danio rerio)* tail regeneration is phenotypically well characterized, neither its dependence on the presence of nerves nor its expression of anterior gradient proteins (*agr1 or 2* in zebrafish*)* during the process have been explored. This study provides the necessary preliminary experiments to ultimately compare amphibian limb and zebrafish caudal fin regeneration. We explored *agr2* expression in the caudal fin during normal regeneration in juvenile zebrafish (4-6 weeks old, chosen to ensure comparisons in later live imaging experiments). Additionally, multiple denervation techniques, including mechanical denervation and denervation by exposure to metronidazole or paclitaxel, were explored. Denervation was verified by comparing anti-acetylated tubulin antibody labeling of caudal fin axons of treated and control fish. We found that the expression of *agr2*was upregulated in the caudal fin during regeneration, although not specifically in the blastema. Additionally, while mechanical denervations did not consistently remove neural input, exposure of fish to 1 and 10 mM metronidazole in system water and intraperitoneal injection of 10 μM paclitaxel were promising methods for caudal fin axon degeneration. These findings can be used in later studies to determine if regeneration is dependent on neural input, as seen in amphibians. Denervation techniques will be utilized prior to amputation, and regeneration and *agr2* expression will be compared to normal phenotypic regrowth and expression. Conserved or contrasting pathways may highlight why most vertebrates have such a limited ability to regenerate.

Title: Transforming growth factor beta regulates expression of fibroblast growth factor -7 in schwann cells

Authors: D. H. NGUYEN[1], A. MUHAMMAD[2], *I. IWUCHUKWU[3], W. O. SULAIMAN[2]; [1]Neurosurg., [2]Ochsner Med. Ctr., New Orleans, LA; [3]NEUROLOGY, Ochsner Clin. Fndn., New Orleans, LA

Abstract: Background and Objective: Our previous works using a chronic denervation and axotomy rat model have demonstrated that transforming growth factor -beta (TGF-β1) and forskolin reactivated Schwann cells (SCs). We also found that expression of fibroblast growth factor-7 (FGF-7) decreased 3.8-fold. In this study, we examined the molecular mechanism of TGF-β and forskolin on the expression of FGF-7 in cultured primary SCs. Methods: SCs were isolated from the sciatic nerve of adult female Sprague Dawley rat. SCs were used at passage 3-6. SCs (5 x10^5 cells) were cultured on poly-L-lysine coated 12-well tissue cluster for 6 days, starved overnight in DMEM, and stimulated with forskolin (0.25 or 0.5 uM), TGF-β (1 or 5ng/mL), or TGF-β plus forskolin for 24 hours. SCs were also pretreated with LY2109761 (0.5uM), a TGF-β receptor type I/II dual inhibitor, for 15 min prior to stimulation with TGF-β (1ng/mL) plus forskolin (0.5 uM) for 6 hours. Total RNA was isolated, reverse transcribed followed by real-time Taqman qPCR amplification. Cycle threshold (Ct) data were normalized to the ribosomal protein (RPLPO) reference gene and fold change relative to the untreated SCs were determined using the delta-delta Ct method. Results: At the concentrations of TGF-β and forskolin used in the *in vivo* studies, treatment of SCs with TGF-β (1ng/mL) alone or in combination with forskolin (0.5 uM) for 24 hours resulted in a 5.3-and 2.8 fold decrease in FGF-7 expression compared to untreated controls. No changes in FGF-7 expression were found with forskolin only treatment. Increasing the concentration of TGF-β (5 ng/mL) resulted in a 9.1 fold reduction in FGF-7 expression; whereas decreasing the concentration of forskolin (0.25 uM) resulted in a 2.2-fold reduction; the combined treatment resulted in a 1.4-fold increase in expression of FGF-7. Treatment with TGF-β/forskolin for 6 hours resulted in a 4.0-fold decrease in FGF-7 expresssion; Blocking of TGF-β receptor with LY2109761 lead to a decrease of 2.7-fold. Conclusion: We showed that expression of FGF-7 in SCs is regulated by TGF-β, and that addition of forskolin modulates TGF-β effect on FGF-7 expression. FGF-7 may have a role in nerve regeneration by affecting the responses of other cells, namely epithelial cells. Hence,

modulation of FGF-7 expression in SCs may be necessary in chronic nerve repair and regeneration.

Title: Cyclophosphamide-induced loss in murine olfactory systems

Authors: N. AWADALLAH[1], K. R. PROCTOR[2], E. R. DELAY[3], *R. J. DELAY[3];
[1]Neurosci. Undergraduate Program, [2]Med. Lab. Sci., [3]Biol., Univ. of Vermont, Burlington, VT

Abstract: Patients undergoing chemotherapy often report profound changes in their ability to taste and smell during and after drug therapy. Cyclophosphamide (CYP), one of the first chemotherapy agents, is an alkylating agent known to disrupt taste functions by its cytotoxic effects on taste buds and by temporarily halting the adult taste cell renewal process. However, little is known about the effects of CYP on the olfactory system. Since the sense of smell depends on the presence of olfactory neurons that undergo replacement similar to the taste system, we asked if a single injection of CYP would affect olfactory neurons? We examined the effects of CYP on olfactory neurons of the main olfactory epithelium (MOE) and the vomeronasal organ (VNO). We used an antibody to Ki67, a protein only expressed in cells undergoing division (G1, S, G2, mitosis). Male C57BL/6J mice were given a single IP injection of CYP (75 mg/kg) or saline and sacrificed from 1 day to 80 days post-injection. Mice were perfused with 4% paraformaldehyde, decalcified with EDTA, cryto-protected, sectioned and incubated with Ki67 antibody (Thermo scientific). There were clear differences between the MOE and the VNO across all the time points. At 1 day post injection the MOE looked damaged, especially in the dendritic region while the VNO was structurally unaffected. However both tissues showed a decrease in KI67 protein label compared to controls. By day 2, neither tissue showed any Ki67 labeling. In addition both the VNO and the MOE showed significant drops in Ki67 labeling 14 days post injection and 60 days post injection compared to controls. So far our data suggest that the MOE was more affected by CYP than the VNO. These findings provide important insights into the loss of olfactory function reported by patients during and after chemotherapy treatment.

Title: Zinc supplementation by zinc plus cyclo-(His-Pro) increases progenitor cell proliferation after hypoglycemia

Authors: *A. KHO[1], J. KIM[1], I. KIM[1], B. CHOI[1], S. LEE[2], M. SOHN[3], S. SUH[1];
[1]Dept. of physiology, [2]Dept. of neurology, Hallym Univ., Chuncheon, Korea, Republic of; [3]Dept. of nursing, Inha university, Incheon, Korea, Republic of

Abstract: Neurogenesis after brain injury contributes to neuronal replacement and functional recovery. Hypoglycemia-induced brain injury increases transient neurogenesis in the dentate gyrus (DG) subgranular zone (SGZ). At four weeks after severe hypoglycemia, progenitor cell proliferation in the SGZ was reduced below baseline in sham-operated rats. In our previous study, zinc chelation or vesicular zinc depletion reduced hypoglycemia-induced neurogenesis. To test whether zinc supplementation can increase hippocampal neurogenesis after severe hypoglycemia we injected zinc with histidine and proline compounds (Cyclo-(His-Pro)) for 3 weeks starting at one week after hypoglycemia. It is well known that histidine-proline-rich glycoprotein plays a role in zinc transport. Cyclo-(His-Pro)(CHP) is a naturally occurring peptide found in the central nervous system (CNS) that can affect brain function after systemic administration. CHP has been used as a dietary supplement and is known to be a neuromodulator capable of crossing the blood-brain barrier (BBB). Several studies found that CHP improves zinc absorption and maintains steady concentrations of zinc for more than 12 hours. To investigate whether zinc supplementation can improve hypoglycemia-induced neurogenesis we used an animal model of insulin-induced hypoglycemia. Acute hypoglycemia was induced by intraperitoneal injection of human insulin (10 U/kg), and then iso-electricity was maintained for 30 minutes. We examined the neurogenic effects of zinc supplementation with zinc plus cyclo-(His-Pro) at 4 weeks after hypoglycemia in the SGZ. Sham-operated rats were also injected with or without zinc plus cyclo-(His-Pro) for 3 weeks. We performed immunohistochemistry using a ki67 antibody to detect progenitor cell proliferation. At four weeks after hypoglycemia, the number of Ki67 (+) cells decreased below baseline compared to sham-operated rats. However, three weeks supplementation of zinc with cyclo-(His-Pro) increased the number of Ki67 (+) cells in the hippocampal SGZ above baseline in hypoglycemia experienced rats. Furthermore, even in sham-operated rats the number of Ki67 (+) cells were higher than baseline levels The present study demonstrated that zinc plus cyclo-(His-Pro) supplementation positively affected hippocampal neurogenesis after severe hypoglycemia.

Title: A G protein-binding domain within the M3-M4 loop of the α7 nicotinic acetylcholine receptor enables a downstream calcium signaling response beyond the time course of channel activation

Authors: ***J. KING**, M.-K. LIN, N. KABBANI;
Krasnow Inst., Fairfax, VA

Abstract: α7 nicotinic acetylcholine receptors (nAChRs) play an important role in various aspects of synaptic transmission via their regulation of intracellular signaling pathways. In recent studies, we have demonstrated an important functional role for α7 nAChR interactions with intracellular heterotrimeric GTP binding proteins in various types of cells. Here we show that direct coupling of the intracellular loop of the α7 receptor to Gαq enables a downstream calcium signaling response that persists beyond the expected time course of channel activation. This process is made possible via an evolutionary preservation of a G protein-binding cluster (GPBC) within the M3-M4 loop of nAChRs. A specific mutation of the GPBC in α7 (α7-345-348A) abolishes interaction with G proteins while having no effect on the synthesis, α-bungarotoxin binding properties, or cell-surface trafficking of the receptor. Expression of α7-345-348A does however significantly attenuate the downstream calcium signaling response following activation of the receptor by the α7 selective agonist choline. This data provides novel evidence on the existence of a metabotropic G protein-binding domain within the α7 receptor and a mechanism for nAChR mediated signaling in cells.

Title: Removal of α4 nAChR subunits from adult VTA neurons alters VTA dopamine neuron excitability and locomotor activity

Authors: *S. E. ENGLE[1], J. N. BERRY[1], M. C. ARVIN[1], J. M. MCINTOSH[2,3], R. M. DRENAN[1];
[1]Medicinal Chem. and Mol. Pharmacol., Purdue Univ., West Lafayette, IN; [2]George E. Wahlen Veterans Affairs Med. Ctr., Salt Lake City, UT; [3]Psychiatry and Biol., Univ. of Utah, University of Utah, UT

Abstract: Nicotinic acetylcholine receptors (nAChRs) containing α4 and/or α6 subunits have a high sensitivity to nicotine and are implicated in nicotine's reinforcing properties. Determining if nicotine's effects are mediated by receptors containing both subunits, α4α6* nAChRs, remains challenging. In these experiments, we sought to study the effect of removing α4 subunits only from ventral tegmental area (VTA) neurons in adult mice. To do this, a viral vector directing expression of Cre recombinase was injected into the VTA of adult mice with loxP sites flanking the α4 subunit gene (α4flox mice). When α4 subunits are removed from the VTA of adult α4flox mice using Cre, nAChR function is diminished, as seen by significantly reduced ACh-evoked currents in VTA dopamine (DA) neurons. VTA DA neuron action potential firing is also modified in α4flox mice upon removal of α4 subunits from the VTA. Using current-clamp mode, we measured firing frequency during 2 sec current injection steps. When α4 subunits are removed, VTA DA neurons are more excitable. Small current injections (+20 pA) cause the firing rate of Cre(+) neurons to increase significantly compared to Cre(-) neurons. From these results we hypothesized that removal of α4* nAChRs from GABAergic neurons in VTA results in less tonic inhibition of VTA DA neurons. To test this we measured spontaneous inhibitory postsynaptic currents (IPSCs) on VTA DA neurons. Indeed, we saw that the frequency, but not amplitude, of IPSCs was significantly reduced when α4 subunits were removed from the VTA. To further test this hypothesis with a behavioral measure, we crossed α4flox mice with α6L9S mice, which express hypersensitive nAChRs containing α6 subunits. In α6L9S mice, low doses of nicotine stimulate locomotor activity via α4α6* nAChRs. Removing α4 subunits from the VTA of adult α6L9S mice using our Cre/loxP approach rendered mice insensitive to injected nicotine in locomotor activation assays (confirming removal of α4 using behavior), but increased spontaneous locomotor activity (consistent with disinhibition of DA neurons). ACh-evoked

currents in VTA DA neurons in α4floxα6L9S mice are also dramatically reduced when α4 subunits are removed from the VTA. Current experiments include assessing the ability of nicotine to alter synaptic plasticity in VTA (with AMPA/NMDA ratios) and nucleus accumbens (by measuring dendritic spine morphology) of adult mice where α4 has been removed from VTA. Overall, this study employing removal of VTA α4 subunits from the adult brain highlights the importance of both 1) α4* nAChRs in VTA GABAergic neurons, and 2) the substantial role played by α4 subunits in α6* nAChR function. Title: Nicotine dependence reveals distinct responses from neurons and their resident nicotinic receptors in medial habenula

Authors: P.-Y. SHIH[1], *R. M. DRENAN[2];
[2]Medicinal Chem. and Mol. Pharmacol., [1]Purdue Univ., West Lafayette, IN

Abstract: Nicotinic acetylcholine receptors (nAChRs) are the molecular target of nicotine. nAChRs in the medial habenula (MHb) have recently been shown to play a role in nicotine dependence, but it is not clear which nAChR subtypes or MHb neuron types are most important. To identify MHb nAChRs and/or cell types that play a role in nicotine dependence, we studied these receptors and cells with brain slice electrophysiology using both acute and chronic nicotine application. Cells in ventral MHb inferior (MHbVI) and lateral (MHbVL) subregions expressed functional nAChRs with different pharmacology. Further, application of nicotine to cells in these subregions led to different action potential firing patterns. The latter result was correlated with a differing ability of nicotine to induce nAChR desensitization. Chronic nicotine caused functional up-regulation of nAChRs selectively in MHbVI cells but did not change nAChR function in MHbVL. Importantly, firing responses were also differentially altered in these subregions following chronic nicotine. MHbVI neurons treated chronically with nicotine exhibited enhanced basal pacemaker firing but a blunted nicotine-induced firing response. MHbVL neurons did not change their firing properties in response to chronic nicotine. Together, these results suggest that acute and chronic nicotine differentially affect nAChR function and output of cells in MHb

subregions. Because the MHb extensively innervates the interpeduncular nucleus (IPN), an area critical for both affective and somatic signs of withdrawal, these results could reflect some of the neurophysiological changes thought to occur in the MHb to IPN circuit in human smokers.

Abstract: Genome-wide association studies (GWAS) have implicated α3β4*-nAChR in susceptibility to tobacco use and dependence, particularly among youth. The associated phenotypes include heavy smoking (daily cigarettes smoked), Fagerström Test for Nicotine Dependence scores, and age dependent severity of dependence. A link has also been established to lung cancer susceptibility. Animal models are consistent with a role for this subtype in nicotine dependence and aversive behavior. We generated α3β4-nAChR-expressing SH-EP1 cell lines using stable transfection with pcDNA3.1zeo and pcDNA3.1hygro vectors, followed by selection of resistant monoclones. Highly-functional monoclones were identified by measuring nAChR-mediated 86Rb+ efflux. One of the monoclones was selected for developing an (HTS)-ready 384-well format assay using FLIPR membrane potential sensing dye. The assay was optimized by fine-tuning several assay conditions including, but not limited to, cell seeding density, incubation time following cell seeding, plate type, dye dilution, dye incubation time, drug addition times and volumes, and data capture time. The optimized assay produced robust (Z' scores ≈0.8), reproducible (signal CV values in range of 4.3 - 7.6 %), nAChR mediated (could be blocked by the non-competitive antagonist mecamylamine) signals. This performance

exceeds that required for acceptance by NIH MLPCN (Z' >0.5 and CV mean signal + 3SD. An agonist/PAM hit rate of ≈1% was observed, with excellent run-to-run reproducibility (25 hits in common across 2 runs, 1 unique hit per run). In antagonist mode, in the presence of EC90 nicotine, hits were identified as < mean signal + 3SD. A total of 36 hits were identified (1.6% hit rate), also with excellent reproducibility. Using 86Rb+ efflux as an orthogonal assay, we confirmed 44 of the 62 total prospective hits identified across both the agonist and antagonist testing modes (a healthy 71% hit-confirmation / validation rate). Most compellingly, three structurally-related compounds were confirmed to have previously-unappreciated PAM activity on α3β4-nAChR. These data serve to validate the completed assay's suitability for use in HTS.

Title: Nicotinic transmission onto layer 6 cortical neurons relies on synaptic activation of non-α7 receptors

Authors: Y. A. HAY, B. LAMBOLEZ, *L. TRICOIRE;
Univ. Pierre Et Marie Curie-CNRS-INSERM, Paris, France

Abstract: Nicotinic excitation in neocortex is mediated by low-affinity α7 receptors and by high-affinity α4β2 receptors. There is evidence that α7 receptors are synaptic, but it is unclear whether high-affinity receptors are activated by volume transmission or synaptic transmission. To address this issue, we characterized responses of excitatory layer 6 (L6) neurons to optogenetic release of acetylcholine (ACh) in cortical slices. L6 responses consisted in a slowly decaying α4β2 current and were devoid of α7 component. Evidence that these responses were mediated by synapses was 4-fold. 1) Channelrhodopsin-positive cholinergic varicosities made close appositions onto responsive neurons. 2) Inhibition of ACh degradation failed to alter onset kinetics and amplitude of currents. 3) Quasi-saturation of α4β2 receptors occurred upon ACh release. 4) Response kinetics were unchanged in low release probability conditions. Train stimulations increased amplitude and decay time of responses and these effects appeared to

involve recruitment of extrasynaptic receptors. Finally, we found that the α5 subunit, known to be associated with α4β2 in L6, regulates short-term plasticity at L6 synapses. Our results are consistent with previous anatomical observations of widespread cholinergic synapses and suggest that a significant proportion of these small synapses operate via high-affinity nicotinic receptors.

Title: Functional characterization of α4β2* nicotinic receptors in principal neurons of the young postnatal mouse hippocampal formation

Authors: B. Y. T. CHUNG, *C. D. BAILEY;
Dept. of Biomed. Sci., Univ. of Guelph, Guelph, ON, Canada

Abstract: The hippocampal formation plays an important role in learning, memory and attention. The normal development and mature function of this compound brain region depends on cholinergic neurotransmission mediated by the nicotinic class of acetylcholine receptor (nAChR). We have recently demonstrated in CD1-strain mice that the α4β2* isoform of nAChR mediates direct inward currents and facilitates excitation in principal (pyramidal) neurons of the hippocampal formation sub-region known as the cornu ammonis area 1 (CA1). This signaling is developmentally regulated with the greatest magnitude of α4β2* nAChR responses occurring during the first two weeks of postnatal life. As the hippocampal formation also comprises the cornu ammonis area 3 (CA3), dentate gyrus (DG), subiculum (SUB) and entorhinal cortex (EC), we sought in this current study to characterize α4β2* nAChR function within the principal neurons of these sub-regions during the first two weeks of mouse postnatal development. Whole-cell electrophysiological responses to acetylcholine (ACh) were recorded for visually-identified principal neurons of the CA1, CA3, DG, SUB and EC layer VI (EC-VI) within acute brain slices collected from male CD1 mice between postnatal days 5 and 10. Recordings were made in the presence of atropine to block muscarinic acetylcholine receptors and methyllycaconitine to block α7 subunit-containing nAChRs, in order to isolate pharmacologically α4β2* nAChR responses. We found that the magnitude of α4β2* nAChR responses varied across sub-regions of the hippocampal formation. Principal neurons in the SUB and EC-VI exhibited greater inward currents and a greater rise in membrane potential in response to α4β2* nAChR activation when

compared with neurons in the CA1, CA3 and DG. Within the hippocampus proper, principal neurons in the CA1 exhibited greater inward currents compared with both the CA3 and DG sub-regions. Interestingly, even though the magnitude of inward currents mediated by α4β2* nAChRs varied significantly across the hippocampal formation, we found no differences in the ability of ACh to accelerate action potential firing frequency among these sub-regions. Our findings demonstrate that functional α4β2* nAChRs are present in principal neurons of the hippocampal formation in young postnatal mice and that the characteristics of their responses to ACh vary across sub-regions of this compound brain region.

Title: Curcumin potentiates human α7-nicotinic acetylcholine receptors

Authors: *K.-H. S. YANG[1], S. M. NURULAIN[2], F. C. HOWARTH[3], M. OZ[2];
[1]Chapman Univ., Orange, CA; [2]Pharmacology, Fac. of Med. and Hlth. Sci., [3]Physiology, Fac. of Med. and Hlth. Sci., UAE Univ., Al Ain, United Arab Emirates

Abstract: Curcumin, a polyphenolic compound isolated from the rhizomes of Curcuma longa (turmeric), has been shown to exhibit a wide range of pharmacological activities including treatments of Alzheimer's disease, and cystic fibrosis, and inflammation. Although mechanisms of these effects are largely unknown, several types of voltage-gated ion channels and transporters have been suggested to be involved in mediating pharmacological actions of curcumin. However, the effects of curcumin on ligand-gated ion channels have not been described earlier. In this study we have investigated the effect of curcumin application on the functional properties of human α7-nicotinic acetylcholine (nACh) receptors. cRNA encoding for homomeric human α7-nicotinic acetylcholine (nACh) receptors were expressed in Xenopus oocytes. Ion currents mediated by the activation of nACh receptors were recorded using two-electrode voltage clamp method. Our results indicated that curcumin caused a significant potentiation of nACh receptor-mediated ion currents. The effect of curcumin (0.1 to 10 μM) was reversible and gradually reached a steady-state level within 10 min application time. Maximal amplitudes of currents activated by 100 μM ACh were significantly enhanced by curcumin in a reversible and concentration-dependent manner. In earlier studies, agonists of α7-nACh receptors have been shown to have therapeutic effects on Alzheimer's disease and inflammation. Therefore, our

results suggest that potentiation of α7-nACh receptors by curcumin can mediate some of its therapeutic actions in Alzheimer disease and inflammation.

Title: Investigating the role of the nicotinic receptor modulator, lynx2, on cholinergic-based anxiety mechanisms

Authors: *K. R. ANDERSON, H. WANG, J. MIWA;
Lehigh Univ., Bethlehem, PA

Abstract: Anxiety disorders are among the most prevalent of mental disorders in modern society. The anxiety response is a normal and advantageous reaction to a stressor but disorders can develop when individuals cannot return to baseline once the stressor has resolved. Current treatments for individuals suffering from anxiety disorders only temporality relive the symptoms without treating the cause, due to a lack of full understanding of the biological underpinnings of anxiety. Additionally, many anxiety sufferers self-medicate by smoking, suggesting a novel role of the cholinergic system in anxiety modulation. We are using a candidate gene approach to uncover these underpinnings, focusing on the role of a cholinergic modulator, lynx2, highly expressed in the basolateral aspect of the anxiety structure, the amygdala (BLA). Lynx2 proteins bind to and suppress cholinergic receptors (nAChRs). Consistent with its high expression, mice lacking lynx2 (lynx2KO), demonstrate elevated anxiety levels across several assays (light-dark, open-field, etc.). We hypothesize that experience-dependent plasticity in the amygdala plays a role in the return to baseline state, and that this is subject to cholinergic modulation. To address this we are performing behavioral pharmacological studies in lynx2KO mice to measure anxiety responses along with electrophysiology studies. Sensitivity to nicotine is augmented in lynx2KO mice in both the light/dark assay and slice physiology. Further investigations into the specific nAChR subtypes are being conducted with several specific inhibitors and uncovering a shift in receptor subtype without lynx2 presence, suggesting a role for lynx2 in receptor subunit

composition. Synaptic plasticity is altered in the BLA between wild-type and lynx2KO mice and normalcy could be restored by pharmacological manipulation of nAChRs. These data suggest that addressing synaptic plasticity may be a promising avenue by which to return individuals back to baseline states. To address this further, fear extinction is being used to assess modification of the fear response over time. Understanding of how amygdalar output can be altered by lynx and cholinergic pathways could help in the development of treatments for anxiety disorders such as PTSD.

Title: Cembranoids structure-activity relationship for protection against diisopropylfluorophosphate damage

Authors: *V. A. ETEROVIC[1], M. CARRASCO[1], D. PEREZ[1], H. Y. EBRAHIM[2], P. A. FERCHMIN[1], K. A. EL SAYED[2];
[1]Biochem., Univ. Central Del Caribe, Bayamon, PR; [2]Dept. Basic Pharmaceut. Sci., Sch. of Pharm., Univ. of Louisiana, Monroe, LA

Abstract: Diisopropylfluorphosphate (DFP) is a toxic organophosphorous compound, which produces neurodegeneration. Post-application of the neuroprotective compound 4R-cembranoid (4R) ameliorates this damage. *In vitro*, the population spike (PS) of the hippocampal slice is decreased by DFP and recovered by post-application of 4R. The protective activity of 4R is triggered by the inhibition of the alpha7 nicotinic acetylcholine receptor (nAChR). A study of neuroprotection produced by fourteen 4R analogues - using the hippocampal slice model - produced a preliminary pharmacophore; which suggested that two hydrophobic regions in the cembranoids molecule are responsible for binding to the receptor and an electronegative atom forms a hydrogen bond with the receptor, which effects receptor inhibition. The purpose of the present work was to further characterize the structure-activity relationship between cembranoid molecular structure and their protective activity against DFP using the hippocampal slice preparation. Concentration-effect curves (nM - μM) were obtained for 21 cembranoids.

Seventeen analogues displayed standard curves, which were fitted to the four-parameters logistic equation. The most potent analogue had an EC50 of 0.6 nM and a maximum effect of 77% PS recovery; the least potent analogue had an EC50 of 2.3 μM and a maximum recovery of 120%; there was no correlation between the EC50 and maximum recovery values. These observations are consistent with the preliminary pharmacophore assumption that the binding and the inhibitory regions are located in different parts of the cembranoid structure. The four remaining analogues displayed a complex behavior; protective activity was seen at low and at high concentrations, but not at intermediate concentrations. Thus the ideal neuroprotective cembranoid must display high affinity and efficacy at the inhibitory site and low affinity for the positive modulator site.

Abstract: Dopamine (DA) neurons of the Ventral Tegmental Area (VTA) show two different firing patterns : a regular pattern associated with a tonic (constant and low) release of DA in the target structures; and a « burst » pattern associated with a phasic release of DA and involved in

reinforcement learning and reward prediction. Previous studies in the lab have identified the β2-containing nicotinic acetylcholine receptor (β2*nAChR) as a major player of the bursting activity : nicotine injection switches the activity of the DA neuron from tonic to phasic, while deletion of the β2 subunit results in DA neurons that only fire tonically and don't respond to nicotine. Assessing the precise role of the β2nAChR in the formation of bursts and in behavioral decision making processes requires methods for the acute, reversible control of this receptor subtype at time scales compatible with synaptic transmission. To this aim, we are developing new technologies for the optical control of specific nAChR subtypes *in vivo*. Notably, we have engineered a β2-containing, light-inhibited nAChR (β2*LinAChR). This designed receptor presents at its surface a free cysteine amino-acid for the anchoring of a chemical photoswitch. The photoswitch Maleimide-Azobenzene-HomoCholine (MAHoCh) is made of three components: a Maleimide group for bioconjugation to the cysteine mutant, an Azobenzene photoswitch that can be photoisomerized between its cis and trans states using violet and green light, respectively, and a Homo-Choline competitive antagonist. After covalent attachment of MAHoCh, β2LinAChRs respond normally to nicotine and acetylcholine, but can be rapidly antagonized using violet light (390 nm). Illumination with green light (520 nm) withdraw the homocholine group from its binding pocket, and restores the function of β2*nAChRs. We are using a lentiviral vector strategy to express β2*LinAChRs selectively in the VTA. Patch-clamp recordings of VTA DA neurons show that LinAChRs can be used to optically inhibit nicotinic inputs to the VTA. Furthermore, using *in vivo* extracellular recordings, we show that β2*LinAChR can be used to rapidly and reversibly modulate not only the spontaneous bursting activity of DA neurons, but also the bursts induced by intravenous injection of nicotine. Our findings establish a causal role for β2*nAChRs in regulating the excitability of VTA DA neurons.

Title: Use of the novel toxin M2E11R to study the role of α6- nAChRs in visual function

Authors: D. BARLOSCIO[1], E. CERRI[1], L. DOMENICI[1], R. LONGHI[2], M. MORETTI[3], C. GOTTI[3], *N. ORIGLIA[1];
[1]CNR- Neurosci. Inst., PISA, Italy; [2]ICRM, [3]Neurosci. Inst., CNR, Milan, Italy

Abstract: Neuronal nicotinic acetylcholine receptors (nAChRs) are highly expressed in the visual system. Increasing attention has been given to α6-containing nAChRs as they have a limited distribution in the brain but are highly and selectively expressed in the mesocorticolimbic and visual pathways. In particular, α6β2 nAChRs are present in the retinal ganglionic cell layer, in the optic nerve and in retina terminals but their physiological role is not well known. We have identified and characterized a family of toxins that are selective antagonists for the α6β2 receptors. We used one of these toxin (M2E11R, m.w.=1738), to investigate the impact of α6-containing nAChRs, on visual function in male Long-Evans rats. Visual function was assessed using flash/pattern (F-ERG and P-ERG) electroretinogram and cortical visual evoked potential (VEPs), after intraocular injection of M2E11R in one eye (1μM), using the vehicle injected contralateral eye as the control. We first used dark (scotopic) and light (photopic) adaptation to record F-ERG responses. Alternating gratings of different spatial frequencies and contrast were used to evoke VEPS and P-ERG. Moreover, the localization of α6-containing receptors in retinal tissue was performed using a fluorescently tagged M2E11R (Alexa Fluo 488) toxin. Our results demonstrate that no significant differences in scotopic and light-adapted F-ERG were found between toxin injected and control eye. In contrast, P-ERG response amplitudes evoked at 0.5 Hz or 4 Hz stimulation frequency showed a significant reduction in the toxin injected eye. Blocking α6-containing receptors at retinal level, also decreased VEPs amplitude recorded at different spatial frequencies in the visual cortex of contralateral injected eye. Moreover, using the fluorescently tagged toxin, we found a predominant distribution of labeling at the level of the ganglion cell layer. Our findings indicate that blocking α6-containing receptors leads to reduced visual function. Since both the cortical and inner retina output were affected by the toxin injection, whereas the photoreceptors output is preserved, we conclude that the reduced visual response resulted from altered function of α6-containing receptors specifically present in the ganglion cell layer.

Title: Nicotinic activity of arecoline, the psychoactive element of betel nuts, suggests a basis for habitual use and anti-inflammatory activity

Authors: *R. L. PAPKE[1], N. A. HORENSTEIN[2], C. STOKES[1];
[1]Dept Pharmacol & Therapeut, [2]Chem., Univ. Florida, Gainesville, FL

Abstract: Habitual chewing of "betel nut" preparations constitutes the fourth most common human self-administration of a psychoactive substance after alcohol, caffeine, and nicotine. The primary active ingredient in these preparations is arecoline, which comes from the areca nut, the key component of all such preparations, along other components such as betel vine leaves or flowers, slaked lime, and about 50% of the time, tobacco. Betel nut effects are usually characterized as being like drinking strong coffee, but an objective observation of betel users might suggest other dominant actions; most striking is the production of copious amounts of saliva, of a bright red color, staining the lips and gums. Arecoline is known to be a relatively non-selective muscarinic partial agonist, accounting for many of the overt peripheral and central nervous system effects. This muscarinic activity, however, is not likely to account for the addictive properties of the drug. We have discovered previously unknown effects of arecoline on select nicotinic acetylcholine receptor (nAChR) subtypes, including the two classes of nAChR most related to the addictive properties of nicotine, receptors containing α4 and β2 subunits and those which also contain α6 and β3 subunits. Expression of α6 and β3 subunits is largely restricted to dopaminergic neurons associated with nicotine reward. Arecoline is a partial agonist with about 6-10% efficacy for the α4* and α6* receptors expressed in *Xenopus* oocytes. Additionally, arecoline is a silent agonist of α7 nAChR; while it does not activate α7 receptors when applied alone, it produces substantial activation when co-applied with the PAM PNU-120696. Methacholine and, to a lesser degree, Oxotremorine are also α7 silent agonists, while muscarine is not, providing insight into the structural requirements for α7 silent agonism. Some α7 silent agonists are effective inhibitors of inflammation, which might account for published reports of anti-inflammatory/immunosuppressive effects of arecoline. Recent epidemiology has indicated that long-term use of betel preparations is a major cause of oral cancer and other diseases of the mouth. Arecoline's activity on nAChR associated with addiction may account for the habitual use of areca nut preparations in spite of the well-documented risk to personal health. This common link between betel and tobacco suggests that partial agonist therapies with cytisine or the related compound varenicline may also be used to aid betel cessation attempts.

Title: Chronic opioid treatment downregulates alpha4beta2 nicotinic acetylcholine receptors while upregulating alpha3* and alpha7 nicotinic acetylcholine receptors in cell lines

Authors: *R. TALKA, O. SALMINEN, R. K. TUOMINEN;
Univ. of Helsinki, Helsinki, Finland

Abstract: Although both opioids and nicotine have their own specific mechanisms of action, there is empirical and experimental evidence of *in vivo* and *in vitro* interactions between these drugs. Our previous *in vitro* studies in cell lines suggested that morphine acts as a partial agonist at α4β2 nicotinic acetylcholine receptors (nAChRs) and as a weak antagonist at α3* nAChRs, whereas methadone acts as an agonist at α7 nAChRs and a non-competitive antagonist at α4β2 and α3* nAChRs. Next we wanted to study the effect of the sub-chronic nicotine or opioid treatment on 3H-epibatidine binding in SH-EPI-hα4β2, SH-EPI-hα7 and SH-SY5Y (expressing α3* and α7 nAChRs) cell lines. The cell cultures were treated for 3 days either with 1 and 10 μM nicotine, methadone or morphine. On the day of assay, cultures were washed for 3×10 min with warm medium; then incubated for 3 h at 37°C before a final wash with warm PBS to remove all traces of drugs from the cultures. Homogenates were prepared and saturation binding assays were conducted as previously described in Talka et al. 2013. Nicotine (10 μM) upregulated 3H-epibatidine binding sites in all cell lines studied, confirming earlier well established paradigm. Both methadone and morphine upregulated the epibatidine binding sites in SH-EPI-hα7 and SH-SY5Y cell lines, the effect being more prominent at the SH-EPI-hα7 cell line with the dose of 10 μM. On the other hand, in SH-EPI-hα4β2 cell line both methadone and morphine downregulated the epibatidine binding sites, and the effect of sub-chronic morphine was especially pronounced in this cell line. These results add further strength to the notion that nicotine and opioids have indeed receptor-level interactions in *in vitro* settings.

Title: α7 nicotinic acetylcholine receptor-mediated intracellular cAMP changes in hippocampal dentate gyrus neurons

Authors: *Q. CHENG[1], P. W. LAMB[2], J. L. YAKEL[2];
[1]Neurobio. Lab., [2]NIEHS, Durham, NC

Abstract: The activation of α7 nicotinic acetylcholine receptors (nAChRs) has been shown to improve hippocampal-dependent learning and memory. α7 nAChRs are widespread among different cell types in the hippocampus. However it is not known if α7 nAChRs mobilize differential signaling mechanisms within the same cell type or among distinct neuronal populations. Recently, we observed α7 nAChR-mediated cAMP rises using a FRET-based biosensor (TEpacVV) in cultured hippocampal neurons. Here, we are going to probe α7 nAChR's differential effects by employing CRE-dependent transgenic mouse lines. We created an AAV virus containing either an improved cAMP sensor (higher sensitivity and smaller size for better distribution) or GCaMP6s in a floxed configuration. We observed that the biosensor expression pattern was in fact limited to granule cell populations after infection of cultured hippocampal slices from these POMC-cre (dentate granule cells specific cre line) mice with the AAV virus. We found that application of the α7 nAChR-selective agonist choline (2 mM; in the presence of the α7 nAChR positive allosteric modulator PNU-120596 (5 μM)) induced a significant change in the YFP/CFP ratio in granule cell bodies, which indicated an increase in intracellular cAMP levels. GCaMP6 imaging revealed robust calcium rises induced by choline and PNU-120596 application in most granule cells. We will determine the heterogeneity of α7 nAChR-induced calcium responses in future analysis. To determine the differential effects of α7 nAChR activation among cell types, we will compare α7 nAChR agonist-induced calcium and cAMP changes between granule cells (POMC-cre) and GABAergic neurons (GAD-cre). We will correlate the changes in cAMP levels with the change of calcium and level of calcium-dependent adenylyl cyclases (ACs). Our findings may provide better understanding of the complex molecular mechanisms of the positive cognitive effects of α7 nAChR agonists in the brain, and strategies for the development of therapeutic treatments for cognitive impairments.

Title: The beta2 subunit C loop of the nicotinic acetylcholine receptor directs allosteric modulator specificity

Authors: *M. M. LEVANDOSKI, A. R. MACK, C. A. SIBBALD;
Grinnell Col., Grinnell, IA

Abstract: Many compounds allosterically modulate neuronal nicotinic acetylcholine receptors (nAChRs), and novel modulators continue to be developed for use in pathologies involving nAChRs, such as nicotine addiction. We study nicotinic receptors heterologously expressed in *Xenopus* oocytes, primarily by electrophysiology. We showed that a pocket in the β(+)/α(–) interface of mammalian α3β2 nAChRs, homologous to the canonical ACh [α(+)/β(–)] site, is a novel binding site for the anthelmintics morantel and oxantel. We have identified several residues necessary for constituting this binding site and determining its specificity; the anthelmintics generally potentiate α3-containing receptors but inhibit α4-containing receptors. We hypothesize that discrete interactions between the C loop of the β2 subunit and residues on the α3(–) face direct selectivity between morantel and oxantel. Co-expressing mutant β2 subunits with a cysteine substitution in the C loop and a paired α3(–) cysteine mutant yields receptors with efficacy susceptible to modification by oxidation and reduction. We have studied a total of eight double-cysteine mutant pairs, combining two positions at the tip of the β2 C loop and four positions in the α3(–) face. Importantly, for a subset of these, the single α3(–) cysteine substitution (e.g. α3K55Cβ2) does not show modulator selectivity, but a double cysteine mutant (e.g. α3K55Cβ2S192C) does. We are extending this analysis to oxidation/reduction perturbations. We predict these experiments will show that the presence of modulator during oxidation treatment prevents disulfide trapping either through steric occlusion or movement of the cysteines to positions unfavorable for reaction, or promotes disulfide bond formation by minimization of the separation of the cysteines. These discrete contacts may differ for morantel and oxantel, thereby contributing to the modulator specificity differences.

Title: Cognitive enhancement through augmentation of alpha7 nicotinic acetylcholine receptor function: *in vitro* and *in vivo* characterization of alpha7 agonist EVP-6124 and alpha7 positive allosteric modulator JNJ-39393406

Authors: *M. GRUPE[1], K. FREDERIKSEN[2], M. JESSEN[2], J. FULLERTON STØIER[3], A. PARACHIKOVA[4], C. BUNDGAARD[5], A. MITTOUX[6], J. BASTLUND[4];
[1]Synaptic Transmission *In vivo*, H. Lundbeck A/S, Valby, Denmark; [2]Mol. Pharmacol., [3]Neurodegeneration *In vivo*, [4]Synaptic Transmission *In vivo*, [5]Discovery DMPK, [6]Psychotic Disorders, H. Lundbeck A/S, Valby, Denmark

Abstract: The alpha7 nicotinic acetylcholine receptors (nAChRs) are homomeric ligand-gated ion channels expressed in brain regions of key importance for cognition, such as the prefrontal cortex and the hippocampus. Through modulation of neurotransmitter release these receptors are hypothesized to be essential for neurotransmission underlying higher cognitive functions, such as memory and attention (Lendvai *et al*., 2013). Additionally, altered expression and function of alpha7 nAChRs has been linked to various brain disorders such as schizophrenia (Freedman *et al*., 1995) and Alzheimer's Disease (Parri *et al*., 2011). These observations have formed the hypothesis that cognitive functioning can be improved by pharmacologically augmenting alpha7 nAChR function, thus making this receptor subtype a highly investigated drug target (Dineley *et al*., 2015). Employing *in vitro* and *in vivo* assays we have here investigated two alpha7 ligands of different pharmacological classes: EVP-6124 is an alpha7 agonist (Prickaerts *et al*., 2012), whereas JNJ-39393406 is an alpha7 positive allosteric modulator (PAM) (Winterer *et al*., 2013). Using two-electrode voltage clamping in *Xenopus* oocytes expressing human alpha7 nAChRs EVP-6124 was confirmed to be an agonist: at +10 nM EVP-6124 evokes a current response at the alpha7 nAChR and at 1 and 3 nM EVP-6124 has co-agonistic properties by potentiating ACh-evoked (30 μM) responses. JNJ-39393406 was found to be a potent and efficacious alpha7 PAM with EC_{50} = 6.3 μM at 30 μM ACh. The pro-cognitive potential of the compounds (0.1/1/10/100 mg/kg) were investigated in the mouse T-maze continuous alternation task (T-CAT) with acute PCP as a disrupter and the rat novel object recognition task (NOR) using a natural forgetting paradigm. At 0.1, 1 and 10 mg/kg EVP-6124 increased alternation scores, whereas only 10 mg/kg increased NOR performance. JNJ-39393406 improved T-CAT performance at only 0.1 and 100 mg/kg, and NOR performance at 1 and 100 mg/kg. This indicates that both compounds can enhance cognitive ability in rodents: EVP-6124 at defined dose ranges, whereas JNJ-39393406 displays a U-shaped dose-response curve. Finally, modulation of local field potentials by EVP-6124 and JNJ-39393406 in rat cortex in various auditory paradigms was investigated as measured by electroencephalogram electrodes. In summary, our findings demonstrate distinct pharmacological profiles of EVP-6124 and JNJ-39393406 on the molecular, synaptic, as well as behavioral level.

Title: Antidyskinetic effect of the novel α7 nicotinic receptor agonist ABT-126 in Parkinsonian monkeys

Authors: M. MCGREGOR[1], *D. ZHANG[1], T. BORDIA[1], X. A. PEREZ[1], M. W. DECKER[2], M. QUIK[1];
[1]SRI Intl., Menlo Park, CA; [2]AbbVie Inc., North Chicago, IL

Abstract: Recent evidence suggests that the nicotinic cholinergic system represents a target for antidyskinetic therapy in Parkinson's disease. Several studies show that the general nicotinic acetylcholine receptor agonist nicotine, as well as drugs acting at β2 or α7 nicotinic receptors, reduce levodopa-induced dyskinesias 60-70% in parkinsonian nonhuman primates, with no worsening of parkinsonism. Here we used parkinsonian monkeys to test the antidyskinetic effect of ABT-126, a novel α7 nicotinic receptor drug that has demonstrated an efficacy signal in a phase 2 study for Alzheimer's disease. 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine-lesioned monkeys were gavaged with levodopa (10 mg/kg)/carbidopa (2.5 mg/kg) twice daily. They were then given ABT-126 or vehicle orally 30 min before levodopa twice daily for 1-2 wk at each ABT-126 dose. A third group of monkeys was given nicotine as a positive control. ABT-126 (0.03, 0.10, 0.30 and 1.0 mg/kg) administration resulted in a dose-dependent decline in dyskinesias with ~60% decrease. A comparable reduction in dyskinesias was observed with both the morning and afternoon levodopa dose, with the latter associated with higher dyskinesia scores. There was no effect of ABT-126 on parkinsonism or cognition. No emesis was observed, a problem with other nicotinic receptor drugs. The effect of ABT-126 was relatively long-lasting, with a 6-week drug discontinuation period required for dyskinesias to return to the levels observed in vehicle-treated monkeys. These data suggest that the novel α7 nicotinic receptor agonist ABT-126 may be useful for the treatment of dyskinesias in Parkinson's disease.

Title: Striatal cholinergic interneurons regulate L-dopa-induced dyskinesias

Authors: *T. BORDIA, X. A. PEREZ, D. ZHANG, M. QUIK;
Ctr. for Hlth. Sci., SRI Intl., Menlo Park, CA

Abstract: L-dopa-induced dyskinesias (LIDs) are a serious complication of L-dopa-therapy for Parkinson's disease for which the neuronal circuitry and cellular mechanisms remain elusive. Recent work suggests a role for the cholinergic system as studies show that treatment with nicotinic cholinergic receptor (nAChR) drugs and ablation of cholinergic interneurons (ChIs) reduce LIDs in parkinsonian animals. Here we used optogenetics as an approach to examine the link between ChI activation and the expression of LIDs. For these studies, transgenic mice expressing cre-recombinase under the control of the choline acetyltransferase promoter (ChAT-cre mice) were lesioned by unilateral injection of 6-hydroxydopamine into the medial forebrain bundle. Two to four weeks later, AAV-DIO-ChR2-eYFP or DIO-eYFP was injected intrastriatally to elicit expression of ChR2-eYFP or eYFP in ChIs and optical fibers were implanted for *in vivo* stimulation. Mice were rendered dyskinetic by once daily injection of L-dopa. Three to four weeks were allowed for stable expression of the virus and L-dopa induced abnormal involuntary movements (AIMs). The mice were then subjected to various stimulation protocols (0.001 s to 20 s laser on, followed by 0.5 s laser off) while dyskinetic for a 2 h period. None of the stimulation regimens affected L-dopa-induced AIMs in mice expressing control virus. In mice expressing ChR2, shorter duration stimulation of 0.001 or 0.005 s enhanced L-dopa-induced AIMs compared to the unstimulated condition. By contrast, longer duration stimulation of 0.02 s resulted in a ~50% reduction in AIMs with comparable results with 1 s and 20 s stimulation. This decline in AIMs with light stimulation was similar to our previously observed decrease in L-dopa-induced AIMs with nicotine treatment. Thus, we next tested if the stimulation-induced changes in L-dopa-induced AIMs were nAChR-mediated. The general nAChR antagonist, mecamylamine blocked the decline in AIMs with longer (0.020 s) stimulation but not the increase observed with shorter (0.005 s) duration stimulation. In addition, parkinsonism on or off L-dopa was not affected by any of the stimulation paradigms suggesting that cholinergic transmission primarily regulates the expression of L-dopa-induced AIMs. In summary, shorter duration stimulation protocols that result in small bursts of acetylcholine increased L-dopa-induced AIMs, while longer duration stimulus protocols that lead to more prolonged acetylcholine release reduced AIMs. Overall, these results suggest that striatal ChIs play a critical role in LIDs and support the idea that decreases in LIDs occur via nAChR desensitization.

Title: Nicotinic receptors control prefrontal cortex activity

Authors: F. KOUKOULI[1], M. ROOY[3], B. GUTKIN[3], K. SAILOR[1], J. STITZEL[4], D. DIGREGORIO[1], *U. MASKOS[2];
[1]Inst. Pasteur, Paris cedex 15, France; [2]Inst. Pasteur, Paris Cedex 15, France; [3]ENS, Paris, France; [4]Univ. Colorado, Boulder, CO

Abstract: The prefrontal cortex (PFC) is integral for high order cognitive processes that can be modulated by cholinergic inputs via nicotinic acetylcholine receptors (nAChRs). Using *in vivo* two-photon imaging of awake mice, combined with network modeling, we show that nAChRs subtypes strongly, but differentially, regulate layer II/III pyramidal neuron activity. Both the interneuron-specific α7 and β2 subunits modulate pyramidal neuron activity by altering their inhibitory control. Efficient lentiviral vector-mediated re-expression of functional β2-subunit-containing nAChRs in PFC neurons of β2 knock-out (KO) mice rescued the neuronal activity to the levels of wild-type mice. We also demonstrate that the β2 subunit is specifically required for synchronized activity patterns. The local generation of sustained activity in neural networks of the cerebral cortex is associated with a striking balance of recurrent excitation and inhibition and, according to our data, this balance is disrupted in the β2 KO neural populations. Furthermore, mice expressing the human single nucleotide polymorphism (SNP) rs16969968 of the α5 subunit, which predisposes to nicotine addiction and schizophrenia, exhibit loss of pyramidal cell activity similar to α5 KOs. Our data suggest that interneuron specific expression of distinct nAChR types enables a diverse and bidirectional regulation of cortical activity and could provide a mechanistic basis for understanding the pathophysiology of genetically linked psychiatric disorders, as well as for identifying drug targets.

Higher Sch. of Econ., Moscow, Russian Federation

Abstract: Neurons in the prefrontal cortex (PFC) and its sub-areas receive significant cholinergic innervation, and a proportion expresses nicotinic acetylcholine receptors (nAChRs). By using *in vivo* two-photon imaging of awake mice, we showed that nAChR subtypes expressed only by interneurons in layer II/III, strongly modulate pyramidal neuron activity. In order to determine the specific circuit level mechanisms for such interneuron specific and nAChR type-specific bidirectional regulation of cortical activity we developed a minimal computational model of the local PFC circuitry. The model was built in order to implement the firing rate time evolution seen in the pyramidal and interneuronal populations of the wild type mice prefrontal cortex. Model parameters were fitted in order to yield the up and down state properties seen experimentally in the different neuronal types. We further incorporated nicotinic receptors models located on specific interneurons in the circuit. Three different subtypes of interneurons were explicitly modelled, in order to reproduce the effects of the different nicotinic subunits. In the model, the Parvalbumin interneuronal population expressed α7 nicotinic subunits, and interacted with the pyramidal population through substractive inhibition. The Somatostatin interneuronal population expressed α7 and β2 nicotinic subunits, and interacted with the pyramidal population through divisive inhibition. The VIP interneural population expressed α5 nicotinic subunits and targeted both Parvalbumin and Somatostatin interneuron populations through substractive inhibition. The model allowed us to account for the the firing rate changes and up-down states transitions seen experimentally in the knock out animals for the α7, α5 and

β2 nicotinic subunits. Analysis of the model allowed us to identify specific contributions of each receptor subtype to the control of the sustained activity dynamics. Our modeling pin-points specific points of entry for the pleotropic mechanisms by which nAChRs control the balance of excitation and inhibition in prefrontal cortical circuits. This approach allows us to delve into the role of nAChRs in the dynamic neural mechanisms underlying fronto-cortically dependent cognitive phenomena such as working memory, attention and cognitive control as well as in fronto-cortical pathologies.

Title: Building a large-scale cortical network model incorporating laminar structure: frequency-specific feedforward and feedback interactions

Authors: ***J. F. MEJIAS**[1], J. D. MURRAY[1], H. KENNEDY[2], X.-J. WANG[1,3];
[1]Ctr. for Neural Science, New York Univ., New York, NY; [2]Stem-Cell and Brain Res. Institute, INSERM and Univ. de Lyon, Lyon, France; [3]NYU-ECNU Inst. of Brain and Cognitive Science, NYU Shanghai, Shanghai, China

Abstract: A major challenge in the development of large-scale cortical network models is to implement area-to-area interactions allowing elucidation of dynamical operations in a biologically constrained manner. These interactions are anatomically organized in a laminar specific manner: feedforward projections preferentially stem from superficial layers, whereas feedback projections originate chiefly from deep layers. Feedforward interactions transmit sensory information to higher brain areas, while feedback interactions may mediate a prediction/expectation signal or top-down attentional modulation of early sensory areas. Quantitative data on laminar-dependent inter-areal connectivity of the macaque cortex have become available only recently. We have incorporated these data in a large-scale dynamical model of the primate cortex endowed with weighted and directed connectivity. Each cortical area is modeled with a superficial and a deep layer. Based on recent physiological evidence, we modeled excitatory and inhibitory neural populations in each layer, with local properties that generate noisy gamma oscillations in the superficial layer and alpha oscillations in the deep layer. Furthermore, the interactions between the two layers are guided by anatomical and

physiological data, with specific superficial-to-deep and deep-to-superficial projections that allow to explain experimental observations of phase-amplitude coupling. We calibrated the model by simulating physiological observations that feedforward interactions are associated with oscillations in the gamma band (40-80Hz), while feedback interactions relate to lower frequencies, in the alpha or low beta frequency range (8-20 Hz). Using Granger causality to establish the directionality of information flow, the model reproduces the observed functional hierarchical order of visual areas (Bastos et al. Neuron 2015). The model identifies several properties of feedback projections as a key factor to explain these hierarchical dynamics, in particular the specific pattern of feedback projections to a target area. We further discuss the usefulness of functional hierarchies to reconstruct structural properties of cortical connectivity. Our results represent a step forward in the advance of a quantitative model of the primate large-scale cortical system.

Title: Diversity of sharp wave-ripples in the CA1 of the macaque hippocampus and their brain wide signatures

Authors: *J. F. RAMIREZ-VILLEGAS[1,2], N. K. LOGOTHETIS[1,3], M. BESSERVE[1,4]; [1]Physiol. of Cognitive Processes, Max Planck Inst. For Biol. Cybernetics, Tuebingen, Germany; [2]Grad. Sch. of Neural & Behavioral Sci., Eberhard-Karls Univ. Tuebingen, Tuebingen, Germany; [3]Ctr. for Imaging Sciences, Biomed. Imaging Inst., The Univ. of Manchester, Manchester, United Kingdom; [4]Dept. of Empirical Inference, Max Planck Inst. For Intelligent Systems, Tuebingen, Germany

Abstract: Sharp wave-ripple complexes are thought to play a major role in memory reactivation, transfer and consolidation. However, the large-scale cooperative mechanisms associated to these episodes and their relationship to the observed SPW-R electrical signature remains largely unknown. A better understanding of the underlying mechanisms of these interactions requires a finer characterization of the SPW-R phenomenon and its associated brain-wide signatures. To address this question, we hypothesize that SPW-R dynamics vary, reflecting distinct interactions with neocortical and subcortical systems depending on the state of the animal. Specifically, the wide-range network reconfiguration required by this process may bring different electrical signatures of SPW-Rs, thus reflecting different memory-related functional roles. Using concurrent hippocampal local field potentials (LFP) recordings and functional Magnetic

Resonance Imaging (fMRI) in anesthetized macaques, we study local changes in neuronal activity during SPW-R episodes and their brain-wide correlates. After detecting SPW-R episodes based on power increases in the ripple frequency band (80-180 Hz), analysis of peri-event SPW-R complexes reveals four well-differentiated SPW-R subtypes in the CA1 LFP. Event-triggered fMRI maps show that SPW-R subtypes relate to differentiated multi-structure activity (MSA). We found that ripples aligned to the positive peak of their SPWs were associated with significantly higher BOLD up-regulations within the hippocampal formation, and in cortical associative areas (namely, anterior cingulate cortex, retrosplenial area, prefrontal, temporal and parietal cortices), as compared to ripples occurring at the trough of their SPW ($p<0.01$ Wilcoxon rank-sum test, FDR-corrected with $q<0.05$). Conversely, detailed analysis of all subcortical domains revealed differentiated BOLD activations in locus coeruleus (LC) and dorsal raphe nucleus ($p<0.002$, pairwise Wilcoxon rank-sum test, FDR-corrected with $q<0.05$), suggesting that emergence of different SPW-R signatures may be influenced by state-dependent neuromodulatory inputs of differentiated nature into the hippocampal formation. Altogether, our results suggest that the variability of CA1 SPW-R episodes reflect different levels of activation over cortical and subcortical domains. We hypothesize that these distinct patterns of SPW-R complexes reflect brain-wide cooperative events, possibly involved in different memory-related functions.

Title: VIP and SOM interneurons compete to cooperate

Authors: ***M. M. KARNANI**, J. C. JACKSON, I. AYZENSHTAT, R. YUSTE;
Biol. Sci., Columbia University, Dept. of Biol. Sci., New York, NY

Abstract: The canonical cortical interneuron circuit involving cardinal interneuron populations is becoming clear. Two major neocortical interneuron populations defined by expression of somatostatin or vasoactive intestinal peptide powerfully inhibit each other while inhibitory connections within these populations are highly infrequent. We used quadruple patch clamp recordings in triple-transgenic mouse brain slices to obtain synaptic parameters and network statistics of these and other previously undocumented synaptic connections among genetically

defined interneuron populations and pyramidal cells. Our results show multiple specializations for well-organized competition between interneuron populations as well as cooperativity within populations. *In vivo* calcium imaging data indicates that these forces are at play in the awake brain as well as in slices, resulting in a high tendency for coactivity within interneuron populations. Supported by the NEI (R01EY011787) and the HFSP.

Title: Neuronal connectivity at resting-state decreased in cortex induced by cocaine

Authors: *G. XIAOCHUN[1,2], J. CHOI[1], N. VOLKOW[3], Y. PAN[1], C. DU[1];
[1]Dept. of Biomed. Engineering, State Univer, Stonybrook, NY; [2]Key Lab. of Developmental Genes and Human Diseases, Dept. of Anat. and Neuroscience, Med. School, Southeast University, Nanjing, 210009, PR China, Nanjing, China; [3]Natl. Inst. on Drug Abuse, NIH, Bethesda, MD

Abstract: Neuroplastic changes in the cortex are implicated in the behavioral disruption observed with substance use disorders. Imaging of functional brain connectivity during the resting-state is increasingly utilized to investigate how drugs affect systems-level brain networks. Although resting-state MRI has provided significant new knowledge on the changes in functional brain connectivity induced by cocaine, it is still a challenge to directly image temporal changes in neuronal activity, which is important when investigating the effects cocaine, which not only affects neuronal activity but also has direct vasoactive effects. Here, we present our optical imaging technique in combination with the genetic calcium labeling (GCamp6f) to study the

neuronal Ca activities in sensorimotor cortex at resting-state; we assessed connectivity across different cortical regions and layers and evaluated cocaine's effects in the connectivity patterns. Two groups of animal were used: Group 1 (n=5), we virus-delivered GCamp6f into the forepaw (FP), hindpaw (HP) and barrel (BC) cortex in Layer II-III (~ 250μm depth), whereas in Group 2 (n=6), the GCamp6f was injected in Layer IV-V of the same cortex (~ 500μm depth). Four weeks late, the animals were imaged with optical/fluorescence imaging (OFI) to simultaneously record the neuronal Ca2+ changes along with the spontaneous hemodynamic fluctuations in the cortex from baseline to cocaine. We also compared the effects in different cortical layers. Our results showed that, the autocorrelations in local FP, HP or BC areas at resting-state were >80% in both upper and deeper cortical layers, thus indicating that local neuronal activities were highly correlated. The cross-correlations between FP, HP and BC cortices were ~70% in the baseline and decreased after cocaine in upper layers (Layer II-III). Specifically, the cross-correlations of BC vs FP, BC vs HP were decreased ~53% (i.e., from 0.77±0.05 to 0.36±0.1, p=0.006) and ~48% (i.e., from 0.76±0.09 to 0.4±0.1, p=0.008), respectively, and those between FP and HP were decreased ~21% (i.e., from: 0.88±0.03 to 0.69±0.07, P=0.04) after cocaine in the upper cortical layers. Interestingly, the cross-correlations between different areas in the deeper cortical layers were not changed after cocaine. The reductions in cross-correlation indicates that neuronal functional connectivity was decreased by cocaine, which might contribute to impaired processing of cortical information during cocaine intoxication.

Title: Spatio-temporal dynamics of network activity coupled to the action of the neuromodulator adenosine

Authors: *M. J. RICHARDSON, F. FERMANI, A. NEWTON, M. THOMAS, M. WALL; Univ. of Warwick, Coventry, United Kingdom

Abstract: We combine experimentally verified models of neocortical-neuron voltage dynamics and network connectivity to derive a framework that describes activity at a tissue scale. The resulting description represents a neuronal field theory in which emergent properties at the coarse-grained level can be causally linked to the physiology of cellular and sub-cellular

components. The description is solvable and also straightforward to simulate, and can be elaborated to include further biophysical details such as multiple neuronal populations to capture the structure of the component microcircuits, synaptic dynamics and filtering as well as distance-dependent delays in signal propagation. We demonstrate the utility of the approach by modelling recent experimental results on the negative feedback coupling between the activity-dependent release of the neuromodulator adenosine, its diffusion in the extracellular space and its subsequent suppression of neocortical activity.

Title: Relating spatial patterns of beta oscillations to their power in macaque motor cortex: a case study in using the "Elephant" data analysis framework in a reproducible analysis workflow

Authors: ***M. DENKER**[1], L. ZEHL[1], B. KILAVIK[2], M. DIESMANN[1], T. BROCHIER[2], A. RIEHLE[2,1,3], S. GRÜN[1,4,3];

Inst., Wako-Shi, Japan; [4]Theoretical Systems Neurobio., RWTH Aachen Univ., Aachen, Germany

Abstract: The unprecedented degree of complexity in electrophysiological experiments has reached a level where well-structured data analysis workflows have become a necessity. Here we introduce a case study that links emerging software tools to form a reproducible analysis

workflow. As a key component of such workflows, we introduce the Electrophysiology Analysis Toolkit ("Elephant", http://neuralensemble.org/elephant/) as a recent community-centered initiative to develop an analysis framework for multi-scale activity data based on common data representations provided by the Neo library [Garcia et al. (2014) Front. Neuroinform 8:10]. During states of increased arousal, motor preparation, and postural maintenance, the local field potential (LFP) in primary motor (M1) and premotor (PM) cortex typically exhibits oscillations in the beta (12-40 Hz) range [Kilavik et al. (2012) Cereb Cortex 22:2148]. Beta oscillations recorded on separate electrodes are often highly correlated, but exhibit a non-zero phase shift. These shifts were shown to organize spatially in the form of planar wave propagation along preferred directions across the cortical surface during an instructed-delay reaching task [Rubino et al. (2006) Nat Neurosci 9:1549]. In this case study we demonstrate that in monkey motor cortex a variety of additional spatial patterns of LFP beta activity may be distinguished outside epochs that exhibit a clear planar wave. We recorded massively parallel neuronal activity using a 10-by-10 Utah electrode array (Blackrock Microsystems), which was chronically implanted in M1 and dorsal PM. The monkey was trained in a delayed reach-to-grasp task [Riehle et al. (2013) Front Neural Circuits 7:48]. Based on the instantaneous phase and phase gradients of the beta-filtered LFP, we introduce and combine measures to identify different spatial activity patterns: (i) planar waves, (ii) quasi-stationary states (all electrodes appear synchronized at near-zero lag), (iii) spatially unstructured states, and (iv) more complex patterns, including circular and radial propagation. We assess the statistical properties of the patterns, including their duration and average direction. In particular, we relate the observed patterns to beta-spindles identified by large instantaneous amplitudes. We find that the wave pattern correlates with the beta power, where the peak of spindles typically coincides with a quasi-stationary state. In combination with previous results [Denker et al. (2011) Cereb Cortex 21:2681], this raises the hypothesis that beta power is indicative of spatio-temporal organization of spike synchronization.

Abstract: Dopaminergic (DA) neurons *in vivo* are constantly bombarded by various excitatory and inhibitory inputs. A substantial proportion of the inhibitory drive to DA neurons in ventral tegmental area (VTA) comes from local GABA neurons, which modulates DA neuron firing and thus the amount of released DA throughout the brain. We investigated how synchronous activity of local VTA GABA neurons influence DA neuron firing patterns. We developed a local circuit model of the VTA consisting of one DA neuron innervated by a population of GABA neurons. The model was calibrated to reproduce dynamic clamp experimental results under application of tonic NMDA and GABA receptor currents. Particularly, burst firing in the model could be reproduced by application of NMDA or through disinhibition from GABA. Similar to the experimental results, background firing was inhibited by tonic GABA inputs to the DA neuron; however, phasic firing evoked by NMDA was preserved. In addition, well-established features of DA neurons modeled before, such as high frequency response to NMDA activation but relatively low firing rates when driven with applied current or AMPA receptor activation, were also reproduced in the model. To better approximate *in vivo* conditions, we explored how networks of GABA neurons modulate DA neuron firing. Modeling revealed that GABA neurons can differently influence the firing pattern of the DA neuron depending on the level of synchronization in across GABA networks. Asynchronous activity of GABA neurons in the population provides constant level of inhibition to DA neuron and acts very similarly to the tonic inhibition as described above. Under the combined influence of desynchronized glutamatergic and GABA populations, the DA neuron fires with frequencies close to those observed during background firing (in the absence of synaptic inputs) but less regularly. In contrast to asynchronous activity, coordinated activity of synchronized GABA neurons can evoke additional spikes in the DA neuron. By hyperpolarizing the cell membrane, GABA current decreases intracellular Ca concentration, because activation threshold for Ca current is -50 mV. With the drop in Ca level the calcium-dependent potassium current decreases. This leads to faster depolarization. In contrast to tonic inhibition, when the GABA population is synchronized inhibition becomes pulsatile providing the DA neuron an opportunity to fire between pulses. Our simulations suggest that synchrony amongst GABA neurons seems to be a critical intermediary that regulates DA neuron activity and, hence, DA release throughout the brain.

Higher Sch. of Econ., Moscow, Russian Federation

Abstract: Experimental data show that alcohol consumption produces an increase of dopamine (DA) release from dopaminergic neurons of the Ventral Tegmental Area (VTA). This brain region, and the computational processes it performs, are crucial for processing information about rewarding stimuli and reinforcement learning, and hence plays a central role in addiction. Consistent with this view, rewarding events and salient stimuli each increase the firing rate of DA neurons, which is argued to play a central role in encoding information about expected rewards and their motivation salience. The primary goal of the current study is to describe and explore how acute ethanol exposure alters the biophysical properties of VTA DA neurons through a computational model of the VTA circuit. A simplified biophysical model of the DA neuron was first implemented to explore the effects of ethanol on firing in the absence of glutamatergic and GABAergic inputs. Towards this goal, changes in DA neuron excitability were quantified by measuring the maximal frequencies evoked by stimuli of varying sizes. Specifically, we show that potentiation of hyperpolarization activated, cyclic nucleotide gated (HCN) channels and activation of GIRK channels mostly cancel each other, and thus have opposing effects on the firing rate of the DA neuron. Furthermore, the HCN current in isolation (when GIRK channel is blocked) mostly affects low frequency firing, but not when firing rate is very high. Thus, these channels are not sufficient to increase the excitability of the DA neuron. Additional simulations identified a subthreshold sodium current as a possible target capable of increasing excitability of the DA neuron. We then investigated effects of ethanol when glutamatergic and GABAergic inputs are included in a local circuit model composed of the DA neuron and GABA population. As suggested by experimental data, we found that acute ethanol effects DA neuron firing through an increase in the AMPA/NMDA ratio, potentiation of GABA synapses on the DA neuron, and a decrease in GABA neuron firing rate. We describe how acute ethanol produces an increase in the number of spikes in bursts by its effect on GABAergic and

glutamatergic inputs received by DA neuron. Moreover, this effect depends on the burstiness of glutamatergic inputs on DA neuron firing when ethanol is applied. We discuss the optimal combination of the intrinsic and network mechanisms that contribute to the excitation of the DA neuron with the future goal of testing these hypotheses directly in experiments. This project is funded by NIAAA grant 1R01AA022821

Title: Spontaneous calcium transients precede hemodynamic activity and produce homotopic functional connectivity maps

Authors: *P. WRIGHT, A. BAUER, G. BAXTER, J. CULVER;
Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Hemodynamic-based markers of cortical activity (e.g. fMRI, optical intrinsic signal (OIS) imaging) are an indirect report of brain function driven by electrical and metabolic activity through neurovascular coupling. Here we extend functional connectivity (FC) analysis, a method for mapping functional relationships using spontaneous brain activity, from hemodynamic to Ca2+-dynamic imaging. Transgenic mice (n=5) expressing a fluorescent calcium indicator (GCAMP3) driven by the Emx1 promoter in cortical glutamatergic neurons and glia were anesthetized using ketaminze/xylazine and imaged transcranially. Sequential LED illumination (λ=470, 530, 590, 625nm) enabled concurrent imaging of both GCAMP3 fluorescence emission (corrected for hemoglobin absorption) and hemodynamics. Somatosensory responses were evoked using a 0.5mA electrical hindpaw block paradigm. FC patterns were generated for low (0.009-0.08Hz) and high (0.2-2Hz) frequency bands. Following paw stimulation, GCAMP3 provided a response time course sensitive to individual high frequency (2Hz) pulse presentations and preceded the stereotypical hemodynamic response function by approximately 1.5 seconds (Fig. 1A&B). Within the high frequency band, pixelwise cross-correlation analysis of

spontaneous data revealed that GCAMP3 again preceded HbO2 by approximately 1.5 seconds across the brain (Fig 1C&D). Furthermore, homotopic FC maps remained intact in higher frequencies relative to HbO2 maps but had similar topography (Fig. 1E). In summary, functional neuroimaging of Ca2+ dynamics in mice provides evidence that spatiotemporal coherence in cortical activity is not exclusive to hemodynamics. This fast Ca2+ signal is more directly coupled to activity at the neuronal level and likely has causal information predictive of the downstream hemodynamic response. Concurrent Ca2+ and hemodynamic-based imaging will enable the dissociation of changes in ionic networks, hemodynamic networks, and neurovascular coupling and provide a framework for subsequent studies of neurological disease, such as stroke.

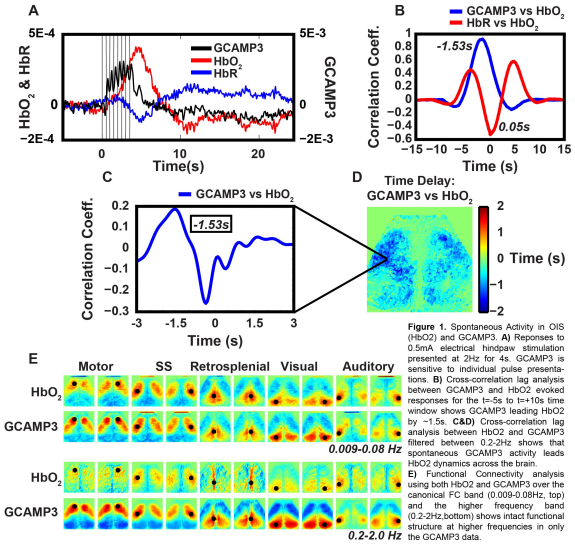

Figure 1. Spontaneous Activity in OIS (HbO2) and GCAMP3. **A)** Reponses to 0.5mA electrical hindpaw stimulation presented at 2Hz for 4s. GCAMP3 is sensitive to individual pulse presentations. **B)** Cross-correlation lag analysis between GCAMP3 and HbO2 evoked responses for the t=-5s to t=+10s time window shows GCAMP3 leading HbO2 by ~1.5s. **C&D)** Cross-correlation lag analysis between HbO2 and GCAMP3 filtered between 0.2-2Hz shows that spontaneous GCAMP3 activity leads HbO2 dynamics across the brain. **E)** Functional Connectivity analysis using both HbO2 and GCAMP3 over the canonical FC band (0.009-0.08Hz, top) and the higher frequency band (0.2-2Hz,bottom) shows intact functional structure at higher frequencies in only the GCAMP3 data.

Title: Modulation of hippocampal gamma oscillation activity by histone acetylation and nuclear receptor family 4a in Alzheimer's disease model mice

Authors: K. TAKASU, K. NIIDOME, M. HASEGAWA, G. SAKAGUCHI, *K. OGAWA; SHIONOGI & CO., LTD., Toyonaka-Shi, Osaka, Japan

Abstract: Hippocampal gamma oscillation is reported to be associated with cognitive functions, and accumulating evidence suggest that deficit of gamma oscillation is related to cognitive

impairment in Alzheimer's disease (AD). Recent studies suggest that post-translational modification of histone protein via acetylation is a fundamental molecular mechanism for regulation of synaptic plasticity and memory formation. However, little is known about roles for histone acetylation in the hippocampal gamma oscillation. In this study, we investigated whether histone acetylation and its downstream signaling pathway, nuclear receptor family 4a (NR4a) regulate kainate-induced gamma oscillation by using acute hippocampal slices of AD model mice (PS/APP transgenic mice). We found that kainate-induced gamma oscillation in the hippocampal slices of PS/APP mice was decreased compared with that in control mice (C57BL/6J mice or PS mice), and application of donepezil, a clinically used drug for AD treatment, recovered the gamma oscillation. Decrease of gamma oscillation was also observed in the hippocampal slices of aged PS mice (14 months) and that of C57BL/6J mice (3 months) treated *in vitro* with amyloid beta$_{1\text{-}42}$. Then, we investigated the effects of histone deacetylase (HDAC) inhibitors (suberoylanilide hydroxamic acid (SAHA) and MS-275) and a NR4a activator (cytosporone B) on the gamma oscillation in PS/APP mice. We found that both SAHA and MS-275 elevated the gamma oscillation level, and the effect of SAHA was accompanied with the elevation of histone H3 and H4 acetylation. The effects of SAHA on the gamma oscillation and histone acetylation were abolished by co-application of histone acetyltransferase (HAT) inhibitor C646, showing that histone acetylation is a key mechanism of the observed SAHA effects. We further demonstrated that NR4a activation by cytosporone B improved the gamma oscillation in PS/APP mice. In C57BL/6J mice, SAHA increased gamma oscillation, while C646 alone abolished gamma oscillation. Our results indicate that histone acetylation modulates kainate-induced gamma oscillation in the hippocampal slices of both normal and AD model mice. As possible pathological mechanism of AD, histone acetylation may be suppressed by the elevated HDAC activity in the hippocampus. Reversal of gamma oscillation deficits by HDAC inhibition and/or NR4a activation appears to be a potential therapeutic approach to improve cognitive function in AD.

Cerebral Dynamics, Boston Univ. Sch. of Med., Boston, MA; [4]Cognitive Neurosci. and Information Technol. Res. Program,, Open Univ. of Catalonia (UOC), Barcelona, Spain

Abstract: In the healthy brain, local and interregional oscillatory activity at specific frequency bands codes for the engagement of different cognitive operations and behaviors. In turn, specific neurological syndromes have been associated to particular alterations of oscillatory mechanisms. More recently, rhythmic Transcranial Magnetic Stimulation coupled to scalp electroencephalography (EEG) has provided evidence of local oscillation entrainment at a frequency band dictated by the stimulation input. These findings have spurred interest for the manipulation of local synchrony, either in search of causal associations between oscillations and brain functions or for the development of novel therapeutic approaches in the field of neuromodulation. However, direct evidence that overcomes the limitations of non-invasive stimulation and recording procedures remains paramount. We here analyzed intracranial EEG (iEEG) signals from multielectrodes implanted in the prefrontal cortex of fully awake epileptic patients (n=3) undergoing focal intracortical stimulation, as part of a clinical procedure aimed to identify the localization of epileptogenic loci. Responses to 5 seconds bursts of biphasic 50 Hz squared electrical pulses delivered at increasing intensities (0.5 to 5 mA) by pairs of adjacent contacts of the same multi-electrode were recorded. Changes in iEEG signals in absence of signs of epileptiform discharges, recorded prior, during and shortly after low intensity stimulation (up to 2 mA) were considered in our study. Our analyses provide direct evidence of 50 Hz oscillatory entrainment along the stimulation burst, characterized by power increases around the input frequency (45-55 Hz) and phase locking to the electrical stimulation signal. The magnitude of this gamma band entrainment depended on stimulation intensity and the distance between the contact pairs involved in the stimulation and the recording of iEEG data. Highlighting the physiological relevance of this phenomenon, the highest entrainment was found in areas with the highest level of synchronization with the stimulated site in absence of stimulation. Artificially modeled iEEG time series and noise served to rule out the confounding of electrical artifacts. Our results provide evidence that direct stimulation of brain tissues entrains physiological oscillatory activity at the input frequency. This outcome opens new avenues to explore the causal role of brain synchrony in specific cognitive processes. Furthermore, it will allow the further development of novel stimulation therapeutic approaches for neurological conditions subtended by dysfunctional oscillatory activity.

Title: The effect of resonance frequency on network oscillations through electrical gap junction coupling

Authors: ***X. LI**[1], Y. CHEN[1], H. G. ROTSTEIN[2], F. NADIM[1,2];
[1]Dept Biol. Sci., Rutgers/Njit, Newark, NJ; [2]Dept Mathematical Sci., New Jersey Inst. of Technol., Newark, NJ

Abstract: Neurons often produce a maximal subthreshold voltage response to oscillatory current inputs at a non-zero input frequency (f_{res}), a property known as membrane potential resonance. Typically, resonance is measured by using the impedance function Z(f) of a neuron over a range of frequencies (f). Recent studies have suggested that f_{res} of constituent neurons is a strong indicator of the network frequency. Nevertheless, how the resonance property influence the network frequency remains unclear. We focus on networks of neurons that are electrically coupled through gap junctions and propose the hypothesis that, in such a network, parameters that shift the resonance frequency also shift the network frequency in the same direction. Additionally, we propose that an increase in the resonance power ($Q=Z(f_{res})/Z(0)$) of participating resonator neurons increases this dependence. We test our hypothesis in an electrically coupled network consisting of a pacemaker neuron (having intrinsic oscillations) and a resonator that does not necessarily have intrinsic oscillations. In a previous computational study of a two-cell model of such a network, we showed that it is the impedance profile of the resonator, not the specific neuron model parameters, that influences the network frequency (Chen et al, SfN Abst 538.24, 2014). We test this hypothesis using dynamic clamp technique in a biological network consisting of pacemaker neurons electrically coupled to a resonator neuron. In the oscillatory pyloric network of the crab *C. borealis*, the network frequency has been found to be correlated with the resonance frequency of its pacemaker group neurons (Tohidi & Nadim, *J Neurosci*, 2009). Additionally, although the non-pacemaker follower neurons do not produce oscillations, they also exhibit resonance but with a different f_{res} than that of the pacemaker neurons (Tseng et al, *J Neurosci*, 2014). To examine our hypothesis, we couple the anterior

burster (AB) and the pyloric dilator (PD) pacemaker group neurons in the pyloric network to a biophysical-inspired model resonator via gap junction using dynamic clamp. In the model resonator, the attributes f_{res} and Q can be varied independently by changing the parameters of the resonator neuron. We show that by shifting the f_{res} of the resonator without changing the shape of the impedance profile, the network frequency shifts in the same direction and this effect is enhanced by increasing the resonance power Q. Our results provide experimental support that resonance frequency and power can strongly influence the network oscillation frequency and therefore modulators may directly target these attributes in order to influence network activity.

Title: Modeling the effects of inhibitory and excitatory synchrony on seizure generation in a CA1 circuit

Authors: *J. R. CRESSMAN[1], D. B. DORMAN[2];
[2]Mol. Neurosci., [1]George Mason Univ., Fairfax, VA

Abstract: The CA1 region of the hippocampus has been implicated in temporal lobe epilepsy. Factors underlying seizure generation and propagation are complex and may depend on the interaction of sodium and potassium concentration dynamics, the balance of region-specific excitation and inhibition, the degree of synchrony of neuronal populations, and synaptic mechanisms such as recurrent collaterals. To understand the interplay of these dynamics, we have developed a mathematical model of a CA1 circuit consisting of conductance based neurons with intra- and extra-cellular ionic concentration dynamics. We include a two-compartment (dendrite and soma) pyramidal cell and single-compartment axo-axonic, basket, and bistratified interneurons. The synaptic strengths and extra-cellular diffusion volume of the four modeled neurons are a simplified representation of the entire CA1 network, such that the activity of any single cell in the model represent the proportion of synchronously active neurons. The synaptic connections are modeled based on estimated quantifications from experimental reports. We stimulate the network by simulating theta and gamma frequency input from CA3 and investigate the dynamics underlying seizure-like activity. Specifically, we show the sensitivity of the network as a function of the degree of synchrony of both interneurons and pyramidal cells, we assess the robustness of the model to extracellular diffusion, and we determine the sensitivity of the CA1 network to the different interneuron populations. Our results suggest experimentally testable predictions that could further elucidate the role of CA1 network dynamics in

epileptiform versus normal activity. Our model shows an optimal window of between 20-40 percent of correlated CA1 pyramidal cells for network throughput in response to CA3 input. Outside this window the network output becomes more decorrelated from CA3 input and can be prone to maintained bursting in the absence of input. This optimal window is also sensitive to correlated interneuron activity.

Title: Intracerebral recordings of slow wave and rapid eye-movement sleep in naturally sleeping pigeons

Authors: *J. VAN DER MEIJ[1], G. J. L. BECKERS[2], N. C. RATTENBORG[1];
[1]Avian Sleep Group, Max Planck Inst. For Ornithology, Seewiesen, Germany; [2]Departments of Psychology and Biol., Cognitive Neurobio. and Helmholtz Institute, Utrecht Univ., Utrecht, Netherlands

Abstract: Mammals and birds both show sleep-related slow oscillations (SO) of neuronal activity, which are thought to be involved in processing hippocampal memories at the systems level in mammals. However, unlike the mammalian hippocampus which receives input from most of the cortex, input to the avian hippocampus is restricted to olfactory and visual information, the latter coming from the hyperpallium. This variation in brain connectivity between mammals and birds may be an indication of fundamental differences in the manner of information processing at the systems level during sleep. Therefore, examining sleep-related brain activity at the systems level in birds provides us with an opportunity to test models proposed in mammals, and to reveal fundamental principles that could expand our understanding of mammalian sleep. The aim of the current study was to explore activity in the avian hyperpallium during both natural slow wave sleep (SWS) and rapid eye-movement (REM) sleep, and to compare this to activity recorded under anesthesia. We used a 32-channel silicon probe connected to a transmitter to make intracerebral recordings of the hyperpallium in naturally sleeping and isoflurane anesthetized pigeons (Columba livia) based on a within-bird design. Local field potential (LFP) recordings reveal high amplitude SO (<2Hz) across most recording

sites during natural SWS. These oscillations show diverse propagation patterns (i.e. slow waves) across the recording array. Similar results are found under anesthesia, with the exception that the SO show higher amplitude and SO activity seems more synchronized between electrode sites. In contrast, LFP recordings during REM sleep show a reduced amount of slow wave activity and lack the traveling SO seen during SWS. In conclusion, this study shows that the traveling nature of slow waves can be found in the avian hyperpallium during both natural SWS and anesthesia. As traveling slow waves have also been described in mammals, this appears to be a fundamental feature of slow wave sleep. However, simultaneous recordings of the hyperpallium and hippocampus during natural sleep are needed to evaluate the potential role that these slow waves play in processing information at a systems level in the avian brain.

Title: Hippocampal rhythm and subfield oscillatory coupling modulation by the hypothalamic vasopressinergic magnocellular system

Authors: ***M. M. MÁRQUEZ**, H. BARRIO-ZHANG, V. S. HERNANDEZ, L. ZHANG; Nacional Autonomous Univ. of Mexico, Mexico City, Mexico

Abstract: The dorsal (dHi) and ventral (vHi) hippocampus have been considered having different roles, such as for "learning and memory" vs. "stress coping and emotional control". However, little is known concerning the oscillations coherence under different brain states between these two sub-regions. Electrophysiological studies have showed that nanomolar concentrations of [Arg8]-vasopressin (AVP) induced a prolonged increase in amplitude and slope of the evoked population response in the hippocampus. This AVP-induced potentiation of the excitatory postsynaptic potential (EPSP) persisted following removal of AVP from the perfusion medium. A pronounced effect of AVP and its metabolite AVP (4-8) was found to elicit a long-lasting enhancement of hippocampal excitability, mostly in neurons within the ventral hippocampus. Although historically the extra-hypothalamic projections of paraventricular and supraoptic nuclei were thought to be sparse, recent studies have showed that the AVP

magnocellular neurosecretory neurons possessed axon-collaterals projecting to hippocampus (Hernadez et al, 2015) and established synaptic contacts with both pyramidal and interneurons (Zhang and Hernadez, 2013). AVP innervation in hippocampus is highly heterogeneous, being the ventral and dorsal CA2 the subfields with highest density respectfully. Hence, it is interesting to evaluate the phase locking value changes between dorsal and ventral CA2 regions (dCA2 vs vCA2) under resting and activated states of the hypothalamic PVN. This investigation examined the oscillation coherence between the dorsal and ventral CA2 regions and between hypothalamic PVN and each of the previous regions, using dual-electrode *in vivo* extracellular recording and juxtacelular labeling post-recording, in rats under urethane anesthesia. PVN activation was evoked with either hypertonicity or hypovolemy, with which the hypothalamic neurohypophysial vasopresinergic pathway is predominantly up-regulated. Evolution map approach (EMA) was employed to determine the direction of information flow between dCa2 and vCA2. Preliminary results showed that salt loading increased theta oscillation / oscillation frequencies in both hypothalamic paraventricular nucleus (PVN) and the ventral CA2 region. The phase locking values of theta rhythms between PVN and the dorsal and ventral hippocampus were also increased. These data provide physiological evidences of a distinct modulatory role of the non-canonic AVP containing hypothalamic pathways on cortical oscillatory functions.

Title: Neural basis of at-rest band-limited fcMRI

Authors: *J. LI[1], W. J. BENTLEY[2], L. H. SNYDER[2];
[1]Washington Univ. In St Louis, Saint Louis, MO; [2]Washington Univ. in St Louis, St Louis, MO

Abstract: Functional connectivity MRI (fcMRI) studies have greatly helped our understanding of the functional organization of the human brain. fcMRI measures temporal correlations in at-rest blood oxygen level dependent signals (BOLD), which, at best, provide an indirect measure of neural activity. Though much effort has been put towards understanding the relationship between neural activity and task-related BOLD, it is unclear whether and how at-rest BOLD correlation is related to neural activity. Here we show that at-rest oxygen correlation reflects

correlated neural activity, including LFP power, slow fluctuation of raw LFP (slow LFP), single-unit spiking activity, and multi-unit spiking activity. We develop a novel method, regression-based dependency analysis, and show that oxygen correlation is largely accounted by slow LFP (72% of the within-network covariance in oxygen and 57% of the across-network covariance in oxygen), and that slow LFP correlation is accounted by spiking activity. This suggests a causal relationship, where oxygen is driven by slow LFP, which is itself driven by spiking activity. This causal link is confirmed by Granger causality analysis. In addition, we also show a feedback effect from slow LFP to spiking activity. This feedback effect is confirmed by the frequency nesting analysis, showing that the phase of slow LFP modulates the amplitude of spiking activity. The fact that spiking activity drives a delayed slow LFP change, which itself drives a feedback activity onto spiking activity could potentially lead to an oscillation in spiking activity. This oscillation could explain the band-limited correlation reported in Li et al 2014 (PNAS). In sum, our results provide conclusive support for the idea that fcMRI reflects patterns of neural activity, present significant challenges to the traditional view of neurohemodynamic coupling, and open up new avenues for exploring the functional significance of fcMRI.

Title: Influence of the stomach electrical pacemaker on spontaneous brain activity measured with fMRI

Authors: ***I. REBOLLO**, C. LEBOULLENGER, A.-D. LODEHO, C. TALLON-BAUDRY; LNC, INSERM, ENS, Paris, France

Abstract: Resting state networks (RSN) are composed of anatomically distinct brain regions whose BOLD signal at rest systematically covary. The slow (<1 Hz) correlated fluctuations in BOLD signal defining RSNs have been so far considered as consequences of factors intrinsic to the brain, such as anatomical connectivity or neural delays. However, brain activity during cognitive rest might be impacted by signals coming from other bodily organs. In particular, the brain is heavily coupled with the stomach, which acts as an autonomous pacemaker generating an electrical slow wave in the frequency range of RSNs, around 0.05 Hz. By placing electrodes over the abdomen it is possible to measure the electrical signal from the stomach pacemaker, a procedure known as Electrogastrography. We sought to investigate the influence of the stomach pacemaker on spontaneous brain dynamics by recording simultaneously the electrogastrogram and resting-state BOLD signal in 21 human participants who were asked to fixate a point during

15 minutes. We measured functional connectivity between the electrophysiological signal of the stomach and BOLD signal at each voxel. Preliminary results so far indicate that the resting-state BOLD signal in a set of areas systematically covaries with the stomach pacemaker. Those areas comprise known visceral regions, such as the insula, but also other regions such as dorsal anterior cingulate cortex, dorsal precuneus or cerebellum. These results suggest that the coupling between the stomach pacemaker and the BOLD signal at rest goes beyond areas known to directly receive inputs from the stomach and recruits in particular portions of the Saliency Network. This in turn suggest that the stomach pacemaker may play a role in shaping the large-scale organization of spontaneous brain activity.

Title: Mapping tACS-entrained brain oscillations using magnetoencephalography (MEG)

Authors: *S. R. SOEKADAR[1], M. WITKOWSKI[1], E. GARCIA COSSIO[2], B. S. CHANDER[1], C. BRAUN[3], L. G. COHEN[4], S. E. ROBINSON[5];

Section, NINDS, [5]MEG Core Facility, NIMH, NIH, Bethesda, MD

Abstract: Transcranial alternating current stimulation (tACS) affects perception, memory, motor and cognitive function. The main mechanisms underlying tACS-related effects were attributed to frequency specific entrainment, i.e. phase alignment of endogenous brain oscillations to the

externally applied oscillating currents. There is, however, no established method for millimeter-precise mapping of entrained brain oscillations near and underneath the stimulator electrodes, a capability important to understand effects of tACS on brain physiology and behavior. Here we describe a new experimental protocol allowing for millimeter-precise localization and reconstruction of entrained brain oscillations underneath the stimulator electrodes, as well as reliable reconstruction of neuromagnetic oscillations across all physiological frequency bands. Reliability of the protocol was tested in a phantom study (study 1) and a group of healthy human volunteers engaging in a motor task (study 2). Source space analysis was applied to data recorded in absence and during amplitude-modulated tACS delivered at different frequencies (11Hz, 23Hz). In study 1, spatial precision of localizing phase-locked activity between an oscillation dipole and tACS was assessed by evaluating drop in phase-lock value (PLV) as a function of distance from a known fixed dipole's position. In study 2, tACS-entrained brain oscillations were mapped on the individual's brain anatomy and results tested for consistency. Use of this approach can open a new window to investigate mechanisms and effects of stimulation protocols that entrain brain oscillations.

Title: Frequency dependent entrainment of spontaneous Ca transients by extracellular AC electric fields in CA1 pyramidal neurons of rat hippocampal slices

Authors: *I. KATO[1], H. MIYAKAWA[2], M. INOUE[2], T. AONISHI[1];
[1]Tokyo Inst. of Technol., Yokohama Kanagawa, Japan; [2]Lab. of Cell. Neurobio., Tokyo university of Pharm. and Life Sci., Hachioji, Japan

Abstract: In central nervous systems, extracellular electric fields are oscillating due possibly to the activities of neural cells. We hypothesized that oscillating extracellular electric fields modulate activity of neuronal population providing a mean to correlate or synchronize neuronal activities. It has been shown that various types of ion channels distributed along the dendrites and endow the dendrites with the capability of generating dendritic spikes including Na spikes, Ca spikes and NMDA spikes. We think it conceivable that generation of dendritic spikes play important roles in sensing extracellular electric field or enhancing ephaptic interactions by

providing current source to generate electric fields. To test the former idea, we developed a method to monitor local Ca transients associated with dendritic spikes in the dendrites of a population of neurons in rat hippocampal slices using spinning disk confocal microscopy and multi-cell dye loading techniques. In a condition where the dendrites of CA1 pyramidal neurons show spontaneous activity because of 50 μM 4-aminopyridine added to external medium and adjusted extracellular potassium concentration (5.5mM), we previously reported that the timing of spontaneously occurring Ca transients in the tufts of the apical dendrites of CA1 pyramidal neurons would be entrained to sub-threshold (1~20mV/mm) 4Hz electric fields applied parallel to the somato-dendritic axis of neurons. Here, we examined the frequency dependence of this entrainment by applying weak (6.5mV/mm) sinusoidal electric fields ranging from 1-16Hz (n=4). We found that within this range, the entrainment was most evident at 2Hz and less evident at other frequencies. Our results support the idea that dendritic action potentials may play important roles in detecting electric oscillating fields.

Title: Effect of inter-modular connection on fast sparse synchronization in clustered small-world networks

Authors: ***S.-Y. KIM**, W. LIM;
Inst. of Computat. Neuroscience, Dept. of Sci. Educ., Inst. of Computat. Neurosci., Daegu, Korea, Republic of

Abstract: We consider a clustered network with small-world sub-networks of inhibitory fast spiking Izhikevich interneurons, and investigate the effect of inter-modular connection on emergence of fast sparsely synchronized rhythms by varying both the inter-modular coupling strength J_inter and the average number of inter-modular links per interneuron M_syn^(inter). In contrast to the case of non-modular networks, modular and global sparsely synchronized states are found. For the case of modular sparse synchronization the population behavior reveals the clustering structure, because the intra-modular dynamics of sub-networks make some mismatching. On the other hand, in the case of global sparse synchronization, the population behavior is globally identical, independently of the cluster structure, because intra-modular dynamics of sub-networks make perfect matching. We use a realistic cross-correlation

modularity measure, representing the matching-degree between the instantaneous sub-population spike rates of the sub-networks, and examine whether the sparse synchronization is global or modular. Depending on its magnitude, the inter-modular coupling strength J_inter seems to play "dual" roles for the pacing between spikes in each sub-network. For large J_inter, due to strong inhibition it plays a destructive role to "spoil" the pacing between sparse spikes, while for small J_inter it plays a constructive role to "favor" the pacing between spikes. Through competition between the constructive and destructive roles of J_inter, there exists an intermediate optimal J_inter at which the pacing degree between spikes becomes maximal. In contrast, the average number of inter-modular links per interneuron M_syn^(inter) seems to play a role just to "favor" global communication between sub-networks. With increasing M_syn^(inter), the degree of effectiveness of global communication increases monotonically. Furthermore, we employ the realistic whole- and sub-population order parameters, based on the instantaneous whole- and sub-population spike rates, to determine the threshold values for the synchronization-unsynchronization transition in the whole- and sub-populations, and the degrees of the global and modular synchronization are also measured in terms of the realistic statistical-mechanical whole- and sub-population spiking measures defined by considering both the occupation and the pacing degrees of the spikes. It is expected that our results have important implications for the role of the brain plasticity which refers to the brain's ability to change its structure and function by modifying the strength or efficacy of synaptic transmission.

Title: *In vivo* characterization of hippocampal theta and gamma spontaneous oscillations in familial Alzheimer's disease mouse models based on mutant presenilin-2

Authors: ***R. FONTANA**[1], M. RUBEGA[2], G. SPARACINO[2], C. FASOLATO[3], S. VASSANELLI[3];
[1]Dept. of Biomed. Sci., Univ. of Padua, Padova, Italy; [2]Dept. of Information Engin., [3]Dept. of Biomed. Sci., Univ. of Padua, Padua, Italy

Abstract: Neuronal network oscillations, measured by electroencephalography (EEG) or local field potential (LFP), have long been linked to several cognitive activities in both humans and rodents. In particular, hippocampal oscillations in the theta and gamma frequency ranges are considered to underlay important computational functions, e.g. providing key reference signals for temporal encoding of information. Indeed, it has been observed that the interaction between

the phase of hippocampal theta oscillations and the amplitude of hippocampal gamma oscillations assessed by phase-amplitude cross-frequency coupling (CFC) analysis plays a pivotal role in learning performance. Alzheimer's disease (AD) is a highly diffuse and severe brain pathology characterized by progressive impairments in cognition and memory. One major histological feature of AD is the accumulation of senile plaques, consisting of amyloid-beta (Aβ) peptides. Aβ derives from the sequential processing of the amyloid precursor protein (APP) by β and γ secretases. Familial AD (FAD) is caused by different missense mutations affecting the genes encoding for APP and presenilin (PS1 and PS2), i.e. respectively the substrate and the core component of γ secretase. Recent evidence suggests an alteration of theta and gamma rhythms in AD. Furthermore, the phase-amplitude CFC in these two frequency bands is impaired in *ex vivo* and *in vivo* AD mouse models. At present, therapies attempting to revert or stop AD are poorly effective at least partially owing to a late diagnosis. Biomarkers for an early diagnosis of the pathology, i.e. before the emergence of the cognitive deficits, are critical for improving the efficacy of current and future strategies to contrast the progression of the disease. The aim of this work is to identify early EEG markers in FAD mouse models characterized by precocious calcium dysregulation in addition to Aβ load and/or plaque deposition, i.e. the homozygous mouse lines PS2.30H and B6.152H, that express respectively the human PS2-N141I mutation alone or in combination with the human APP Swedish mutation. Within this frame we have recorded spontaneous LFP activity from the hippocampus of urethane-anesthetized mice and characterized theta and gamma oscillations together with their phase-amplitude CFC - before and after amyloid plaque deposition. Preliminary data suggest an increased power in the slow gamma range (25-45 Hz) in the PS2.30H and B6.152H lines along with an altered theta-gamma CFC in the B6.152H line in both 3 and 6 months old female mice with respect to age- and sex-matched wild-type mice.

Title: Spike-field coupling does not imply spike-spike coupling

Authors: *E. PETERSON, B. VOYTEK;
Cognitive Sci., U.C. San Diego, San Diego, CA

Abstract: The origin and function of oscillatory activity remains a major outstanding question in neuroscience. One prominent hypothesis for the functional role of gamma oscillations is 'communication through coherence'. This theory posits that regional coherence enhances communication by increasing the precision of spike timing, i.e. spike-spike coupling. The focus on coherence has lead to computational investigations of already oscillating populations. While important in establishing coherence as useful for communications, and in showing how information flow is maximized when coherence between oscillating pairs is maximized, these studies skip over a basic question: is spike-time precision enhanced by the onset and amplitude of gamma oscillations? By definition, oscillating neural populations have repeating periods of decreased firing. If all else is held equal, these periods of relative silence would mean a decrease in information flow. As firing declines so does information. If oscillations increase information flow, they must alter spiking to overcome these 'silent costs'. Keeping with the idea that oscillations alter spike timing, and using Hodgkin-Huxley neurons in classic excitatory-inhibitory configurations, we simulated the effect of gamma onset and amplitude on spike precision and on information flow. Our simulations suggest a much larger range of parameters can generate gamma oscillations, compared to only a narrow range of parameters that can actually increase precision and information transmission in excitatory neurons. From a theoretical perspective, our results suggest the 'communication through coherence' hypothesis may require fairly stringent biophysical constraints to function as proposed. When aggregating over all models, gamma power does not statistically predict spike precision, nor does a change to spike-field coupling imply a change in spike-spike coupling. In sum these results suggest gamma oscillations, when driven solely by excitatory-inhibitory interactions, reflect mostly silent periods rather than the spike-time shifting necessary for enhanced precision.

Title: Investigating spiking resonance in computational models of oriens-lacunosum/moleculare (O-LM) hippocampal interneurons with dendritic synaptic inputs

Authors: *V. SEKULIC[1,2], J. J. LAWRENCE[4], F. K. SKINNER[1,3,2];
[1]Toronto Western Res. Inst., Univ. Hlth. Network, Toronto, ON, Canada; [2]Physiol., [3]Med. (Neurology), Univ. of Toronto, Toronto, ON, Canada; [4]Pharmacol. and Neurosci., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: The theta rhythm (4-12Hz) is a prominent network oscillation observed in the mammalian hippocampus and is correlated with spatial navigation and mnemonic processing. Inhibitory interneurons of the hippocampus fire action potentials at specific phases of the theta rhythm, pointing to distinct functional roles of interneurons in shaping this rhythmic activity. One prominently studied interneuron type is the oriens/lacunosum moleculare (O-LM) cell, which provides direct feedback inhibition and regulation of pyramidal cell activity in the CA1 region. O-LM cells express the hyperpolarization-activated, mixed-cation current (Ih) and, *in vitro*, demonstrate spontaneous firing at theta frequencies that is impaired upon blockade of Ih. Recent work using dynamic clamp (Kispersky et al. 2012) has shown that in the presence of theta frequency-modulated artificial synaptic inputs, O-LM cells exhibit a spiking resonance at theta that is not dependent on Ih. Due to the somatic injection limitation of dynamic clamp, the study could not examine the potential contributions of dendritic conductances and the integration of dendritically-located synaptic inputs. Here, we used previously developed multi-compartment computational models of O-LM cells to begin to address these issues. The models were extracted from our previous ensemble modeling work that showed that dendritic expression of Ih supports appropriate O-LM cell firing. We selected models with dendritic Ih and inserted excitatory and inhibitory synaptic inputs onto the dendritic tree of the models. The synapses were randomly activated at rates according to a Poisson distribution. Modulation of the input at various frequencies resulted in changes in the power spectral density of the model spiking activity. Our results indicate that models with synaptic inputs spread across the dendritic tree express enhanced resonant firing at theta frequencies compared to models with synaptic inputs in the soma only. Thus, the presence of dendritic Ih may interact with synaptic inputs onto dendrites to enhance spiking output in O-LM cells at theta frequencies. This implies that theta-timed inputs onto O-LM cells, such as from the medial septum, may preferentially target their dendrites in order to maximally recruit O-LM cell firing at theta frequencies. Investigating these network interactions are of critical importance for elucidating O-LM cell contributions to theta rhythm activity in the CA1 microcircuit.

Title: Predicting cell-type specific active properties by developing multi-compartment models using databases and electrophysiological feature constraints: Application to interneuron specific 3 (IS3) cells in the hippocampus

Authors: *A. T. GUET-MCCREIGHT[1,2], O. CAMIRÉ[4,5], L. TOPOLNIK[4,5], F. K. SKINNER[1,2,3];
[1]Toronto Western Res. Inst., Toronto, ON, Canada; [2]Dept. of Physiol., [3]Dept. of Med. (Neurology), Univ. of Toronto, Toronto, ON, Canada; [4]Ctr. de Recherche de l'Institut Universitaire en Santé Mentale de Québec, Québec City, QC, Canada; [5]Dept. of Biochemistry, Microbiology and Bioinformatics, Univ. Laval, Québec City, QC, Canada

Abstract: In hippocampus, interneuron-specific type 3 (IS3) cells make GABAergic synapses onto specific types of interneurons, including oriens lacunosum-moleculare (OLM) cells. These synapses possess relatively weak synaptic transmission properties, but despite this, IS3 cells are able to control OLM cell firing patterns (Tyan et al, 2014). As such, we assume that IS3 spikes need to be initiated with minimal synaptic inputs so that synaptic summation is more likely to occur. Morphological and synaptic aspects of IS3 cells are being examined, but what type, how much and where voltage-gated channels (VGCs) are present on IS3 cells has not been determined. Other hippocampal interneuron types are known to have high densities of VGCs on their dendrites. High densities of some types of VGCs (e.g. sodium) along IS3 dendrites may serve to facilitate spike initiation. Using a combination of the NEURON software environment for running simulations and a MATLAB toolbox called PANDORA (Günay et al, 2009) for experimental and simulation analysis, we used both automation and hand tuning to develop IS3 cell models. Data on the active and passive membrane properties of IS3 cells was acquired experimentally, and two-photon calcium imaging was used to assess the spread of back-propagating action potentials in IS3 dendrites, which were seen in dendritic branches as far as 150 μm away from the soma. Using this data as a target reference, we generated databases of multi-compartment models, each one possessing unique combinations of channel types & conductance values. Models that did not capture the features that were seen in experimental recordings were eliminated from each database. We then identified the remaining models in each database whose measurements most closely resembled those seen in experimental traces. Once these models were identified, we computed the minimal excitatory synaptic input necessary to elicit a somatic spike when the synapse was applied at different points along the dendritic arbor. Given the present correspondence with data, our models predict relative conductance balances of different channel types in IS3 cells. Our models also predict that transient sodium and fast delayed rectifier potassium VGCs are present in the proximal dendrites and that the synaptic input necessary to elicit somatic spikes is minimized when A-type potassium channels are

restricted to the soma. Moving forward, our models can serve as a basis for understanding the functional roles of IS3 cells in the hippocampus, a central structure in memory formation.

Title: Dendritic integration in dentate gyrus parvalbumin expressing perisoma inhibiting interneurons

Authors: *C. ELGUETA, M. BARTOS;
Freiburg Univ., Freiburg Im Breisgau, Germany

Abstract: Parvalbumin (PV^+) positive GABAergic perisoma-inhibiting interneurons (PIIs) enable cortical circuits to perform complex operations by providing precisely timed feed-forward or feedback inhibition into principal cells. In despite of their central role during neuronal network computations, little is known regarding how signals are processed in their dendritic trees. Using a combination of single cell voltage sensitive dye imaging (VSDI) and glutamate uncaging in acute slice preparations of the rat dentate gyrus, we have characterized the integrative properties of PV^+ PII dendrites. First we determined speed and attenuation of back-propagating action potentials. We observe a monotonic decline in size of APs as a function of distance when traversing from the soma along both, basal and apical dendrites. In agreement with the low density of sodium conductances, blocking voltage-gated sodium channels did not changed AP attenuation. In line with the high density of Kv3-type potassium channels, blocking them with 4AP had a facilitating effect on action potential backpropagation. Second, a combination of VSDI and glutamate uncaging revealed strong attenuation and deceleration of locally evoked excitatory postsynaptic potentials, suggesting that PII dendrites favor precision and speed during signal integration. Moreover, irrespective of the spatial distribution of the evoked localized EPSPs, summation of excitatory signals at the soma was always sub-linear. Third, we examine how $GABA_A$ receptor-mediated inhibition modulates the EPSPs integration

in PII dendrites by analyzing the effect of localized GABA uncaging using DPNI or RUBI-GABA onto size and shape of EPSPs evoked by glutamate microiontophoresis (miEPSPs). We observe that distal (off-path) inhibition is more effective than proximal (on-path) inhibition in reducing the amplitude of miEPSPs recorded at the soma, although this depended in the size of the excitatory potential and the chloride reversal potential at the uncage locations. In summary, our data suggest than proximal $GABA_A$ receptor-mediated inhibition is better suited to control action potential generation while distal inhibitory inputs favor the regulation of size and shape of excitatory signals.

Title: Characterization of dendritic processing for signal propagation in model primary neurons

Authors: *H. KIM;
Daegu Gyeongbuk Inst. of Sci. & Technol., Daegu, Korea, Republic of

Abstract: Primary neurons in the central nervous system show very distinctive morphology of their dendrites that contain thousands of synaptic contacts as well as a variety of voltage-gated ion channels. The goal of this study is to investigate how cell type-specific dendritic structure is related to dendritic processing for signal propagation in primary neurons. We first anatomically reconstructed model primary neurons: spinal motor neuron, hippocampal pyramidal neuron, neocortical pyramidal neuron, and cerebellar Purkinje neuron. Dendritic signal propagation was then characterized by calculating the voltage attenuation factor between the soma and all points in the dendrites as a function of path length from the soma. We found: 1) that the voltage attenuation data could be well captured with a single fitting equation as a function of distance for both (soma-to-dendrite and dendrite-to-soma) signal propagation directions, and 2) that all anatomically reconstructed models of primary neurons display a similar asymmetric signal propagation in their dendrites: voltage attenuation was much severer for the direction from the dendrites and the soma compared to the opposite direction from the soma to the dendrites. These results may serve to bridge the gap between realistic and reduced neuronal models in a basis of physical distance along the dendrites.

Title: Graded boosting of synaptic signals by low threshold voltage activated calcium conductance

Authors: M. CARBÓ-TANO[1], *L. SZCZUPAK[2,1];
[1]IFIByNE UBA-CONICET, Buenos Aires, Argentina; [2]Univ. de Buenos Aires, Buenos Aires, Argentina

Abstract: Estilo predeterminado; The neuritic tree is the cellular domain at which neurons integrate and process synaptic inputs. In the past decades it became clear that dendrites do not rely purely on their passive membrane properties but are supplied with voltage-activated conductances that affect their processing capabilities. Among these conductances, low threshold voltage-activated calcium conductances (LT-VACCs) play a substantial role in shaping the biophysical attributes of neurites suggesting their involvement in synaptic processing. However, it is not known to what extent the activation of these conductances shapes the synaptic responses. Here we have investigated how LT-VACCs affect synaptic integration in a premotor nonspiking (NS) neuron of the leech nervous system. These cells exhibit an extensive neuritic tree, do not fire Na^+-dependent spikes but express a LT-VACC that was sensitive to 250 μM Ni^{2+} and 100 μM NNC 55-0396 (NNC). Calcium imaging studies showed that this LT-VACC is distributed throughout the main branches and is activated by synaptic responses evoked by stimulation of pressure sensitive (P) neurons. The resulting Ca^{2+} signals were a graded function of the electrophysiological synaptic responses and spread throughout the neuritic tree with no major attenuation. Thus in NS neurons synaptically-evoked Ca^{2+} signals are a graded function of synaptic inputs that spread globally. NNC decreased these synaptic responses and abolished the concomitant widespread Ca^{2+} signals. Coherent with the interpretation that the LT-VACC amplified signals at the postsynaptic level, this conductance also amplified the responses of NS neurons to direct injection of sinusoidal current. Synaptic amplification thus is achieved via a positive feedback in which depolarizing signals activate a LT-VACC that, in turn, boosts these signals. The results presented here indicate that LT-VACC amplified the responses to synaptic inputs. This boosting was achieved in a graded manner and the amplified signal preserved a linear relationship with the firing frequency of the presynaptic neuron. The wide distribution of LT-VACC could support the active propagation of depolarizing signals, turning the complex NS neuritic tree into a relatively compact electrical compartment.

Title: Continuous gradients of gene expression underlie prominent CA1 pyramidal neuron variability

Authors: ***M. S. CEMBROWSKI**, J. L. BACHMAN, L. WANG, K. SUGINO, B. SHIELDS, N. SPRUSTON;
Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA

Abstract: Tissue and organ function has been conventionally understood in terms of the interactions among discrete and functionally homogeneous cell types; however, this discretization approach has traditionally proved difficult in neuroscience. Here, we systematically evaluated the extent to which a discrete cell-type framework characterizes a canonical cell population of the mammalian forebrain - hippocampal CA1 pyramidal cells (CA1 PCs). Using next-generation RNA sequencing (RNA-seq) of subsets of CA1 pyramidal cells, we found differences in CA1 PCs to be markedly greater than detected using previous methods, with hundreds of genes being differentially expressed across the long (dorsal-ventral) axis of CA1. We show that CA1 PC transcriptional identity emerges from a spectrum of gene expression gradients, resulting in the CA1 PC population existing as a diverse continuum of cells, rather than conforming to discrete cell types. These transcriptional differences extend to both proteomic and functional levels. Surprisingly, the overall difference within CA1 PCs across the long axis rivals that of differences across pyramidal cell classes, suggesting that these within-class differences may produce prominent spatially variable computation in CA1 PCs. This work demonstrates an unexpected amount of variability present within a canonical and narrowly defined neuronal population, and suggests that within-class neuronal variation may be an important and feature of neuronal circuits.

Title: Localized synaptically activated sodium signals in hippocampal pyramidal neurons show both AMPA and NMDA receptor components

Authors: *K. MIYAZAKI, W. N. ROSS;
New York Med. Col., Valhalla, NY

Abstract: Na+ imaging can reveal information about the location and properties of synaptically activated glutamate receptors and voltage gated Na+ channels. It can indicate events due to AMPA receptor activation, which are not revealed by calcium imaging since these receptors are impermeant to Ca2+ in most pyramidal neurons. We developed a system to simultaneously detect both [Na+]i and [Ca2+]i changes at high speed (250 Hz in each channel). [Na+]i changes were detected with either SBFI or ANG-2. Both Na+ and Ca2+ indicators were loaded together with a patch electrode on the soma. Fluorescence changes from dendrites on neurons in hippocampal slices were detected with a high speed CCD camera. Trains of 3-5 synaptic stimuli at 50 Hz at subthreshold intensities reliably evoked [Na+]i increases in a localized region (3-10 μm) of the dendrites. Careful examination suggested that the origin of the signals was more localized and that some of the spread was due to Na+ diffusion. These signals persisted in the presence of CPP, suggesting that the signals were due to Na+ entry through AMPA receptors. Consistent with this interpretation no [Ca2+]i changes were detected although Ca2+ signals from bAPs were reliably detected at the same locations. In most cases the Na+ signals did not begin until the 3rd or later synaptic response, although occasionally signals were detected from the 1st stimulus. Experiments with bAPs showed that the system detected Na+ signals with only a few ms delay from the spike, demonstrating that the synaptic delay was real. With stronger stimulation, or more stimuli (but still subthreshold) a later, APV sensitive signal was detected, suggesting an NMDA receptor component. This signal persisted longer than the AMPA component. As previously reported, bAPs, by themselves, evoked very small [Na+]i changes in the dendrites. In some trials bAPs, either evoked by the synaptic train or by intrasomatic stimulation, generated a sharp increase in [Na+]i at the synaptic site at the time of the spike, suggesting that the spike triggered Na+ entry. However, in many other trials the spike triggered no additional signal even when the synaptic train evoked a subthreshold Na+ signal. Therefore, the importance of a bAP for coincident activation of NMDA receptors is not clear. Stronger stimulation, especially in the basal dendrites, evoked much larger [Na+]i and [Ca2+]i signals that were detected over a wider region. These signals had the characteristics of an NMDA spike. Most of the Ca2+ signal was blocked by APV, while most of the Na+ signal remained, suggesting that even following a regenerative NMDA receptor event most Na+ entry is through AMPA receptors at pyramidal neurons synapses.

Title: Two-photon subcellular optogenetic stimulation of layer 2/3 cortical pyramidal neurons *in vivo* during network activity

Authors: *L. FERRARESE[1,2], J. F. A. POULET[1,2];
[1]Max Delbrueck Ctr. Berlin-Buch, Berlin, Germany; [2]Neurosci. Res. Ctr. and Cluster of Excellence NeuroCure, Charité-Universitätsmedizin, Berlin, Germany

Abstract: *In vivo*, synaptic transmission and integration in cortical neurons occurs on a background of ongoing, depolarized, subthreshold activity during active brain states. To investigate subthreshold integration *in vivo* we made targeted somatic whole-cell recordings of L2/3 pyramidal neurons expressing Channelrhodopsin2 in primary somatosensory cortex of urethane anaesthetised mice that oscillate between hyperpolarised, quiescent Downstates and active depolarized Upstates. We then mimicked synaptic input with brief (10 ms) two-photon laser pulses that triggered reliable subthreshold depolarizing potentials at different subcellular targets. At the soma, optogenetic potentials was significantly reduced in amplitude during Upstates to 82% of the Downstate amplitude and showed an increase in half-width (from 20 ms to 34 ms). Similar changes in amplitude and half-width were seen during periods of depolarizing current injection during Downstates, Isopotential of Upstate. The broadening of the optogenetic potential was linked to an increase in somatic input resistance during Upstates. Depolarising potentials recorded at the soma could also be evoked on dendritic branches up to 140 μm from the somatic recording site. Dendritic stimulation triggered smaller amplitude, longer latency responses than somatic stimulation and showed differing degrees of state dependent modulation. *In vivo* subcellular optogenetic stimulation provides a new approach to study subthreshold integration during active cortical states and suggests that the postsynaptic input site is a key determinant of state dependent modulation in response amplitude.

Title: *In vivo* adrenergic modulation of dendritic HCN channels in layer 5 pyramidal neurons

Authors: *M. LONDON, C. LABARRERA MØNSTED;
Edmond and Lily Safra Ctr. for Brain Sci. and Life Sci. Inst., The Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: The hyperpolarization activated cation current Ih generated through HCN channels is an important current shaping the synaptic integration properties in cortical pyramidal neurons of layer 5. The density of HCN channels is non-uniform over the dendritic tree of these cells and is concentrated in the distal apical tree. In addition it has been suggested that Ih is a key player in persistent activity of pyramidal neurons during working memory tasks and that its modulation through cAMP by Guanfacine (an alpha 2A receptor agonist) enhances this effect. To better understand the interaction between the dendritic distribution of Ih and the effects of its modulation we performed whole-cell recordings from layer 5 pyramidal neurons in awake head restrained mice. We first established that Ih can be blocked under these conditions using ZD 7288. We then show that Ih is modulated by application of Guanfacine but surprisingly that this modulation has little effect on some membrane properties such as action potential threshold and resting membrane potential. We hypothesized that due to its dendritic distribution, modulation of Ih by Guanfacine will affect the coupling between the somatic compartment and the apical tuft. To test this hypothesis we used the critical frequency protocol. We demonstrated that application of either ZD 7288 or Guanfacine significantly reduces the threshold for Ca nonlinear activity in the distal dendrites. We conclude that adrenergic modulation of Ih in the apical dendrites of cortical pyramidal neurons has an effect on Ca nonlinear integration in the apical tuft and on the interaction between soma and dendrites. This effect implies that adrenergic modulation of Ih may serve as a regulator of the coupling between feedforward input arriving at the basal dendritic tree of L5 neurons and feedback input arriving at the apical tuft.

Title: Functional role of coupling axons to dendrites in layer 5 pyramidal neurons

Authors: *M. S. HAMADA, M. H. KOLE;
Axonal Signaling, Netherlands Inst. for Neurosci., Amsterdam, Netherlands

Abstract: The axon initial segment (AIS) is a unique domain of axons in the nervous system converting the graded synaptic inputs into axonal action potential (AP) rate and temporal codes. While most studies depict the axon origin at the soma base, more than hundred years of anatomical studies from many different cell types indicate that axons also regularly branch from dendrites. In order to understand the functional implications of axon coupling to dendrites, we recorded from thick-tufted layer 5 pyramidal neurons using whole-cell patch-clamp and correlated their structural features with the functional properties (n = 40). Neurons were subsequently stained for AIS-specific anchoring protein markers and biocytin-streptavidin and scanned with confocal laser-scanning microscopy. Approximately ~40% of thick-tufted L5 neurons possessed axons with a basal dendrite origin. As expected, the AIS onset in these axo-dendritic neurons was significantly further away from the soma edge (~10 μm; $P < 0.0001$). The AIS length was, however, not different. Morphological analyses of 3D reconstructions revealed a lower dendritic branch order complexity and thinner apical dendritic diameter in axo-dendritic neurons compared to axo-somatic neurons (6.4 vs. 8.2 μm; $P < 0.00001$). Interestingly, the apical dendrite diameter linearly and negatively correlated with the AIS onset ($r = -0.7148$, $P < 0.0001$, $n = 40$). Analysis of AP properties showed that axo-dendritic neurons had a ~3 mV lower voltage threshold ($P = 0.02$) and a higher firing rate at steady-state current injection (23 Hz at 0.8 nA; $P = 0.022$) which was confirmed in computational modelling to scale with the experimentally observed differences in axon onset location. The combined empirical and modelling data revealed that differential axon onsets enable tuning and normalization of synaptic integration in the face of varying geometries of the dendritic trees.

Title: Active dendritic integration in L5 pyramidal neurons forms a conjunctive sensorimotor representation that contributes to learning

Authors: *G. NATTAR RANGANATHAN[1], N.-L. XU[2], J. C. MAGEE[1];
[1]Howard Hughes Med. Inst., Ashburn, VA; [2]Inst. of Neurosci., Shanghai Inst. for Biol. Sciences, Chinese Acad. of Sci., Shanghai, China

Abstract: Rodents scan their immediate facial environment by active whisker sensing. This process requires combining of sensory and motor inputs in order to adapt whisking behavior to changing sensory conditions. Layer 5 (L5) pyramidal neurons in the rodent barrel cortex preferentially receive sensory and motor inputs onto spatially separated regions of their dendritic arbor. Active dendritic mechanisms in these neurons have been shown to enable the integration of coincident but spatially separated sensory and motor inputs during a whisker-dependent object localization task. The global dendritic plateau potentials that mediate this integration have been observed to have joint feature selectivity to both sensory and motor information. Here we present that the somatic output of L5 pyramidal neurons also carries a similar conjunctive representation of sensory and motor information. Responses of individual neurons are dependent on the strength of whisker touch measured from changes in curvature, but also modulated by the whisker position in which touch occurred. L5 neuronal activity at the population level indicates a mixed representation of joint feature selectivity, with varying degrees of modulation at a wide range of whisker positions across the population. Preferential silencing of the dendritic plateau potentials through optogenetic methods interferes with learning in a sensory cue driven motor refinement task. These data indicate that active input integration in the distal apical dendrites of L5 pyramidal neurons mediates a conjunctive sensorimotor representation in the L5 population. Disruption of this representation by silencing active dendritic integration results in the impairment of learned refinement in whisking behavior. Experiments are being conducted to measure the precise effects of optogenetic silencing on the population representation of L5 pyramidal neurons during the sensorimotor task.

Title: Integration of synaptic input during active firing in the L5 pyramidal neurons of mouse motor cortex

Authors: *N. C. DEMBROW[1,2], G. S. NEWKIRK[1], W. SPAIN[1,2];
[1]Physiol. & Biophysics, Univ. of Washington, Seattle, WA; [2]Neurol., VA Epilepsy Ctr. for Excellence, Seattle, WA

Abstract: It is evident from *in vivo* recordings that cortical pyramidal neurons (PNs) transition between periods of actively firing action potentials and relative quiescence. Such changes in PN activity result from changes in the spatial and temporal patterns of their synaptic inputs. How synaptic inputs are integrated depends upon both the intrinsic properties of the target neuron as well as their temporal and spatial distribution. These features are difficult to control in the awake, intact brain but can be studied in the *ex vivo* slice preparation. To do this, we recorded from L5 PNs in motor cortex in Thy1-h YFP mice using whole-cell patch clamp combined with 2-photon glutamate uncaging. Individual spines within basal and proximal apical oblique branches of L5 neurons were activated by uncaging glutamate with brief, focused pulses of light (200 μs at 720 nm). Single spine responses recorded at the soma were variable in size (0.52 ± 0.35 mV; 109 spines from 10 neurons). As has been described in other neuron types, activating multiple spines upon a single branch with near temporal synchrony (2000 Hz) triggered somatic EPSPs that were greater than the linear sum of individual inputs. We observed supralinear responses in 7/9 Thy1-h neurons (47.5 ± 11.1% increase in 7 cells), suggesting active currents in the dendrites enhanced the measured somatic response. To test how the activation of individual spines altered the firing frequency, we stimulated single spines while driving the neuron to fire with step current injection (10-20 Hz). Single spine responses elicited a 5-20% increase in the instantaneous firing frequency (0.75 ± 0.35 Hz, across 71 responses). While the increase in the instantaneous firing frequency depended upon EPSP size (r^2 = 0.36182, slope = 1.73 Hz/mV), in some cases even small (<0.3 mV) EPSPs triggered 1-2 Hz increases in firing rate. When current noise (exponentially filtered noise, tau = 5 ms, SD of 50 pA) was included in the somatic current injection, the effects of single spine inputs became less apparent. We next tested whether activation of multiple spines on a single branch (>10) with near synchrony drove more robust increases in the firing rate. Supralinear branch integration is inhibited by backpropagating action potentials in some cell types, and thus such nonlinearities may not persist in the active firing regime. The near synchronous multi spine activation caused large elevation of firing rate when paired with either step or noisy somatic current injections (40.69 ± 17 Hz, 8 neurons). Combined our data shows that during the active firing regime both single and spatiotemporally clustered spine activation can influence neuronal output.

Title: Dendritic nonlinearities are tuned to fast synaptic inward currents

Authors: B. KALMBACH[1], *R. A. GRAY[1], D. JOHNSTON[1], E. COOK[2];
[1]Ctr. for Learning and Memory, The Univ. of Texas At Austin, Austin, TX; [2]Physiol., McGill Univ., Montreal, QC, Canada

Abstract: We applied a systems-identification approach to quantitatively describe the nonlinear behavior of dendrites. Dendritic membrane potentials (whole-cell patch) were recorded from L5 pyramidal neurons in mouse prefrontal cortex in response to either small (subthreshold) or large (suprathreshold) 10 kHz white-noise current injections. Convolving the small current injection with a linear filter fully accounted for the dendritic membrane potential (median variance accounted for or VAF = 99%). The filters were relatively fast, with an initial exponential-like decay (median 1/e decay = 2 ms) followed by an under-shoot that produced a theta resonance. The large suprathreshold injections produced both somatic action potentials (spikes) and dendritic spike-like nonlinearities. The large injections produced the same linear filters as the small injections, but they accounted for less of the membrane potential because of the additional nonlinearities (median VAF = 94%). Deconvolution was used to isolate the nonlinear components from the linear response. The results of the deconvolution revealed nonlinear inward current spikes (median rate of ~20 spikes/sec), that when added to the white-noise current injection, accounted for 100% of the dendritic membrane potential. In individual neurons, these dendritic spikes varied in amplitude by over a factor of 10 and were abolished by TTX, but not APV. We modeled the isolated dendritic spikes using a second linear spike-filter followed by a static nonlinearity. When convolved with the large stimulus, the spike-filter/nonlinear cascade described both the dendritic spike amplitude (median VAF = 85%) and the time that each dendritic spike occurred. In comparison to the filters that described the linear membrane potential, the dendritic spike-filters were much faster (median 1/e decay = 0.5 ms). Our results show that the dendritic membrane potential in response to a white-noise current injection is well described by two components: 1) A filter that captures the linear membrane response and, 2) A second faster spike-filter followed by a static nonlinearity that captures the nonlinear dendritic spikes. The shape of the spike-filter suggests that dendritic nonlinearities are tuned to the rise time of fast inward current events such as AMPA-mediated synaptic inputs.

Title: The interplay between synaptic and nonsynaptic activity

Authors: Y. BUSKILA[1], *J. C. TAPSON[2], J. MORLEY[3], A. VAN SCHAIK[1];
[1]The MARCS Inst., Univ. of Western Sydney, Bankstown, Australia; [2]Director's Unit, Univ. of Western Sydney, Penrith, Australia; [3]Sch. of Med., Univ. of Western Sydney, Cambelltown, Australia

Abstract: Neurons in the brain use action potentials (spikes) to communicate with each other. In the postsynaptic cell, these spikes lead to synaptic signals (EPSPs) that propagate through the dendrites and are finally summed at the site of spike initiation. Cortical and hippocampal neurons are sensitive to the timing of their synaptic inputs as they can synchronize their firing on a millisecond time scale, and follow rapid stimulus fluctuations with high temporal precision. In recent years, several studies have reported large variability of spike propagation delays in networks of neurons processing these signals, and it is thought that these delays are modulated to enhance signal integration and thus optimize synaptic inputs. Moreover, computational studies refer to the spike propagation delays as storage capacity units, and predict that the neuronal networks use these delays to time signals and encode information. In order to understand how synaptic, and intrinsic nonsynaptic, properties interact and integrate to optimize neuronal output, we have established an STDP protocol using photoactivation of Channelrhodopsin-2 containing neurons, and recorded synaptic activity arriving from multiple sites along the dendritic tree of cortical and hippocampal pyramidal neurons. Our findings indicate a correlation between the synaptic modifications and propagation velocity along the dendritic branch, suggesting that nonsynaptic modifications along the dendrites are accompanying the synaptic changes.

Abstract: Understanding gene expression in specific neuronal populations can provide important insight into cellular identity and functionality. Here, we used next-generation RNA sequencing (RNA-seq) to produce a quantitative, whole-genome transcriptional atlas of gene expression spanning every excitatory neuronal population in the hippocampus; namely, granule cells and mossy cells of the dentate gyrus, and pyramidal cells of areas CA3, CA2, and CA1. Moreover, for the granule and pyramidal cells comprising the classical trisynaptic loop, we profiled transcriptomes at both dorsal and ventral poles, producing a cell class- and region-specific transcriptional atlas for these canonical populations. This atlas defines the transcriptional properties and identities of lesser known cell types (mossy cells and CA2 pyramidal cells), reveals unexpectedly large variations in the trisynaptic loop across the dorsal-ventral axis, and ultimately presents a cohesive, large-scale characterization of the transcriptional rules of the hippocampus. We have created an interactive website - HippoSeq - that enables user-friendly analysis and visualization of these data. These transcriptional profiles and associated website will act as a quantitative, whole-genome roadmap for further dissection of the molecules, cells, and circuits in the hippocampus.

Abstract: Granule cells in the dentate gyrus (DGCs) are continuously generated in the adult mammal brain. Their integration into the hippocampal network has been linked to important brain functions such as pattern separation and spatial memory formation. Interestingly, DGCs show a critical time window, in which they express higher excitability, synaptic plasticity and excitation-to-inhibition ratio, each phenomenon linked to specific protein expression or connectivity. A data-driven single-cell compartmental model with realistic morphology and ion channel composition would provide an excellent tool to analyze the effect of all these changes in intrinsic and synaptic properties on neuronal computation. However, existing active compartmental models of DGCs have limited predictive capability since they were constructed *ad hoc* in order to replicate mostly one single experiment. Here we present a novel active model for mature DGCs based on raw electrophysiological traces combined with pharmacology in mice (*1*). Our new model includes a corrected calcium buffer model, an inward rectifier potassium (Kir) channel, several isoforms of voltage-gated potassium channels and modified distributions of BK, SK as well as L-, T-, N-type calcium channels, consistent with the known DGC ion channel composition. The resulting model reproduces experimental electrophysiology in mature DGCs. Furthermore, the calcium dynamics, as well as spiking characteristics such as afterhyperpolarization, depolarizing afterpotential and spiking adaption are in a realistic range indicating that the DGC compartmental model is consistent across a variety of experimental paradigms. The model can now be adapted to simulate synaptic integration and plasticity in adult-born DGCs. Our preliminary simulations suggest, that NMDA subunit composition alone might not suffice to fully explain the increased capability for synaptic plasticity during the critical time window (*2*). In summary, we created a novel active DGC compartmental model, which is consistent in ion channel composition and electrophysiology, enabling us to make valuable predictions about single-cell computation in mature and adult-born DGCs. 1) L. a Mongiat, M. Title: Synaptic input patterns underlying dendritic computation *in vivo*

Authors: L. GOETZ[1], M. R. GROEN[1], *A. ROTH[2,1], M. HAUSSER[1];
[1]Wolfson Inst. for Biomed. Res., [2]Univ. Col. London, London, United Kingdom

Abstract: The computations performed by an individual neuron critically depend on the spatiotemporal patterns of synaptic input it receives onto its dendrites. While the detailed synaptic input patterns are still largely inaccessible to experiment, the ability to use dendritic patch-clamp recording to measure sensory-evoked local dendritic spikes *in vivo* (Smith et al., Nature 2013) provides valuable constraints on possible spatiotemporal patterns of synaptic input. Furthermore, extensive experimental data on the biophysical properties of dendrites, the statistics of sensory responses of neurons, as well as the characteristics and function of synaptic inputs *in vivo* have recently become available. Using these experimental results, we have developed a detailed active biophysical model of a neocortical layer 2/3 pyramidal neuron to explore which spatiotemporal patterns of synaptic inputs can drive the observed neuronal input-output transformations. Our model generates fast dendritic spikes heterogeneous in amplitude, time course and spatial extent as observed *in vivo* (Smith et al., 2013), which are abolished by removing NMDA receptors. We used spike-triggered averaging to identify the spatiotemporal synaptic input patterns preceding dendritic spikes. Dendritic spikes are preferentially triggered by excitatory synapses which are spatially and temporally clustered on the local branch and neighbouring branches. The temporal patterns of excitatory synaptic input preceding spikes are stereotyped and tend to be surprisingly sparse. Notably, only some dendritic spikes are effective in evoking action potential output, while others remain local. We used cluster analysis to differentiate between these cases and establish global conditions under which specific spatiotemporal patterns of synaptic input can influence neuronal output. Thus, our simulations provide a mechanistic explanation for neuronal computations observed *in vivo*, for example how output tuning to stimulus features arises from both tuned and untuned inputs. To summarize, we derive spatial and temporal rules for how synaptic inputs drive dendritic spikes. These results suggest that synaptic input patterns may be optimized to locally exploit dendritic excitability to shape the input-output relation of the neuron.

Title: Dendritic serotoninergic neuromodulation in the anterior cingulate cortex alleviates neuropathic pain

Authors: M. SANTELLO, A. BISCO, *T. NEVIAN;
Univ. of Bern, Bern, Switzerland

Abstract: Neuropathic pain is caused by long-term modifications of neuronal function in the peripheral nervous system, the spinal cord, and supraspinal areas. Although functional changes in the forebrain are thought to contribute to the development of persistent pain, their significance and precise subcellular nature remain unexplored. Using somatic and dendritic whole-cell patch-clamp recordings from neurons in the anterior cingulate cortex, we discovered that sciatic nerve injury caused a dysfunction of hyperpolarization-activated cyclic nucleotide-regulated (HCN) channels in the dendrites of layer 5 pyramidal neurons resulting in enhanced integration of excitatory postsynaptic inputs and increased neuronal firing. Consistent with a HCN channel hypofunction, resonance frequency was lower in CCI neurons. The pathology was caused by an activity-dependent decrease in HCN channel density in the apical dendrite. Specific activation of the serotonin receptor type 7 (5-HT7R) alleviated the lesion-induced pathology by increasing HCN channel function, restoring normal dendritic integration, and reducing mechanical pain hypersensitivity in nerve-injured animals *in vivo*. Thus, serotoninergic neuromodulation at the forebrain level can reverse the dendritic dysfunction induced by neuropathic pain and may represent a potential therapeutical target.

Title: Local dendritic modulation by multimodal sensory input

Authors: *L. M. PALMER[1], M. E. LARKUM[2];
[1]Florey Inst. of Neurosci. and Mental Hlth., Univ. of Melbourne, Melbourne, Australia;
[2]Humboldt Univ., Berlin, Germany

Abstract: In the living animal, sensory systems are generally not stimulated in isolation but are instead activated collectively. In response to multimodal sensory stimulation, the dendrites of pyramidal neurons in the primary somatosensory cortex receive both feedforward input from the thalamus and feedback input from other cortical areas. The influence of this feedback multimodal input on dendritic function is input specific and largely unknown. We investigated dendritic activity in the hindpaw somatosensory cortex during contralateral hindpaw stimulation alone and during activation of additional sensory-evoked feedback input. Using both single-cell electrophysiology and dendritic 2-photon calcium imaging *in vivo*, we show that sensory input from the stimulation of a second sense, in this case forepaw stimulation, had different effects on the distal and proximal dendrites of layer 2/3 pyramidal neurons. Forepaw stimulation caused a decrease in the Ca2+ activity of tuft dendrites whereas proximal dendrites had an increase in synaptic input. Taken together, this multimodal input onto layer 2/3 pyramidal neurons led to a balancing of sensory information resulting in no change to the evoked firing rate. These results not only illustrate the counterbalancing interaction of multimodal input in cortical neurons but it also highlights the complexity of local dendritic activity in sensory perception.

Title: Control of spatially patterned gene expression in dendrites

Authors: *A. H. WILLIAMS[1], C. O'DONNELL[2], T. SEJNOWSKI[2], E. MARDER[3], T. O'LEARY[3];
[1]UC San Diego, La Jolla, CA; [2]Salk Inst. for Biol. Studies, La Jolla, CA; [3]Brandeis Univ., Waltham, MA

Abstract: The subcellular spatial distribution of ion channels and synaptic plasticity-related proteins is dynamic, nonuniform, and critical for determining the electrical properties of neurons. How neurons control these expression patterns is unknown, but is believed to involve microtubular-based transport. Using mathematical analysis and numerical simulations, we show how transport can support these phenomena in complex neuron morphologies. While the results we derive are general to any cell type, we examine CA1 pyramidal morphology as a case study, specifically examining: 1) HCN and K ion channel gradients in dendrites and 2) spatial expression of plasticity-related proteins such as Arc. We compare two non-exclusive models for achieving spatial expression: local versus global control. For the local-control class, we derive simple rules that relate the local transport rate along neurites to the global steady-state distribution of cargo, and illustrate how this rule can be encoded by a second-messenger molecule, such as Ca2+. We identify two strategies that precisely achieve any desired expression profile. The first distributes cargo uniformly along the microtubules, and locally captures cargo in proportion to the target expression level. The second distributes cargo non-uniformly to match the target expression pattern and locally releases cargo at a uniform rate. There is experimental evidence for both of these strategies [1,2]. We also considered a second class of models based on global control, in which the steady-state distribution of cargo along the microtubules is not achieved. In this case, the distribution of cargo might be controlled by tuning the microtubular transport kinetics to match the rate of local release/capture of cargo. A major difference between these two classes of models is that the first can be locally tuned, while the second must be engineered from a global level. We suggest that local mechanisms might be useful to produce flexible trafficking, while global mechanisms provide efficient solutions for coarse, rapid transport. We highlight experiments that might disambiguate between these two cases.

Title: Active dendrites and differential calcium channel distribution allow Golgi cells to independently regulate dendritic processing and spontaneous firing

Authors: *S. RUDOLPH[1], C. HULL[2], W. G. REGEHR[1];
[1]Neurobio., Harvard Med. Sch., Boston, MA; [2]Neurobio., Duke Univ. Sch. of Med., Durham, NC

Abstract: Golgi cells (GoCs) are spontaneously active interneurons that continuously release GABA to inhibit granule cells and thereby control the excitability of the input layer of the cerebellar cortex. Previous studies concluded that GoC dendrites lack voltage-gated sodium, calcium and potassium channels. As a result of their passive properties, synaptic inputs onto distal dendrites are strongly attenuated. Here, we use a combination of whole-cell recording and dendritic calcium imaging to re-examine dendritic properties and calcium-dependent regulation of firing in GoCs. We find that GoC dendrites contain voltage-gated sodium channels, and support back-propagating action potentials that open voltage-gated calcium channels throughout the dendritic tree. We also find that calcium channel subtypes are differentially distributed and functionally specialized. R-type and T-type calcium channels are absent from the soma, but present in distal dendrites. T-type calcium channels promote burst firing and boost synaptic inputs onto distal dendrites. Conversely, N-type calcium channels are primarily present near the soma where they regulate spontaneous firing through their close association with calcium-activated potassium channels. We find that GoCs have a low calcium buffer capacity, and as a result a modest calcium channel density produces large dendritic calcium signals. In light of our finding that GoCs dendrites are active, the manner in which GoCs process synaptic inputs from granule cells must be reevaluated. The differential distribution of calcium channels allows dendritic T-type channels to boost synaptic inputs and N-type channels near the soma to regulate spontaneous firing.

Title: Electrophysiological properties of nodes of ranvier revealed by patch-clamp recordings from intact afferent nerve fibers of mammals

Authors: *J. GU, H. KANDA, W.-P. CHANG, J. LING;
Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Electrophysiological properties of nodes of ranvier are important for saltatory conduction along myelinated nerve fibers and have pathological implications. Much of what we know about the electrophysiological properties of nodes of ranvier came from previous studies performed on large axons of the invertebrates, and due to technical challenge patch-clamp recordings have not been applied to nodes of ranvier in an intact nerve fiber. In the present study, we developed a whole-cell patch-clamp recording method to study electrophysiological properties of nodes of ranvier of intact rat trigeminal afferent nerve fibers. We observed two major currents at nodes of ranvier in responses to voltage steps, a large voltage-activated fast inward current and a large leak current. The fast inward current was mediated by voltage-gated Na^+ channels since it was completely blocked by TTX. The large leak current was resistant to both TTX and intracellular Cs^+ and was most likely due to axonal conductance. Action potentials could be elicited at nodes of ranvier by depolarizing currents and they were completely blocked by TTX. Action potentials were not significantly altered when 135 mM Cs^+ was included as a voltage-gated K^+ channel blocker in the recording internal solution. In addition to the two major currents, we also observed a small tail current which could be inhibited by linopirdine, a KCNQ channel blocker. Linopirdine reduced resting membrane potentials (less negative) and action potential rhoebase. We studied propagation of action potentials through nodes of ranvier by electric stimulation at a distant site (1 cm) from the recorded node of ranvier. Nodes of ranviers could well follow electric stimulation at the frequency up to 100 Hz with full-sized action potentials. At the stimulation frequency above 100 Hz, action potential firing at nodes of ranvier showed frequency-dependent reduction of their action potential amplitudes. Taken together, our results provide new insights into electrophysiological properties of nodes of ranvier of mammals.

Title: Expression of APP and its processing enzymes in glial cells of APP transgenic mice with or without Npc1 protein

Authors: *A. SASSE;
Univ. of Alberta, Edmonton, AB, Canada

Abstract: Evidence suggests that increased levels of amyloid beta (Aβ peptides derived from amyloid precursor protein (APP) contribute to the development of Alzheimer's disease (AD). The regions primarily affected in AD brains are hippocampus and cortex, whereas striatum and cerebellum are relatively spared. Although neurons are considered to be the major source of Aβ in the brain, the activated astrocytes associated with neuritic plaques, the key neuropathological hallmark of AD brains, have also been shown to accumulate Aβ Since cholesterol has been shown to influence Aβ production, it is of interest to determine whether accumulation of cholesterol within endosomal-lysosomal system, the major site of Aβ production, can influence levels and/or processing of APP. To address this issue we used mutant APP transgenic (APP-Tg) mice, mice lacking Neimann Pick Type C1 (Npc1-null) protein required for intracellular cholesterol transport and our recently developed bigenic ANPC mice that overexpress mutant human APP in absence of Npc1 protein. The results obtained so far indicate that APP and its processing enzymes involved in Aβ production such as β-secretase BACE1 and four components of γ-secretase complex (PS1, nicastrin, Pen2 and APH1) are expressed in a subset of reactive astrocytes in ANPC, APP-Tg and Npc1-null mice but not in age-matched wild-type control mice. The relative number of astrocytes expressing APP and its processing enzymes appear more in ANPC>APP-Tg>Npc1-null mice. These results indicate that reactive astrocytes may have an important role in the generation of Aβ-peptides in AD-related pathology. Additionally, accumulation of cholesterol within endosomal-lysosomal system may influence APP levels/processing in the activated astrocytes.

Title: Astrocytes control synapses formation and pruning: is FGF signaling pathway involved?

Authors: *S. SCUDERI[1], H. E. STEVENS[1,4], S. TOMASI[1], F. DRAGO[5], F. M. VACCARINO[1,2,3];
[1]Child Study Ctr., [2]Dept. of Neurobio, [3]Kavli Inst. for Neurosci, Yale Univ., New Haven, CT; [4]Carver Col. of Med., Univ. of Iowa, Iowa City, IA; [5]Biomed. and Biotechnological Sci., Univ. of Catania, Catania, Italy

Abstract: Astrocytes are emerging as key elements in many aspects of brain development, function and disease. In particular, there is evidence for dynamic neuroglial interactions at the so-called "tripartite synapse". Astrocytic processes intimately interact with synapses, but little is known about the role of astrocytes in the control of synapse number and plasticity in the developing and adult brain. Previous data link fibroblast growth factor (FGF) signaling to astrocyte differentiation, morphology and functions. Based on this, we hypothesized that under normal conditions astrocytes utilize FGF receptors 1 and 2 (FGFR1/2) and other adhesion molecules located at their lamellar processes to interact with and modulate the number of synaptic connections. To test this, we induced an astrocyte-specific loss of Fgfr1/2 in the early postnatal period by using transgenic mouse lines. Brain tissue was collected from three month old mice with induced Fgfr1/2 loss (FgfR1/2 iKO) and control mice; synaptic markers (VGLUT/PSD95, VGAT/Gephyrin) and adhesion molecules were assessed using immunohistochemistry, western blot analysis and Real Time PCR. Increased expression of vesicular transporters for both excitatory and inhibitory synapses (VGLUT1 and VGAT) was observed at both mRNA and protein levels in FgfR2 iKO brains compared to control. These perturbations were not randomly distributed in the cortex, but were more pronounced in the upper cortical layers. Furthermore, in mutant mice, an altered expression of cell adhesion molecules expressed at astrocyte-neuron membrane contacts was observed. Interestingly, the FgfR iKO mice also showed locomotor hyperactivity and impairments in cognitive and social behavior compared to control littermates. Our findings support the idea that astrocyte Fgf signaling controls synaptic remodeling in early postnatal development, which may be a process that may exert a profound impact on neural network function and behavior.

Title: Regulatory role of proinflammatory cytokines in the expression of aromatase in reactive astrocytes

Authors: *J. WANG[1], R. K. VADLAMUDI[2], D. BRANN[1];
[1]DNRM, Georgia Regents Univ., Augusta, GA; [2]Obstetrics and Gynecology, Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: Numerous studies have shown that the steroid hormone, 17β-Estradiol (E2) is not only a gonadal-derived hormone but also a brain-derived neuroprotective factor. So far little is known regarding how the local production of E2 in the forebrain is controlled. The expression of brain aromatase, the enzyme that catalyzes the conversion of testosterone into E2, is generally found to be restricted to certain neuronal populations under normal conditions. We recently reported that de novo expression of aromatase in astrocytes can be induced by global cerebral ischemia and exerts anti-inflammatory and neuroprotective actions in the rodent hippocampus. It is important to note that induction of high aromatase expression in the injured brain was accompanied by the astrocyte reactivation. To investigate the regulatory mechanism that underlie the induction of aromatase in reactive astrocytes after injury, we examined the expression of aromatase in primary astrocytes cultured from male and female neonatal mouse brain under different treatments (oxygen and glucose deprivation [OGD], extracellular ATP, and Lipopolysaccharide [LPS]). These treatments are all well known as triggers of astrocyte reactivation, and mimic the *in vivo* events of ischemia, cell damage and inflammation after brain injury. The results of the study revealed that LPS induced a significant increase of aromatase expression in astrocytes in an acute phase (2-4 hour post treatment). OGD also increased aromatase expression in astrocytes, but the effect occurred later (after 24 hours). These findings support a potential role for injury-induced inflammation in the induction of aromatase expression in reactive astrocytes. We next examined the effect of proinflammatory cytokines (IL-1βand IL-6) upon induction of aromatase in cultured astrocytes. The results revealed that both cytokines were able to enhance aromatase expression as efficiently as LPS. While the mechanism of the cytokine up-regulation of aromatase is unclear, the up-regulation of aromatase by the cytokines was associated with an elevated expression of the CCAAT/enhancer binding protein beta (C/EBPβ). This is intriguing as C/EBPβ is a transcription factor implicated to mediate proinflammatory cytokine actions, and the aromatase gene is known to contain 16 C/EBPβ binding sites. Taken as a whole, our findings suggest that ischemic injury-induced release of proinflammatory cytokines can drive induction of aromatase expression in astrocytes, and that this effect may involve mediation by the transcriptional factor, C/EBPβ. Title: The novel state of astrocyte for inducing long-term memory with contexture fear conditioning test

Authors: *M. CHOI, H.-S. KIM;
Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Astrocytes are the most abundant cell type in the central nervous system (CNS). It is well-known that astrocytes maintain ion homeostasis in the extracellular space and also release immune response factors. However, recent studies regarding the tripartite synapse suggest that astrocytes may directly modulate synapses by releasing neuroactive molecules such as glutamate, ATP, and D-serine, or by uptaking neurotransmitters from synaptic cleft. Such evidence suggest that astrocytes may play a key role in long-term depression (LTD) and in long-term potentiation (LTP). Astrocytes have two different states, which are the resting state and the reactive state. The reactive state is shown in inflammation and neuronal disorders, such as Alzheimer's disease (AD). Morphological changes in the reactive state include increase in thickness and number of processes, and increase in size of soma. Molecular changes also occur, such as an increase in expression of glial fibrillary acidic protein (GFAP). These morphological and molecular changes may be in line of functional changes. However, the specific morphological and molecular changes in the event of long-term memory formation have not been explored. In this study, we induced long-term memory by subjecting mice to the contextual fear conditioning test (CFC), and check for changes of astrocytes that correspond to the reactive state. Results show that in the memory induction stage, astrocytes exhibit a unique condition which differs from the resting or reactive state. Further studies may be conducted to elucidate this novel state, and possibly link changes in this state with cognitive dysfunction or neurodegenerative diseases such as AD.

Title: Cultured astrocytes exhibit high-frequency voltage oscillations

Authors: *S. THEISS[1], W. FLEISCHER[2], J. SLOTTA[2], A. SCHNITZLER[2];
[1]Inst. of Clin. Neurosci., [2]Inst. of Clin. Neurosci. and Med. Psychology, Univ. of Duesseldorf, Duesseldorf, Germany

Abstract: High frequency oscillations (HFOs) occur in brain tissue both under physiological and pathological conditions, and have been recorded *in vitro*, in animals and in humans. In the healthy brain they likely support memory related functions, while in epilepsy patients they have been associated with seizure onset zones. In an *in vitro* model of dissociated neuronal networks cultured on microelectrode arrays (MEAs), localized HFOs were recorded in response to brief electrical stimuli, and persisted under blockage of action potentials and synaptic transmission. In order to examine the role of astrocytes in the generation of HFOs, we cultured cortical astrocytes from P0 rats on microelectrode arrays (square grid of 8x8 Ti/TiN electrodes, diameter 30 µm, spacing 200 µm), and applied ten single biphasic rectangular voltage pulses (800 mV, 200 µs/phase) to a subset of electrodes. Recordings were performed in low osmolarity HEPES-buffered saline solution similar to Neurobasal medium at pH 7.4. Stimulus-averaged spectral power of oscillations was calculated from the signal's time-frequency representation. In response to the electrical stimulus pulses, astrocytes exhibited strong extracellular voltage fluctuations in a broad frequency spectrum (100 to 600 Hz) that could last several seconds. These aperiodic HFOs were constrained to the stimulated electrode. The voltage-gated calcium channel antagonist cilnidipine dose-dependently decreased oscillation power. HFOs were dependent on intracellular calcium, since the Ca2+-chelator BAPTA-AM suppressed HFOs as well as substitution of extracellular Ca2+ by Ba2+. Incubation with bafilomycin A1 showed that vesicular release of transmitters played only an inferior role in the emergence of HFOs. Gap junctions and volume-regulated anionic channels had just as little functional impact, which was demonstrated by the addition of carbenoxolone (100 µM) and NPPB (100 µM). Hyperpolarization with low potassium in the extracellular solution (2 mM) dramatically raised oscillation power. A similar effect was seen when we added extra sodium (+50 mM) or if we replaced it with NMDG+ (50 mM). The purinergic receptor antagonist PPADS suppressed oscillation power, while the agonist ATP (100 µM) had only an increasing effect when the bath solution pH was slightly lowered to pH 7.2. We conclude that astrocytic voltage oscillations were triggered by activation of voltage-gated calcium channels and driven by a downstream influx of cations through channels that are permeable for large ions such as NMDG+. Most likely candidates are subtypes of pore-forming P2X channels with a low affinity for ATP.

Title: Acoustic trauma-induced strial vascular degeneration is associated with motile myofibroblastic PCs

Authors: *X. SHI, Dr., Z. HOU, J. CAI, X. WANG, J. ZHANG;
Oregon Hearing Res. Ctr., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Stria vascularis capillary destruction and regression after loud sound trauma has long been observed, but the mechanism underlying the pathology has not been understood. In this study, we found a proportion of strial pericytes (PCs) had converted to the phenotype of motile myofibroblastic PCs at approximately one week after loud sound stimulation. Using both *in vivo* animal based and *in vitro* primary cell line based models, the strial PCs transition is highly associated with increased transforming growth factor beta 1 (TGF-β1). The transition to myofibroblastic PCs is significantly reduced when TGF-β1 is suppressed with the TGF-β1 receptor blocker, SB431542, or blocked using a recombined adenovirus carrying a PEDF gene (ad-PEDF) to up-regulate pigment epithelium derived factor (PEDF). Reduced capillary density following acoustic trauma was correlated with PC phenotype changes. With newly established *in vitro* three-dimensional cell-based co-culture models, we demonstrated that PCs are essential for maintaining normal vascular architecture and stability. The architecture becomes markedly thicker with branches less finely articulated with changes in PC phenotype. The results suggest that loud sound triggered emergence of motile myofibroblastic PCs may be one of causes for noise-induced capillary degeneration.

Title: The death mechanism of extracellular acidosis on neonatal rat astrocytes

Authors: *Y. WANG[1,2], Y.-F. CHEN[3], Y.-M. LEUNG[4];
[2]Dept. of Chinese Pharmaceut. Sci. and Chinese Med. Resources, [3]Dept. of Pharmacol., [4]Dept. of Physiol., [1]China Med. Univ., Taichung, Taiwan

Abstract: During brain ischemia, acidosis, resulting from the metabolism elements of the anaerobic glycolysis, is a critical consequence of causing neuronal cell death. Astrocytes serve many important roles, including nourishing and providing mechanical support for the neurons, metabolizing neurotransmitters and secreting gliotransmitters to modulate neurotransmission. Numerous evidence indicates insult in these astrocyte functions during brain ischemia can crucially influence neuron survival. However, much less is known about the fate of astrocyte in acidosis. The purpose of our study was to investigate cell death mechanisms of rat astrocytes in acidosis per se (independent of hypoxia). We isolated cortical astrocyte cultures from 1 to 2-day-old Sprague Dawley rats. Before each experiment, primary astrocytes were incubated in different acidic pH culture media for indicated time courses. MTT assay was used to determine cell viability. In addition to elucidate the signaling pathway acidosis-induced activation, we used fura-2 as the Ca2+ -sensitive fluorescent dye for performing microfluorimetric measurement of cytosolic Ca2+ concentration, immunoblotting for analysis of individual proteins, and ApoSENSOR ADP/ATP ratio assay kit for detecting ADP/ATP ratio. Our results showed that astrocytes suffered from cell death after challenge by acidic pH (6.8, 6.0, 5.0) for 2-24 h. Exposure to acidic pH caused intracellular Ca2+ release and extracellular Ca2+ influx; however, abrogation of cytosolic Ca2+ elevation by BAPTA did not prevent acidic pH-induced cell death. Acidic pH caused p38 MAPK activation, Akt inhibition, mitochondrial depolarization, decreased reactive oxygen species (ROS) formation and increased ADP/ATP ratio. Cyclosporin A, which binds to cyclophilin D and hence inhibits mitochondrial permeability transition pore (PTP), could prevent acidity-induced cell death. In conclusion, these findings suggest acidosis caused astrocyte death not by cytosolic Ca2+ overload but by p38 MAPK activation and mitochondrial PTP opening.

Title: Modulation by metformin and AICAR of astrocytic glucose metabolism

Authors: *I. ALLAMAN[1], G. GRENNINGLOH[1], C. BARRIERE BORGIONI[1], P. J. MAGISTRETTI[1,2];
[1]EPFL/Brain Mind Inst., Lausanne, Switzerland; [2]Div. of Biol. and Envrn. Sci. and Engin., KAUST, Thuwal, Saudi Arabia

Abstract: Metformin is a widely used drug for the treatment of type 2 diabetes. While it increases peripheral glucose uptake and utilization in patients, its actions on the central nervous system are less characterized. In the present study, we first aimed to determine the effects of metformin on astrocytes, a cell type playing a key role in cerebral energy metabolism. Using primary cultures of mouse cortical astrocytes, we observed that metformin at 500 uM stimulates 3H-2-deoxyglucose uptake (i.e. glucose utilization) in a time-dependent manner, with a maximal effect after 4 hours of treatment (+239% versus control values). A more detailed characterization of metformin's effects showed that stimulation of glucose utilization is accompanied by an increase in lactate release (+160% versus control values) as well as a decrease in glycogen levels (26% of control values). In contrast to the observed increase of glycolytic metabolism, oxidative metabolism of glucose was not significantly modified by metformin as determined by measurement of total CO2 production using 14C(U)-glucose as substrate (93% of control values). As some of metformin's peripheral metabolic effects are known to be mediated by AMP-activated kinase (AMPK), we evaluated the impact of AMPK activator AICAR on astrocytic glucose utilization. Surprisingly we observed that AICAR was not only unable to reproduce the stimulatory action of metformin but even presented an opposite effect, decreasing glucose utilization (by 75%). This latter observation suggested that the above described metabolic effects of metformin were independent of AMPK activation. Further supporting such view, the stimulation of glucose utilization induced by metformin was unaltered in the presence of the AMPK inhibitor Compound C. By contrast, the inhibitory effect of AICAR on this metabolic index was fully prevented by Compound C, then establishing the AMPK-dependent action of this kinase activator. Finally, we observed that metformin also stimulated glucose utilization in primary cultures of mouse cortical neurons, whereas AICAR remained without effect in this cell type. As a whole, these results demonstrate that both metformin and AICAR strongly modify glucose metabolism in astrocytes and neurons. More specifically, metformin altered glucose metabolism in astrocytes by turning them into a more glycolytic state through an AMPK-independent mechanism which remains to be characterized.

Abstract: Reprogramming astrocytes to neural stem cells and neurons is a potential strategy for neurological repair. Due to the proliferation of astrocytes and neuronal cell loss after ischemic stroke, reprogramming astrocytes to a neuronal phenotype may be a possible therapeutic strategy. Previous studies have shown that the sex-determining region, Y-box 2 (SOX2), is sufficient to induce mouse and human astrocytes to differentiate into neural stem cells and cells with a neuronal phenotype. This work aimed to re-program adult rat astrocytes to a neuronal phenotype, *in vitro*, using a SOX2 lentivirus. To our knowledge this is the first study looking at *in vitro* reprogramming of rat astrocytes. Furthermore, this study evaluated the survivability and effectiveness of reprogramming adult rat astrocytes with SOX2 under oxidative stress. This research has the potential to provide further information for the use of *in vivo* injections of SOX2 after ischemic injury.

Title: Phenotypic changes during an endothelin-induced cell cycle in rat cortical astrocytes in culture

Authors: N. ZAFEIRAKOU[1], M. MELISSOURGOU[1], E. TSIRIMONAKI[1], A. GAITANAKI[2], N. SAKELLARIDIS[3], *D. A. MANGOURA[1];
[1]Biomed Res. Found Athens Acad., Athens, Greece; [2]Natl. and Kapodistrian Univ. of Athens, Athens, Greece; [3]Fac. of Medicine, Sch. of Hlth. Sciences, Univ. of Thessaly, Larissa, Greece

Abstract: Endothelin-1 (ET-1) is a mito¬gen for astro¬cytes and it is implicated in many CNS patho¬logies that involve reactive glio¬sis, through the activation of a com¬plex net¬work of in¬ter¬connected sig¬nal¬ing cascades that apparently include modification of phenotypic markers, like expression of GFAP. Indeed, other mitogens like prolactin concomitant signal proliferation and differentiation in conditions that fast gain in both numbers and extent of differentiation in the astrocytic population is required, for example during development or reaction to trauma. A major effector of both ET-1 receptors is ERK1/2, an important regu¬lator for both pro¬liferation and diffe¬rentiation. We have shown that among the receptor-proximal effects that lead to a biphasic ERK1/2 activation is an acute activation of Ras, which controls mainly the second amplification peak of ERK activation in rat cortical astrocytes in culture. We have now probed the longer term effects of ET-1 signalling in this model, namely phenotypic effects that take place within the first 24 hr of ET-1. First we verified that ET-1 signalling leads to proliferation, as the vast majority of cells had incorporated BrdU, and nuclear expression of CENPE and cyclin B were significantly upregulated, all pinpointing that astrocytes had progressed to G2. We then examined protein and mRNA levels of GFAP, S100b, and cJUN and found that by 6h there were small but significant upregulations, probably intended to increase the load of GFAP and S100b for cytokinesis. Once the cells progressed to S phase and de novo expression of cell cycle proteins started, transcription for GFAP and S100 was reduced. Next, using *in vivo* crosslinking of the proteins and high Triton-X-removal of membranes prior to fixation for best visualization of cytoskeleton, and confocal microscopy, we observed that the changes in GFAP expression with ET-1 were accompanied by a remarkable remodeling of GFAP positive filaments. Specifically, untreated cells exhibited thick, stubby, heavily loaded with GFAP processes, while cells exposed to ET-1 appeared with larger, enriched in GFAP somata and long, thin processes with fewer GFAP filaments. Importantly, when Ras activation was simulated with overexpression of v-Ras or siRNA-mediated depletion of the Ras-GAP neuro-fibromin (after nucleofections) we observed elongated processes that were highly enriched in GFAP; after 24h of ET-1, somata were further enlarged with very dense GFAP filaments. Collectively these results indicate that mitogen ET-1 activates concurrent signalling cascades that affect differentiation programs, controlled by Ras.

Title: Purines modulate growth of plasma membrane extensions in isolated astrocytes

Authors: *M. CHISARI, A. SCUDERI, M. A. SORTINO;
Univ. of Catania, Catania, Italy

Abstract: It has been shown that astrocytes exert their function in the tripartite synapse and make contact with brain vessels by plasma membrane (PM) extensions (perisynaptic processes and perivascular endfeet, respectively). Such PM extensions express aquaporin-4 (AQP-4) and K+ inward rectifying (Kir) channels, regulating both water and K+ homeostasis. Astrocyte activity is largely modulated by purines, such as adenosine. Therefore in the present study we focused on effects of purines in PM extension growth in astrocytes. In western blot analysis, we observed an increased expression of P2Y1 receptor over time in cultured hippocampal astrocytes. In isolated cells, we validated functional P2Y1 receptor (endogenous Gq protein coupled receptor) by monitoring calcium flux in living cells loaded with Fluo-4 calcium indicator, after stimulation with the selective agonist 2-methylthioadenosine diphosphate (2MeSADP, 100 μM). In order to evaluate PM extensions in astrocytes, living cells were stained with the fluorescent PM dye CellMask Orange, stimulated with 2MeSADP and imaged for 20 min. Number and length of PM extensions increased over time and such effect was prevented by pre-treatment with selective P2Y1 antagonist, MRS 2179 (1 μM). Since calcium mobilization by Gq-mediated pathway might contribute to PM extension growth, we performed experiments in presence of calcium chelator EGTA in the buffer. In cells loaded with Fluo-4 indicator and incubated with 10 μM EGTA for 10 min, astrocytes stimulated with 2MeSADP did not show either intracellular calcium increase or PM extension growth. In a different set of imaging experiments, cells treated with phospholipase C inhibitor U73122 (3 μM) showed a dramatic decrease of PM extensions in length and number. Based on this observation we hypothesized that reduction of PM extensions will affect both AQP-4 expression and Kir function. Western blot analysis of AQP-4, in conditions tested in imaging experiments, did not show any changes in protein level. Patch-clamp recordings were performed in isolated astrocytes applying voltage-steps (-180 mV to 60 mV) to elicit Kir current in basal condition and after U73122 application. A dramatic increase in current through K+ channels at negative potentials (-180 mV to -100 mV) was observed within 3 min in U73122. At positive potentials (20 mV to 60 mV), K+ current was reduced over time up to 10 min. These data show a dynamic modulation of astrocytes PM extensions by adenosine through P2Y1 receptors and the Gq-mediated pathway, suggesting their role in astrocyte buffering function, crucial for brain homeostasis.

Title: Functional maturation of astrocytic syncytium during postnatal development in mice hippocampus

Authors: S. ZHONG[1], C. M. KIYOSHI[1], B. MA[1], X. LIU[2], *M. ZHOU[1];
[1]Dept. of Neurosci., Ohio State Univ., Columbus, OH; [2]Dept. of Neurosci., Shanghai 10th People's Hospital, Tongji Univ. Sch. of Med., Shanghai, China

Abstract: It is generally believed that the basic function of astrocytes is achieved at the syncytial (system) level in the adult brain. However, the mechanism underlying this important functional aspect remains largely unknown. We show that, in the adult hippocampus, an extensive gap junction coupling synchronizes the membrane potential among coupled astrocytes to achieve a syncytial isopotential. However, when this occurs during the postnatal development and how this is associated with the maturation of the organizational patterning of syncytia are questions that remain to be answered. In the present study, the developmental change in syncytial organization was monitored by confocal morphometric analysis of hippocampal CA1 syncytia disclosed by intracellular biocytin loading through patch pipette. The functional maturation of the syncytial network in the same region was analyzed by use of K^+-free pipette solution. In the adult hippocampal CA1 region, a quasi-physiological membrane potential can be maintained due to a powerful electrical and ionic coupling provided by the associated syncytium. In contrast to the mature syncytium, K^+-free pipette solution can induce membrane potential depolarization. We further show that the syncytial function reaches to a mature level around P11. Altogether, we show that the syncytial function can be readily detected by our newly established method, and the functional maturation of hippocampal syncytium undergoes developmental regulation.

Title: Complement peptide C3a promotes astrocyte survival in response to ischemic stress

Authors: *M. PEKNA, N. SHINJYO, Y. DE PABLO, M. PEKNY;
Univ. of Gothenburg, Gothenburg, Sweden

Abstract: Astrocytes are the most numerous cells in the central nervous system with a range of homeostatic and regulatory functions. Under normal conditions as well as after ischemia, astrocytes promote neuronal survival. We have previously reported that the complement-derived peptide C3a stimulates neuronal differentiation of neural progenitor cells and protects the immature brain tissue against hypoxic-ischemic injury. Here, we studied the effects of C3a on the response of mouse cortical astrocytes to ischemia. We have found that chemical ischemia, induced by combined inhibition of oxidative phosphorylation and glycolysis, up-regulates the expression of C3a receptor in cultured primary astrocytes. C3a treatment protected wild-type but not C3a receptor deficient astrocytes from cell death induced by chemical ischemia or oxygen-glucose deprivation by reducing ERK signaling and caspase-3 activation. C3a attenuated ischemia-induced upregulation of glial fibrillary acidic protein, however the protective effects of C3a were not dependent on the presence of the astrocyte intermediate filament system. Pre-treatment of astrocytes with C3a during recovery abrogated the ischemia-induced neuroprotective phenotype of astrocytes. Jointly, these results provide the first evidence that the complement peptide C3a modulates the response of astrocytes to ischemia and increases their ability to cope with ischemic stress.

Title: The examination of the distribution of proteins within complex three-dimensional astrocytes

Authors: *A. L. BENEDIKTSSON[1], K. MILLOY[1], N. RASIAH[2], L. ALVIS[3];
[1]Biol., Mount Royal Univ., Calgary, AB, Canada; [2]Hotchkiss Brain Inst., [3]Fac. of Nursing, Univ. of Calgary, Calgary, AB, Canada

Abstract: Historically, the model of the synapse consisted of the pre- and post-synaptic neurons. New research suggests that astrocytes, a type of brain glial cell, play a crucial role in synapse structure and function. Astrocytes have a highly complex 3-D morphology that includes intricate connections with synapses, the vasculature and other astrocytes; as such, they have a variety of functions, including trophic and metabolic support of neurons, synaptic development and signalling, control of the microvasculature and co-ordination of neuronal networks. However, it is unclear whether astrocytes possess specialized regions to compartmentalize these functions. Our hypothesis is that astrocytes possess functional microdomains, specialized morphological compartments within a cell with a specific, highly localized array of proteins necessary for regional specialization and cellular function. To investigate this hypothesis we have combined DiOlistics, a biolistic technique for labelling the complete morphology of individual cells in brain tissue with lipophilic fluorescent dye, with immunocytochemistry to label individual proteins. We examined the distribution of these proteins within the complex three-dimensional morphology of individual adult murine brain astrocytes using confocal microscopy, and then determined their distribution in three-dimensions using Imaris™, a 3-D confocal rendering software. Our preliminary studies suggest differences between the distribution of proteins among astrocytes from similar brain regions, as well as astrocytes differing in GFAP expression.

Title: Modeling isopotentiality in the astrocytic syncytium

Authors: R. BUCKALEW, B. MA, M. ZHOU, *D. H. TERMAN;
Ohio State Univ., Columbus, OH

Abstract: Due to their high and selective membrane permeability to K+ ions, astrocytes act as nearly perfect potassium electrodes. As a result, experimental efforts to measure the strength and nature of the gap junction connections between astrocytes have been largely ineffective: in patch clamp experiments, the vast majority of injected current is shunted across the cell membrane rather than flowing through the gap junction channels. We have created a network model of the astrocytic syncytium to aid in theoretical understanding of the gap junction connections, as well as to verify recent experimental results from Ma et al using a new cytosol-replacement protocol that avoids the problem of current shunting. Each astrocyte is modeled as a single compartment following the Hodgkin-Huxley formalism. The model includes variables for membrane potential, K+ and Na+ concentrations (intra- and extra-cellular), as well as bath and electrode pipette concentrations. Electrical currents and ionic fluxes across the cell membrane and through gap junction channels are calculated according to the Goldman-Hodgkin-Katz equation for electrodiffusion, using ionic permeabilities obtained from the literature. The model predicts the recently discovered ‘isopotential’ effect in coupled astrocytes, whereby membership in a syncytium serves to synchronize membrane potentials among the cells and prevent large depolarizations due to localized ionic or electrical perturbations. The model is further able to predict the strength of coupling across the gap junction channel via a fitting parameter s=P_(K,gap)/P_K . The predicted value of s is 1, corresponding to a maximum conductance of 240.5 nS across a gap junction connection. The major physiological implication of the isopotential effect is increased capacity for K+ uptake from the extracellular space, which greatly enhances the effectiveness of K+ spatial buffering by astrocytes. Our model predicts that a syncytium consisting of cells coupled with 11 neighbors is sufficient to maintain a physiological membrane potential in the presence of a 20 mM extracellular increase in K+ concentration, and to efficiently distribute the excess potassium across the syncytium on a time scale of seconds.

Title: Gap junction coupling confers isopotentiality on astrocyte syncytium

Authors: *B. MA[1], R. BUCKALEW[2], Y. DU[1], C. KIYOSHI[1], C. ALFORD[1], W. WANG[1], D. MCTIGUE[1], J. ENYEART[1], D. TERMAN[3], M. ZHOU[1];
[1]Dept. of Neurosci., [2]Mathematical Biosci. Inst., [3]Dept. of Mathematics, The Ohio State Univ., Columbus, OH

Abstract: Astrocytes are extensively coupled through gap junctions into a syncytium. However, the basic role of this major brain network remains largely unknown. Here, we use electrophysiological and computational modeling methods to demonstrate that the membrane potential (VM) of an individual astrocyte in a hippocampal syncytium, but not in a single, freshly isolated cell preparation, can be well-maintained at quasi-physiological levels when recorded with reduced or K+ free pipette solutions that alter the K+ equilibrium potential to non-physiological voltages. We show that an astrocyte's associated syncytium provides powerful electrical and ionic coupling that synchronizes the astrocyte's VM to levels comparable to its neighbors. Functionally, this minimizes VM depolarizations due to elevated levels of local extracellular K+ and thereby maintains a sustained driving force for highly efficient K+ uptake. Thus, gap junction coupling functions to achieve an isopotentiality in astrocytic networks, whereby a constant extracellular environment can be powerfully maintained for crucial functions of neural circuits

Title: Loss of GSK-3 causes abnormal astrogenesis and behavior in mice

Authors: E.-M. JUNG, *W.-Y. KIM;
Developmental Neurosci., Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Altered activity of glycogen synthase kinase-3 (GSK-3) is associated with psychiatric diseases and neurodegenerative diseases. GSK-3 is a key regulator in multiple aspects of neuronal differentiation in the brain. However, little is known about the role of GSK-3 in astrocyte regulation. To examine the role of GSK-3 in astrocytes, we generated a conditional knockout mouse using a GFAP-cre driver, in which the GSK-3 alpha and beta genes are deleted in astrocytes. We found that GFAP-cre-mediated GSK-3 deletion led to a larger brain. The number and size of astrocytes were increased in GSK-3 mutant brains. The levels of GFAP and phospho-STAT3, indicators of astrogenesis, were elevated in GSK-3 mutants. Furthermore, we found upregulation of astrocyte regulatory molecules such as phospho-AKT, phospho-S6, and cyclin D in GSK-3 mutant brains. Finally, GSK-3 mutant mice exhibited aberrant anxiety and social behavior. Our results suggest that GSK-3 plays a significant role in astrocyte regulation and behavioral control in mice.

Title: Nitric oxide modulation of phosphodiesterase activity and cAMP levels in astrocytes

Authors: *R. KO, H. B. CHOI, B. A. MACVICAR;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Astrocytic cAMP signaling plays an important role in several crucial physiological processes in the brain, including metabolic coupling to neurons. However, the regulation of cAMP levels by phosphodiesterases in astrocytes has not been determined. Here we investigate the hypothesis that phosphodiesterase 3 (PDE3) is an important regulator of astrocytic cAMP levels in the brain. The presence of PDE3 in astrocytes could have intriguing functional impact as this PDE is inhibited by cGMP. Recent transcriptome and protein analyses have confirmed high levels of astrocytic PDE3. Interestingly, nitric oxide (NO)-stimulated cGMP production has been demonstrated to potentiate cAMP levels via PDE3 inhibition in blood vessels. To examine the role of PDE3 in modifying cAMP levels, we performed ELISAs in both acute rat hippocampal brain slices and primary astrocyte cultures. Our preliminary data indicate that the PDE3 inhibitor, cilostamide (10μM), enhances forskolin-induced cAMP increase. In addition,

application of the nitric oxide (NO) donor, SNAP (100 μM), also potentiated the cAMP increase, consistent with PDE3 sensitivity to cGMP. To further confirm that NO-induced cGMP is modulating cAMP levels through PDE3 inhibition, the experiment will be repeated in the presence of the soluble guanylyl cyclase inhibitor, ODQ. We are also examining the downstream consequences of increasing astrocytic cAMP by NO modulation. We have previously shown that activation of metabotropic glutamate receptors on astrocytes leads to prostaglandin E2 release and subsequent vasodilation. Intriguingly, cAMP elevation leads to lactate efflux from astrocytes which inhibits prostaglandin reuptake transporters. Hence NO may potentiate vasodilation by enhancing PGE2 signaling. Additionally, cAMP also modulates connexin43 (Cx43) expression and gap junction assembly in hepatoma cells. We therefore predict that NO can alter Cx43 levels and subsequent gap junction coupling of astrocytes. Thus we will perform immunoblotting and dye flux imaging to assess the level of plasma membrane Cx43 and astrocyte coupling, respectively. NO can be generated by either constitutive or inducible NO synthase in several different cell types such as interneurons and microglia. This raises an intriguing possibility that crosstalk may occur between different cell types and astrocytes to modulate cAMP-dependent pathways in astrocytes that are important in maintaining the healthy brain.

Title: Astrocytic syncytial isopotentiality in grey matter and white matter of adult mice

Authors: ***S. ZHONG**[1], C. M. KIYOSHI[1], B. MA[1], X. LIU[2], M. ZHOU[1];
[1]Neurosci., The Ohio State Univ. Wexner Med. Ctr., Columbus, OH; [2]Dept. of Neurol., Shanghai 10th People's Hospital, Tongji Univ. Sch. of Med., Shanghai, China

Abstract: Within an astrocytic syncytium of adult mice hippocampus, a powerful electrical and ionic coupling equalizes the membrane potentials among the coupled cells to achieve a syncytial isopotentiality. The existence of a syncytial isopotential is indicated by the ability of syncytial coupling to maintain a physiological membrane potential for any individual astrocyte in the network when K^+ ions were totally substituted by other monovalent cations in the whole-cell recording pipette solution, whereas the same experimental condition depolarizes freshly dissociated single astrocyte to ~0 mV as predicted by the Goldman-Hodgkin-Katz equation. To answer whether the observed syncytial isopotential in the adult hippocampus represents a general

functional aspect of astrocyte network, the same experimental method was used to examine astrocyte syncytia in other grey matter regions, such as hippocampal dentate gyrus and various subregions of cerebral cortex, as well as the white matter of the corpus callosum. In confocal morphometric analysis, we show that the density and spatial organization patterns do vary within various grey matters, and between grey and white matter. However, independent of these variations, a similar syncytial isopotentiality always exists in all the brain regions examined. Therefore, syncytial isopotential is most likely a universal characteristic of the astrocyte syncytial network that serves as a fundamental mechanism for the homeostatic support function of astrocytes throughout the brain.

Title: Highly purified adult astrocytes display diverse stimulus-dependent activation and cytokine secretion

Authors: H. ZHANG[1], M. JUNGBLUT[1], S. REISS[1], L. ZATRIEB[1], S. RÜBERG[1], L. WILLNOW[1], S. WILD[1], J. KOLLET[1], S. TOMIUK[1], R. FEKETE[2], *A. BOSIO[1,2];
[1]Miltenyi Biotec, Bergisch Gladbach, Germany; [2]Fluidigm Corp., South San Francisco, CA

Abstract: The inflammatory response in the central nervous system is a multifactorial process involving resident neural cells as well as infiltrating immune cells. These cells communicate by secreting cytokines, chemokines, and growth factors. Astrocytes are known to play multiple roles in neuroinflammation but there are no detailed studies to classify the heterogeneity of activated astrocytes according to their cytokine and chemokine secretion profile. In the past we have set up an automated dissociation procedure for neonatal brain using the gentleMACS Octo Dissociator with an optimized enzymatic treatment. For isolation and culture of adult neural cells we have further improved the method and included a novel protocol for removal of debris and erythrocytes, yielding 2-4 x10E6 living cells per mouse brain. To assess and compare neonatal and adult astrocyte diversity we first analyzed their transcriptome by mRNA sequencing of single cells. Astrocytes were separated to a purity of > 98,5 % using MicroBeads (MACS®) coupled to a specific pan-astrocyte marker, Anti-ACSA-2. The C1 Single-Cell Auto Prep System (Fluidigm) was used for capturing single cells in integrated fluidics circuits (IFCs), and

subsequent reverse transcription and cDNA amplification in a nanoliter reaction volume. The single cell transcriptome analyses revealed a divers molecular profile of both neonatal and adult astrocytes. Next, we characterized the cytokine secretion profile of activated neonatal and adult astrocytes. Immunocytochemistry analyses showed that neonatal and adult astrocytes expressed a broad range of cytokines and chemokines. When lipopolysaccharides (LPS) or conditioned media from LPS-stimulated microglia were added to neonatal astrocytes, an increased level of GM-CSF was detected by MACSPlex Cytokine Kit (Miltenyi Biotec). In case of adult astrocytes a distinct secretion profile dominated either by GM-CSF or IL23 was detected when activating adult astrocytes with LPS+TNFa or LPS+IFNg, respectively. This points to diverse astrocyte subtypes which are capable of reacting to different stimuli. In summary, we present a novel technology to purify functional astrocytes from neonatal and adult mouse brain paving the way for sophisticated molecular and cellular analyses. Single cell transcriptome analyses revealed general molecular diversity of astrocytes while cytokine secretion analyses of activated astrocytes demonstrate their functional diverse and stimulus-dependent polarization. The characterization of astrocyte polarization will help to further understand and modulate the inflammatory response in the CNS in diseases such as multiple sclerosis.

Title: Valproic acid promotes fibroblast growth factor 21 gene expression and neurite-like elongation through inhibition of HDAC2 and 3 in glial cells

Authors: ***Y. LENG**, J. WANG, Z. WANG, H.-M. LIAO, P. LEEDS, D.-M. CHUANG; Mol. Neurobiol Section, Natl. Inst. Mental Health/NIH, Bethesda, MD

Abstract: Fibroblast growth factor 21 (FGF-21) is an identified regulator of glucose and lipid metabolism, and has been proposed as a potential target for treating diabetes, obesity, and hyperlipidemia. Valproic acid (VPA), a mood stabilizer and an anticonvulsant drug, is a histone deacetylase (HDAC) inhibitor, and regulates gene expression via chromatin remodeling through epigenetic mechanisms. Recently, our lab reported that FGF-21 mRNA and protein can be markedly induced in rat brain-derived neurons by combined treatment with the mood stabilizers VPA and lithium, while VPA alone was ineffective (Leng et al., Mol Psychiatry 2015). As an extension of our previous work, this study investigated the effects of VPA and other HDAC inhibitors on the expression of FGF-21 in glial cells. Incubation of C6 glioma cells with VPA and other pan HDAC inhibitors such as sodium butyrate, trichostatin A (TSA) and SAHA, all robustly increased FGF-21 mRNA levels in a dose and time-dependent manner. Class I HDAC inhibitors such as MS-275, apicidin, FK-228 and MGCD103 also caused a dose-dependent increase in FGF-21 mRNA; however, the HDAC6-specific inhibitors rocilinostat (ACY-1215) and tubastatin A had no significant effects. To identify the class I HDAC isoform(s) involved in the regulation of FGF-21 expression, we employed lentiviral shRNA-mediated knockdown technology. Knock down of HDAC2 or 3 isoforms in C6 glioma with their specific shRNA, elevated FGF-21 mRNA level by 8- or 3-fold, respectively. In contrast, HDAC1 isoform knockdown produced no FGF-21 mRNA expression changes in these cells. Knock-down of either HDAC2 or 3, but not HDAC1 markedly increased neurite-like elongation in C6 cells, similar to effects of VPA. Furthermore, knock-down of endogenous FGF-21 with lentivirus-mediated shRNA significantly reduced VPA-induced neurite-like elongation in C6 cells. Conversely, lentivirus-mediated overexpression of recombinant FGF-21 increased the length of neurite projection. Additionally, in rat cortical primary astroglia-enriched cells, VPA and SAHA upregulated the FGF-21 mRNA level by 4- and 8-fold, respectively, and this was associated with a marked increase in neurite-like projections in cortical astrocytes. Taken together, our results suggest that inhibition of HDAC2 and 3 by VPA or other HDAC inhibitors up-regulates FGF-21 and neurite-like elongation in glial cells. The neurobiological significance of FGF-21 up-regulation in glia requires further investigation.

Title: Monoacylglycerol lipase inhibitors block astrocyte cytokine/chemokine secretions following LPS *in vitro*

Authors: *S. SUTTON[1], Y. HE[2], N. TAYLOR[2], N. DERECKI[2], A. BHATTACHARYA[2], P. BONAVENTURE[2];

Abstract: Recent publications have shown stimulation of brain cytokines, chemokines and prostaglandin E2 (PGE2) in mice following peripheral injections of 20 mg/kg lipopolysaccharide (LPS). In these studies monoacylglycerol lipase (MGL) inhibitors have been shown to reduce LPS-stimulated cytokine and PGE2 elevations in brain extracts. These observations suggest MGL inhibitors may be capable of reducing neuroinflammation. Here we use cultured primary mouse astrocytes to model neuroimmune effects of MGL inhibitors, comparing those effects to FAAH inhibitor JNJ-40355003. Results of these studies show secretion of cytokines such as Il-6, Il-13, IP-10/CXCL-10, KC/CXCL-1, MCP-1 and RANTES are stimulated by 10 ng/ml LPS in primary mouse astrocytes, and these secretions are blocked by 10 uM of the MGL inhibitors but not by 10 uM of the FAAH inhibitor. While a wide variety of cells participate in neuroimmune signaling including astrocytes, microglia, endothelial cells, pericytes, neurons and infiltrating peripheral immune cells, these observations suggest aspects of brain cytokine modulation by MGL inhibitors observed *in vivo* can be modeled with primary astrocytes *in vitro*. Title: Untangling GFAP via Alexander disease patient derived astrocytes

Authors: *J. JONES[1,2], R. KRENCIK[2], M. DOERS[1], T. HAGEMANN[1], R. BRADLEY[1], M. DUBOVIS[1], A. MESSING[1], S.-C. ZHANG[1];

Abstract: Glial fibrillary acidic protein (GFAP) is widely regarded as an astrocyte marker. However, its function in astrocytes remains largely unknown. Point mutations in either GFAP allele are sufficient to induce a disease known as Alexander disease. Though rare, the existence of Alexander disease suggests critical roles for GFAP. We endeavored to investigate Alexander disease in an effort to not only understand disease mechanisms, but also to explore the function of GFAP within astrocytes. To that end, we established induced pluripotent stem cells (iPSCs) from Alexander disease patients with different GFAP mutations. We also generated isogenic iPSCs by correcting the GFAP mutations with CRISPR/CAS9. Strikingly, astrocytes differentiated from patients' iPSCs exhibited GFAP aggregation, hallmark pathology of Alexander disease. Functional analysis revealed altered metabolic properties,glutamate buffering capacity, and interaction with neurons. These results highlight the functions of GFAP beyond a cytoskeletonprotein. This study has also demonstrated the feasibility of human disease modeling *in vitro* as well as elucidated potential future directions for understanding roles of GFAP and astrocytes in human health and disease.

Title: Astrocytes engulf apoptotic cells through the Megf10 scavenger receptor

Authors: *T. IRAM[1,2], D. FRENKEL[1,3], J. EL KHOURY[4];
[1]Sagol Sch. for Neuroscience, Tel Aviv Univ., Tel Aviv-Yafo, Israel; [2]Dept. of Neurobilology, Tal Aviv Univ., TelAviv, Israel; [3]Dept. of Neurobilology, Tal Aviv Univ., Tel Aviv, Israel; [4]Ctr. for Immunol. and Inflammatory Dis., Mass Gen. Hosp. and Harvard Med. Sch., Charlestown, MA

Abstract: Efficient phagocytic clearance of apoptotic cells in the central nervous system (CNS) is necessary to avoid toxicity and auto-immunity. Astrocytes, the most abundant cells in the brain, were shown to take part in debris clearance and tissue repair in several brain pathologies such as Mutliple Sclerosis, Alzheimer's disease and traumatic brain injury. Extensive work has been done on the clearance of apoptotic cells in *C. elegans* and *Drosophila* and several receptors such as cell death abnormality protein 1(CED-1) and Draper have been identified. However, in the mammalian and rodent CNS, the receptors involved in the clearance of apoptotic cells have not been definitively identified yet. Multiple EGF-like domains 10 (Megf10) is a type-I receptor that consists of all the structural features of CED-1, positioning it as a high-potential candidate for the mammalian CED-1 homologue. We and others have found that Megf10 is highly enriched in the brain, specifically in astrocytes. Moreover, Megf10 mediates engulfment of apoptotic neurons in-vitro. Furthermore, to study the function of Megf10 as an engulfment receptor in-vivo we generated a Megf10 knockout (Megf10-KO) mouse and found that lack of one or two copies of Megf10 results in an accumulation of apoptotic cells in the developing cerebellum and to locomotor deficits in the adult mouse. Notably, our results demonstrate for the first time, a role for Megf10 expressed on astrocytes in apoptotic-cells clearance ex-vivo, indicating that the accumulation of apoptotic cells in-vivo might be due to altered astrocytic-phagocytic activity. This data is highly relevant to EMARDD patients, which on top of the obvious muscle deficits might have cerebellum-related motor impairments due to failure of proper clearance of apoptotic cells. All together, these findings indicate that Megf10 plays an important role in astrocyte-mediated clearance of apoptotic cells.

Title: Mitochondrial glutamate carrier SLC25A22 inhibition in astrocytes does not result in energy failure

Authors: ***F. MOLINARI**[1], E. GOUBERT[1], Y. MIRCHEVA[1], F. M. LASORSA[2], J. C. SUTERA-SARDO[1], H. BECQ[1], F. PALMIERI[2], L. PALMIERI[2], L. ANIKSZTEJN[1]; [1]INMED - INSERM U901, Marseille, France; [2]Dept. of Pharmaco-Biology, Lab. of Biochem. and Mol. Biol., Bari, Italy

Abstract: The SLC25 carrier family drives the import of a large diversity of metabolites into mitochondria, a key cellular structure involved in many metabolic functions such as ATP synthesis by oxidative phosphorylation, tricarboxylic acid cycle or fatty acid oxidation.

Dysfunctions of these carriers result in severe diseases affecting organs requiring a high energy production such as muscles, heart, liver and brain. Moreover, direct dysfunction of the mitochondrial respiratory chain resulting in ATP synthesis deficiency are involved in diverse epileptic syndromes such as MERRF, MELAS, Alpers syndrome and some cases of early epileptic encephalopathies. In this study, we focus on the mitochondrial glutamate carrier SLC25A22 (also named GC1), which is involved in early epileptic encephalopathy and migrating partial seizures in infancy, and wondered if these syndromes could be due to a defect in ATP synthesis. In brain, GC1 is highly expressed in astrocytes and is the principal glutamate gate to entry into mitochondria. Here, we combined RNA interference to trigger GC1 knockdown to electroporation-mediated transfection using the Neon® Transfection System in order to target a high number of primary astrocytes. We measured several biochemical parameters such as NADH, mitochondrial membrane potential and level of cytosolic ATP. We found that the global ATP amount was similar in presence or absence of GC1. Our results suggest that GC1 is not crucial for energy formation and that GC1-related epileptic encephalopathies are not due to an energy failure in astrocytes.

De Biologia Mol. Severo Ochoa, Madrid, Spain

Abstract: In the brain, calcium regulates mitochondrial respiration both by activation of ATP consumption and by Ca signaling. Ca signaling in mitochondria may regulate respiration: i) after Ca entering through mitochondrial uniporter (MCU), activating mitochondrial dehydrogenases and F0F1-ATPsynthase; or ii) activating Ca-binding mitochondrial carriers, ARALAR and SCaMCs from the outer face of the inner mitochondrial membrane, which involves metabolite supply. In neurons, ARALAR contributes significantly to workload and Ca-induced respiration (1). In brain astrocytes, ARALAR levels are undetectable and this work aims to study the metabolic response of cultured astrocytes to different workloads and the possible role of Ca in response, using different ligands, glutamate (L-Glu) and ATP. L-Glu is transported into the astrocytes resulting in increased Na+ uptake, which drives ATP breakdown, and also acts on metabotropic L-Glu receptors. L-Glu (200 μM - 500 μM) produced a small rise in Cai in cultured astrocytes, increased glucose utilization, lactate production and stimulated oxygen consumption in an acute and stable way (OCR, by Seahorse XF24 Extracellular Flux Analyzer) and maximal uncoupled respiration (MUR) in the presence of 2.5 mM glucose. A transportable but non-metabolizable glutamate analog, D-aspartate (D-Asp) (500 μM), which also increases Cai, stimulated respiration in a way similar to L-Glu, but failed to increase MUR, clearly showing that L-Glu is used as respiratory substrate by cultured astrocytes. L-Glu and D-Asp-stimulation of respiration was only slightly reduced in the absence of Cao, consistent with a major role of ATP demand in stimulation of OCR. ATP (100 μM - 1 mM) activates metabotropic and ionotropic purinergic receptors and induces a larger Cai rise than L-Glu in cultured astrocytes. ATP caused an increase in glucose utilization and lactate production, and also an acute and transient rise in OCR, which was dependent on Cao. Whether this is due to increased Ca-dependent workload or to the effects of Ca on upregulation of respiration is part of the ongoing work. Remarkably, MUR was also Ca-dependent, especially in astrocytes exposed to high ATP concentrations. It is likely that glycogen breakdown via Ca-dependent adenylate cyclase and PKA (2) plays a role in increasing MUR in the presence of Ca. Further studies are required to dissect the role of MCU and SCaMC-3 and Ca-dependency with each stimulus. 1. Llorente-Folch et al. J Neurosci (2013) 33:13957-71. 2. Müller MS et al. Title: Astrocytic mitochondria undergo delayed fragmentation and degradation in response to an *in vitro* model of ischemia/reperfusion injury

Authors: *J. C. O'DONNELL[1], J. G. JACKSON[2], M. B. ROBINSON[1];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Several recent studies show that mitochondria are found in astrocytic processes and may even be found in the fine peripheral astrocytic process (PAPs). In fact, we recently showed that these mitochondria are mobile and that neuronal activity positions mitochondria near glutamate transporters and excitatory synapses (Jackson et al., J. Neuroscience, 2014). Mitochondrial dysfunction in neurons and excitotoxicity from failure of astrocytic glutamate uptake are at the core of delayed neuronal death after a transient ischemic insult. Aside from inducing hypothermia, this secondary pathology is currently untreatable. We hypothesized that astrocytic mitochondrial dynamics would be altered during secondary pathology; this could impair glutamate clearance and exacerbate excitotoxicity. To test this hypothesis we exposed organotypic hippocampal slice cultures to transient (30 min) oxygen glucose deprivation (OGD) after selective biolistic transfection of astrocytes to label mitochondria and plasma membrane. In agreement with the literature and as is observed with stroke *in vivo*, we observe preferential and delayed cell death in area CA1 that was blocked by ionotropic glutamate receptor (iGluR) antagonists. We found that this insult results in a dramatic, delayed loss of mitochondria in astrocytic processes. Mitochondrial fractionation (increased number, decreased length) was apparent by 9 hrs after OGD injury, followed by progressive loss of mitochondria from 12 to 24 hrs. By 18 hrs after injury, the fraction of process length occupied by mitochondria was reduced by ~40%, and mitochondrial length was reduced by ~60%. We observed a time-dependent increase in the colocalization of mitochondria with a transfectable autophagosome marker (EGFP-LC3B) indicative of increased mitophagy. Treatment with N-methyl-D-aspartate (100 μM for 30 min), which causes acute neuronal death, also caused a loss of astrocytic mitochondria. iGluR antagonists partially blocked the effects of OGD on astrocytic mitochondria. Cyclosporin-A, which inhibits mitochondrial fission and increases mitochondrial capacity for calcium buffering, also attenuated the loss of mitochondria after OGD and was protective. We are currently investigating possible physiologic and pathologic consequences of this loss of mitochondria. Understanding the mechanisms underlying this loss of astrocytic

mitochondria after transient OGD could provide new therapeutic targets for the currently untreatable secondary pathology following transient ischemic stroke.

Title: Acute exposure to methamphetamine decreases activity of K2P channels and voltage-gated K+ channels in primary human fetal astrocytes

Authors: ***S. DAVE**, C. YU, C. E. KHODR, M. SEATON, L. CHEN, L. AL-HARTHI, X.-T. HU;
Rush Univ. Med. Ctr., Chicago, IL

Abstract: Methamphetamine (Meth) is a potent and commonly-abused psychostimulant. Chronic exposure to Meth induces decreased neuronal activity in the medial prefrontal cortex and nucleus accumbens (key regulators of cognition and addiction in the reward pathway), which may contribute to the mechanisms underlying Meth addiction. It is not fully understood whether such decrease results from alterations in synaptic/intrinsic excitability of neurons, or dysregulation of the extracellular environment (e.g., glutamate and K^+ levels) mediated by surrounding astrocytes. To fill this knowledge gap, we assessed the acute effects of Meth on functional activity of certain voltage-gated ion channels in the cell membrane of primary human fetal astrocyte (HFA) using whole-cell voltage-clamp recording. We firstcharacterized the activity of K^+ channels in HFAs. Under blockade of voltage-gated Na^+ and Ca^{2+} channels, we found that HFAs showed a resting membrane potential (RMP) of -48±2 mV (-26 to -73 mV range). Blockade of the two-pore domain K^+ channel (K_{2P}) with quinidine (1 mM) induced depolarization of RMP in vehicle-treated control cells ($p<0.05$), revealing the role of K_{2P} channels in maintaining RMP of HFAs. HFAs showed predominant voltage-sensitive, out-flowing K^+ currents (VGKCs, a characteristic of immature or reactive astrocytes) at depolarized membrane potential levels (V_m, 60-100 mV). Bath-applied TEA (a selective K^+channel blocker, 20 mM) suppressed these currents ($p<0.001$), indicating that these currents were mediated by, and passed through activated VGKC channels. In another set of experiments, voltage-gated Ca^{2+} currents were not found in HFAs. Exposure of HFAs to acute Meth (20, 100, or 300 μM for 3-6 hrs) induced depolarization of RMP (all $p<0.05$). With K_{2P} channel blockade, Meth-induced

depolarization showed no significant difference *vs*. that induced by vehicle (p=0.5), suggesting that Meth decreased K_{2P} channel activity. Exposure to Meth (20, 100, or 300 μM) also induced a significant reduction in VGKCs compared to vehicle-treated controls (all p<0.05). There was no significant difference between the reduced VGKCs induced by TEA and by TEA+Meth (p>0.2), indicating that acute Meth also induced a decrease in VGKC channel activity. Together, these novel findings suggest that Meth disturbs HFA activity partly by decreasing activity of K_{2P} and VGKC channels. This could reduce K^+ out-flow and consequentially decrease local extracellular K^+ levels ($[K^+]_e$). If a similar decrease of $[K^+]_e$ occurs in mature astrocytes in the brain, it may contribute to lowering $[K^+]_e$, and thereby decreasing excitability of neurons surrounded by astrocytes.

Title: Robust and reliable Ca^{2+} response in microdomains of astrocytes

Authors: *R. GARCIA, R. RIKHYE, M. SUR;
Brain & Cognitive Sci., MIT, Cambridge, MA

Abstract: Astrocytic intracellular Ca^{2+} signaling has come to light as a prominent feature of neuronal-glial interactions. The majority of astrocyte Ca^{2+} signaling studies are performed in either culture or *in situ* brain slices, both of which rely on electrical stimulation or pharmacological methods to examine the spatial and temporal coding of astrocyte Ca^{2+} signals. We have investigated visually evoked Ca^{2+} responses in astrocytes of the visual cortex of awake, head-fixed mice using two-photon microscopy. Initially, our studies involved the use of viral-mediated delivery of genetically encoded calcium indicators. However, in order maintain an intact and unperturbed cortex, we have chosen to use a recently developed line of conditional

transgenic animals that express GCaMP5G in astrocytes throughout the mouse brain. We have found that Ca^{2+} transients in distal processes of cortical astrocytes are more frequent than those observed in anesthetized preparations, exhibiting a variable relationship to somatic responses. Furthermore, we found discrete structural regions of distal processes of single astrocytes that responded to sinusoidal drifting gratings and were tuned to specific orientations. Natural movies (NM) are known to evoke sparse, but reliable, responses from V1 pyramidal neurons. Surprisingly, we found discrete processes of astrocytes also respond reliably to natural movies. Responses to sinusoidal gratings were also less reliable than to natural movies. We hypothesize that these reliable astrocytic microdomain Ca^{2+} transients are due to the synchronous activation of neighboring ensembles of synapses. Together our results suggest that astrocytes could play an important role in modulating information processing in V1, potentially by modulating response reliability at pyramidal cell synapses.

Title: Modulators of the activity threshold for evoked astrocyte Ca^{2+} signals during neurovascular coupling

Authors: *A. INSTITORIS[1], G. R. GORDON[2];
[1]Univ. Of Calgary, Calgary, AB, Canada; [2]Univ. of Calgary, Calgary, AB, Canada

Abstract: Ca^{2+}-dependent pathways in neurons and astrocyte endfeet initiate changes in arteriole diameter to regulate local brain blood flow. We have described that there exists a threshold of synaptic activity that must be met before astrocytic Ca^{2+} elevation can be observed during neurovascular coupling. Although other work has shown that 'supra-threshold' astrocyte activation was the result of synapse-borne glutamate spillover, the factors that set the sensitivity of astrocytes (i.e. change the threshold) to increasing synaptic activity is unknown. Here we test various candidates that may tune the astrocyte activation threshold such as neuromodulators (noradrenaline and acetylcholine), metabolic substrates (oxygen, lactate and adenosine) and extracellular potassium. We used two-photon fluorescence microscopy to examine synaptically evoked synthetic or genetic Ca^{2+} indicator signals around penetrating arterioles in acute slices of the rat neocortex. Our preliminary data exploring the role of extracellular $[K^+]$ found that

although spontaneous Ca^{2+} transients were suppressed by higher external [K^+] (5mM), activation threshold of astrocyte soma and endfeet was not different from that of physiological [K^+] (2.5mM). Our continued work in this area will explore the remaining candidates.

Title: *Drosophila* astrocytes transport glutamate at identified synapses

Authors: *S. E. MACNAMEE[1], K. E. LIU[1], S. GERHARD[2,3], R. D. FETTER[2], L. P. TOLBERT[1], A. CARDONA[2], L. A. OLAND[1];
[1]Univ. of Arizona, Tucson, AZ; [2]HHMI Janelia Res. Campus, Ashburn, VA; [3]Inst. of Neuroinformatics, Univ. of Zurich and ETH Zurich, Zurich, Switzerland

Abstract: The neuronal circuits that generate behaviors are actively modulated by numerous factors, including the rate at which neurotransmitter transport occurs in neighboring neuronal and glial cells. Details of the neuronal circuit map of the *Drosophila* larval ventral nerve cord are developing rapidly, so we decided to use this model system to probe the effects of altered astrocyte physiology on neuronal circuit output. Here, we examined the anatomical and physiological relationships between *Drosophila* astrocytes and a defined population of pre-motor synapses. We identified a group of neurons with dvGlut-positive terminals that form inhibitory pre-motor connections. These neurons have been named “loopers”, after the looped morphology of their primary process, or “period-positive median segmental interneurons” (Kohsaka et al., 2014). First, we ascertained the distance between looper-motor neuron synapses and astrocyte processes because the temporal dynamics of astrocyte modulation of synaptic transmission depend, in part, on distance. To address this, we used a serial electron micrograph (EM) image

set extending through ventral nerve cord segments A2 – A5. Looper neurons were identified by the ventro-medial location of their cell bodies and the distinct morphology of their primary process in the CATMAID (Collaborative Annotation Toolkit for Massive Amounts of Image Data) environment. We then selected small 3D EM volumes encompassing distal synapse-rich segments of looper neurons and exported them into Reconstruct software. Looper neuron processes, their associated pre-synaptic active zones, and all astrocyte processes within the 3D volume were traced and reconstructed, and the distance between an active zone and the nearest astrocyte membrane was measured. Many looper synapses had no apposing astrocyte processes, and the distance separating active zones from the nearest astrocytic process varied one-hundred-fold from 0.01 to 0.99 microns. Despite this variation in distance, whole-cell recordings from astrocytes revealed that optogenetically-mediated looper activation induces in the astrocytes an inward current with a peak amplitude of 14.4 pA +/- 5.1 SD with delay of approximately 25 ms. 86% of the peak current amplitude was blocked by bath application of the glutamate transporter blocker DL-threo-β-benzyloxyaspartate (DL-TBOA). We currently are examining the effects on motor neurons of pharmacological as well as genetic astrocyte manipulation, allowing us to generate a robust model of astrocyte-synapse modulation.

Title: Modulation of neural activity affects astrocyte morphology in *Drosophila*

Authors: J. CHARLTON, C. TRAN, S. MACNAMEE, L. P. TOLBERT, *L. A. OLAND; Dept. of Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: Astrocytes are known to maintain a proper ionic balance in the central nervous system, take up neurotransmitters after synaptic signaling, and modulate synaptic activity - and much of this is done through a reciprocal conversation in which neuronal activity induces responses in glial cells that, in turn, modulate neuronal activity. Our long-term goal is to

elucidate the significance and underlying mechanisms of neuron-glia interactions using pharmacological and genetic alterations of neuronal activity in *Drosophila* melanogaster. We previously reported that constitutive RNAi knockdown of the GABA transporter in astrocyte-like glia of the 3rd-instar ventral nerve cord (VNC) strongly reduced larval locomotion, indicating that altering astrocyte function modulates activity in neurons comprising the motor circuitry (MacNamee et al., SfN abstract 2013). Here we have manipulated neural activity in the larva in two ways, to assess the impact of altered neuronal activity on astrocytes. In one set of experiments, we fed larvae picrotoxin, which blocks GABAA receptors and glutamate-gated chloride channels; we used a FLP-out genetic construct to visualize the detailed morphology of astrocytes in the VNC. Results to date indicate that the pharmacological treatment, which would be expected to change the balance of inhibition and excitation, significantly reduced locomotor activity and concomitantly led to a marked decrease in the volume occupied by the branching processes of astrocytes. In a second set of experiments, we used the Q system to overexpress in all neurons a temperature-sensitive allele of shibire to reduce synaptic transmitter release; in the same flies, we used the GAL4/UAS system to drive expression of membrane-targeted green fluorescent protein in astrocytes. We developed a heat-shock protocol that maximizes the period of diminished neural activity, maximizes larval survival, and minimizes time for possible compensatory changes in astrocytes. Overexpression of shibire dramatically reduced larval locomotion. The impact on glial morphology is being assessed using 3-D reconstructions of high-magnification confocal microscopic images.

Title: Morphological analysis of astrocyte-like glial cells in the *Drosophila* ventral nerve cord

Authors: E. HERNANDEZ, K. LANCE, J. CHARLTON, S. MACNAMEE, L. A. OLAND, *L. P. TOLBERT;
Neurosci., Univ. of Arizona, Tucson, AZ

Abstract: Understanding the ongoing signaling between neurons and glial cells requires a detailed analysis of basic glial cell morphology and physiology. In particular, the shapes and distribution of glial cells help to dictate the roles those cells play in regulating neuronal function. In each segment of the ventral nerve cord of *Drosophila* melanogaster, the neuropil is organized into distinct motor, interneuron, and sensory neuropils. Each hemisegment of the neuropil is served by just six astrocyte-like glial cells, with cell bodies in characteristic positions around the edge of neuropil. We are asking: What are the detailed morphological features of these astrocytes, and how are their processes arrayed in the synaptic neuropil? We have combined the GAL4/UAS and FLP/FRT systems to stochastically express green fluorescent protein (GFP) in individual astrocytes in the ventral nerve cords of 3rd-instar larvae. For background staining, all astrocyte nuclei were labeled using either an anti-Repo antibody or mCherry targeted to astrocytes, and major axonal tracts (serving as fiducial markers) were visualized with an antibody to Fasciclin II (Fas II). Images were collected on a laser scanning confocal microscope and reconstructed in 3-D. The detailed morphology of each labeled astrocyte and its location within the neuropil were analyzed. 3-D images of 42 individual cells revealed a variety of cell morphologies: some cells are compact with highly branched arbors, some have multiple highly branched arbors, and others have branches that extend out from the compact arborization to wrap around Fas II-positive tracts. To our surprise, 45% of the astrocytes have a process that crosses the midline, 36% have a single thin, unbranched process that travels along the outer rim of the neuropil to a nearby glial cell body, and 9% have a single thin process that leaves the CNS in a peripheral nerve. In separate experiments, we used the GAL4/UAS Flybow system to stochastically label adjacent glial cells with different fluorophores. Overall, we found that astrocytes roughly “tile” the neuropil (as previously noted by Stork et al. 2014); however, the distal processes of adjacent cells often overlap to varying degrees.

Title: Comparative effects of methylmercury on type 1 cerebellar and cortical astrocytes

Authors: *R. JAIMAN, W. D. ATCHISON;
Neurosci., Michigan State Univ., East Lansing, MI

Abstract: Although methylmercury (MeHg) primarily affects neurons, especially the granule cells in the cerebellum, astrocytes are also targets of this environmental neurotoxic metal. MeHg-induced neurotoxicity in astrocytes has been studied in the cortical layer. However, effects on cerebellar astrocytes are less studied, and regional differences can occur in astrocytes between the two areas. The goal of this study was to compare the toxicity of MeHg on Type 1 cerebellar and cortical astrocytes. Effects on MeHg on Type 1 astrocytes are especially important, because they modulate cell functions in the synaptic cleft and MeHg affects synaptic function of cerebellar granule cells. Determining if MeHg differentially affects Type 1 astrocytes from these two brain regions could help delineate the cellular mechanisms underlying the preferential sensitivity of cerebellar granule cells to MeHg. Primary astrocyte cultures from the cerebellum and cortical forebrain layer were obtained from C57BL/6 male mice. At 13-15 DIV, cells were exposed for 3h to 0μM, 1μM, 2μM, or 5μM MeHg. Cytotoxicity was measured 24h later using EthD-1 and Calcein AM. Type 1 astrocytes were identified immuncytochemically using GFAP and A2B5. Type 1 astrocytes were GFAP+/ A2B5-. In parallel cell cultures, GFAP and the nuclear fluorogenic indicator DAPI were used to calculate the percentages of astrocytes in the cultures. The percentages in the cerebellar and cortical cell cultures were 98% and 100% respectively. The mean percentage of cell death in the cerebellum was: 0 %, 21%, 63%, and 95% at 0, 1, 2, or 5μM MeHg respectively. In the cortical layer it was: 1.1%, 1.3%, 20%, and 73% respectively. Cell viability of cerebellar astrocytes was significantly reduced at 2-5 μM MeHg; in cortical astrocytes viability was reduced only at 5μM. At low MeHg concentrations, cortical astrocytes were less affected by MeHg; the effect was significant at 2 μM MeHg when cerebellar and cortical astrocytes were compared. The LC50s of the cerebellum and cortical layers were 1.15 μM and 4.24 μM MeHg, respectively. In conclusion, Type 1 cerebellar astrocytes are more susceptible to MeHg-induced cytotoxicity than Type 1 cortical astrocytes and brain region-dependent differences in cytotoxicity of astrocytes occur in response to MeHg.

Title: Neuronal activity controls astrocyte proliferation through NMDA receptor signaling

Authors: ***Y. CHEN**[1,2], M. WEBER[1], F. CHU[1], Z. MODRUSAN[1], J. KAMINKER[1], M. SHENG[1];
[1]Genentech INC, Roche Group, South San Francisco, CA; [2]Ircbc, Chinese Acad. of Sciences, SIOC, Shanghai, China

Abstract: Astrocytes are the most abundant cell type in the brain with critical roles in facilitating synapse/circuitry development and functions. But the underlying mechanism that regulates astrocyte proliferation has not yet been demonstrated. We hereby report a surprising result that astrocyte proliferation is bi-directionally regulated by neuronal activity via NMDA receptor (NMDAR) signaling. Using whole genome mRNA profiling, we found that a significant number of cell cycle related genes were altered by the treatment with an NMDAR antagonist in dissociated hippocampal cultures. Interestingly, these cell cycle related genes were expressed and regulated specifically in astrocytes. Furthermore, NMDAR inhibition blocked baseline astrocyte proliferation both *in vitro* and *in vivo*. And evoked neuronal activity was sufficient to promote astrocyte proliferation through NMDARs, suggesting NMDAR signaling could bi-directionally control astrocyte proliferation. Additional mechanistic studies identified an NMDAR-induced molecule, expressed only in neurons, was responsible for this process. In summary, we have found a novel NMDAR-initiated trans-cellular signaling event that controls astrocyte proliferation.

Title: Astrocytes affect the electrical activities of neurons to sound in medial geniculate body

Authors: ***X. SUN**[1], M. HUANG[2];
[1]Hangzhou Normal Univ., Zhejiang, China; [2]Hangzhou Normal Univ., Hangzhou, China

Abstract: Astrocyte(AS)involved in the plasticity of several neurons. But little is known about the characteristics of AS in the auditory processing system. Here we investigated the contributions of astrocyte to the plasticity of medial geniculate body (MGB). We used extracellular electrophysiological recording techniques to record the changes of electrical activities of neurons in MGB. SD rats with unilateral cochlear ablation at different survival time were stimulated by pure tones of different frequency. Before and after the fluorocitrate injection, the electrical activities of the neurons in MGB were recorded. We find that 3 hours after fluorocitrate injection (1) the First spike latency (FSL) was shortened in 24 hours cochlear ablation group (ab24); but for ab14 group the FSL is significantly extended. While FSL of ab30 group exhibited a continuous prolong, we find that ab14 group showed a longer FSL. (2) After some reduction of the spike counts, the non-unilateral cochlear-ablation group (non-ab) showed an increase of spike counts after 2 hours fluorocitrate injection. The spike counts of ab24 and ab14 groups reduced after fluorocitrate injection; and the spike counts of ab30 days group showed an increase first then reduce after fluorocitrate injection. The spike counts of ab24h, ab14d and ab30d were all at their least after 2 hours fluorocitrate injection. The spike counts of ab14d showed a significantly less in all of the groups. (3) According to the frequency tuning curve (FTC), we found that all the characteristic frequency (CF) of non-ab, ab24, ab14 and ab30 group had a tendency moving to the high-frequencies. The minimum threshold (MT) of non-ab group increased first then reduced after fluorocitrate injection; the MT of ab7 and ab30 groups kept increase. The MT of ab24 showed no significant changes to fluorocitrate injection. Our results showed that the functional changes of AS can affect the response to sound of MGB neurons after unilateral cochlear ablation; and the effects are related with the time points of unilateral cochlear ablation. We suggest that AS involved in the plasticity of neurons in medial geniculate body (MGB) to adopt the modulation of auditory processing.

Title: NF-κB-mediated regulation of astrocyte-secreted signals affects the neurogenic potential of adult hippocampal neural progenitors

Authors: V. BORTOLOTTO[1], S. CVIJETIC[1], M. MANFREDI[2], E. RANZATO[3], E. MARENGO[3], P. L. CANONICO[1], *M. GRILLI[4];

Abstract: The hippocampal SubGranular Zone (SGZ) is characterized by the presence of the neurogenic niche, a highly specialized microenvironment which is both instructive and permissive for adult neural progenitor cells (NPC) and their progeny. In previous work we proved that members of the NF-kappaB family of transcription factors are important contributors of signalling pathways in the SGZ neurogenic niche. Within the family, the p50 subunit appears to play a crucial role since p50KO mice display dramatically reduced adult hippocampal neurogenesis in association with short-term memory defects. However, when adult NPC derived from wt and p50KO mice are cultured *in vitro*, no significant differences can be observed in their neurogenic potential, suggesting a potential contribution of other cell subpopulations within the niche to defective neurogenesis in mutant mice. To this purpose we have set up enriched astrocyte cultures from hippocampi of p50KO and wt neonatal mice and studied their influence on wt or p50KO NPC by using astrocyte-conditioned medium (ACM). When wt NPC where exposed to wt ACM, an increased rate of differentiation towards both neuronal and astroglial lineages was observed, in comparison with standard medium. Conversely, p50KO ACM significantly increased the percentage of newly generated astrocytes, but lacked proneurogenic effects on wt NPC. Moreover, wt and p50KO ACM promoted neither neurogenesis nor gliogenesis in p50KO NPC. We then decided to actively pursue the identification of proneurogenic and/or antineurogenic signals that, under control of NF-kappaB p50, may be differentially regulated in astrocytes. To this purpose we analyzed wt and p50KO secretome through a high throughput label-free protein quantitation method called SWATH-MS which allows the relative determination of secreted proteins so to identify molecules differentially modulated in absence or presence of p50. Altogether our data suggest that neurogenic defects observed *in vivo* in p50KO mice are both cell autonomous and non-cell autonoumous, and that they may also involve phenotypic changes in the secretome of astroglial cells. In addition, they add another level of complexity to the role of NF-kappaB p50 in the regulation of adult hippocampal neurogenesis.

Title: Are astrocytes involved in extending serotonin-mediated neuromodulatory actions to every synapse?

Authors: E. QUON, *L. K. BEKAR;
Pharmacol., Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Single astrocytes can ensheath over 100,000 synapses within their domain. Thus, astrocytes are ideally positioned to integrate signals from a few synapses to have impact on all ensheathed synapses with high efficiency. As neuromodulators are released in a volume manner and are known to illicit astrocyte calcium responses, we hypothesized that astrocytes may be effector cells, extending neuromodulator action to every synapse. Using live mouse brain slices and extracellular recordings of evoked excitatory postsynaptic potentials (eEPSPs), we assessed pharmacologically the astrocytic involvement in serotonin-mediated shaping of a simple cortical network containing both excitatory and inhibitory activity. Using a paired-pulse stimulus repeated every 20 seconds, serotonin was administered as a bolus to the bath perfusate upstream of the recording site in order to assess transient effects on the network. To assess the astrocytic role in serotonin effects, serotonin was applied both before and after bath application of pharmacological agents considered to affect astrocyte function or signaling mechanisms. In the absence of neuromodulators or pharmacological agents the first eEPSP is much larger in amplitude than the second due to the recruitment of longer-lasting inhibitory activity resulting from the first stimulus. Pharmacological disruption of gap junctions/hemichannels or impairment of astrocyte metabolism resulted in a significant loss of evoked inhibition in field recordings, suggesting that astrocytes may play a role in tonic aspects of network inhibition. Furthermore, serotonin effects on frequency transmission in the cortical network are significantly lost following so-called astrocyte pharmacological disruption. Lastly, serotonin-mediated frequency transmission could also be disrupted using P2 antagonists suggesting that ATP signaling (astrocyte currency) may be involved. These data highlight the possibility for astrocyte involvement in cortical inhibitory activity seen in this simple cortical network and that serotonin acts on astrocytes to partially exert its modulatory influence.

Title: Role of astrocytic Ca^{2+} signaling in structural synaptic plasticity

Authors: *P. RAGUNATHAN, Y. JUNG, A. DUNAEVSKY;
Developmental Neurosci., Munroe-Meyer Institute, Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Astrocytes are in intimate structural relationship with synapses and astrocytic contact with dendritic spines can promote their stability. Astrocytes display activity-mediated Ca2+ responses and Ca2+ signaling in astrocytes is thought to be involved in astrocyte-neuron signaling possibly through release of gliotransmitters. Astrocytes have therefore been implicated in regulating synaptic transmission and long-term potentiation. It has been shown recently in slices that increased Ca2+ signaling regulates motility of astrocytic processes leading to an enhanced astrocytic coverage of spines and their stability. Whether astrocytic Ca2+ signaling *in vivo* promotes spine stability has not been examined. In order to determine the relationship between astrocytic Ca2+ signaling and dendritic spine structural plasticity, we use the hM3Dq DREADD designer receptor system to selectively stimulate astrocytic Gq-GPCR signaling *in vivo*. Adeno-associated viral injection for expression of hM3Dq in astrocytes was performed in mice expressing GCaMP3 in astrocytes and cranial windows were implanted. Oscillatory-like Ca2+ signals were repeatedly elicited in astrocytes expressing hM3Dq by intraperitoneal injection of CNO (0.025-0.05 mg/kg). Acute and lasting effects of enhanced astrocytic Ca2+ signaling on dendritic spine turnover are being examined by repeated *in vivo* imaging. Understanding the role of astrocytic Ca2+ activity in structural and functional synaptic plasticity is important as this could represent one of the mechanisms by which astrocytes participate in the cellular processes of learning and memory.

Title: Reduced rate of glutamate clearance by astrocytes at cortical excitatory synapses in a mouse model of familial hemiplegic migraine type 2

Authors: C. CAPUANI[1], A. TOTTENE[1], G. CRIVELLARO[1], P. PIZZO[1], M. MELONE[2], L. BRIGINA[2], G. CASARI[3], F. CONTI[2], *D. PIETROBON[1];
[1]Univ. Padova, Padova 35100, Italy; [2]Universita' Politecnica delle Marche, Ancona, Italy; [3]Universita' Vita Salute San Raffaele, Milano, Italy

Abstract: Loss-of-function mutations in ATP1A2, the gene encoding the α2 subunit of the Na+/K+-ATPase, cause familial hemiplegic migraine type 2 (FHM2), a rare subtype of migraine with aura. In the adult brain the α2 Na+/K+-ATPase is expressed almost exclusively in astrocytes. The α2 Na+/K+-ATPase protein is reduced to half in the brain of heterozygous FHM2 knockin (KI) mice carrying the human mutation W887R. Interestingly, these mice show a lower threshold for induction and a higher velocity of propagation of experimental cortical spreading depression (CSD), the phenomenon that underlies migraine aura and can initiate the headache mechanisms. The mechanisms underlying facilitation of experimental CSD in FHM2 KI mice are unknown. Given the key role of NMDA receptors in CSD ignition and propagation and the evidence that the α2 Na+/K+-ATPase and the glial glutamate transporters are colocalized in astrocytic processes surrounding cortical glutamatergic synapses, we investigated whether the rate of glutamate clearance by astrocytes is reduced in FHM2 KI mice as a consequence of the reduced density of α2 Na+/K+-ATPases. We measured the glutamate transporter current elicited in layer 1 astrocytes by extracellular stimulation in acute slices of barrel cortex from P22-23 wild-type (WT) and heterozygous W887R KI mice. The time course of the synaptically activated glutamate transporter current, which reflects the rate of glutamate clearance from the perisynaptic extracellular space, was slower in FHM2 KI compared to WT mice; the slowing down of glutamate clearance was larger after a train of action potentials at high frequency than after a single action potential. Immunogold electron microscopy of parietal cortex revealed that in FHM2 KI mice the density of glutamate transporters GLT1 is reduced in astrocytic processes contacting cortical excitatory synapses, and is unaltered in excitatory axon terminals. This suggests that a decreased density of GLT-1 transporters in perisynaptic astrocytic processes contributes to the reduced rate of glutamate clearance produced by the FHM2 mutation. Our data are consistent with the hypothesis that reduced rate of glutamate clearance at cortical excitatory synapses and consequent increased activation of NMDA receptors particularly during intense neuronal activity may contribute to the facilitation of CSD in FHM2.

Title: Astrocytic ALDH7A1 dysfunction in the pathophysiology of neuropsychiatric disorders

Authors: *T. E. FAUST[1,2], T. CASH-PADGETT[1], D. WOOD[1], S. ZOUBOVSKY[1], H. JAARO-PELED[1], A. SAWA[1];
[1]Psychiatry, [2]Neurosci., Johns Hopkins Univ. SOM, Baltimore, MD

Abstract: The function of astrocytes as supporting cells in the brain has long been recognized. However, astrocytes have increasingly been shown to affect neuronal signaling through glutamate uptake, release of gliotransmitters, regulation of extracellular K+ levels and maintenance of osmotic balance. Disruption of astrocyte function plays an important role in central nervous system (CNS) disorders. Recent studies have reported that aldehyde dehydrogenase 7a1 (ALDH7A1; also antiquitin) is enriched in astrocytes compared to other CNS cell types, although its function in astrocytes remains unknown. In non-CNS cells, ALDH7A1 plays a central role in the lysine degradation pathway. It also has been shown to protect against certain cell stressors including osmotic pressure and reactive oxygen species. Clinical studies have identified mutations in the human ALDH7A1 gene as the primary cause of pyridoxine-dependent epilepsy, a childhood form of epilepsy treated with high doses of pyridoxine. The loss of ALDH7A1 enzymatic activity in these patients results in buildup of the toxic intermediates piperideine-6-carboxylate and pipecolic acid which react with pyridoxal phosphate, depleting the brain of an important enzymatic co-factor. We found that ALDH7A1 is highly expressed in multiple astrocyte subpopulations in the adult mouse CNS. We have also found that expression of ALDH7A1 is decreased in biopsied neural tissues from patients with schizophrenia (SZ) and in the frontal cortex a mouse model of psychosis (PCP). Clinical evidence is suggestive of co-morbidity between SZ and epilepsy; functionally, these diseases are linked by alterations in neuronal excitability. In SZ, cognitive changes include working memory (WM) and/or frontal functional deficits influenced by oxidative stress. To study how decreased expression of ALDH7A1 may affect signaling in the brain, we have generated a conditional knockout mouse containing a floxed allele of Aldh7a1. Aldh7a1 knockout mice show reduced seizure threshold and deficits in spatial memory, sensorimotor gating, and forced swimming. Metabolomic analysis also revealed deficits in the lysine degration pathway. No change in GFAP reactivity was observed at baseline, but we found evidence of increased oxidative stress in astrocytes and reduced hippocampal parvalbumin immunoreactivity. We hypothesize that ALDH7A1 dysfunction renders astrocytes more susceptible to oxidative and osmotic stress, disrupting their ability to effectively modulate synaptic signaling and disturbing hippocampal excitatory-inhibitory balance. Through dietary intervention, we may attempt to prevent and/or reverse the observed deficits.

Title: Astrocytic modulation of striatal neurotransmission and endocannabinoid-signaling in Wistar rats

Authors: *L. ADERMARK, F. IVARSSON, A. LOTFI;
Addiction Biol. Unit, Gothenburg, Sweden

Abstract: Astrocytes are pivotal for optimal neurotransmission and participate in several aspects of synaptic functions ranging from trophic support to the fine-tuning of neurotransmission. The precise role of astrocytes in regulating synaptic properties and transmission, however, remains to be investigated. Previous research has shown that mice with a genetic deletion of the astrocyte-specific glutamate transporter GLAST display reduced alcohol preference and impaired endocannabinoid signaling at cortico-striatal synapses, indicating that astrocytes might be directly involved in regulating synaptic plasticity. Using slice electrophysiology, the aim of this study was thus to define the role of astrocytes in modulating synaptic activity and plasticity, with special focus on endocannabinoid-signaling in Wistar rats. Our data show that pretreatment with a low concentration of the glutamate transporter blocker DL-TBOA (200nM), which should act selectively on GLAST and GLT-1, slightly depresses evoked excitatory postsynaptic field potentials (fEPSPs) in the limbic prefrontal cortex, nucleus accumbens (nAc), the dorsolateral striatum (DLS) and the dorsomedial striatum (DMS) in acutely isolated brain slices from both juvenile and adult Wistar rats. Pre-treatment with DL-TBOA inhibited the robust depressant effect on fEPSP amplitude induced by the cannabinoid 1 receptor agonist WIN55,212-2 (1μM) in all brain regions tested. Administration of the mGluR2/3 antagonist LY 341495 (20nM) blocked the acute effect displayed by DL-TBOA on fEPSP amplitude, but did not restore the WIN55,212-2-induced depression. In addition, the astrocytic glycine transporter GlyT1 inhibitor Org24598 (200nM), which did not influence evoked fEPSPs, prevented the WIN55,212-2-induced depression in all brain regions tested. The acute effect displayed by ethanol (50mM) on fEPSC amplitude was not affected by pre-treatment of either DL-TBOA or ORG24598 in any brain region. The data presented here suggests that astrocytes are recruited during endocannabinoid-signaling and that astrocytic transporters may regulate neurotransmission and synaptic plasticity mechanisms in both cortical and striatal subregions.

Title: 3D Ca^{2+} imaging provides new insight into the biology of astrocytes

Authors: E. BINDOCCI[1], N. LIAUDET[1], I. SAVTCHOUK[1], C. DÜRST[1], D. BECKER[1], A. AGARWAL[2], D. E. BERGLES[2], *A. VOLTERRA[1];
[1]Univ. of Lausanne, Lausanne, Switzerland; [2]Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Recent studies highlight the existence in astrocytes of a highly diverse gamut of Ca^{2+} dynamics, suggestive of complex functional roles. A single astrocyte exhibits Ca^{2+} signals that range (a) spatially: from “microdomain” events, occurring at focal locations (1-4 μm) along processes, to “expanded” events occupying large portions of a process, to events involving also the cell body; (b) temporally: from rapid sub-sec transients to prolonged multi-sec elevations, occurring either asynchronously or in a more coordinated fashion (reviewed in Volterra et al, Nature Rev Neurosci, 15:327-335, 2014). Despite these key advances, understanding of astrocyte biology is still importantly limited by Ca^{2+} activity being sampled from a single focal plane, which unavoidably loses the 3D+time cell context. Astrocytes have intrinsic 3D complexity, with only a small cell portion remaining confined to any given optical plane. Moreover, they lack any clearly defined compartments (like neuronal spines), yet possess multiple processes that contact blood vessels, synapses, and other neighboring cells along variable 3D trajectories. Our goal here has been to capture astrocytic Ca^{2+} activity in its real 3D context of sub-cellular morphology and neighborhood connectivity. To this end, we equipped a two-photon microscope with piezoelectric actuator and acousto-optic deflector. Thereby, using combined Ca^{2+}-sensitive and Ca^{2+}-insensitive indicators, we could image the full volume of single functioning hippocampal astrocytes in adult (P30-60) mouse brain slices exhibiting endogenous firing activity and observe astrocytic Ca^{2+} dynamics in their 3D cell context. In parallel, we developed a dedicated analysis framework able to handle the “big data” generated from 3D+t multispectral acquisitions. As a result, we observed several types of Ca^{2+} events that expanded differentially across the 3D astrocyte. Such events were affected by agents modifying neuronal firing (e.g. TTX and 4-AP). Importantly, a large proportion of this astrocytic Ca^{2+} activity would have been missed or incompletely reported with current 2D approaches, even using the “best case” 2D focal plane. These data suggest that classic somatic recordings, still often used to study and interpret astrocyte biology, do not faithfully reflect or predict the 3D Ca^{2+} activity of an astrocyte. As an example, in our conditions, activity at processes contacting blood vessels was largely dissociated

from somatic activity. In conclusion, our 3D Ca^{2+} imaging approach provides relevant new insight towards correct understanding of astrocyte biology.

Title: Expansion of astrocytic processes and reduction of extracellular space volume through activation of β-adrenergic receptors in rat visual cortex

Authors: *A. D. SHERPA[1], F. XIAO[1], N. JOSEPH[2], C. AOKI[3], S. HRABETOVA[1]; [1]Dept. of Cell Biol., SUNY Downstate Med. Ctr., Brooklyn, NY; [2]Herrick High Sch., New Hyde Park, NY; [3]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Previous results using cultured astrocytes indicate that astrocytes respond to β-adrenergic agonists by changing morphology. Within intact neuropil, this response could facilitate synaptic spillover of neurotransmitters and neuropeptides, thereby enhancing interactions among adjacent neurons and astrocyte endowed with corresponding receptors. We hypothesized that β-adrenergic agonist-induced alteration in the morphology of astrocytic processes impacts upon structural parameters of brain extracellular space (ECS). Brain ECS is a narrow interconnected channel that surrounds brain cells. The two macroscopic parameters - volume fraction (α) and tortuosity (λ) govern the spatiotemporal distribution of substances, including metabolites, signaling molecules, and drugs in the ECS. Volume fraction is the ECS volume, relative to the total tissue volume. Tortuosity is a measure of the hindrance that molecules experience in the ECS, compared to a free medium. We tested our hypothesis by assessing the change in morphology of astrocytic processes within acutely prepared visual cortical slices of adult female rats treated with or without a β-adrenergic agonist, DL-isoproterenol (2 μM) (ISO) for 70 min. Electron microscopy (EM) was used to analyze the neuropil ultrastructure, while kept blind of the drug-treatment condition. The total cytoplasmic area (μm2) of astrocytic processes per micrograph (kept constant at 48.43 μm2) increased significantly, relative to control [1.31 + 0.08 (126); mean ± SEM (number of micrographs) for control; 2.02 ± 0.21 (84) with ISO]. The total plasma membrane length (μm) of astrocytic processes per micrograph significantly increased from a control value of 21.47 ± 0.89 (126) to 29.11 + 1.54 (84) with ISO. The total number of astrocytic profiles per micrograph significantly

increased from 14.75 ± 0.55 (126) in the control condition to 19.55 ± 1.07 (84) with ISO. Values of α and λ were measured in visual cortex with ISO using the real-time iontophoretic (RTI) method. The ECS volume decreased from 0.22 ± 0.01 (mean ± SD; n = 17 records in 5 animals) in the control condition to 0.18 ± 0.01 (n = 23 records in 5 animals) with ISO, while tortuosity remained constant at [1.63 ± 0.01 (n = 17 records in 5 animals) for control; 1.62 ± 0.01 (n = 23 records in 5 animals) with ISO]. Since noradrenergic volume transmission is elevated during the awake state, these findings suggest that one way the awake state, boosted by adrenergic signal, decreases α is through increases in astrocytic volume. The decrease in α would increase ECS concentration of neurotransmitter and neuromodulators, which could facilitate neuronal communication in the visual cortex.

Title: Changes to AMPAR-mediated glutamatergic signaling at neuron-glia synapses in developing corpus callosum

Authors: ***B. T. KULA**[1], A. HOVHANNISYAN[1,2], T.-J. CHEN[1], B. NAGY[1], M. KUKLEY[1]; [1]Neuron Glia Interactions, Werner Reichardt Ctr. For Integrative Neurosci., Tuebingen, Germany; [2]Biol. Sci., Univ. of California, Santa Cruz, CA

Abstract: Majority of oligodendrocytes in rodents rise during first postnatal weeks from oligodendrocyte precursor cells (OPCs) - a population of progenitors widespread through grey and white matter regions of central nervous system. After the end of myelination OPCs remain in the tissue where they occupy repulsion-driven domains. White matter OPCs come into contact with axons and receive glutamatergic synaptic input mediated mainly by AMPA receptors. Up to now electrophysiological properties of axon-OPC connections were investigated in juvenile and adult animals. However, many studies employed different approaches making direct comparisons of these properties difficult. Additionally, morphological changes of OPCs during development are poorly known. Our work aims at addressing those questions in developing mouse corpus callosum. We employed whole-cell voltage clamp combined with axonal electrical stimulation to investigate properties of callosal neuron-OPC signaling at 3 key developmental ages: P8-11 - callosal OPCs are mainly proliferating, myelination is sparse; P19-22 - peak of callosal

myelination; P50-53 - myelination is largely completed. First, we investigated pre- and postsynaptic properties of neuron-OPC synapses. Our results indicate no changes to kinetics of axon-glia currents, a modest increase in their amplitude and a drop in the release probability as the animals progress in age. Additionally, current-voltage relationship showed little rectification at the youngest age, while an increase in rectification was observed at older ages indicating downregulation of the GluA2 subunit. To address changes in OPC morphology we crossed ROSAmT/mG line carrying membrane-tagged tdTomato/EGFP with NG2CreERTM line carrying tamoxifen-inducible Cre recombinase under NG2 promoter. Upon 4-hydroxytamoxifen (4-TM) administration the mT cassette is deleted allowing expression of mG cassette specifically in OPCs and their progeny. Animals were sacrificed 3 days post 4-HT injection. Confocal image stacks were acquired with 63x magnification and individual OPCs were traced and analyzed with Neurolucida software. We observed differences in cell domain sizes, process structure and complexity. Our findings indicate that OPCs change their physiological and morphological properties during callosal development. Remarkably high variability of many investigated parameters suggests that within each age group OPC population constitutes of cells at different stages of maturation.

Title: Astrocytic K+ buffering as a mechanism to modulate neuronal oscillations

Authors: ***J. W. MORLEY**, Y. BUSKILA;
Univ. of Western Sydney, Sydney, Australia

Abstract: Different behavioural states are associated with different neural network oscillation frequencies (waves) in the brain. Transition between these states is accompanied with changes in neuronal resonance frequency. One of the major questions in neuroscience is how the activity of single neurons, each with a preferred membrane resonance frequency, can lead to network oscillations. It is clear that this is the result of the responses of multiple neurons being synchronised, but it is unclear exactly how this happens. Furthermore, the mechanism underlying the transition between the different oscillation frequencies remains largely unknown. We have explored the potential involvement of astrocytes in the modulation of neural network

oscillations. As astrocytes form a multicellular network through their intracellular connections, they are in a position to convey local modifications from single neurons and spread them through their glial network to modulate neuronal network behaviour. Moreover they can modulate excitability of neurons by changing the concentration of potassium ions [K+] in the extracellular environment. Using selective inhibition of the K+ influx through astrocytes, we show that increased extracellular K+ concentration can modulate the biophysical properties of individual neurons such as excitability, synchronization and oscillation frequency. As astrocytes are the only cells in the brain capable of K+ buffering through their intracellular connections (gap junctions), our study indicates that modulation of their inherent capabilities to clear K+ from the extracellular milieu is a potential target to impact neural oscillations and thus tuning brain waves.

Title: Potassium efflux through postsynaptic NMDA receptors suppresses astrocytic glutamate uptake

Authors: *O. TYURIKOVA[1], P.-Y. SHIH[2], L. SAVTCHENKO[3], D. RUSAKOV[3,1], A. SEMYANOV[1];
[1]Neurosci. Ctr. of the Inst. of Biol. and Biomedicine, Univ. of Nizhny Novgorod, Nizhniy Novgorod, Russian Federation; [2]Purdue Univ., West Lafayette, IN; [3]UCL Inst. of Neurol., London, United Kingdom

Abstract: Potassium ions accumulate in the synaptic cleft of glutamatergic synapses during repetitive activity. We have recently demonstrated that the bulk of these ions is contributed by potassium efflux through postsynaptic NMDA receptors (Shih et al., 2013). Potassium mediated depolarization of presynaptic terminal increases glutamate release probability. Here we investigated the effect of potassium accumulation on astrocytic glutamate uptake because glutamate transporters are both electogenic and potassium-dependent. We recorded glutamate transporter currents in CA1 str.radiatum astrocytes of mouse hippocampal slices in response to electrical stimulation of Schaffer collaterals or local glutamate uncaging. Increases in the extracellular potassium concentration from 2.5 mM to 7.5 mM or 20 mM significantly reduced

the amplitude of uncaging induced transporter currents. In addition, we observed substantial potassium mediated membrane depolarization in current-clamped astrocytes. Mimicking this depolarization in voltage-clamp mode reduced the transporter current to the same extent, reflecting the fact that astrocytic depolarization but not potassium dependence of glutamate transporters suppresses glutamate uptake during potassium accumulation. Repetitive stimulation of Schaffer collaterals (5 stimuli at 50 Hz) produced progressively increasing peaks of transporter currents. This increase was suppressed by 50 μM D-APV, NMDA receptor antagonist. This finding is consistent with our previous results showing the increase in glutamate release probability due to NMDA receptor mediated potassium efflux. However, we also found that D-APV reduced the progressive increase in the decay time of the transporter currents produced by repetitive stimulation. This is consistent with NMDA-receptor dependent reduction of glutamate uptake. Our observations were consistent with predictions of a detailed biophysical model. We suggest that the NMDA receptor dependent accumulation of intracleft potassium during repetitive synaptic activity could inhibit local glutamate uptake, which could potentially extend glutamate dwell-time in the synaptic cleft thus boosting glutamate spillover effects. Abstract: Aquaporin-4 (AQP4), the most abundant water channel in brain, plays a crucial role in brain water homeostasis. In mice, AQP4 expression is restricted to ependymal cells and astrocytes, being highly concentrated in astrocytic endfoot membranes at the brain-blood and

brain-cerebrospinal fluid interfaces. The subcellular distribution of AQP4 in the human cortex is poorly characterized. Here we performed a high resolution immunogold analysis of AQP4 expression in non-lesional cortical tissue resected from 12 patients with temporal lobe epilepsy (n=9), aneurism (n=2) or tumor (n=1), and compared data with those obtained in adult mice. Immediately after resection the tissue was immersed into a fixative containing 4% paraformaldehyde and 0.25% glutaraldehyde. Tissue blocks were subjected to freeze substitution, embedded in Lowicryl HM20 resin and processed for postembedding immunogold cytochemistry. In human subjects the AQP4 distribution pattern mimicked that of mice, but showed much higher immunogold labeling densities over perivascular astrocytic endfoot membranes. We present AQP4 immunogold data for endfeet at different segments of the vasculature and compare AQP4 polarization between the two species.

Title: Abnormal astrocytic Ca^{2+} signaling in the sclerotic hippocampus of awake mice: a two-photon imaging study using the intracortical kainate injection model of mesial temporal lobe epilepsy

Authors: *R. ENGER[1,4], K. HEUSER[4], C. NOME[4], W. TANG[2], V. JENSEN[2], P. J. HELM[2], K. VERVAEKE[3], P. BEDNER[5], C. STEINHÄUSER[5], E. TAUBØLL[4], E. A. NAGELHUS[2]; [2]Inst. of Basic Med. Sci., [3]Dept. of Biosci., [1]Univ. of Oslo, Oslo, Norway; [4]Dept. of Neurol., Oslo Univ. Hospital, Rikshospitalet, Oslo, Norway; [5]Univ. of Bonn, Inst. of Cell. Neurosciences, Bonn, Germany

Abstract: A growing body of evidence links astrocytes to epileptogenesis and epilepsy. Astrocytic Ca2+ signals are elevated several days after status epilepticus and could contribute to neuronal death as well as seizure formation by facilitating Ca2+ dependent glutamate release. The aim of this study was to characterize astrocytic Ca2+ dynamics in mice with chronic

epilepsy. We used the unilateral intracortical kainate injection model of mesial temporal lobe epilepsy (Bedner P et al., Brain 2015 May;138(Pt 5):1208-22) and *in vivo* two-photon microscopy. Non-injected and sham operated mice served as controls. Three months after kainate injection the genetically encoded Ca2+ indicator GCaMP6f was delivered by recombinant adeno-associated virus (rAAV) injection, using the GFAP promoter to drive expression in astrocytes. Subsequently chronic cranial windows to the CA1 region of the hippocampus were made, enabling repetitive two-photon imaging recordings of astrocytic Ca2+ dynamics in awake, head-fixed mice resting and running on a spherical treadmill. Initial observations revealed a highly abnormal astrocytic Ca2+ signaling pattern in the sclerotic, epileptic hippocampus compared to the hippocampus of control mice. Specifically, we observed a prominent increase in basal Ca2+ fluctuations, as well as frequent, long-lasting Ca2+ transients of high amplitude that involved whole astrocytic territories. In some cases Ca2+ waves spread to several neighboring astrocytes. We conclude that astrocytic Ca2+ dyshomeostasis is a prominent feature in chronic experimental mesial temporal lobe epilepsy.

Title: Lactate dehydrogenase is an electrical regulator in astrocyte-neuron lactate shuttle of the hippocampus

Authors: ***T. INOUE**, N. SADA;
Okayama Univ., Okayama, Japan

Abstract: Lactate dehydrogenase (LDH) is an enzyme located in the astrocyte-neuron lactate shuttle, a metabolic pathway that transports lactate from astrocytes to neurons in the brain. In the lactate shuttle, glucose is first transported into astrocytes, and converted to lactate via LDH. The lactate is then released and transported into neurons, and converted to pyruvate via LDH. In this study, we examined effects of LDH inhibition on membrane potentials in CA1 pyramidal cells, using patch-clamp recordings from hippocampal slices. Our recordings revealed that pyramidal cells were hyperpolarized by bath application of oxamate, an LDH inhibitor. The hyperpolarization was reversed by the downstream metabolite (pyruvate), but not by the

upstream metabolite (lactate). In contrast to pyramidal cells, the hyperpolarization caused by LDH inhibition was not observed in inhibitory fast-spiking cells. EPSCs in pyramidal cells were also reduced by LDH inhibition, whereas IPSCs were hardly changed. Thus, the excitatory components (pyramidal cells and EPSCs) in the hippocampus are strongly responsive to LDH inhibition. We then made double patch-clamp recordings from pyramidal cells and astrocytes, and applied the LDH inhibitor only into astrocytes via the patch pipette. The LDH inhibition in astrocytes hyperpolarized neighboring pyramidal cells. The hyperpolarization was not observed in the presence of extracellular lactate, which further supports electrical regulation by the lactate shuttle. These results show that pyramidal cells in the hippocampus can be electrically regulated by LDH enzymes in the astrocyte-neuron lactate shuttle.

Title: Astrocyte glutamate and metabolic abnormalities in Juvenile Batten Disease

Authors: ***M. BOSCH**, T. KIELIAN;
Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Juvenile Neuronal Ceroid Lipofuscinosis (JNCL) is a neurodegenerative lysosomal storage disease caused by a mutation in *CLN3*. Children with JNCL experience progressive visual, cognitive, and motor deterioration with a decreased life expectancy (late teens-early 20s). There is currently no effective treatment for children with JNCL. Studies have shown that astrocyte activation precedes and predicts regions of neuronal loss in JNCL, suggesting alterations in supportive glial functions. Glutamate is elevated in JNCL brains and neuronal loss is hypothesized to result, in part, from glutamate excitotoxicity. Astrocytes are responsible for removing glutamate at the synapse and regulating neuronal activity. Currently, little is known about aberrant glutamate cycling in astrocytes during JNCL progression. Studies conducted in our laboratory utilizing $CLN3^{\Delta ex7/8}$ mice, which harbor a 1.02 kb mutation spanning exons 7 and 8 (the most common mutation found in ~85% of JNCL patients), have revealed a significant decrease in glutamine synthetase in the $CLN3^{\Delta ex7/8}$ brain. Additionally, expression of the glutamate transporter GLAST was significantly reduced in multiple brain regions of $CLN3^{ex7/8}$ mice. From these results, we hypothesized that CLN3 is critical for maintaining glutamate cycling pathways and homeostatic communication between astrocytes and neurons. Recent data

from our laboratory has shown that glutamate transporter expression and function is significantly decreased in primary $CLN3^{ex7/8}$ astrocytes following exposure to stimuli elevated in the JNCL brain (i.e. TNF-α and IL-1β or ceramide and neuronal lysate). A role for CLN3 in astrocyte metabolism was demonstrated by the finding that $CLN3^{\Delta ex7/8}$ astrocytes had significantly lower levels of basal mitochondrial respiration, ATP production, and maximal respiration under resting conditions. These differences were further exacerbated when $CLN3^{\Delta ex7/8}$ astrocytes were treated with TNF-α and IL-1β or ceramide and neuronal lysate. Glutamate regulation is an energy-demanding process and disruptions in metabolic pathways could further disrupt glutamate cycling. Accordingly, our findings revealed decreased Ca^{2+} signaling in $CLN3^{\Delta ex7/8}$ astrocytes that was coupled with heightened $CLN3^{\Delta ex7/8}$ neuron activity, suggesting that aberrant glutamate cycling disrupts vital homeostatic signaling networks. Further elucidation of the key regulatory mechanisms that are involved in astrocyte-neuron cross-talk during JNCL will be critical to understanding disease progression and may ultimately unveil novel therapeutic targets that will extend the quality-of-life for children suffering from JNCL.

Title: Astroglial type-1 cannabinoid receptors (CB1) are necessary for object recognition memory and synaptic plasticity

Authors: *L. M. ROBIN[1,2], J. F. OLIVEIRA DA CRUZ[1,2,3], V. C. LANGLAIS[1,2], A. BUSQUETS-GARCIA[1,2], E. SORIA-GOMEZ[1,2], F. DRAGO[3], A. PANATIER[1,2], F. GEORGES[2], M. METNA-LAURENT[1], S. OLIET[1,2], G. MARSICANO[1,2];

Abstract: Astrocytes express a wide variety of G protein-coupled receptors (GPCR) that can influence cognitive functions such as learning and memory. Cannabinoids and endocannabinoids modulate memory processes through the GPCR CB_1 receptor. Similarly to neurons, astrocytes express functional CB_1 receptors capable of modulating the effects of exogenously administered cannabinoid agonists on hippocampal synaptic plasticity and working memory. However, the physiological roles of astroglial CB_1 receptor in long-term memory and synaptic plasticity remain unknown. Here, we show that the conditional genetic deletion of CB_1 receptor in astrocytes (GFAP-CB_1-KO mice) impairs both *in vitro* and *in vivo* hippocampal N-methyl-D-Aspartate receptor (NMDAR)-dependent long-term potentiation (LTP) induction and long-term

object recognition memory. Notably, administration of D-serine, a NMDAR) co-agonist, which is released by astrocytes, restores the long-term memory deficit and the induction of LTP in our mutant mice. Finally, GFAP-CB_1-KO mice present strongly reduced occupancy of the co-agonist binding site of NMDARs. Thus, astroglial CB_1 receptors are necessary for long-term memory and the induction of NMDAR-dependent LTP, via the modulation of the occupancy of the NMDAR co-agonist binding site. This study reveals an unexpected role for astroglial CB_1 receptors in neural information processing and memory formation.

Title: The role of astrocytic versus neuronal cannabinoid receptors in developmental plasticity of the visual cortex

Authors: *R. MIN[1], B. LUTZ[2], G. MARSICANO[3], C. N. LEVELT[1];
[1]Mol. Visual Plasticity group, Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [2]Inst. of Physiological Chem., Univ. Med. Ctr. of the Johannes Gutenberg Univ., Mainz, Germany; [3]Endocannabinoids and Neuroadaptation, INSERM U862 NeuroCentre Magendie, Bordeaux, France

Abstract: Endocannabinoids are small lipid signaling molecules involved in synaptic plasticity. They are ligands for the cannabinoid CB1 receptor, and play an important role in the postnatal refinement of synaptic connections in the sensory cortex. As a consequence, interfering with endocannabinoid signaling in young animals leads to aberrant sensory map formation. At the synaptic level, endocannabinoids are thought to regulate sensory plasticity by mediating a developmental form of long-term synaptic depression (LTD) at both excitatory and inhibitory synapses. Previous studies have suggested that CB1 receptors on (PV-positive) interneurons in the visual cortex are crucial for a developmental form of LTD of inhibitory synapses (i-LTD). Furthermore, the ability of inhibitory synapses to show i-LTD was suggested to be related to the presence of ocular dominance (OD) plasticity during the critical period in developing visual cortex. Therefore, we tested whether removal of CB1 receptors specifically from interneurons would interfere with critical period OD plasticity. Surprisingly, we found that the OD shift in

primary visual cortex observed after three days of monocular deprivation of the contralateral eye was fully intact in interneuron specific CB1 receptor knockout mice. Interestingly, we and others have recently shown that astrocytes express functional CB1 receptors, and that these astrocyte CB1 receptors are involved in some forms of endocannabinoid mediated LTD. In line with this, we find that astrocytes in the developing visual cortex respond to cannabinoid receptor activation with increased calcium signaling, indicating that they express functional CB1 receptors. We are currently testing whether specific removal of astrocyte CB1 receptors affects OD plasticity and LTD in primary visual cortex. With these experiments we will determine whether neuronal or astrocytic CB1 receptors control developmental visual cortex plasticity.

Title: Somatostatin and parvalbumin interneuron signalling to astrocytes

Authors: L. MARIOTTI[1], G. LOSI[1], M. SESSOLO[1], I. MARCON[1], S. BOVETTI[2], T. FELLIN[2], *G. CARMIGNOTO[1];

Abstract: The reciprocal communication between neurons and astrocytes represents a fundamental mechanism for the control of brain functions. While astrocyte interplay with excitatory glutamatergic neurons has been intensively studied, many fundamental aspects of neuron-astrocyte partnership remain unexplored. Indeed, whether the information gained from the tripartite glutamatergic synapse can be extended to the other large family of synapses in the

brain, the inhibitory GABAergic synapse, is unclear at present. We here reveal that in somatosensory cortex (SSCx) slice preparations, obtained from P15-P22 mice after loading with the Ca2+ indicator Fluo-4 AM and the astrocytic marker SR101, astrocytes exhibited repetitive Ca2+ elevations in response to challenge with GABA or the GABAB receptor agonist Baclofen applied in the presence of Tetrodotoxin (TTX, 0.5 μM). Most importantly, similar responses were observed in astrocytes from the somatosensory cortex of young adult mice (P35-40) in both slice and *in vivo* preparations. We also used optogenetic techniques to investigate the specific response of astrocytes to synaptic GABA release. To this aim, the expression of the light-gated channel channelrhodopsin-2 (ChR2) in Parvalbumin (Pv) or Somatostatin (Som) interneurons was induced by injecting AAV vectors carrying the doublefloxed ChR2 sequence in Pv- or Som-Cre mice at postnatal day 0-2. Blue light illumination (λ=473 nm) was used to selectively activate Pv or Som interneurons expressing virally delivered ChR2. In two-photon laser-scanning microscope experiments in SSCx slice preparations we found that a selective optogenetic activation of Som or Pv interneurons (20÷200 ms pulse duration; 1 Hz for 30÷60s; illuminated area 0.33 mm2; mean power 38 mW/mm2) evoked Ca2+ events in astrocytes at the level of soma, proximal and distal processes. We also investigated whether GABA released from individual GABAergic interneurons can be sufficient to activate neighbouring astrocytes. We found that an intense AP firing induced in individual Pv or Som interneurons by depolarizing intracellular current pulses (200-300 pA for 100 ms at 0.5-1Hz) evoked Ca2+ elevations in neighbouring astrocytes. GABA-mediated inhibition represents a fundamental operational mechanism in the brain and GABAergic interneurons are possibly involved in the pathophysiology of many brain disorders, including epilepsy. The specific signaling between specific GABAergic interneuron populations and astrocytes open up new perspectives in our understanding of the astrocyte role in the brain.

Title: Role of astrocytic coupling in rhythmogenesis in rat trigeminal neurons involved in mastication

Authors: *S. CONDAMINE[1], R. LAVOIE[2], A. KOLTA[1];
[1]Dept. de Neurociences, Univ. De Montréal, Montreal, QC, Canada; [2]Douglas Mental Hlth. Res. Inst., Montréal, QC, Canada

Abstract: Neurons in the dorsal part of the trigeminal main sensory nucleus (NVsnpr) have intrinsic bursting properties. Because they receive sensory inputs and project to motoneurons, they have been postulated to form the rhythmogenic core of the masticatory CPG. In absence of Ca2+, bursting is spontaneous in NVsnpr neurons, but in presence of Ca2+ it can be induced by local application of NMDA or electrical stimulation of sensory inputs. Riluzole impairs neuronal bursting induced under all of these conditions, demonstrating the involvement of a voltage-dependent sodium persistent current (INaP), which is modulated by the extracellular Ca2+ concentration ([Ca2+]e). Our previous work shows that S100β, an astrocytic Ca2+ binding protein, decreases [Ca2+]e and induces INaP dependent bursting in neurons. Blockade of S100β or inactivation of astrocytic networks with intracellular dialysis of BAPTA prevents bursting in neurons .These data raise the hypothesis that astrocytic coupling may play an important role in rhythmogenesis. To test this hypothesis, we first investigated whether coupling is modulated by stimuli that induce neuronal bursting in NVsnpr using biocytin filling of astrocyte during patch clamp recordings. Little coupling was observed between NVsnpr astrocytes when no treatment was applied during recording. Networks observed under control conditions (n=14) had an average area of 19374 ± 6973 μm2, and were composed of 9± 3 cells. Electrical stimulation of sensory fibers projecting to NVsnpr induced membrane depolarisation in 11/17 astrocytes tested. Networks associated to responding astrocytes (n=11) had an average area of 35427 ± 13248 μm2 and counted 16 ± 7 cells. Those not showing a depolarisation (6/17) were composed of 8 ± 3 cells and had an average area of 32502 ± 19686 μm2. Local NMDA applications were also associated to large membrane depolarisation and increased coupling (29 ± 3 cells; average area: 85655 ± 15962μm2). Similar increases in coupling were observed when lowering [Ca2+]e (n=31; 32 ± 31cells; average area:55816 ± 49749μm2). All astrocytic networks remained confined to the dorsal part of NVsnpr, and within this area, adjacent networks revealed in double dye filling experiments did not overlap. Bath application of carbenoxolone (20μM), a large connexin inhibitor, inhibited coupling under all conditions and disrupted NMDA-induced neuronal bursting. Bursting was restored by local application of S100β. These results suggest that astrocytes are organized in non-overlapping networks that are regulated by sensory inputs and that these networks are necessary for neuronal bursting.

Title: Unique Ca^{2+} responses of subpial and perivascular astrocytic endfeet to hypo-osmotic stress: a two-photon imaging study using acute cortical slices from adult mice

Authors: *M. EILERT-OLSEN[1], V. JENSEN[1], R. ENGER[2], P. J. HELM[1], T. WANNAN[3], A. E. THOREN[1], E. A. NAGELHUS[1,2,3];

Abstract: Being encased in the rigid skull the brain must possess mechanisms for effective volume control. Astrocytic endfoot processes form the outermost layer of nervous tissue and are thus strategically positioned to regulate the movement of solutes and water between the parenchyma and the extracerebral liquid compartments, e.g. cerebrospinal fluid and blood. Astrocytic Ca2+ signals have been implicated in brain volume homeostasis, but endfoot Ca2+ signals are poorly characterized. The advent of ultrasensitive genetically encoded Ca2+ indicators have enabled investigation of Ca2+ signaling in cellular microdomains, including astrocytic endfeet. Here we used two-photon microscopy to assess the Ca2+ response of astrocytic somata, fine processes and endfeet in adult mouse cortical slices subjected to 20% reduction of artificial cerebrospinal fluid osmolarity. Astrocytic Ca2+ signals were detected by GCaMP6f delivered by recombinant adeno-associated virus 2-4 weeks prior to imaging. Lowering external osmolarity elicited a 4-5 fold increase in the frequency of Ca2+ signals in astrocytic endfeet bordering pia mater and ensheathing cortical blood vessels, whereas Ca2+ signaling in fine astrocytic processes within the neuropil was only moderately elevated. In contrast, the frequency of Ca2+ signals in astrocytic somata remained unchanged. The pattern of Ca2+ signals differed between subpial and perivascular endfeet. Specifically, oscillatory Ca2+ signals were only observed in endfeet underneath the pia. In mice deficient in dystrophin, a crucial component of the aquaporin-4 anchoring complex in endfoot membranes, the Ca2+ response to hypo-osmotic stress was significantly reduced only in subpial endfeet. We conclude that astrocytic endfeet at the brain-CSF and brain-blood interfaces display unique Ca2+ responses to hypo-osmotic stress, and that subpial and perivascular endfeet differ in Ca2+ signaling.

Title: Volume dynamics of astroglial endfeet during cortical spreading depression in adult mice: an *in vivo* two-photon imaging study

Authors: *D. B. DUKEFOSS[1], B. ROSIC[1], V. JENSEN[1], A. THOREN[1], R. ENGER[1,2], E. A. NAGELHUS[1,2];
[1]Dept. of Mol. Med., Univ. of Oslo, Inst. of Basic Med. Sci., OSLO, Norway; [2]Dept. of Neurol., Oslo Univ. Hosp., Oslo, Norway

Abstract: Cortical spreading depression (CSD) is a slowly propagating wave of almost complete grey matter depolarization followed by temporary EEG silencing. The phenomenon is thought to underlie the migraine aura and is associated with neuronal swelling and profound increase in extracellular glutamate and potassium. During CSD arterioles contract despite that the parenchyma is severely metabolically stressed and in need for enhanced oxygen and glucose supply. The aim of this study was to investigate volume dynamics of perivascular endfeet in CSD, as endfoot volume dyshomeostasis could contribute to vascular uncoupling and tissue metabolic stress. CSD was evoked by focal epidural application of KCl in a distant separate craniotomy to the imaging window. Astrocytic endfeet were imaged in anesthetized mice expressing enhanced green fluorescent protein under the astrocyte specific Glt1-promoter. The vasculature was outlined by Texas Red-labelled dextran. Two-photon microscopy revealed that the initial arteriolar contraction in CSD was accompanied by a profound increase in cross-sectional area of periarteriolar endfeet. Our data suggest that astrocytic endfoot volume dyshomeostasis occurs in CSD.

Title: A computational model of purinergic modulation of synaptic transmission by astrocytes

Authors: *A. G. PILLAI, S. NADKARNI;
Computat. Neurobio. Lab., IISER Pune, Pune, India

Abstract: Recent studies suggest ATP release from glial cells as a potential mechanism through which astrocytes are able to influence synaptic transmission. However, the contribution of ATP, to ongoing activity, unlike glutamate, is quite difficult to quantify. This is due to the presence of multiple receptor subtypes which lack specific antagonists and the relatively large diversity in their time profile. In the present study we develop a biophysically detailed model of gliotransmitter release from astrocytes that is in agreement with experimental data. Further we investigate synaptic modulation at a hippocampal synapse by ATP and glutamate released from astrocytes in a computational model of a tripartite synapse. Activity in glutamatergic hippocampal synapses during different behavioral stages range from a fraction of hertz to tens of hertz. This leads to distinct levels of ambient glutamate that can activate astrocytes causing them, in turn, to release gliotransmitters like glutamate and ATP. Via both ionotropic and metabotropic receptors, ATP and adenosine target presynaptic calcium and potassium currents, modulate neuronal excitability and synaptic transmission. Separately, presence of purine receptors in astrocytes sets in a feedback loop that alters IP3 coupled calcium release from these cells. How do these neurotransmitters and gliotransmitters either independently or synergistically regulate synaptic transmission? Our model describes astrocytic modulation of synaptic transmission in response to ongoing 1) Basal 2) Medium 3) High frequency activity. Our computational paradigm gives valuable insights into purinergic modulation of synaptic plasticity by astrocytes.

Title: *In vivo* exosome-mediated transfer of microRNA from neuron to astroglia

Authors: ***N. H. BOWENS**, J. YELICK, Y. YANG;
Tufts Univ., Boston, MA

Abstract: Neuron to astrocyte signaling is essential for functional tripartite synapses in the mammalian central nervous system. Accumulating evidence has emerged that miRNAs are packed into exosomes that are secreted into the extracellular space from the multivesicular body. This has been considered a new intercellular communication mechanism. Previous evidence in our lab showed that neurons up-regulate the expression of GLT-1 protein via exosomal transfer of microRNA 124 (miR-124). However, exosome mediated transfer of miRNA has not been demonstrated *in vivo*. Here we investigated miRNA transfer from spinal cord motor neurons to

astrocytes using retrograde transport of labeled miRNAs in astrocyte reporter BAC-ALDH1L1-eGFP and EAAT2-tdTomato transgenic mice. Labeled miRNAs are mixed with fluoro-Gold and are injected into the sciatic nerve of the hind limb. We examined spinal cord sections 7d, 14d, and 21d post-injection. Interestingly, we found labeled miRNAs in extracellular space. Some of the labeled miRNAs are overlapped with eGFP or tdTomato labeled astrocytes. In addition, we performed immunogold EM of cd63, a membrane marker of exosomes on brain sections and identified exosome structure near post-synaptic dendritic spines. Overall, our current study provides *in vivo* evidence for exosome mediated transfer of miRNAs from neurons to astrocytes.

Title: Neurons diversify astrocytes in the adult brain through Sonic Hedgehog signaling

Authors: *W. T. FARMER[1], T. ABRAHAMSSON[1], S. CHIERZI[1], C. LUI[1], E. JONES[1], B. PONROY[1], J. PENG[2], F. CHARRON[2], P. SJOSTROM[1], K. MURAI[1];
[1]Ctr. for Res. in Neurosci., McGill Univ., Montreal, QC, Canada; [2]Mol. Biol. of Neural Develop., Inst. de Recherches Cliniques de Montréal, Montreal, QC, Canada

Abstract: Astrocytes play key roles in the healthy brain from regulating extracellular neurotransmitter/ion homeostasis and synaptic plasticity to controlling neurovascular coupling. The ability of astrocytes to fulfill such diverse responsibilities relies on their heterogeneous molecular and physiological profiles. However, the source of astrocyte heterogeneity in the mature brain and the mechanisms involved remain poorly understood. We examined gene expression databases for signaling pathways that were differentially expressed in astrocytes to uncover the origin astrocyte heterogeneity. We found that the genes necessary for the reception

of the morphogen Sonic Hedgehog (Shh) were expressed at high levels in specific populations of astrocytes in the adult brain while other astrocyte expressed lower levels. We also found that the secreted ligand Shh is expressed by neurons throughout the adult brain. These expression patterns indicate that the Shh pathway could be a novel mode of neuron to astrocyte communication. To understand the importance of the Shh pathway in regulating the properties of adult astrocytes *in vivo*, we utilized conditional loss- and gain-of-function genetic tools for Shh pathway components coupled with 2-photon imaging, neurotransmitter uncaging, whole-cell electrophysiology, and quantitative RT-PCR (qRT-PCR). We found that increasing and decreasing the activity of the Shh pathway in the mature brain led to bi-directional changes in the expression of key astrocyte molecules that mediate neurotransmitter detection, neurotransmitter uptake, and ion homeostasis. The observed changes in gene expression led to corresponding changes in astrocyte physiology. Interestingly, astrocytes in different brain regions appear to show different responses to activating or eliminating the Shh pathway. Our results demonstrate that mature astrocytes display extensive molecular plasticity in the mature, uninjured brain and the molecular and physiological properties of astrocytes are not hardwired during development but are dependent on neuron-derived Shh. The ability of neurons to control the molecular properties of astrocytes likely ensures that astrocytes are equipped with an optimal molecular toolkit to meet the physiological demands of specific brain circuits. Further work is needed to determine if neuron-astrocyte communication through Shh pathway is disrupted in various brain diseases.

Title: Calcium imaging of cocultured GABAergic interneurons with FGFR1 knock out astrocytes

Authors: *D. J. ROGERS[1], M. JACKSON[2], H. TORRES[2], B. FORET[2], G. WATSON[2], K. M. SMITH[2];

[1]Univ. of Louisiana at Lafayette, Rayville, LA; [2]Biol., Univ. of Louisiana at Lafayette, Lafayette, LA

Abstract: Astrocytes in the cerebral cortex have many functions that support neuronal integrity. One such function is maintaining ionic homeostasis of the extracellular fluid; this may involve the regulation of the ionic environment, release of neurotransmitters or rapid reuptake of excess neurotransmitters. Alterations in astrocyte function could affect the associated neuronal field, in turn, effecting neuronal activity or neuronal survival. We previously published that transgenic *FGFR1*$^{Flox/Flox;NestinCre}$ mice have a decreased number of cortical interneurons. Interneurons grown on *FGFR1*$^{Flox/Flox;NestinCre}$ mouse astrocytes presented smaller soma size and fewer dendritic processes when compared to their littermates. The physiology underlying this morphological phenotype is unknown. One possible hypothesis is *FGFR1*$^{Flox/Flox;NestinCre}$ cortical astrocytes are unable to maintain the proper extracellular environment for proper function and/or survival of these interneurons. A coculture model using P2-P4 *FGFR1*$^{Flox/Flox;NestinCre}$ knockout mice or control littermate astrocytes to form a feeder layer for embryonic medial ganglionic eminence derived *Gad-67 GFP* + labeled GABAergic interneurons was developed to better understand the function FGFR1 has in astrocyte physiology. Techniques using intracellular calcium imaging with Fluro 3-AM, revealed calcium waves in neurons and astrocytes of knock out and control mice. Movies of these waves were analyzed using Image J. The inhibitory interneurons grown on *FGFR1*$^{Flox/Flox;NestinCre}$ knockout astrocytes had significantly fewer calcium peaks when compared to control. (*FGFR1*$^{Flox/Flox;NestinCre}$ knockout astrocytes =4.75 ± 3.38 peaks, *FGFR1*control astrocytes =20.13 ± 3.38, p=0.0063*) An anecdotal point to be further investigated was the oservation that the calcium peaks of cocultured interneurons on the knockout astrocytes were lower amplitude than control. These results suggest that eventhough we have previously shown that there was no significant difference in the calcium amplitude response between the *FGFR1*$^{Flox/Flox;NestinCre}$ knockout and control astrocytes. There are definitely significant differences when interneurons are applied to these astrocytes, indicating the importance of the astrocyte-neuron interaction.

Title: Retroaxonal barrage firing in NPY interneurons of the hippocampus: a role for astrocytes

Authors: *T. DEEMYAD[1], N. SPRUSTON[2];
[1]Howard Hughes Med. Institute/Janelia Farm, Ashburn, VA; [2]Howard Hughes Med. Institute/Janelia, Ashburn, VA

Abstract: In CA1 area of the hippocampus, repeated stimulation of NPY-GFP+ GABAergic interneurons leads to a form of persistent firing called retroaxonal barrage (RaB) firing (Sheffield et al. 2011, 2013). We have shown previously that a decrease in extracellular calcium concentration or block of voltage-gated calcium channels inhibits RaB firing. However, intracellular BAPTA in NPY-GFP+ interneurons did not prevent RaB firing. Furthermore, inhibition of gap junctions blocks RaB firing, but gap junctions other than Cx36, the major connexin between CA1 interneurons, are responsible for this effect. These observations led us to the hypothesis that the calcium signaling and gap junctions necessary for RaB firing could be in astrocytes. To explore this hypothesis, we used a combination of electrophysiology, calcium imaging and optogenetics in astrocytes. All experiments were performed in hippocampal slices prepared from the CA1 area of the hippocampus in mice expressing GFP under the NPY promoter in interneurons. Double recordings from astrocytes and NPY-GFP+ interneurons revealed a subset of astrocytes (n=8/28) that depolarized >10 mV near the onset of RaB firing (onset range: 18 sec before to 10 sec after RaB). Enhancing the astrocytic network depolarization by bath application of BaCl2 facilitated RaB firing in all recordings (n=6/6). To further study the relation between calcium transients in the network of astrocytes and RaB firing, we used the genetically encoded calcium indicator, GCaMP3 in astrocytes. While no synchronized calcium activity was observed in the network, many astrocytic processes exhibited increased fluorescence prior to and during RaB firing (onset range: 7-21 sec prior to RaB generation; peak range from onset of RaB: 45-95 sec) and stayed relatively stable for the duration of RaB firing. To investigate the connection between astrocytic calcium signaling and RaB firing, we used intracellular BAPTA for astrocyte recordings. RaB firing was first generated in interneurons and a nearby astrocyte was subsequently patched using pipettes containing BAPTA (50mM). In some cases, this resulted in complete block or an increase in the number of spikes required for induction of RaB firing (n=7/25). Finally, stimulation of astrocytes with channelrhodopsin (ChR2) increased calcium transients in astrocytes and decreased the threshold for RaB firing by ~45% (n=8/12); in some cases ChR2 stimulation was sufficient to generate RaB without depolarizing stimulation. Together, these findings suggest that the astrocytic network plays a direct role in regulating the induction of RaB firing in NPY interneurons.

Title: Fibroblast growth factor receptor signaling in astrocytes

Authors: *K. M. SMITH[1], L. B. RUBIN[2], L. CHOUBEY[2], J. COLLETTE[2], R. R. H. DEEGAN[3], F. M. VACCARINO[4];

Abstract: Fibroblast growth factors (fgfs) are a family of 22 cytokines and 4 receptors, many of which play a critical role in cortical development. Fgf ligands, including Fgf2, and the Fgfr1 and Fgfr2 receptors are expressed by astrocytes and astrocytic stem cell lineages of the developing and adult CNS. Previous work has shown that the inactivation of Fgfr1 in radial glial progenitors of the developing cortex presents with an impairment in the postnatal maturation of parvalbumin positive interneurons (PV+). This interneuron defect is associated with increased locomotor hyperactivity. PV+ interneurons have an extensive postnatal maturation process which may be regulated by other cell types in the cortical environment, including glial cells expressing Fgfr1. We have characterized the expression of Fgfr1 in the developing cortex and hippocampus with the tgFgfr1-EGFP transgenic line (GENSAT). We demonstrate that there is an extensive expression of Fgfr1 in glial cells throughout postnatal development, at the time that interneuron maturation is occurring, and in DCX positive neuroblasts in the hippocampal dentate gyrus. We have further inactivated Fgfr1 in postnatal astrocytes by tamoxifen inducible Cre mediated recombination using the hGFAP-CreERT2 (GCE) transgene. We targeted astrocytes by postnatal injections of tamoxifen (P14-17, 60 mg/kg i.p.). Postnatal loss of Fgfr1 alone resulted in hyperactivity, and decreased anxiety on the elevated plus maze test. No differences in learning were observed on a modified one-day morris water maze test. Previous studies have shown that fgfr2 can have compensatory effects during the inactivation of fgfr1 (for example, in cerebellar development). We are currently investigating the effects of Fgfr1 and Fgfr2 double mutants mediated by tamoxifen inducible GCE recombination. We will determine whether the double mutants have a more extensive behavioral phenotype than Fgfr1 single mutants, and compare the effects of Fgfr1 single and Fgfr1/Fgfr2 double mutants upon PV neuron maturation, and postnatal hippocampal proliferation.

Title: Dissecting the role of IP3-Receptor subtypes in hippocampal LTP

Authors: *M. W. SHERWOOD[1,2], M. ARIZONO[3], C. HISATSUNE[3], H. BANNAI[3,4], E. EBISUI[3], J. L. SHERWOOD[5], A. PANATIER[1,2], S. H. R. OLIET[1,2], K. Abstract: Astrocytic Ca2+ signaling is required for LTP at the Hippocampal Schaffer Collateral to CA1 (SC-CA1) synapses. Controversy, however, remains as IP3 receptor (IP3R) type-2 knockout mice (IP3R-2KO), which are reportedly deficient in astrocytic Ca2+ signaling, exhibit normal LTP. It is possible that an astrocytic Ca2+ channel hitherto unknown is required for LTP and that some Ca2+ transients still prevail locally, at the level of the processes, in IP3R-2KO mice. In the current study, we address this hypothesis by visualizing sub-cellular Ca2+ dynamics within astrocytic processes, focusing on Ca2+ release through all IP3R subtypes (1,2,3) and their role in LTP. To image Ca2+ dynamics in astrocytic processes we used two-photon imaging of GCaMP3 expressed in cultured hippocampal slices. We also performed two-photon Ca2+ imaging in acute slices, in this case we loaded the Ca2+ indicator Fluo-4 via an astrocytic whole-cell patch-pipette. To evoke Ca2+ responses in astrocytes, we bath applied the group 1 metabotropic glutamate receptor agonist DHPG, or performed high frequency stimulation (HFS, 1sec at 100Hz) of the Schaffer Collaterals. In contrast to the premise of previous studies, we observed substantial astrocytic Ca2+ responses in slices prepared from IP3R-2KO mice. As the activation of astrocytic group 1 mGluRs is known to trigger Ca2+ release via IP3Rs, we decided to investigate the contribution of other IP3R subtypes. To this end we repeated the above experiments using hippocampal slices prepared from IP3R type-2/-3 double KO mice (IP3R-2/3KO) and used heparin, introduced via an astrocytic whole-cell patch-pipette, to inhibit all IP3R subtypes. We thus identified two new astrocytic Ca2+ channels, namely IP3R-1 and IP3R-3. Having identified two new functional Ca2+ channels in astrocytic processes we tested their involvement in LTP. In accordance with Ca2+ imaging data, 2xHFS-LTP was intact in slices prepared from IP3R-2KO, and IP3R-2/3KO mice. Finally, inhibiting all astrocytic IP3R subtypes with heparin inhibited 2xHFS-LTP. Our results show for the first time that IP3R-1 and IP3R-3 are functional Ca2+ channels within astrocytes, and that they could be required for LTP induction at hippocampal CA3-CA1 synapses.

Title: TNFα suppresses drug induced synaptic plasticity and behavior

Authors: ***S. C. KONEFAL**[1], G. M. LEWITUS[1], K. AUGEREAU[2], S. CHIERZI[1], K. MURAI[1], D. STELLWAGEN[1];
[1]Ctr. for Res. in Neurosci., [2]McGill Univ., Montreal, QC, Canada

Abstract: Repeated administration of cocaine results in the development of behavioral sensitization in rodents, which is a progressive increase in locomotor response following repeated drug exposure. The nucleus accumbens (NAc) serves as a cross point between corticolimbic and motor regions, therefore playing an important role in generating motivated behaviors to natural rewards and drugs of abuse. Behavioral sensitization is accompanied by a decrease in excitatory synaptic strength in the NAc through an unknown mechanism, which slowly potentiates during withdrawal. Repeated exposure to cocaine also produces an enduring increase in dendritic spine density in the NAc. Here we show that repeated administration of cocaine activates microglia and induces TNFα expression in the NAc, which in turn depresses glutamatergic synaptic strength and limits the development of behavioral sensitization. Further, TNFα KO mice show an increased spine density and cocaine-induced spinogenesis in the NAc, suggesting a regulatory role for TNFα in dendritic spine formation or maintenance. TNFα is known to be produced by glia in the brain and glial cells are activated by a variety of drugs of abuse. Their contribution to the development of addictive behaviors is not well characterized. We utilized a Cre-loxP system to selectively delete TNFα from distinct subclasses of cells in the brain, CX3CR1-Cre mice for microglia and GFAP-Cre mice for astrocytes. Mice that lack microglia-derived TNFα show a significantly higher level of sensitization to cocaine.

Conversely, mice that lack astrocytic TNFα do not have elevated sensitization. We hypothesize that TNFα is part of an important adaptive response to chronic cocaine involving microglia. However, our results suggest that cocaine-induced activation of microglia and TNFα expression occurs only during a narrow window following cocaine exposure, and re-activating microglia could be therapeutic. Accordingly, we found that re-activation of microglia and induction of TNFα expression by a weak TLR4 agonist depresses synaptic strength in the NAc and acutely suppresses cocaine-induced sensitization without inducing sickness behavior. In conclusion, manipulating microglia and TNFα levels in the NAc is a potential avenue for regulating cocaine-induced plasticity and behavior.

Title: The influence of immune and endocrine signaling on the neuroanatomy of the bed nucleus of the stria terminalis

Authors: *R. KHALID[1], J. A. FOSTER[1,2];
[1]Psychiatry and Behavioural Neurosci., McMaster Univ., Hamilton, ON, Canada; [2]St. Joseph's Healthcare, Brain Body Inst., Hamilton, ON, Canada

Abstract: The immune and endocrine system influence behaviour and contribute to the development of the central nervous system (CNS) in a sexually dimorphic manner. The bed nucleus of the stria terminalis (BST) is a highly sexually dimorphic brain region; in most mammalian species the male BST is larger than the female BST. Previously, our lab has shown a loss of this sexual dimorphism in mice lacking functional T cells. The present study investigates the mechanism by which T lymphocytes may be influencing sexual dimorphic development. Using immunohistochemistry and the microglial marker, anti-Iba1, microglia were examined in WT and mice lacking the β and δ chains of the T cell receptor (TCRβ-/-δ-/). Sex differences in brain volume of the BST are present early in postnatal life and microglial analysis of brain tissue from postnatal day 7 mice is ongoing. Serum levels of anti-Müllerian hormone (AMH), a

gonadal hormone implicated in development of the BST, will also be assessed in postnatal mice. Our preliminary results from adult mice showed significant sex and genotype effects between WT and TCRβ-/-δ-/- mice. In the dorsal BST, females showed a greater number of small microglia compared to males, and WT males had a greater number of small microglia compared to TCRβ-/-δ-/- males. In the ventral BST, the genotype effect in the male groups was reversed with WT males showing a reduced number of small microglia compared to TCRβ-/-δ-/- males. The influence of immune and endocrine signaling will be further explored during early development of TCRβ-/-δ-/- mice to illustrate the contribution of these systems on sexual dimorphic development of the brain. Title: Glial miRNA regulates Progesterone's neuroprotective function by altering the PGRMC1/KLF4 signaling

Authors: *T. NGUYEN, M. SINGH, C. SU;
Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: Stroke has been reported as the fourth leading cause of death for Americans and it is a leading cause of adult disability. The risk of ischemic stroke increases significantly with aging. Gender appears to play a profound role, with the incidence being higher in women. A large body of studies has suggested that women in postmenopausal state are at greater risk of ischemic stroke and are likely to experience much more severe impacts. A considerable amount of research has supported that P4 is a potent neuroprotectant that may exert beneficial effects in various neurodegenerative disorders, including stroke. Our laboratory has reported that Brain-derived neurotrophic factor (BDNF), which has well-defined roles in synaptogenesis and neuronal survival is a critical mediator for P4 neuroprotective actions. We have also recently found that P4 enhances BDNF release from glia, but not from neurons, by acting via a novel membrane-associated progesterone receptor, Pgrmc1. We recently have identified a member of the Let-7 miRNA family that could potentially regulate PGRMC1 by suppressing its transcription. Furthermore, our data demonstrated an inverse association between Let-7 miRNA and Pgrmc1 expression levels in post-ischemic mouse hippocampus. This correlation was

reported in normal aging brain where the antagomir (synthetic inhibitor) of Let-7 miRNA significantly reduced infarct volume and improved neurological deficits in a rodent ischemic stroke mode. These lines of evidence have strongly supported our hypothesis that in normal aging or in the stroked brain, Let-7 miRNA negatively regulates Pgrmc1 gene expression, which disrupts P4-induced BDNF release from glia and ultimately leads to the attenuation of P4's positive effect on synaptogenesis and neuronal survival.

Title: D-Serine promotes synapse maturation and axonal branch stabilization in the developing visual system of the Xenopus tadpole

Authors: ***M. VAN HORN**[1], L. POLLEGIONI[2], E. RUTHAZER[1];
[1]Neurol. and Neurosurg., McGill Univ., Montreal, QC, Canada; [2]Dept. of Biotech. and Mol. Sci., Univ. of Insubria, Varese, Italy

Abstract: The gliotransmitter D-serine is a co-agonist for N-methyl-D-aspartate receptors (NMDAR) and has been shown to modulate synaptic transmission and plasticity mediated by this receptor. Here we examined the role D-serine plays in shaping neuronal activity and axonal remodeling in the developing visual system of the Xenopus tadpole. We find acute D-serine (100 μM) wash-on acutely enhances NMDAR currents of optic tectal neurons, whereas degradation of D-serine by RgDAAO reduces NMDAR currents, indicating that endogenous D-serine is normally present below saturating levels. Using D-serine amperometric biosensors, we found that α-Amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR) activation results in an increase in D-serine release *in vivo*. To investigate the influence of D-serine availability on circuit maturation, we tested whether chronically elevating D-serine levels could influence the maturation of glutamatergic synapses. We find that tadpoles raised in D-serine (100 μM) for 2 days have higher frequencies of miniature excitatory postsynaptic AMPAR currents and higher retinotectal synaptic AMPA/NMDA ratios compared to control animals. Conversely, decreasing the amount of available D-serine, with a local injection of RgDAAO, results in a decrease in the amplitude and frequency of mEPSCs 24hrs after the injection. To examine the effects of D-serine on morphological development of retinotectal axons, images of EGFP expressing retinal axons were collected daily, over 4 days to assess growth and branch

elaboration and at shorter (10 min) intervals to assess branch stabilization. We find that increasing available D-serine results in the hyperstabilization of retinal axon branches, with axonal arbors becoming less complex compared to control axons over 4 days of treatment with D-serine. These findings are consistent with the hypothesis that D-serine enhancement of NMDAR currents promotes synaptic maturation and leads to stabilization of axonal branches. Taken together, these results suggest that D-serine levels are modulated by glutamatergic neurotransmission *in vivo* and promote the maturation of retinotectal synapses and axonal stabilization.

Title: EphB3 receptors control synaptic NMDAR functions

Authors: ***V. C. LANGLAIS**, S. H. R. OLIET, A. PANATIER;
Neurocentre Magendie INSERM U862, Bordeaux Cedex, France

Abstract: Astrocytes are key partners of neurons and synapses. One of their main functions at CA3-CA1 hippocampal synapses is to regulate the activity of synaptic NMDA receptors (NMDARs) through the supply of the coagonist D-serine. Importantly, the detailed mechanism controlling the release of D-serine in the synaptic cleft is still unknown. In this work, we have investigated whether astrocytic EphB3 receptors play a role in controlling NMDAR coagonist availability and thus NMDAR functions. Using electrophysiological approaches on acute hippocampal slices of adult mice, we here show that exogenous stimulation of EphB3 receptors with clustered ephrinB3-Fc ligands leads to an increase of NMDAR activity at CA3-CA1 synapses. Importantly, this modulation is due to an increase of the coagonist-binding site occupancy. Furthermore, disrupting endogenous ephrinB3-EphB3 interaction induces an impairment of synaptic NMDAR activity and its associated long-term synaptic potentiation. Both are rescued by exogenous supply of D-serine. We are presently carrying out experiments, to assess the role of astrocytic versus neuronal EphB3 receptors, in this pathway. All together, our data reveals that EphB3 receptors regulate synaptic NMDAR functions through the control of the coagonist-binding site occupancy.

Title: Astrocyte neuron interactions in synchronous bursting behavior

Authors: K. R. SANCHEZ, *M. TEMBURNI, M. HARRINGTON;
Biol., Delaware State Univ., Dover, DE

Abstract: Establishing functional neuronal networks during brain development requires synchronous oscillatory activity among neurons. However, the mechanisms of synchronization are not fully understood. Current models of neuronal synchronous activity assume that it is a process intrinsic to neurons. Evidence that glial cells particularly astrocytes modulate synchronous activity in networks of neurons is accumulating - for example during sleep, during prodromal oscillations preceding spreading depression, and the slow inward currents (SICs) resulting in synchronous activity in hippocampal neurons, thalamus and nucleus accumbens. Astrocytes participate in neuronal communication by releasing “gliotransmitters” like glutamate, ATP and D-serine. We hypothesize that astrocyte-neuron interactions are crucial for the development of synchronous activity seen in the developing vertebrate brain. We tested this hypothesis by establishing pure and mixed (astrocyte and neuronal) cultures from the developing chicken brain (optic tectum) and recording total neuronal activity using the multi-electrode array system, MED64. Pure neuronal cultures were obtained by treating cultures with the mitotic inhibitor 5-fluorodeoxyuridine (FUdR) which kills mitotically active astrocytes but spares post-mitotic neurons. Neurons were kept alive in the absence of astrocytes by supplementing the culture medium with 50% astrocyte conditioned medium. Mixed cultures of astrocytes and neurons show random spiking activity in one week and synchronous activity in two weeks whereas pure neuron only cultures show random spiking activity without synchronization even after two weeks - thus clearly establishing a role for astrocytes in the development of synchronous activity. To further confirm the involvement of astrocytes we have reintroduced astrocytes into the randomly spiking pure neuronal cultures after synchronous activity was observed in the control mixed cultures. We observed an immediate increase in spiking activity which synchronized within a week of reintroduction of astrocytes into the FUdR treated pure neuronal cultures. To further dissect the molecular pathways involved we are targeting GPCR pathways within astrocytes that mediate intracellular Calcium release. Activation of these G-protein coupled receptors by their respective neurotransmitters mobilizes intracellular calcium release leading to exocytosis of either glutamate or ATP. We are expressing dominant negative

peptides designed to disrupt downstream signaling pathways of these receptors and thereby calcium mobilization and exocytosis of gliotransmitters in chick embryo astrocytes.

Title: Measurement of H+ fluxes from cultured rat cortical astrocytes using self-referencing H+-selective microelectrodes

Authors: *J.-I. CHOI[1,2], C. GOEKE[4,5], M. GUIZZETTI[4,5], R. P. MALCHOW[2,3];
[1]Univ. of Illinois At Chicago, Chicago, IL; [2]Biol. Sci., [3]Ophthalmology & Visual Sci., Univ. of Illinois at Chicago, Chicago, IL; [4]Dept. of Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR; [5]VA Portland Hlth. Care Syst., Portland, OR

Abstract: Glial cells are believed to play a key role in regulating extracellular levels of glutamate in the nervous system, transporting extracellular glutamate into the cytoplasm of the glial cells. This transport process is often associated with changes in extracellular levels of H+, which can by itself have a potent modulatory effect on neuronal excitability and synaptic transmitter release. In the present study, we have used self-referencing H+-selective microelectrodes to examine standing levels of extracellular H+ from quiescent cortical astrocytes cultured from rats, and have also examined changes in the level of extracellular H+ that occur upon addition of the neurotransmitter glutamate. Cultured astrocytes in a bicarbonate-based saline solution exhibit a standing acidic flux. When the normal 24 mM bicarbonate in the solution is replaced with 1 mM HEPES, a standing flux remains but is smaller in magnitude. The standing flux observed in the 1 mM HEPES condition remained when all of the extracellular sodium was replaced with choline. Application of glutamate induced a transient extracellular alkalinization, consistent with its transport into the glial cells. These results are the first to show extracellular H+ levels adjacent to quiescent glial cells and suggest the possibility that changes in extracellular H+ by glial cells may play a role in modulation of activity within the nervous system.

Title: Directed differentiation of human induced pluripotent stem cells to astrocytes for the study of spinal muscular atrophy

Authors: *S. LOH[1,2], L. W. STANTON[1,2];
[1]Stem Cell and Regenerative Biol., Genome Inst. Singapore, Singapore, Singapore; [2]Sch. of Biol. Sci., Nanyang Technological Univ., Singapore, Singapore

Abstract: Spinal Muscular Atrophy (SMA) is a neuromuscular childhood disease. SMA arises due to the mutation of *SMN1*. Motor Neurons (MNs) are particularly sensitive to the low levels of functional SMN protein and they selectively degenerate. In SMA mice models, overexpression of the SMN protein in MNs alone did not confer extended survival or increase muscle mass. However, when SMA protein levels were increased in both MNs and astrocytes, SMA mice displayed improved survivability and muscle mass, indicating the importance of astrocytes in SMA pathology. To study the roles of astrocytes in SMA pathology in human genetic background, we established an efficient method of generating SMA and WT astrocytes from induced pluripotent stem cells (iPSCs). We are performing studies such as glutamate uptake tests and calcium imaging on the iPSCs-derived astrocytes to uncover functional differences between WT and SMA conditions. We are also examining the levels of intracellular reactive oxygen species to determine the presence of cellular oxidative stress in iPSCs-derived astrocytes, which is an important indicator of astrocytes pathology. We hypothesize that iPSCs-derived SMA astrocytes will exhibit functional abnormalities and have the propensity of inducing cell death of the surrounding MNs in SMA conditions.

Title: Determining the role of TREM-2 in cerebral ischemic reperfusion injury

Authors: *Y. TANG, X. RONG, P. XU, Y. XU, R. WU;
Sun Yat-Sen Mem. Hospital, Sun Yat-Sen Univ., Guangdong, China

Abstract: Background: Ischemic stroke remains a public health burden across the globe. Although thrombolysis is the class I recommendation for treatment, it may lead to ischemic reperfusion injury. Immunoinflammatory response is a profound pathogenic mechanism existing in the whole process of ischemic reperfusion. TREM2 (Triggering receptor expressed on myeloid cells - 2), belonging to the immunoglobulin and lectin-like superfamily, can facilitate phagocytosis and inhibit pro-inflammation. However, its role in the cerebral ischemic reperfusion injury is still unclear. **Objectives:** To estimate the role of TREM2 in cerebral ischemic reperfusion injury. **Materials and methods:** *In vitro* study, we established an oxygen-glucose deprivation and reoxygenation (OGDR) model with primary microglia to detect the intracellular mRNA and protein expression of TREM2. By using TREM2 siRNA Oligonucleotides, we further compared the secretion of inflammatory cytokines such as TNF-α,IL-1β,iNOS and IL-10 in microglia among different TREM2 levels. In addition, using the co-culture model of primary hippocampal neurons and primary microglia, we evaluated the effect of microglia with different TREM2 level on neuron apoptosis. *In vivo* study, male C57BL/6J mice were used to establish middle cerebral artery occlusion (MCAO) model. We firstly determined the location and expression of TREM2 as well as the expression of a series of inflammatory cytokines. After injection of TREMs siRNA to the right latreal ventricle of the mice, the change of infarct area and the number of apoptotic neurons in peri-infract area were detected by TTC staining and double immunofluorescent staining. **Results:** We found that the expressions of TREM2 in microglia after OGDR increased with a peak at 24 hours and then gradually decreased. So did the trend of the TREM2 expressions in peri-infarct area in MCAO mice. Through TREM2 knockdown, the IL-1β secretion increased at 6 hours and TNF-a, IL-1β, iNOS expression increased at 12 hours,while IL-10 decreased both at the two time points. By overexpressing TREM2, IL-1β as well as TNF-a, IL-1β, iNOS and IL-10 showed a contrary trend. Being co-cultured with OGDR microglia, more primary hippocampal neurons suffered from apoptosis, and the injury could be alleviated by overexpressing TREM2. In MCAO model, TREM2 mostly expressed in microglia which located in peri-infarct area. Lower expression of TREM2 leaded to a higher level of inflammatory cytokines and poor neurological outcomes. **Conclusions:** TREM2 could inhibit the expression of pro-inflammatory cytokines and neuronal apoptosis, which is good for tissue repair and neurological recovery.

Abstract: The energy requirements of signaling in the cerebral cortex are met by a variety of metabolic cascades that take place within neurons and glia and are supplied by the local microvasculature. The shuttle of lactate from glia to neurons (ANLS) constitutes a critical energy baton between the two cell types that sustains the energetic requirements of synaptic transmission. This energy relay is also critical for the maintenance of the transmembrane concentration balance of the neurotransmitter glutamate. Of particular interest is the relative sourcing of lactate from either glycogen mobilization or glycolysis. Glycogen is located within the glia and is thought to be a storage center for glucose and the lactate that is eventually transported to the energy-requiring neurons. The metabolic cost of maintaining a glycogen shunt for the storage and retrieval of glucose for lactate production is greater than that of glycolysis, thus begging the question of the role of this alternative pathway. The neurological and psychiatric deficits presented by patients with glycogen metabolism disorders also point to a significant constitutive function of the glycogen shunt in the brain. Using a computational model of the neuro-glia-vasculature (NGV) within a cortical column containing synthetic astrocytes, we explored the metabolic behavior of the NGV during various activity regimens, focusing on the contribution of the glycogen shunt to metabolic patterns arising from frequency-dependent cortical activity. We investigated the relative timing of ANLS development versus glycogen shunt activity to determine the contribution of glycogen to the oxygen to glucose index (OGI). We further examined neurotransmitter-mediated regulation of glycogen formation by norepinephrine (NE) and vasoactive intestinal peptide (VIP) and asked how they impact the activation of cAMP-dependent kinases, the regulation of glycogen and OGI under conditions of normal and enhanced synaptic transmission.

Title: Astrocytic lesions that spare neurons in the nucleus tractus solitarii interfere with cardiorespiratory control

Authors: G. B. RICHERSON[1], D. N. DRAGON[2], S. JONES[2], Y. WU[2], *W. T. TALMAN[2,3]; [1]Neurol., [2]Carver Col. of Medicine, Univ. Iowa, Iowa City, IA; [3]Neurol., Dept. of Veterans Affairs Med. Ctr., Iowa City, IA

Abstract: Conjugates of saporin (SAP) have been widely used to target specific neurons while leaving other neurons undisturbed. We found that killing catecholamine neurons bilaterally in the nucleus tractus solitarii (NTS) by injection of the SAP conjugate containing an antibody to dopamine-β-hydroxylase (antiDBH-SAP) spared non-catecholamine neurons but led to attenuation of baroreceptor reflexes, lability of arterial pressure, and, in some animals, sudden death. In contrast, selective targeting of catecholamine neurons with 6-hydroxydopamine produced no such cardiovascular events. We hypothesized that SAP conjugates may target non-neuronal cells in the NTS. Indeed, we found that local astrocytes were killed by the conjugates as well as by unconjugated SAP itself. SAP injections into the NTS led to death of astrocytes that expressed glial fibrillary acidic protein (GFAP) but did not affect neuronal structural markers and neuronal biosynthetic enzymes. Our recent studies further suggest that local neurons are physiologically intact. Nonetheless, SAP injections into the NTS significantly reduced cardiovascular responses elicited by glutamate agonists injected into the NTS, and bilateral injections of SAP into the NTS led to attenuation of cardiovascular reflexes whose pathways pass through the NTS, lability of arterial pressure, damage to cardiac myocytes and sudden death resulting from asystole. When asystole and death followed SAP treatment the fatal arrhythmia followed progressive bradycardia. In that treated animals demonstrate altered ventilatory function, we conjecture that it is altered ventilation that leads to cardiac compromise and death.

Title: Cellular contributions of gap junctions to gamma oscillations in the hippocampus

Authors: *A. D. JOHNSTON, B. S. KHAKH;
Physiol., UCLA, Los Angeles, CA

Abstract: Gap junctions, formed by connexin proteins, function as conduits between the intracellular milieu of many cell types. These pores have been difficult to study due to their distal locations at junctions and the lack of selective pharmacological tools. In neurons, they form electrical synapses which are important for synchronizing neural circuits. For example, it has been previously described that removal of neuronal connexin36 diminishes gamma oscillations in the CA3 region of the mouse hippocampus. These oscillations, ranging from 20-100 Hz are thought to underlie attention, learning, and working memory. Gap junctions are also found in abundance in other cell types of the brain, including astrocytes that exist in numbers at least equal to neurons and form close spatial interactions with pyramidal neurons and interneurons. Astrocyte gap junctions play important developmental roles and facilitate intercellular coupling and regulation of synaptic transmission. However, their contributions to circuit level functions such as gamma oscillations are not well described. Additionally, unopposed connexin and pannexin pores, known as functional hemichannels, release neuromodulators such as ATP and glutamate which have also been shown to modulate neuronal activity. Using targeted genetic and pharmacological approaches, we investigated the contribution of gap junctions and hemichannels in both neurons and astrocytes to network oscillations in the hippocampus. Using a broad pharmacological approach, we have confirmed that functional gap junctions are required for the maintenance of gamma oscillations and are developing genetic approaches to specifically disrupt junctional coupling in astrocytes. Additionally, we have found that, while functional hemichannels exist in hippocampal astrocytes, the function of pannexin hemichannels does not seem to be necessary for gamma oscillations. Overall, we will report new data on how gap junction proteins within astrocytes affect gamma oscillations in the hippocampus.

Title: Pyruvate carboxylase rate determined in awake rats using [2-13C]glucose

Authors: *L. F. MCNAIR[1], G. F. MASON[2], H. S. WAAGEPETERSEN[1], K. L. BEHAR[3]; [1]Dept. of Drug Design and Pharmacol., Univ. of Copenhagen, Kobenhavn O, Denmark; [2][1] Dept. of Diagnos. Radiology, Magnetic Resonance Res. Ctr. [2] Dept. of Psychiatry, [3]Dept. of Psychiatry, Magnetic Resonance Res. Ctr., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Our knowledge about the brain is steadily increasing; still, essential metabolic functions of brain cells have not been fully characterized. The astrocyte, which is a glial cell abundant in the mammalian brain, has an important role in anaplerosis by housing pyruvate carboxylase (PC), the enzyme needed for *de novo* synthesis of glutamate. The PC rate has been measured *in vivo* in single cortical samples of human and rodent brain, but not yet regionally. The aim of this study was to apply MRS with [2-^{13}C]glucose to measure the PC rate in several brain regions of the awake rat. 57 freely moving young adult male Sprague-Dawley rats (210±10g, mean±SD) were infused with either [1-^{13}C] or [2-^{13}C]glucose. 8, 15, 30, 60 or 120 min after start of glucose infusion rats were euthanized by Focused Beam Microwave Irradiation (n = 5-7 per time point), blood was collected and the brain removed and dissected into 6 regions: cortex, cerebellum, hippocampus, striatum, thalamus, and hypothalamus. Extracted brain and plasma samples were analyzed by proton-observed carbon-edited NMR spectroscopy to obtain time courses of ^{13}C-enrichments at different carbon positions of glutamate, glutamine, and GABA, as well as total metabolite concentrations. These data were combined and fitted in a three-compartment model (i.e. astrocyte, GABAergic and glutamatergic neuron) using CWave (Graeme F. Mason, Yale University), to derive the metabolic fluxes. Analysis of cortex extracts from [2-^{13}C]glucose infusions revealed that by 120min of infusion, enrichments at glutamine C3, glutamate C3 and GABA C3, resulting predominantly from PC activity, reached 6-8%. Glutamate C4, glutamine C4 and GABA C2 from [1-^{13}C]glucose infusions reached 30-40% at 120min, and formed the primary basis to estimate tricarboxylic acid cycle flux (V_{TCA}) and the glutamate-glutamine cycle (V_{cycle}) flux, happening in and between both neurons and astrocytes. Metabolic rates from initial modeling of cortex data were V_{cycle}=0.73, V_{TCA}=1.72, and V_{PC}=0.38umol/min/g. Further data analysis is needed to finalize metabolic rates for all brain regions.

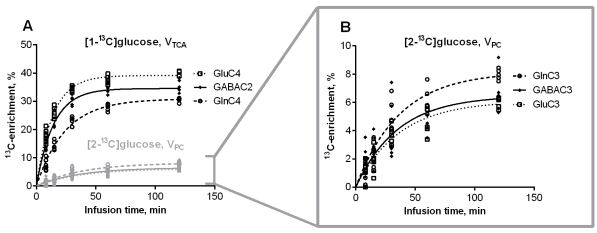

Fig. ^{13}C-enrichment time courses for rat cortex illustrating that pyruvate carboxylase rate (V_{PC}) is lower than the rate of tricarboxylic acid cycle (V_{TCA}). (A) Black symbols/lines, showing glutamate C4 (GluC4), GABA C2, and glutamine C4 (GlnC4) enrichments from [1-^{13}C]glucose infused rats (*n = 27*) are significantly higher than glutamate C3 (GluC3), glutamine C3 (GlnC3), and GABAC3 from [2-^{13}C]glucose infused rats (*n = 30*) shown in gray. **(B)** An amplification of the gray time courses for glutamate, glutamine and GABA C3 shown in (A) enabling better visual separation of these. Metabolic rates from initial modelling of data: V_{cycle}=0.73, V_{TCA}=1.72, V_{PC}=0.38 umol/min/g. *n* for each time point is 5-7 rats.

Title: Astrogliosis: changes in astrocyte KIR expression and function in Alzheimer's

Authors: ***L. M. OSBORN**[1], L. KOOIJMAN[1], W. KAMPHUIS[2], W. J. WADMAN[1], E. M. HOL[3];
[1]Univ. of Amsterdam, Amsterdam, Netherlands; [2]Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [3]Dept. of Translational Neurosci., Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

Abstract: Alzheimer's disease (AD) is the main cause of dementia in the elderly and begins with a subtle decline in episodic memory followed by a more general decline in overall cognitive abilities. Though the exact trigger for this cascade of events remains unknown the presence of the misfolded amyloid-beta (Aß) protein triggers reactive gliosis, a prominent neuropathological feature in the brains of AD patients. lt is likely that the physiological function of astrocytes is affected in AD, resulting in altered synaptic physiology and having consequences for the stability of microcircuits within key brain regions. We analyzed microarray data from an aged mouse model of Alzheimer's (APPswe/PS1dE9) and found crucial changes in astrocyte-specific genes associated with ion homeostasis including a global down-regulation of glutamate (GLT-1 and GLAST) and GABA (GAT-1) transporters, Na/K-ATPase (AMOG), and outward (TWIK-1 and TREK2) and inward potassium rectifiers (Kir4.1 and Kir5.1). Further immunohistochemical analysis of KIR expression surprisingly revealed localized increases of channel expression in astrocytes directly surrounding amyloid plaque deposits. By focusing on potassium currents in the membrane using patch-clamp and field potential recordings we were characterized the electrophysiological properties of astrocytes during several stages of astrogliosis. We investigated the KIR conductance in astrocytes surrounding plaques as well as those further from plaque deposition and were able to show that reactive astrocytes surrounding plaques have a higher potassium conductance when compared to those further from plaque pathology. Additionally, we investigated local synaptic activity by using the astrocytes as a field potential sensor (aEPSPs). We also determined the potassium current in the astrocytes as a direct consequence of stimulation of the surrounding neuronal network. The latter observations were compared to currents induced by fast local pressure application of a high potassium solution. Our preliminary results suggest that functional changes in reactive astrocytes disrupt potassium homeostasis with potential consequences for normal neuronal and synaptic function. We

hypothesize that astrogliosis is an important player in the development of dementia. If astrocytes have a modulatory role in normal neuronal communication, reactive astrocytes are likely to interfere with synaptic efficacy and plasticity.

Title: Specific expression and function of the metabolic master regulator PGC-1α in the brain

Authors: *H. BAYER[1], E. BARTH[1], T. LUCAS[2], I. MERDIAN[1], P. WEYDT[1], A. WITTING[1]; [1]Exptl. Neurol., [2]Dept. of gene therapy, Ulm Univ., Ulm, Germany

Abstract: Peroxisome proliferator-activated receptor (PPAR) gamma coactivator 1-α (PGC-1α) is a transcriptional coactivator involved in metabolic responses. We recently reported specific PGC-1α isoforms which are under the control of a brain-specific promoter1. The role of these brain-specific PGC-1α isoforms is currently unknown. There is evidence that PGC-1α contributes to the pathogenesis of neurodegenerative disease spectrum disorders. We investigated the expression of canonical PGC-1α and its brain-specific isoforms in different brain areas and primary cells of the brain. Further we focused on their cell-specific function. We found that brain-specific PGC-1α isoforms are mainly expressed in neurons. Furthermore PGC-1α expression is stimulated by lactate selectively in neurons. This increased PGC-1α expression induced only selected PGC-1α target genes suggesting a specific role of PGC-1α in the brain. Co-transfection of neuro2a cells with the canonical or brain-specific PGC-1α isoforms and luciferase-constructs containing promoters of known PGC-1α target genes showed diverging activities of the different brain-specific PGC-1α isoforms compared to the canonical form. Also a microarray analysis of striatum of PGC-1α knock-out animals suggests a divergent functional role of PGC-1α in the brain in contrast to other peripheral tissues. We identified and confirmed via qPCR BDNF, SOD3 and PDK4 as down-regulated in PGC-1α knock-out neurons. The expression of these genes is increased by lactate stimulation. Our results suggest that PGC-1α might have a specific role in the brain energy metabolism. References 1. Soyal SM, Felder TK, Auer S, et al. Title: Status epilepticus increases microglial engulfment of newborn cells

Authors: ***C. LUO**, K. RYUTA, Y. IKEGAYA;
The Univ. of Tokyo., Tokyo, Japan

Abstract: Microglia, the brain-resident immune cells, contribute to the homeostasis of neural circuits via phagocytosis of dead cells, cell debris, and immature synapses. It has been suggested that microglia regulate adult neurogenesis in the dentate gyrus via phagocytosis of dead neural progenitor cells (NPCs). Newborn NPCs increases in the brain of patients with temporal lobe epilepsy and their animal models; however, whether and how microglia are involved in the aberrant proliferation and survival of NPCs after seizures remain unclear. Here, we show that the engulfment of newborn cells by microglia is facilitated after status epilepticus in mice, which regulates the density of newborn cells in the dentate gyrus. We induced status epilepticus (SE) by administering kainic acid in both wild-type and CX3CR1-GFP mice, in which microglia are labeled by GFP. Then, we labeled post-SE proliferating newborn cells with 5-ethynyl-2'-deoxyuridine (EdU) and immunohistochemically assessed the interaction between EdU-labeled newborn cells and microglia. We found that the phagocytosis rate of post-SE born cells by activated microglia increased in SE mice and most post-SE born cells were ablated in one week. Thus, our findings suggest that microglia may contribute to the homeostasis of neural circuits by engulfing excess newborn cells after seizures.

Title: Microglial modulation affect respiratory rhythm generation and autoresuscitation

Authors: *J. LOREA[1], T. MORALES[2], F. PEÑA[2];
[1]neurobiología del desarrollo y neurofisiología, [2]Univ. Nacional Autónoma De México (UNAM), Queretaro, Mexico

Abstract: Pro-inflammatory conditions disturb respiratory function which in turn has been associated with the induction of apneas and Sudden Infant Death Syndrome. Several proinflammatory mediators inhibit breathing when applied peripherally or directly into the central nervous system (CNS). Considering that peripheral inflammation can activate microglia in the CNS and that this cell type can directly release all proinflammatory mediators that regulate breathing, it is likely that microglial activity can regulate breathing generation. It might even do so more prominently in hypoxia, since microglia is highly sensitive to hypoxia and peripheral proinflammatory conditions affect gasping generation and autoresuscitation. Here, we tested whether or not microglial activation with lipopolysaccharide (LPS) or inhibition with minocycline (MIN) affected respiratory rhythm generation (in normoxia and hypoxia) both *in vivo* and *in vitro*. By measuring breathing by plethysmographic means as well as the activity of the respiratory rhythm generator (the preBötzinger complex), we found that both LPS and MIN, applied intracisternally *in vivo* or in the recording bath *in vitro*, affect the generation of the respiratory rhythms both in normoxia and hypoxia and, in the case of LPS, affected the ability of the animals to autoresuscitate from hypoxic conditions. Moreover, we found that the inhibitory effect of MIN on the respiratory rhythm generator *in vitro* were reproduced by the microglial toxin l-leucine methyl ester, which dramatically reduced microglia in the brainstem slice preparation without affecting neuronal activity. In conclusion, our data show that microglial modulation alters respiratory rhythms generation and autoresuscitation.

Title: Microglia rapidly adopt a filopodia-rich phenotype upon oxygen depletion by sensing tissue acidosis

Authors: *L.-P. BERNIER, L. DISSING-OLESEN, J. K. HEFENDEHL, J. M. LEDUE, B. A. MACVICAR;
Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Microglia are highly motile cells that play a pivotal role in monitoring brain homeostasis by constantly probing the environment and responding to extracellular cues. They are involved in long-term stroke recovery, however the acute responses of microglia to the metabolic stresses of ischemia remain unclear. Here, we used two-photon imaging *in vivo* and in acute brain slices to monitor the initial effect of anoxia on the morphological phenotype and dynamic properties of microglia. The highly ramified morphology of resting microglia is rapidly transformed during oxygen depletion with extension of fine actin-dependent filopodia followed by retraction of microtubule-dependent ramifications. This rapidly reversible switch in morphology drives significant changes in microglial sensing behavior, affecting microglial cells capacity to respond to tissue damage. Our observations indicate that increased intracellular cyclic AMP is a key trigger of both filopodia extension and retraction of ramifications. During short anoxia insults, this phenotypic switch is induced by the accompanying acidic shift in the extracellular environment. This pH drop causes microglia to adopt a filopodia-rich phenotype through an increase in cyclic AMP induced by activation of the Gs-coupled proton-sensing receptor TDAG8. Characterizing the highly specialized sensing structures of microglia and defining the molecular cues responsible for the functional switch of microglial behaviour observed upon oxygen depletion will likely provide promising targets for stroke treatment.

Title: Selective inhibition of sEH phosphatase function attenuates oxygen-glucose deprivation/reperfusion-induced microglial activation

Authors: *H.-T. LEE;
No 155, Section 2, Li-Nong Street, Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: Stroke, also known as cerebrovascular accident, is a condition caused by the interruption of blood supply to the brain, resulting to neuroinflammation due to lack of oxygen and nutrients. Our study used oxygen-glucose deprivation followed by reperfusion (OGD/R) 24 hours to mimic early stage of ischemia- reperfusion phase. Microglial cells are the resident macrophages in health brain, they constantly monitor their environment for signals from the CNS by moving their cellular processes. Upon encountering insults such as ischemic-hypoxia attack, microglia undergo transformation in morphology, proliferation, and becoming immune effector cells by releasing pro-inflammatory molecules and increasing expression of immunomodulatory surface antigens. However, it is now well-documented that microglia can function not only in pro-inflammatory but also neuroprotective fashion via growth factors release and immune response modulation which both can promote regeneration. Here, we present one novel candidate for such function: soluble epoxide hydrolase (sEH) whose expression is elevated in various brain injury models. sEH, is a bi-functional pro-inflammatory enzyme, with wide distribution in various tissues. Acute stroke leads to neuroinflammation which could trigger the production and release of arachidonic acid which is subsequently converted into epoxyeicosatrienoic acids (EETs). EETs have been shown to exert anti-apoptotic and anti-inflammatory effects. The C-terminal epoxide hydrolase function of sEH, is responsible for the metabolic conversion of EETs into dihydroxyeicosatrienoic acids (DHET). The N-terminal lipid phosphatase (PT) function of sEH, is thought to act on lipophilic compounds, but recent study has shown that it may also directly act on phosphorylated proteins, resulting complex pathway regulation. In our study, we found that mouse microglial cell, BV2 after OGD/R showed elevated sEH expression and morphological changes indicating activation. We then used sEH selective functional inhibitors, AFC and AUDA to target N- and C- terminus, respectively to delineate which domain is responsible for microglia activation. Our results indicated that inhibition of sEH phosphatase function leads to less morphological activation.

Title: Annexin-1 promotes microglial activation and migration during oxygen-glucose deprivation/reperfusion via formyl peptide receptors

Authors: *L. LIU, Y. GAO, S. LIU, J. SHI;
Dept. of Neurobio., Tongji Med. College, HUST, Hubei, China

Abstract: Annexin-1 (ANXA1) has been shown to have neuroprotective effects in the brain, and microglia play significant roles during CNS injury, yet the underlying mechanisms remain unclear. In this study, we sought to determine if ANXA1 regulates the microglial response to oxygen-glucose deprivation/reperfusion (OGD/R) treatment in rat hippocampal slices, BV-2 cells (a microglial-like cell line) and primary microglia. Using immunofluorescence imaging, we determined that expression of ANXA1 and formyl peptide receptors (FPRs), which are targeted by ANXA1, were increased after OGD/R treatment in hippocampal slices. Correspondingly, microglial activation in the CA1 region of the hippocampus was enhanced by OGD/R treatment. These effects were reversed by the FPR antagonist brother of CDO-1 (Boc1). In trans-well and scratch wound migration assays, we found that Ac2-26(the N-terminal peptide of ANXA1) treatment during OGD enhanced BV-2 migration, whereas Boc1 treatment during OGD/R inhibited migration. In primary microglia, we proved that AC2-26 could polarize microglia to an anti-inflammatory M2 phenotype to protect neurons from ischemia-like injury. Taken together, our findings indicate that ANXA1 promotes microglial activation and migration during OGD/R via FPRs to protect neurons.

Title: The induction of hippocampal long-term potentiation increases the motility of microglial processes and their engagement with dendritic spines

Authors: *T. PFEIFFER, E. AVIGNONE, V. NAGERL;
CNRS UMR 5297, Univ. of Bordeaux, Interdisciplinary Inst. For Neurosci., Bordeaux, France

Abstract: In the healthy brain microglia continuously scan their surroundings by rapidly extending and retracting their highly ramified processes. During this scanning activity microglia establish transient contacts with synapses in an activity-dependent way. Microglia can sense

changes in neuronal activity and their processes are steered towards active neurons, which may be mediated through the activation of neuronal NMDARs. Furthermore, recent work has implicated microglia in synapse remodeling during development and experience-dependent plasticity, giving rise to the idea that microglia might play a role in synaptic plasticity. However, very little is known about how microglia actually associate with synapses during basal synaptic transmission, and whether microglia can sense and respond to the induction of synaptic plasticity. Here, we investigated these questions using a combination of two-photon time-lapse imaging and electrophysiological recordings in acute hippocampal brain slices from transgenic mice, where microglia and neurons are fluorescently labeled. We analyzed the scanning motility of microglia and their physical interactions with dendritic spines of CA1 pyramidal neurons before and after the induction of hippocampal LTP using high-frequency electrical stimulation (HFS). Our analysis reveals that at any point in time only a very small fraction of dendritic spines were contacted by a microglial process. However, due to their high motility this fraction grew substantially over time. Contacts between microglial processes and dendritic spines were brief during basal synaptic transmission. After LTP induction microglial scanning motility was enhanced, while contact duration was prolonged and their number reduced. The application of the NMDAR antagonist APV prevented the HFS-induced changes in microglial scanning behavior and microglia-spine interactions. The elevated microglial motility and microglia-synapse contact stability during LTP corroborate the idea that microglia contribute to activity-dependent remodeling of synapses in the healthy mature brain. Recently, we have also used super-resolution STED microscopy to investigate the dynamic interactions between microglial processes and dendritic spines at the nanoscale in acute brain slices.

Sci., Nagoya, Japan

Abstract: Recently, it has been demonstrated that erythropoietin (EPO), a hematopoietic hormone, has a neuroprotective effect and EPO receptor (EPOR) is expressed in the central nervous system (CNS). In our previous study, brain immune cells microglia had higher EPOR

expressions than astrocytes and neurons. In this study, we investigated whether EPO could attenuate the cytotoxic activity of microglia stimulated by lipopolysaccharide(LPS). *In vitro*, we assessed the effect of EPO using microglial cell line BV-2 activated by LPS. The gene expressions of cytokines were analyzed by RT-PCR. LPS increased the gene expressions of cytokines in BV-2, but these increases were significantly suppressed by EPO. Next, we assessed the capacity of the phagocytosis of BV-2 using fluorescent polystyrene beads. LPS increased the phagocytosis in BV-2 compared with untreated BV-2, but this increase was significantly suppressed by EPO. *In vivo*, we investigated the effect of EPO on the brains of mice stimulated by LPS. LPS increased the gene expressions of cytokines in mouse brains. Most of the increases of cytokines were significantly suppressed by EPO. We also assessed the morphology of microglia in the brains of mice stimulated by LPS and EPO. LPS induced microglia to be activated types, but EPO alleviated the active morphological change. These data indicated that LPS made microglia activated and cytotoxic, but EPO-EPOR signal might attenuate LPS-induced microglial cytotoxic activation.

Abstract: Glaucoma is a retinal degenerative disease characterized by degeneration of retinal ganglion cells (RGCs) and damage of the optic nerve, and elevated intraocular pressure (IOP) is a major risk factor. Retinal neuroinflammation has been described in human glaucoma and in experimental models of the disease. Several reports have shown that microglia become reactive in glaucomatous eyes, which may contribute to RGC loss. Evidence shows that the blockade of adenosine A2A receptor (A2AR) affords protection against several noxious conditions, presumably through the control of microglia-mediated neuroinflammation. In this study, we aimed to assess whether blocking A2AR is able to control microglia reactivity elicited by elevated hydrostatic pressure (EHP), which mimics elevated IOP. Retinal primary neural cell cultures and microglial cell cultures (BV-2 cell line) were pre-treated with 50 nM SCH 58261, a selective A2AR antagonist, and exposed to EHP (70 mmHg above normal atmospheric pressure). Control cells were incubated in a standard cell incubator. Microglial cell morphology, phagocytosis, proliferation, migration, and the release of inflammatory cytokines were assessed. Exposure of retinal neural cell cultures to EHP for 24h increased microglia reactivity and the release of IL-1β and TNF, assessed by alteration in microglia morphology and ELISA, respectively. Furthermore, EHP increased microglia proliferation, as determined by EdU incorporation. The blockade of A2AR decreased cell proliferation and cytokine release elicited by EHP in primary retinal cultures. In BV-2 cells, exposure to EHP increased mRNA and protein levels of A2AR, as assessed by qPCR and western blotting, respectively. In addition, EHP increased microglia migration, determined by the scratch wound assay and modified Boyden chamber assay, as well as phagocytosis and the release of IL-1β and TNF. Pretreatment of BV2 microglia with SCH 58261 decreased migration, phagocytosis efficiency and cytokine release. Our results demonstrate that the blockade of A2AR is able to prevent microglia-mediated neuroinflammatory processes, controlling microglia reactivity, thus suggesting that A2AR antagonists could be envisaged as a therapeutic strategy for the management of retinal neuroinflammation in glaucoma.

Title: MicroRNA including exosome shuttling as a mechanism of neuron-microglia communication

Authors: *E. A. OLD, M. MALCANGIO;
Wolfson CARD, King's Col. London, London, United Kingdom

Abstract: The treatment of neuropathic pain remains problematic; patients' responses to current pharmacological interventions are often poor and associated with a number of undesirable side-effects, thus the identification of new targets for treating this debilitating condition is needed. A wealth of evidence has been obtained in recent years demonstrating the importance of neuron-glia communication in pain signaling in both its physiological and pathological form, and the manipulation of this process is proving a viable means to halt the development of chronic pain. Here we explore the contribution to neuron-glia signaling of microRNAs contained within exosomes. Exosomes are small vesicles (30-150nm) containing RNA or protein cargos that are secreted by all cells types, as such they occur endogenously in bodily fluids including blood and CSF. Indeed, whilst initially thought to be a cellular mechanism of waste disposal, exosomes are now considered to be highly specified enablers of intra- and intercellular communication, and recent evidence has indicated that exosomes can be speificically targeted to recipient cells. A number of *in vitro* and *ex vivo* approaches have been adopted to obtain the results presented here. The release of microRNAs containing exosomes has been induced from primary cultured dorsal root ganglia (DRG) neurons, and dorsal horn neurons in *ex vivo* slice mounts. These exosomes, isolated from the cell media or slice superfusates have been subjected to analysis by western blot and RT-QPCR to determine their contents. In addition to their protein or RNA rich core, exosomes are enriched in several raft-associated lipids, such as ceramide, and specific surface proteins which have these small vesicles to be immunofluroescently labeled and tracked as they are applied to and engulfed by non-neuronal cells *in vitro*. Here we report the uptake of neuron-derived exosomes by non-neuronal cells, and demonstrate that these exosomes express microRNAs likely to significantly regulate pain-associated genes following nerve injury, including the pro-inflammatory microRNAs let-7b and the pro-resolution associated microRNAs mir21. Additionally we demonstrate that the application of a noxious stimulus to neurons is able to alter the expression of microRNAs found with exosomes.

Title: Acute effects of glutamate on brain and spinal microglia

Authors: *S. BASKAR JESUDASAN[1], M. CHURCHWARD[2], K. G. TODD[1], I. R. WINSHIP[1];
[1]NMHI, Neurochemical Res. Unit, Dept. of Psychiatry, [2]Neurochemical Res. Unit, Dept. of Psychiatry, Univ. of Alberta, Edmonton, AB, Canada

Abstract: Microglia are a unique population of central nervous system (CNS) cells that, though haematopoietic in origin, play a key role in homeostasis of the CNS. Recent studies have shown microglia are involved in regulating neural progenitor populations, pruning of synapses during development, monitoring the heath of the adult CNS, and initiating responses to any perturbation in the CNS. Understanding the role of environment in moderating microglial activity will further enhance our knowledge of their role in outcome after an insult to the CNS. It has been shown that ischaemic stroke and spinal cord injury cause neuronal and glial morbidity, leading to release of neurotransmitters such as glutamate, ATP and increase in cellular debris in the extra cellular milieu. Glutamate released in the extra cellular milieu induces excitotoxic injury to neurons and chemotaxis of microglia during the early stages of ischaemia in the CNS. To what extent glutamate induces release of pro-inflammatory molecules and phagocytosis is unknown. Here, we tested the acute effects of varying concentrations of glutamate, mimicking physiological and ischaemic glutamate levels, on release of cytokines including interleukin (IL)-1β, IL-6 and tumour necrosis factor alpha (TNF-α) and phagocytic activity of microglia derived from the brain or spinal cords of neonatal rats. We found that glutamate at physiological concentrations as well as at concentrations mimicking ischaemia did not induce a significant increase in the level of TNF-α, IL-1β and IL6. However, an overall reduction in TNF-α release by spinal cord microglia was observed relative to brain microglia. Phagocytic activity of brain and spinal microglia was not significantly affected by glutamate at physiological or at concentrations mimicking ischaemia. These data suggest that glutamate is not an inducer of pro-inflammatory factors such as TNF- α, IL-1β and IL-6, and that the major role of glutamate is to recruit microglia to the site of excitotoxic injury. The inflammation observed at sites of excitotoxic injury could be due to interaction of microglia with the myriad of molecules that are released at such sites and interaction with other glial as well as infiltrating cells

Title: Microglia establish region specific phenotypes in the basal ganglia and exhibit variable responses to normal aging

Authors: *L. M. DE BIASE[1], Z. H. FUSFELD[1], K. E. SCHUEBEL[2], K.-W. JAIR[2], H. ZHANG[1], Q.-R. LIU[1], S. P. RIBEIRO[1], R. CIMBRO[3], I. A. HAWES[1], H. SHEN[1], Z.-X. XI[1], D. GOLDMAN[2], A. BONCI[1];
[1]Natl. Inst. on Drug Abuse, Baltimore, MD; [2]Natl. Inst. on Alcohol Abuse and Alcoholism, Rockville, MD; [3]Rheumatology, Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Microglia promote brain homeostasis by removing debris from the extracellular space and responding to diverse CNS insults. Microglia can also influence synaptic transmission through release of inflammatory and trophic signaling factors and activity-dependent phagocytosis of synapses. Although regional differences in microglial density and morphology have been reported, these cells are generally assumed to be functionally equivalent throughout the CNS. We used transgenic mice that express EGFP within microglia to quantify anatomical, electrophysiological, and molecular properties of these glia within the basal ganglia (BG), a collection of brain nuclei that regulate goal-directed behaviors and are pathologically altered during addiction and neurodegenerative disease. Immunohistochemical analysis revealed that microglial density in the nucleus accumbens (NAc) was comparable to that reported for cortex, while density in the substantia nigra pars reticulata (SNr) was markedly elevated and that in the ventral tegmental area (VTA) and substantia nigra pars compacta (SNc) was significantly depressed. SNr and NAc microglia also displayed highly complex morphologies compared to VTA and SNc microglia. These anatomical distinctions were accompanied by differences in intracellular lysosome content and distribution, suggesting that microglial phagocytotic activity or metabolic state may vary across BG nuclei. Electrophysiological recordings of microglia in acute brain slices revealed that SNr microglia have more negative resting membrane potential than VTA or SNc microglia. In addition, 65% of microglia within the SNr exhibited delayed rectifier potassium currents, whereas only 9% of VTA and SNc microglia displayed such currents, which have been linked to expression of P2Y12 receptors. Whole transcriptome RNA sequencing of microglia isolated from distinct BG nuclei revealed broad similarities in gene expression between BG microglia and cortical microglia. In addition, microglia from each BG nucleus also exhibited unique gene expression signatures, challenging the idea that these cells are functionally equivalent. During the course of normal aging, region-specific differences in microglial branching complexity are largely maintained. However, abnormal soma shape and bulbous swellings along cell processes were more prominent in midbrain as compared to forebrain BG nuclei. Together these findings indicate that microglia establish region-specific phenotypes within the BG and raise important questions about the impact of this heterogeneity on neuronal function and susceptibility to neurodegeneration and other pathologies.

Title: Early inflammation dysregulates neural circuit formation *in vivo* via microglial activation and IL-1β

Authors: *N. FAROOQI, J. P. ANTEL, E. S. RUTHAZER;
McGill Univ., Montreal, QC, Canada

Abstract: Studies of maternal infection and genome-wide association studies strongly implicate the immune system in the aetiology of neuropsychiatric disease including autism and schizophrenia. The mechanistic links between immune activation and neural circuit formation remain largely obscure. We investigate these links by acutely exposing larval zebrafish to bacterial lipopolysaccharide (LPS) and observing neural development before and after inflammation. Bath-exposure to LPS induces acute upregulation of inflammatory cytokines (TNFα, IL-1β, IL-6) and induces microglia to adopt an amoeboid morphology consistent with activation. *In vivo* two-photon microscopy of retinal ganglion cells (RGCs) after two-hour LPS exposure demonstrates acutely increased rates of axonal branch addition and retraction. Daily imaging of axons after LPS exposure, however, reveals a stunted developmental trajectory with smaller, simpler arbors and fewer presynaptic puncta. Acute structural hyperplasticity followed by reduced arborisation may suggest a failure to stabilise nascent synapses. To investigate the cellular and molecular mechanisms of these effects, we performed morpholino knockdown of the SpI1/Pu.1 transcription factor to deplete the myeloid lineage. Morphant animals lack microglia and macrophages. RGCs in Spi1/Pu.1 morphants exposed to LPS do not demonstrate either the acute or lasting perturbations of arborisation seen in wildtype LPS-treated animals, suggesting that microglial activation is necessary for these effects. Morpholino knockdown of IL-1β phenocopies the effect of myeloid depletion and administration of recombinant IL-1β mimics the effect of LPS, demonstrating that IL-1β is necessary and sufficient to mediate the developmental effects of inflammation. By indicating mechanistic links between early inflammation and neurodevelopmental processes, this work may suggest therapeutic interventions to mitigate the effects of inflammatory insult on a developing brain. Title: Metabolic Stress and Survival of Microglia

Authors: *M. A. CHURCHWARD, K. G. TODD;
Psychiatry, Univ. of Alberta, Edmonton, AB, Canada

Abstract: As the primary immune cells of the central nervous system (CNS), microglia have been increasingly recognized for their contributions to development and maintenance of the CNS including activity-dependent synaptic refinement, maintenance of neural progenitor populations, and homeostatic control. In conditions of injury, infection, or duress however, microglia are responsible for surveillance, initiation of inflammatory cascades, and clearance of debris from sites of injury. As a consequence of this role microglia are capable of surviving and proliferating in conditions that are injurious to other cell types. The core of an ischemic injury is defined by the absence of blood flow resulting in oxygen and glucose deprivation, though microglia migrate to and proliferate in the ischemic core. We sought to investigate the factors contributing to the survival of primary cultured microglia in adverse conditions. Glucose deprivation (GD) for extended periods (up to 48 h) was insufficient to increase release of inflammatory factors from microglia *in vitro*, however phagocytosis was markedly increased after 24 h GD relative to normal glucose. Glucose deprivation did not adversely affect the viability of microglia: in fact increased cell counts were observed following 24 h GD, suggesting increased survival and/or proliferation in the absence of glucose. Pharmacological manipulation of lipid metabolism yielded effects that were dependent on the presence of glucose: inhibition of triglyceride biosynthesis increased both microglial viability and phagocytosis in the presence, but not absence of glucose. These data suggest microglia may survive hostile conditions in injury by metabolism of alternative energy stores including lipids in order to sustain essential protective and reparative functions.

Title: LPS enhanced M2-polarized macrophages/microglia promote robust remyelination in lysolecithin demyelination injury

Authors: ***M. K. MISHRA**, K. RAWJI, M. B. KEUOGH, Y. FAN, V. W. YONG;
Clin. Neurosci., Univ. of Calgary, Calgary, AB, Canada

Abstract: Macrophages and CNS-resident microglia are broadly classified into pro-inflammatory M1 and anti-inflammatory M2 subtypes, and they may switch from one state to the other depending on the microenvironment. Using well-described culture conditions, specifically interferon-γ/lipopolysaccharide (LPS) and IL-4/IL-13 respectively, we have generated M1 and M2 cells in order to address their effects on neurons and oligodendrocyte precursor cells (OPCs) in culture, on altering the functions of the chondroitin sulfate proteoglycans (CSPGs) implicated in inhibiting remyelination, and on mediating recovery from demyelination in mice. Unexpectedly, we discovered that the LPS stimulation of M2 cells during their polarization further enhanced M2 characteristics and their beneficial properties, in part through elevation of IL-4 receptor and IL-10 expression. The LPS-enhanced M2 cells did not kill neurons and OPCs in culture, unlike the M1 cells generated by interferon-γ and LPS. To investigate the impact of polarized macrophages/ microglia *in vivo*, we inflicted demyelination of the dorsal column of the mouse spinal cord using lysolecithin; 3 days after, saline, M1 and M2-polarizing conditions, or M2+LPS were locally applied at the site of injury. Treatment that generated M1 exacerbated injury, M2 had negligible effect on the evolving insult, while the LPS-enhanced M2 treatment diminished the accumulation of inhibitory CSPGs, increased the number of oligodendrocyte precursors, and reduced lesion volume. LPS enhanced M2 treatment promotes remodelling at the lesion microenvironment that results in robust remyelination at day 21 after lysolecithin demyelination. These data suggest that toll-like receptor-4 stimulation of M2 cells during their polarization can dramatically enhance their beneficial M2 characteristics to favor recovery from CNS insults.

Title: Pharmacological depletion of microglia attenuates experimental autoimmune encephalomyelitis

Authors: *J. NISSEN, S. E. TSIRKA;
Pharmacol., Stony Brook Univ., Stony Brook, NY

Abstract: Multiple sclerosis (MS) is a chronic autoimmune disease of the central nervous system (CNS) that is characterized by the progressive demyelination and degeneration of neurons. As MS progresses, T cells that are normally excluded from the CNS cross the compromised blood-brain barrier due to recruitment by the resident CNS immune cells, microglia. These microglia then become activated and release a variety of inflammatory cytokines that greatly contribute to disease progression. Thus, therapeutic approaches in MS focus on diminishing inflammation and promoting expansion of anti-inflammatory immune cell populations. Here, we show that drug-based ablation of microglia significantly improves symptoms in experimental autoimmune encephalomyelitis (EAE), an animal model of MS. Further, we show that this treatment addresses the pathological hallmarks of MS as well, for ablation of microglia reduces demyelination and immune activation. Taken together, these findings indicate that manipulation of microglial numbers is a promising treatment for MS.

Title: *In vivo* activating microglia imaging in multiple sclerosis using PET with DPA-713

Authors: *S. KONO[1], T. TERADA[2], Y. OUCHI[2], H. MIYAJIMA[1];
[2]Dept. of Biofunctional Imaging, Med. Photonics Res. Ctr., [1]Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan

Abstract: *In vivo* activating microglia imaging in multiple sclerosis using PET with DPA-713 Abstract *Introduction:* Multiple sclerosis (MS) is an inflammatory demyelinating disease of the central nervous system. Activated microglia and macrophages play a key role in the immunopathogenesis of MS. Microglia activation is associated with elevated expression of the 18 kDa mitochondrial translocator protein (TSPO). This study evaluated imaging of activated microglia in MS patients using the PET tracers [^{11}C]-DPA-713, TSPO-specific radioligands. *Methods:* Six relapsing and remitting type of MS patients (mean age 38.8 ± 10.8) in the early stage of disease (EDSS 1 or 2) and six age-matched normal controls (37.8 ± 22.3) underwent [^{11}C]-DPA713-PET scan. The MS patients were treated with disease modifying therapy including interferon β1b (IFNβ1b) and fingolimod. All patients were followed-up and the second PET scan was performed one year later. The binding potential (BP_{ND}) was estimated using simplified reference tissue model. Statistical Parametric Mapping (SPM) was used to compare regional BP_{ND} levels between the MS and control groups. *Results:* All the MS patients displayed a significant increase of DPA BP_{ND} in the left cerebellum, the bilateral putamen, the bilateral cerebral area, and brainstem at the first PET scan in the ROI analysis. Accumulation of DPA was observed in cortical area as well as white matter which are independent from demyelinating plaques. Furthermore, increases in [11C]-DPA713 BP were found more broadly in the whole brain at the second PET scan in the SPM analysis. There were no difference in change of DPA BP_{ND} in the MS patients with treatment with fingolimod and IFN1b *Conclusion:* The DPA-PET study indicates that activated microglia is implicated in the normally appearing white matter and cortical area even in the early stage of MS. The effect of disease modifying therapy can be monitored *in vivo* by measuring the degree of microglial activation on DPA-PET.

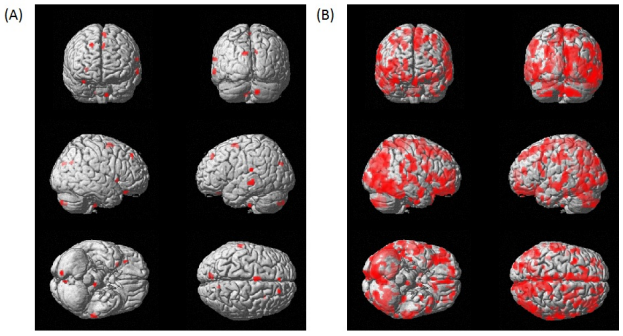

Figure legend
The regions of statistically significant increase in [11C]DPA binding potential in Multiple Sclerosis patients group (A) at first scan compared to age-matched controls group, and (B) at second scan after one year later (p<0.001, uncorrected, extend threshold 10).

Title: Selective manipulation of spinal microglia by chemogenetics: implications for allodynia and inflammatory signaling

Authors: *P. M. GRACE[1], X. WANG[1], D. J. URBAN[2], M. V. BARATTA[1], E. L. GALER[1], K. A. STRAND[1], Y. ZHANG[1], H. YIN[1], B. L. ROTH[2], S. F. MAIER[1], L. R. WATKINS[1]; [1]Psychology and Neurosci., Univ. of Colorado, Boulder, Boulder, CO; [2]Univ. of North Carolina, Chapel Hill, NC

Abstract: The absence of selective pharmacological tools is a major barrier to the *in vivo* study of microglia. To address this issue, we developed a Gq- and Gi-coupled Designer Receptor Exclusively Activated by a Designer Drug (DREADD) to enable selective stimulation or inhibition of microglia, respectively. DREADDs under a CD68 (microglia/macrophage) promoter were intrathecally transfected via an AAV9 vector. Naïve rats intrathecally transfected with Gq (stimulatory) DREADDs exhibited significant allodynia following intrathecal administration of the DREADD-selective ligand clozapine-N-oxide (CNO), which was abolished by intrathecal interleukin-1 receptor antagonist. Chronic constriction injury-induced allodynia was attenuated by intrathecal CNO in rats intrathecally transfected with Gi (inhibitory) DREADDs. To explore mechanisms, BV2 cells were stably transfected with Gq or Gi DREADDs *in vitro*. CNO treatment induced pro-inflammatory mediator production per se from cells expressing Gq-DREADDs, and inhibited lipopolysaccharide-induced pro-inflammatory mediator production from cells expressing Gi-DREADDs. These studies are the first to manipulate microglia using DREADDs, which allow the role of glia in pain to be conclusively demonstrated, unconfounded by neuronal off-target effects that exist for all other glial inhibitors. Hence, these studies are the first to conclusively demonstrate that *in vivo* stimulation of resident spinal microglia in intact spinal cord is a) sufficient for allodynia, and b) necessary for allodynia induced by peripheral nerve injury. DREADDs are a unique tool to selectively explore the physiological and pathological role of microglia *in vivo*.

Title: Intracellular calcium dynamics in cortical microglia responding to focal laser injury

Authors: ***P. TVRDIK**, A. POZNER, B. XU, S. PALUMBOS, J. GEE, M. R. CAPECCHI; Human Genet., Univ. of Utah, Salt Lake City, UT

Abstract: Microglia are highly reactive to tissue injury. In response to focal damage, microglia extend their processes toward the compromised tissue. The cell motility aspects of this behavior have been characterized, but the intracellular events, particularly the Ca2+ responses, have not been systematically studied in microglia due to technical difficulty. Here we used live two-photon imaging in the PC::G5-tdT reporter mouse expressing the genetically encoded Ca2+ indicator GCaMP5G and fluorescent marker tdTomato in cortical microglia. We found that spontaneous Ca2+ transients in microglial somas and processes were generally low (only 4% of all microglia showing transients within 20 min), but baseline activity was markedly increased when the animals were subcutaneously injected with LPS 12 h before imaging. When challenged with focal laser injury, an additional surge in Ca2+ activity (up to 67%) was observed in the somas and protruding processes, particularly in close proximity to the damaged tissue. Notably, coherent and simultaneous Ca2+ rises in multiple microglial cells were occasionally detected in LPS- and bicuculline-treated animals. We have demonstrated that Ca2+ transients were predominantly mediated via purinergic receptors. We also compared the speed of process extension in BAPTA-AM- and the purinergic receptor antagonist PPADS-treated animals and showed that BAPTA-AM significantly slowed the process protrusion, but PPADS did not. This study illustrates the suitability of the PC::G5-tdT mouse reporter for investigations of microglial physiology.

Title: Macrophages and microglia that phagocytose myelin debris acquire a unique activation status and produce factors that stress axons

Authors: *M. M. STANDIFORD, C. L. HOWE;
Mayo Grad. Sch., Rochester, MN

Abstract: There are several treatments for multiple sclerosis (MS) that reduce relapse rate and lesion accumulation on MRI, however, at present none of these therapies are of proven benefit in reducing the progression of long-term clinical disability. Although MS is characterized as a demyelinating disorder, neurologic disability associated with the disease is correlated with markers of axonal injury rather than markers of demyelination. This suggests that damage to axons is the principal cause of irreversible disability in MS and that the mechanisms underlying demyelination and axon injury may be fundamentally different from one another. Nonetheless, we know that demyelination is a necessary, albeit insufficient, condition for axon injury in MS. We therefore tested the hypothesis that macrophages and microglia exposed to myelin debris acquire an activation phenotype that creates an environment within demyelinated lesions which, in turn, drives immunological recognition of denuded axons. On axons cultured in microfluidic chambers, we have observed that interferon gamma induces upregulation of MHC class I molecules loaded with endogenous neoantigen peptides and that this renders the axons susceptible to perforin- and granzyme-dependent injury by antigen-specific CD8+ T cells. We have also observed that myelin debris triggers a unique activation pattern in macrophages and microglia that is consistent with the production of cytokines that drive MHC class I expression on axons. This activation phenotype has a blend of traditional M1 and M2 characteristics and is unique to myelin stimulation. We conclude that demyelination results in immune-mediated axon injury via an indirect mechanism that involves macrophage and microglial activation by myelin debris.

Title: CSF from progressive MS patients stimulates microglial activation pathways *in vitro* and *in vivo*

Authors: *M. CRISTOFANILLI, K. MCDERMOTT, B. PAGANO, D. GRATCH, S. A. SADIQ;
Tisch MS Res. Ctr. of New York, New York, NY

Abstract: Microglia are resident immune cells in the CNS that act as macrophages when activated by injury or disease. This activation is a characteristic of inflammatory diseases like multiple sclerosis (MS) in which two main phenotypes occur: classically activated pro-inflammatory M1 and alternatively activated anti-inflammatory M2. However, the exact role of M1/M2 cells in MS is not fully understood. In this study, we investigated the effect of MS cerebrospinal fluid (CSF) on microglial activation using our recently published mouse model of progressive MS. In this model, mice develop inflammatory demyelinating brain lesions after serial intracerebroventricular injections of acellular CSF obtained from untreated progressive MS patients. Here we injected mice with CSF from 7 primary progressive (PP), 7 secondary progressive (SP), and 5 relapsing remitting (RR) MS patients, as well as from 4 non-MS inflammatory controls (IC) and 2 healthy individuals (HC). Microglia/macrophages were extracted from mice brains (n=3 per patient) with a Percoll gradient for FACS analysis. Compared to naïve mice or mice injected with artificial CSF, animals in all other groups displayed an upregulation of CD11b+/CD45high macrophages. In addition, the number of these cells was significantly higher in the PP and SP groups than controls. Remarkably, CSF derived from progressive MS patients who were clinically stable following therapy had greatly diminished capacity to activate microglia/macrophages compared to the paired untreated samples. To further investigate the mechanism of CSF-induced microglial activation, we stimulated BV-2 cells, a homogenous murine cell line expressing phenotypical and functional markers of macrophages, with the same CSF cohort described above. FACS and q-PCR analysis were used to asses M1/M2 polarization. The number of M1 macrophages was significantly increased in the PP group compared to the RR and control ones. A similar trend was found for the SP group without statistical significance. M2 macrophages were significantly higher in both the PP and HC groups compared to the RR and IC ones. Once again, the SP group showed a similar trend to the PP group without statistical significance. Interestingly, M1 were more abundant than M2 for each group with the exception of the HC treated samples, which had an even cell distribution. In conclusion, our preliminary evidence suggests the existence of intrinsic differences related to microglial activation between MS and non-MS patients and within MS

subtypes. Future studies will aim to pinpoint specific factors in the progressive MS milieu responsible for the reported microglia polarization toward M1/M2 phenotypes.

Title: Triggering a moderate brain inflammatory response by MPL or Pam3Cys preserve normal performance in a rat model of Alzheimer's disease

Authors: *H. G. BADIE[1,2], M. SAYYAH[2], B. KHOSHKHOLGH-SIMA[2], S. CHOOPANI[2], M. SHOKRGOZAR[3];
[1]Neurosci. Res. Ctr., Neurosci. Res. Ctr., Tehran, Iran, Islamic Republic of; [2]Physiol. and Pharmacol., [3]Pasteur Inst. of Iran, Tehran, Iran, Islamic Republic of

Abstract: Introduction: Alzheimer's disease (AD) is a neurodegenerative disorder characterized by the accumulation of amyloid β (Aβ) in brain parenchyma. Inflammation along with the progression of the disease, is associated with the production of cytokines by activated microglia. Although Aβ oligomers fail to fully activate microglia, Aβ plaques can trigger the exaggerated release of cytokines and neurotoxic mediators which could be detrimental to neurons. On the other hand, activated microglia can clear Aβ via increased phagocytosis and proteolytic degradation, which may be neuroprotective. Toll-like receptors (TLRs), especially TLR2 and TLR4, on the surface of microglial cells play a critical role in clearance of Aβ. Therefore, in this study the possible neuroprotective effect of pretreatment with agonists of these receptors were examined. Methods: Pretreatment with MPL (Monophosphoryl lipid A) and Pam3Cys, partial agonists for TLR4 and TLR2 respectively, were examined in cell culture and *in vivo* to indicate whether they could prevent or attenuate the symptom of AD in a rat model of AD by implanting Alzet pump filled with Aβ. Results: In the cell culture experiment, we found that whereas Aβ oligomers did not significantly stimulate BV-2 cells to produce cytokines, pretreatment with MPL or Pam3Cys led to increase release of TNF-α, IL6 and IP10. However,their levels were less than those pre-retriggered by LPS. In western blot, MPL and Pam3CYS increased the expression of FPR2 protein which is involved in clearance of Aβ. AD animals pretreated with MPL and Pam3Cys showed improved reference spatial and working memory. However, pretreatment by LPS has not improved behavioral performance in these rats. Conclusion: Further studies are needed in this context, however, our data provide an early promising result in preventing AD by triggering an early and specific moderate neuroinflammatory reaction.

Title: The effect of polysaccharide of cistanche deserticola on synaptic plasticity in mice

Authors: ***G. LI**, M. GUO, H. ZHANG, Y. WU, R. YIN;
Inner Mongolian Med. Univ., Hohhot, China

Abstract: Cistanche deserticola MA is a “Yang-invigorating” tonic herb in Chinese medicine. We isolated a polysaccharide from C. deserticola (CDP), studied the effect of the polysaccharide on memory acquisition impairment. Aim: To study the effect of polysaccharide of Cistanche deserticola (CDPS) on synaptic plasticity and in studying and learning. Methods: Memory acquisition impairment model in mouse was established with scopolamine,the improvement in the memory acquisition impairment of mouse after was observed by step-down test and morris water maze assays.The ultra-thin specimens of hippocampus were observed under transmission electron microscope. Western blotting analysis were used to examined the expression of PSD-95,GAP-43 and SYP, respectively. Results: polysaccharide of Cistanche deserticola(50mg/kg,100mg/kg)could significantly reduce the number of errors and extend the incubation period in the step-down test.CDP (50mg/kg) could shorten the incubation period of female mouse in the water maze test. polysaccharide of Cistanche deserticola 100mg/kg could shorten the incubation period of male mouse in the water maze test. The ultra-thin specimens of hippocampus: 1)In the sham-operated group,the neuron and neuropil of hippocampus showed ultrastractual detail of normal range. 2)In the model group , the number of synapse was reduced,perforated or dysmorphic synapses were observed,and synapse vesicles were destroyed to be homogenized. We can see from the results of western blot that the expression of PSD-95,GAP-43 and SYP in hippocampus of mouse were increased significantly.Conclusion:Our findings suggest that polysaccharide of Cistanche deserticola markedly improved the behavior-learning and memory in mouse,which may be related to improvememt of the plasticity of synaptic morphology.

Title: Neurochemical characterization of xanomeline and a selective muscarinic M4 receptor positive allosteric modulator in the rat and non-human primate

Authors: *M. KANDEBO[1], J. MARCUS[2], M. STRANIERI MICHENER[3], B. E. SMITH[3], S. M. SMITH[4], L. YAO[4], J. A. MORROW[1];
[1]Late Discovery Psychiatry & Psychosis, [2]Late Discovery AD Cognition & Sleep, [3]Clin. Services, [4]Early Discovery Biol., Merck & Co., Inc., West Point, PA

Abstract: Xanomeline is a M1/M4 preferring muscarinic receptor agonist that has shown to alleviate behavioral (psychosis) and cognitive disturbances in Alzheimer's disease and schizophrenia patients. Xanomeline, however, has limited clinical use because of its adverse parasympathetomimetic effects associated with its muscarinic subtype selectivity profile. Preclinical data has shown that the antipsychotic-like profile of xanomeline is mediated predominantly by activation of striatal muscarinic M4 receptors in D1 receptor expressing direct pathway medium spiny neurons. Selective M4 muscarinic agonists and positive allosteric modulators demonstrate equivalent therapeutic potential to xanomeline in preclinical models of psychosis however with reduced propensity for adverse effects. To further elucidate the M1 versus M4 muscarinic receptor mediated effects of xanomeline, catecholamine profiles in the cerebrospinal fluid of non-human primate (NHP) were determined following single dose administration of xanomeline and Compound A, a selective M4 positive allosteric modulator. 0.2mg/kg dose of xanomeline and a 1mg/kg dose of Compound A resulted in significant accumulation of DA metabolites, dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA) in NHP CSF. Neither xanomeline nor Compound A had a significant effect on DA concentrations. Furthermore, xanomeline, but not Compound A administration, significantly increased norepinephrine concentrations in NHP CSF suggesting this effect may be mediated through M1 muscarinic receptors. Conversely, Compound A, but not xanomeline administration, significantly decreased histamine (HA) and tele-methylhistamine (t-MeHA) in the NHP CSF. Further *in vivo* neurochemical characterization in rodents produced similar effect of xanomeline and Compound A on accumulation of DA metabolites in the striatum of Sprague Dawley rat with no effect on DA concentrations. Additionally Compound A attenuated the effects of Thioperamide, a H3 antagonist, on t-MeHA accumulation in the striatum of Sprague Dawley rat, providing additional evidence for the role of M4 muscarinic receptors in the modulation of histaminergic neurotransmission. These results demonstrate that xanomeline and selective M4 PAMs possess similar neurochemical profiles in terms of their effects on DA and DA metabolites but differentiate in terms of their effects on NE and HA/t-MeHA. Together, these

findings provide an insight into M4 muscarinic receptor mediated DA signaling and are the first to provide evidence of a role for M4 muscarinic receptors in modulation of histaminergic neurotransmission.

Title: Role of Somatostatin in RA induced neurogenesis of SH-SY5Y cells and βA induced toxicity

Authors: S. PAIK, R. K. SOMVANSHI, *U. KUMAR;
Pharmaceut. Sci., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Introduction: Somatostatin (SST, SRIF) is a growth hormone inhibitory peptide first isolated from hypothalamus. SST is widely expressed in different body parts and is also produced in neuroendocrine cells and regulates variety of physiological functions including hormonal secretion and cell proliferation. Previous studies have reported that the SST is one of the most consistently down-regulated genes across all Alzheimer's Disease (AD) patients, both in post-mortem brain and in cerebrospinal fluid (CSF). Consistent with these findings, our lab has also observed significant loss (>70%) of SST-immunoreactive neurons in the frontal cortex of AD brains. In the present study, we aim to elucidate the exact role of SST in neurogenesis of human-derived neuroblastoma cell line as well as to study its protective role against β-Amyloid (βA) induced toxicity. Methods: SH-SY5Y cells were differentiated with 10μM of retinoic acid (RA) with or without SST (concentration and time dependent manner) for 5-7 days. Post treatment cells were processed for the expression of SST receptor (SSTR) subtypes and neuronal markers including DCX (doublecortin), GFAP (Glial fibrillary acidic protein) and MAP2 (Microtubule-associated protein 2) at the level of mRNA and protein using qRT-PCR, Western blot and immunofluorescence immunocytochemistry. Also, βA induced toxicity in non-differentiated and/or differentiated cells were determined using MTT assay in absence or presence of SST. Results: Morphological analysis revealed significant elongation of neurites in RA-induced neuro-differentiation which was further enhanced in presence of SST in concentration dependent manner when compared to RA treatment alone. Furthermore, qRT-PCR

and western blot analysis support promotion of neurogenesis in presence of SST as indicated by increased expression of DCX, GFAP and MAP2 as well as loss of Nestin (marker for stemness). In addition, MTT assay and Hoechst dye staining clearly indicate protective role of SST in βA induced toxicity and inflammation in concentration and time dependent manner. Conclusion: Taken together, the results presented here indicate that SST enhanced RA mediated neurite elongation and markers of neurogenesis as well as exert a neuroprotective role against βA induced neurotoxicity.

Abstract: In spite of high morbidity rate among the elderly, there is no effective treatment capable of slowing the progression of Alzheimer's disease (AD). A few drugs for AD, such as acetylcholine esterase inhibitor and N-methyl-D-aspartate receptor antagonist, has been developed and used in clinic, although the efficacy seems not to be enough. We previously reported that centrally acting antitussives inhibit G-protein-coupled inwardly rectifying potassium (GIRK) channel currents in brain neurons. Interestingly, these drugs at antitussive effective doses ameliorated symptoms of the animal models of various intractable brain diseases. We also demonstrated that donepezil, therapeutic drug of AD, at relatively low concentrations inhibits GIRK channel current. Recently, it was reported that selective activation of dopamine

D_1/D_5 receptors protects neurons from synaptic dysfunction induced by amyloid β (Aβ) oligomers. In addition, environmental enrichment mitigates cognitive deficits in APP and APP/PS1 mice and increases the dopamine level in the nucleus accumbens. These reports suggest that activation of dopamine system in the brain may be important for effective therapy for AD. Interestingly, we revealed that antitussives increase the dopamine level in the prefrontal cortex and nucleus accumbens in rodents. According to these findings, antitussives possessing GIRK channel inhibiting action may be a potential candidate of effective therapeutic drugs for AD, having the novel mechanism of the action. In this study, therefore, we examined an effect of tipepidine and cloperastine, possessing GIRK channel inhibiting action, on $A\beta_{25-35}$ injected mice known as one of the useful models of AD. We used male ICR mice (5-week-old). Mice were intra-cerebroventricularly (i.c.v.) injected vehicle (3.2 μL) or $A\beta_{25-35}$ (3 nmol/3.2 μL), according to the method of Haley and McCormick (1957). Then, we performed the novel object recognition test (NORT) on days 5-8 after i.c.v. injection. Tipepidine and cloperastine at 40 mg/kg were subcutaneously administered 30 min before the training session of the NORT. Both drugs reversed to the same extent $A\beta_{25-35}$ induced decrease in discrimination of index in the retention session of the NORT, suggesting that tipepidine and cloperastine may have antiamnesic like effects. Pharmacological mechanisms of antiamnesic like effects of both drugs are now under investigation.

Title: CB2 receptors are not required in ameliorating Alzheimer’s disease neuropathology by inhibition of MAGL

Authors: J. ZHANG[1], *C. CHEN[2];
[1]Neurosci. Ctr., [2]LSU Hlth. Sci. Ctr., New Orleans, LA

Abstract: We and others reported previously that inhibition of monoacylglycerol lipase (MAGL), the primary enzyme that metabolizes the endocannabinoid 2-arachidonoylglycerol (2-

AG) in the brain, produces profound anti-inflammatory and neuroprotective effects and improves synaptic and cognitive function in mouse models of Alzheimer's disease (AD). However, the molecular mechanisms underlying the beneficial effects produced by inhibition of 2-AG metabolism are still not clear. CB2 receptors are primarily expressed in astroglial cells in the brain and play an important role in neuroinflammation. To determine whether CB2 receptors are involved in ameliorating AD neuropathology produced by MAGL inactivation, we created amyloid precursor protein (APP) transgenic mice lacking the CB2 receptor (TG-CB2 KO). The results show that expression of APP, β-site amyloid precursor protein cleaving enzyme 1 (BACE1) and formation of total Aβ, Aβ42 and CTFβ/α were still elevated in TG-CB2 KO mice when compared with those in wild-type (WT)-CB2 KO mice. The elevation was reduced by JZL184, a selective and potent inhibitor for MAGL. To determine whether suppression of neuroinflammation by inhibition of 2-AG metabolism is mediated via CB2 receptors, expression of GFAP, an astrocytic marker, was detected in TG-CB2 KO mice. GFAP immunoreactivity in the brains was reduced in TG-CB2 KO mice that received JZL184. Similarly, the number of degenerated neurons in the brain was decreased in animals treated with JZL184. Importantly, spatial learning and memory assessed by the Morris water maze were significantly improved in TG-CB2 KO mice treated with JZL184 when compared with that of vehicle controls. In addition, reduced expression of glutamate receptor subunits in TG-CB2 KO mice was rescued by treatment with JZL184. Our results suggest that CB2 receptors do not play an important role in alleviating neuropathology and improving cognitive function produced by inhibition of 2-AG metabolism.

Title: L-3-n-butylphthalide improves cognitive impairment in APP/PS1-AD transgenic mouse model by enhancing neurogenesis

Authors: *Y. PENG, H. LEI, Y. ZHANG, S. XU, J. LI, L. WANG, X. WANG;
Inst. of Materia Medica, Beijing, China

Abstract: Alzheimer's disease (AD) is an age-related and irreversibly progressive neurodegenerative disorder that occurs gradually and results in memory, behavior and personality changes. L-3-n-butylphthalide (L-NBP), an extract from seeds of *Apium graveolens Linn* (Chinese celery), has been demonstrated to have neuroprotective effects on ischemic, vascular dementia and amyloid-ß (Aß)-infused animal models by inhibiting oxidative injury, neuronal apoptosis and glial activation, regulating APP processing and reducing Aß generation. In the current study, we examined the effect of L-NBP on learning and memory deficits in a APP/PS1-AD transgenic mouse model 3-month-old transgenic mice were given 15mg/kg L-NBP by oral gavage for 3 months. After behavioral testing was completed, the mice were sacrificed. The brains were removed for immunohistochemistry and Western blot. The results showed that L-NBP treatment significantly improved the spatial learning and memory deficits compared to the vehicle-treated APP/PS1 mice. L-NBP treatment significantly reduced the diffuse and compacted fibrillar Aβ plaques in the hippocampus. Furthermore, we found that L-NBP markedly enhanced soluble amyloid precursor protein secretion (αAPPs) release, but had no effect on the level of steady-state full-length APP. The effect of L-NBP on decreasing Tau phosphorylation at Thr231 was significant. L-NBP treatment significantly reduced Iba-1 immunoreactivity compared to the vehicle-treated APP/PS1 mice. Furthermore, L-NBP markedly increased $BrdU^+$ cells in hippocampal DG region and partially reversed the down-regulation of neurotrophin expressions compared to the vehicle-treated APP/PS1 mice. Moreover, L-NBP markedly enhanced pTrkA(Y490)/TrkB(Y516),pCREB,pAkt and pSTAT3 expression. In addition, we checked whether L-NBP regulated neuronal stem cells (NSCs) proliferation, migration, and differentiation *in vitro*. The results showed that L-NBP increased the total number of neurospheres and the number of large neurospheres (greater than 60μm in diameter), and enlarged the migration distance of neurospheres. L-NBP raised the number of Tuj-1 positive neurons, and non-significantly decreased GFAP positive astrocytes amount, indicating that L-NBP might induce the neuronal differentiation of NSCs toward mature neurons. Taken together, L-NBP shows promising preclinical potential as a multi-target drug for the prevention and/or treatment of Alzheimer's disease.

Title: Transient receptor potential ankyrin 1 (TRPA1) is important for AβO-induced toxicity: a new perspective for Alzheimer's disease?

Authors: *M. A. BICCA[1,2], E. C. S. SANTOS[1], K. L. VIOLA[2], G. LOCH-NECKEL[1], W. L. KLEIN[2], J. B. CALIXTO[1];
[1]UFSC - Univ. Federal de Santa Catarina, Florianopolis, Brazil; [2]Neurobio., Northwestern Univ., Evanston, IL

Abstract: Alzheimer's disease (AD) is a neurodegenerative and progressive disease for which there is no current cure or effective treatment. The search for new targets that could be useful models for drug development is indispensable. TRPA1 arises as a new approach, first considered by our research group to be related to AD. Endogenous molecules that activate the TRPA1 receptor (Reactive Oxygen Species (ROS), Ca2+ and products of inflammation) are also up-regulated during the initiation and progression of AD. We aimed to investigate the possible role of TRPA1 in experimental models of AD. In order do to that, we used primary neuronal cell culture from rat cortex (CT) and hippocampus (HP), Swiss mice (3 months-old) injected i.c.v. with Amyloid-β-oligomers (AβO) and also transgenic 5XFAD mouse model of AD. Cells and animals were treated with TRPA1 antagonist (HC030031) at different concentrations and schedules according to the protocol (UFSC Protocol: PP00625/2011; NU Protocol: 2014-3406). Results showed that TRPA1 is expressed in neurons and microglia but not astrocytes. AβOs induced TRPA1 redistribution and up-regulation in neurons and microglia, respectively. TRPA1 blockage in neuronal cells with HC030031 prevented AβO-induced ROS formation, mitochondrial membrane disturbance and neuronal death. Notably, when we evaluated TRPA1 expression in Swiss mice CT and HP by immunohistochemistry we observed higher expression after 24h and 7 days after AβO-treatment in the microglia and surrounding the neuronal cell body, while blot results confirmed quantifications. 5XFAD brains slices (7 m.o.) also shown up-regulated TRPA1 in CT and HP, specially surrounding amyloid plaques (AP). Of note, HC030031 pre-treatment prevented AβO-induced memory deficits in AβO injected Swiss mice while oral treatment (60 days, once a day) ameliorated memory deficits in the 5XFAD mice when compared to vehicle-treated mice. Besides, 5XFAD treated with HC030031 presented low levels of burden AP and oligomers. In summary, we are reporting for the first time the substantial role of TRPA1 in AD related experimental models. Our data suggest TRPA1 as a potential attractive target for the AD therapeutics. Authors thank CNPq, CAPES and FAPESC for the financial support.

Title: Therapeutic effect of novel cholinesterase inhibitor 6-chlortacrine on cognitive deficit induced by 3-quinuclidinyl benzilate in rats performing the water maze task

Authors: *J. MISIK[1], M. HRABINOVA[3], J. KORABECNY[2], E. NEPOVIMOVA[2], O. SOUKUP[2], K. KUCA[4], J. KASSA[2];
[1]Fac. of Military Hlth. Sci., Czech Republic; [2]Fac. of Military Hlth. Sci., Hradec Kralove, Czech Republic; [3]Fac. of military health sciences, Hradec Kralove, Czech Republic; [4]Fac. Hosp., Hradec Kralove, Czech Republic

Abstract: The cognitive decline observed in patients suffering from Alzheimer's disease could be mitigated using cholinesterase inhibitors. In this preliminary study, pro-cognitive effect of newly-developed cholinesterase inhibitor 6-chlortacrine was investigated. 6-chlortacrine was administered to male Wistar rats in three different therapeutic doses (corresponding to 10, 20 and 40% of LD50) and the effect of the compound on 3-quinuclidinyl benzilate (QNB)-induced spatial navigation deficit was observed in water maze task. Brain cholinesterase inhibition of tested doses was evaluated in separate *in vivo* experiment using spectrophotometric method. 40 rats were divided into 5 groups of 8 animals and subjected to the WM acquisition test with a hidden platform performed as a one day session with 10 consecutive trials (swims) and an inter-trial interval of 15 min. The location of the submerged platform remained unchanged during whole sessions whereas starting positions varied randomly between trials. Each trial was videotaped and analyzed with an image tracking system (TSE VideoMot2, Bad Homburg, Germany) that provided dependent measures of e.g. escape latency (s), total path (cm) and total speed (cm.s-1). Treated groups received i.p. injection of QNB (2.0 mg.kg-1) in a volume of 1 mL.kg-1 1 h before the session followed 30 min later by the therapeutic dose of 6-chlortacrine (0.9, 1.8 or 3.6 mg.kg-1) or saline (non-treated QNB group). The decrease in the total path within the acquisition session in treated rats was compared to that of non-treated controls which received normal saline instead of cholinesterase inhibitor and blank controls which received saline instead of both, QNB and inhibitor. Data were log-transformed and subjected to factorial ANOVA, followed by Dunnett's test or Tukey's post-hoc. Saline-treated controls reduced their total path substantially from swim 1 to swim 10 ($F(9, 0.53) = 5.14$, $p < 0.001$) whereas no progression was found in group treated with QNB only ($F(9, 0.14) = 1.67$, $p = 0.11$). When the treatment with 6-chlortacrine was provided, significant improvement was evident in group treated with the dose of 1.8 mg.kg-1 ($p < 0.05$) representing brain cholinesterase inhibition of 49.0%. Other two tested doses were responsible for brain cholinesterase inhibition 39.0 and 68.5%, respectively and showed weaker effect. In general, novel cholinesterase inhibitor 6-

chlortacrine ameliorated QNB-induced cognitive impairment and will be further investigated, including detailed pharmacokinetic and behavioral studies.

Title: Isopimaric acid protects hippocampal neural injury and improves learning-memory deficits in APP/PS1 mice

Authors: ***L. WANG**[1], Z. LIU[2], J. JIA[3], Z. TANG[4], Y. SHUI[5], J. JIAO[6];
[1]China-Japan Friendship Hosp., Beijing, China; [2]Dept. of Neurology, China-Japan friendship hospital, Beijing, China; [3]Dept. of Physiology, Capital Med. Univ., Beijing, China; [4]Dept. Med. Genetics, Capital Med. Univ., Beijing, China; [5]Pain Mgmt. Center, China-Japan friendship hospital, Beijing, China; [6]Dept. of Neurology, China-Japan friendship hospital., Beijing, China

Abstract: Alzheimer disease is the most common and important neurodegenerative disease. The extreme atrophy of the hippocampus is the most prominent finding in pathology. The present experiment investigated the protective effect of isopimaric acid (ISO), the BK_{Ca} channel activator, on hippocampal neural injury in 4-month-old APP/PS1 mice. In the Morris water maze, the probe test demonstrated an improved spatial memory after chronic injection of ISO into the lateral ventricle. We did electrophysiological experiments using hippocampal slices of mice after behavior. Field excitatory postsynaptic potential (fEPSP) was recorded in CA1 region of hippocampus. Compared with WT group, the paired-pulse facilitation (PPF) was significantly decrease and long-term potentiation (LTP) was suppressed in APP/PS1 mice. Both PPF and LTP of hippocampus were recovered by ISO treatment. Whole-cell patch-clamp recordings were performed to assess the excitability of hippocampal pyramidal cells by calculating the frequency of evoked spikes and BK_{Ca} channel activity by measuring the half-width of evoked action potentials. In contrast to WT group, activity of the BK_{Ca} channels was suppressed and excitability of hippocampal neurons was elevated in the APP/PS1 group. The recovery of BK_{Ca} channel activity accompanied reduction of neuronal excitability in hippocampal pyramidal cells

by ISO treatment. The present findings suggest that ISO can normalize hippocampal neural injury and improve learning-memory deficits in AD.

Title: Deficits in Morris water maze performance exacerbated by minimal neocortical injury in a mouse model of Alzheimer's disease

Authors: ***N. KATO**, J. ZOU;
Dept Physiol, Kanazawa Med. Univ., Ishikawa, Japan

Abstract: Brain injury is known as a major risk factor for Alzheimer's disease (AD). If injury limited to the neocortex induced deficits in hippocampus-dependent learning, remote effects would have to be involved, which might influence the hippocampal function electrophysiologically and biochemically. This possibility was tested by using Morris water maze test (MWM) twice. Wild-type and 3xTg-AD model mice were subjected to the first Morris water maze test. Based on the MWM performance, each type of mice was grouped into two, with the average MWM score esenssially the same between the two. Then, a tiny amount of glutamate (0.1 M, 0.2 μl) as neurotoxin, or the same amount of saline as vehicle control, was injected into the parietal cortex, thus creating 4 experimental groups. After a 2-week survival, the second MWM was performed, with a different goal location. The MWM score was normal and did not show difference between the glutamate and saline groups in wild-type mice, whereas glutamate-treated 3xTg mice performed the test worse than controls. After behavior, hippocampal tissue removed from the 4 groups was subjected to DNA microarray analysis with Mouse Gene 1.0 ST (Affimetrix). Glutamate-induced lesion significantly changed expression of two genes more than 1.5 fold in wild-type mice only, and expression of 7 other genes in 3xTg only. Synaptic transmission in the hippocampal CA1 synapses was more efficient in the 3xTg glutamate group than in the others. Three mice from each group were used to assess the size of parietal cortex lesion histologically. These results suggest that even a small injury restricted to the parietal cortex, which failed to induce learning deficits in wild-type mice, may remotely affect the hippocampal function in 3xTg mice, changing the profile of gene expression and the strength of synaptic transmission.

Title: Low-dose ketamine, spine density and cognition in a mouse model of Alzheimer's disease

Authors: J. SMITH, P. N. PALLIER, A. T. MICHAEL-TITUS, *G. J. MICHAEL;
Barts & London SMD, London, United Kingdom

Abstract: Alzheimer's disease (AD) is a neurodegenerative disease that affects millions worldwide, but currently treatment options for this condition are very limited. Synaptic loss is a major pathophysiological feature of AD that correlates with disease severity. It has been shown that low-dose ketamine has antidepressant properties and induces synaptogenesis and dendritic spine growth. As AD is associated with major synaptic changes, we hypothesised that low-dose ketamine could reverse the synaptic loss seen in AD, and thereby improve cognition. The study was carried out in the TASTPM murine model of AD. Mice (6-7 months old) were tested in the open field (OF), the novel object recognition (NOR), and the Morris water maze (MWM) tests. TASTPM mice and matched wild-type C57BL/6J mice received either ketamine (10 mg / kg) or 0.9% saline i.p. (n=6). The ketamine dose was based on previous studies that had shown antidepressant and pro-synaptogenesis effects at this dose. All injections were performed a minimum of 4 hours before the start of behavioural testing. All mice were tested in the OF, and then in the NOR test, followed by the MWM test. Each mouse received three repeated injections of saline or ketamine spaced over two weeks. TASTPM mice were clearly hypoactive in the OF, and this was not modified significantly by ketamine. Ketamine treatment induced anxiolytic-like effects in wild-type mice, as shown by an increased time spent in the centre zone of the OF, but this effect was not seen in TASTPM mice. No behavioural deficit was found in the NOR test or in the acquisition phase or probe trial of the MWM test in TASTPM mice, compared to wild-type mice. Ketamine led to a moderate and non-significant improvement in performance in both wild-type and TASTPM mice in the probe trial of the MWM test. Spine density was assessed using Golgi-Cox staining in the hippocampus CA1 region; no differences were found between genotypes or drug treatment groups. Overall, the results do not support the hypothesis that low-dose ketamine exerts beneficial effects in this mouse model of AD; however, the TASTPM mice, unexpectedly, had very limited alterations in behaviour compared to wild-type mice. Future studies investigating whether, in this murine model of AD, ketamine can improve the histopathology and the behavioural deficits at a later stage of the disease, when basal impairment in performance is much clearer, are warranted.

Title: Activation of α7 nACh receptors in Aβ overproducing transgenic mice augments hippocampal theta oscillation

Authors: ***M. STOILJKOVIC**[1], D. NAGY[1], G. P. HAJOS[1], C. KELLEY[1], G. KOENIG[2], T. PISER[2], L. LEVENTHAL[2], M. HAJÓS[1];
[1]Comparative Med., Yale Univ. Sch. of Med., New Haven, CT; [2]FORUM Pharmaceuticals Inc., Watertown, MA

Abstract: Selective activation of α7 nicotinic acetylcholine receptors (α7 nAChRs) is considered as a potential new symptomatic treatment strategy for cognitive deficits in Alzheimer's disease (AD). In fact, exploratory and clinical Phase II trials suggest that α7 nAChR agonists may improve cognitive function in AD patients. However, a multifaceted interaction between amyloid ß (Aβ) and α7 nAChRs has been shown, indicating that pharmacological effects of α7 nAChR agonists in AD patients might be modified by high level Aβ proteins. Therefore, in the present study efficacy of a recently characterized α7 nAChR agonist FRM-17874 was evaluated in 8-month old Aβ overproducing APP/PS1 transgenic (APP/PS1), and compared to that in age-matched wild-type mice. Hippocampal theta oscillation was elicited by stimulation of the brainstem nucleus pontis oralis (nPO) in APP/PS1 and WT mice under urethane anesthesia. In line with our earlier findings, TG mice showed reduced hippocampal theta power in response to nPO stimulation (Scott et al., 2012), as well as significantly reduced gamma power and theta phase - gamma amplitude coupling (expressed as Modulation Index). Previous studies have shown that α7 nAChR agonists, including FRM-17874 augment theta oscillation in the hippocampus CA1 region (Siok et al., 2006), which is considered as a possible mechanism contributing to their pre-cognitive effects. FRM-17874, at an already established effective dose (3 mg/kg, sc) significantly augmented power of elicited hippocampal theta oscillation in both APP/PS1 and WT mice ($F(3,28) = 9.913$, $p = 0.0005$). Furthermore, compared with their saline-treated respective controls, FRM-17874 caused a significant increase in theta power in both groups of mice showing identical efficacy, but did not affect the peak theta frequency in either group. The magnitude of drug effect in 8 months old WT and TG animals was comparable to previously observed effects in 3 months old mice and rats as well as with effects of current AD

drugs donepezil and memantine tested using the same assay. FRM-17874 did not change power of elicited gamma (30-90 Hz) power in WT or APP/PS1 mice; however it increased theta phase frequency (4-7 Hz) and higher frequency (75-95 Hz) gamma band amplitude coupling in WT mice. These results indicate that high levels of amyloid ß peptides do not interfere with ability of the pharmacology of α7 nAChR agonists to augment power of hippocampal theta oscillation, and provide further support for targeting α7 nAChRs as potential AD pharmacotherapy.

Title: The role of the locus coeruleus projection system in neuronal and cerebrovascular dysfunction in preclinical AD

Authors: *S. C. KELLY[1,2], E. J. MUFSON[4], P. T. NELSON[5], S. E. COUNTS[1,3,6]; [1]Translational Sci. and Mol. Med., [2]Cell and Mol. Biol. Program, [3]Dept. of Family Medecine, Michigan State Univ., Grand Rapids, MI; [4]Neurobio., Barrow Neurolog. Inst., Pheonix, AZ; [5]Pathology and Lab. Med., Univ. of Kentucky, Lexington, KY; [6]Haunstein Neurosci. Inst., Mercy Hlth. St. Mary's, Grand Rapids, MI

Abstract: Noradrenergic locus coeruleus (LC) neuron loss is a major feature of Alzheimer's disease (AD). The LC is the primary source of norepinephrine (NE) in the brain, where it modulates attention, memory, and arousal in vulnerable cognitive regions such as prefrontal cortex and hippocampus. Previously, we demonstrated a ~35% loss of LC neurons in postmortem tissue of subjects who died with an antemortem clinical diagnosis of amnestic mild cognitive impairment (aMCI, a prodromal AD stage) compared to subjects who died with no cognitive impairment (NCI) ($p<0.01$) obtained from the Rush Religious Orders Study. However, the extent to which LC neurodegeneration occurs in preclinical, pre-MCI stages of AD is unclear. Furthermore, LC-mediated NE signaling has been shown to play a role in cerebrovascular (CV) health, including blood brain barrier maintenance and neurovascular coupling, suggesting that LC degeneration may impact the high comorbidity of CV disease and AD. However, the effect of LC degeneration on CV function during disease onset is also unclear. To begin to address these issues, we analyzed LC tissue obtained postmortem from University of Kentucky AD Center subjects classified antemortem as NCI but who displayed varying levels of Braak stage neuropathology at autopsy. In particular, NCI subjects who died with Braak stages III-V are believed to have been in the preclinical stages of AD. In preliminary studies, LC tissue from NCI-Braak 0, NCI-Braak II, and NCI-Braak IV (n = 5/group) was immunostained with tyrosine hydroxylase (TH, a marker for NE synthesis) and analyzed using unbiased stereology to estimate total LC neuron number (neuromelanin-containing LC neurons +/- TH) and the percentage of TH+ LC neurons. Preliminary analysis revealed a ~18% loss of LC neurons in NCI-Braak IV (e.g., preclinical AD) cases compared to NCI-Braak 0-II cases. Furthermore, we found a ~15-20% loss of TH+ LC neurons in NCI-Braak IV compared to NCI-Braak 0-II cases. Pilot studies also revealed a substantial increase in the presence of pathological markers (e.g., tau AT8, TDP-43, 8-OHG) in LC neurons in NCI-Braak IV compared to NCI-Braak 0-II. Hence, LC neurodegeneration appears to mark the preclinical stages of AD prior to the onset of MCI. To begin to understand the relationship between LC neuropathology in preclinical AD and CV function, morphometric data will be correlated with postmortem CV variables (e.g., microinfarcts). Taken together, these data should give us a better understanding of how multifactorial noradrenergic pathways contribute to neuronal and vascular pathologies during the onset of AD.

Title: Somatostatin receptor subtype-4 agonist enhances learning and memory in aged SAMP8 mice

Authors: *K. A. WITT[1], A. M. CRIDER[2], J. E. MORLEY[3], S. A. FARR[3], K. E. SANDOVAL[2]; [1]Pharmaceut. Sci., Southern Illinois Univ. Edwardsville, Edwardsville, IL; [2]Pharmaceut. Sci., Southern Illinois Univ. Edwardsville Sch. of Pharm., Edwardsville, IL; [3]Intrnl. Med., St. Louis Univ. Sch. of Med., Saint Louis, MO

Abstract: Use of a selective somatostatin receptor subtype-4 (SSTR4) agonist has been identified as a potential means to mitigate the cognitive decline in pathologies such as Alzheimer's Disease (AD), via enhancement of neprilysin activity and/or direct receptor action within the neocortex and hippocampus. Herein we evaluated the somatostatin receptor SSTR4 agonist NNC 26-9100 effects using the senescence accelerated mouse prone-8 (SAMP8) model of cognitive decline at pre-pathology (4-month), early-pathology (12-month), and later-pathology (15-month) stages of development. Mice were chronically treated with NNC 26-9100 (10 mg/kg, i.p. daily for 28 days) or matched vehicle. NNC 26-9100 treatment reduced acquisition learning (T-maze, day-21) in 4-month mice, while enhancing learning in 12-month mice, and showing no change in 15-month mice when compared to their respective age-matched vehicle treated controls. In 4-month mice NNC 26-9100 did not impact memory retention (T-maze, day-28); however, it enhanced memory in both 12- and 15-month mice when compared to respective age-matched vehicle treated controls. Cortical tissues were extracted for neprilysin activity and Western blot analysis. NNC 26-9100 treatment did not increase neprilysin activity in 4-month mice, but increased activity in both 12- and 15-month mice compared to vehicle. Amyloid precursor protein and SSTR4 expression levels did not change, while neprilysin expression increased in 15-month mice with NNC 26-9100 treatment, compared to vehicle. These findings suggest the use of a selective SSTR4 agonist may mitigate the cognitive decline in aged pathologic mice, but not in pre-pathologic mice.

Title: Quercetin protects against the Aβ-induced amnesic injury through inhibiting RAGE-mediated pathway and preserving the neurovascular unit

Authors: *R. LIU, D. ZHOU, X. BAI, C. HUANG, J. SONG, G. DU;
Inst. of Materia Medica, Chinese Acad. of Me, Beijing, China

Abstract: Quercetin is one of the most common flavonoids existing widely in many edible plants. It has demonstrated protective effects against Aβ-induced toxicity on both neurons and endothelial cells. However, whether or not quercetin has an effect on the neurovascular coupling is unclear. In the present study, we aim to investigate the anti-amnesic effects of quercetin and to explore the underlying mechanisms. The aggregated Aβ25-35 was injected into the right lateral ventricle in mice. Quercetin was administrated orally for 8 days after injection. Learning and memory behaviors were evaluated by measuring spontaneous alternation in Morris Water Maze test and the step-through positive avoidance test. The regional cerebral blood flow was monitored before the Aβ25-35 injection and on seven consecutive days after injection. Mice were sacrificed and cerebral cortices were isolated on the last day. The effects of quercetin on the neurovascular unit (NVU) integrity, microvascular function and cholinergic neuronal changes, and the modification of signaling pathways were tested. Our results demonstrate that quercetin treatment for Aβ25-35-induced amnesic mice improved the learning and memory capabilities and conferred robust neurovascular coupling protection. In these effects, quercetin improved the spatial learning and memory effectively across the acquisition training period and the memory capability trials in behavioral tests. Furthermore, quercetin maintained the integrity of NVU major components, reduced the level of neurovascular oxidation, modulated the rCBF value of cerebral microvessels, improved the function of cholinergic system, and regulated the neurovascular RAGE signaling and ERK/CREB/BDNF pathways. In conclusion, in Aβ25-35-induced amnesic mice, optimal doses of quercetin administration were beneficial. Quercetin protected the NVU through reduction of oxidative damage, inactivation of RAGE-mediated pathway and preservation of cholinergic neurons, offering an alternative medication for Alzheimer's disease.

Title: Changes in the purinergic and glutamatergic neurotransmission in a model of Alzheimer's disease modulated by P2X receptors

Authors: *F. SÁEZ-ORELLANA, P. A. GODOY, T. SILVA-GRECCHI, K. M. BARRA, J. FUENTEALBA;
Univ. De Concepción, Concepción, Chile

Abstract: Currently there are around 24 million cases of dementia worldwide, the most common cause of dementia is Alzheimer´s Disease (AD) affecting mainly elderly people. The etiology of AD is still unknown, but it is believed that the main culprits are the soluble oligomers of Amyloid beta (Aβ) peptide. In literature is reported that Aβ increases the expression of P2X7 *in vitro* and *in vivo*, and also has been demonstrated that there are changes in the levels of GluN2A and GluN2B. Another effect of Aβ is a diminishment of AMPAR at synaptic level, which explains the memory loss. The aim of this work was to study the effects of acute (1h) and chronic (24h) exposition to Aβ (0.5 μM) on the glutamatergic, GABAergic and purinergic transmission. Acute Aβ incubation induced an increase in the amplitude and frequency of mEPSC in primary hippocampal cultures (Control: 100±15%, 14±0.2 pA; Aβ: 248±33%, 19±0.3), which was prevented by the non-selective P2XR antagonist PPADS (10μM) and also by ATP hydrolysis with apyrase (3U/ml) (Aβ+PPADS: 111 ±18%, 11 ±0,4pA; Aβ+apyrase: 99 ±17%, 14 ±0.6pA); besides, we observed an acute increased insertion of AMPAR that could explain the increased amplitude of mEPSC. On mIPSC we observed a non-significant reduction of frequency and a significant diminishment in amplitude (control: 100 ±19%, 19.3 ±0.7 pA; Aβ: 70 ±11%, 14.7 ±0.9 pA). In chronic treatment we observed that Aβ induced a decrease in the frequency and amplitude of mEPSC in primary hippocampal cultures (control: 100±20%, 9.7±0.2pA; Aβ: 28±7%, 6.3±0.1pA); and interestingly, we found an increase in the amplitude of ATP-evoked currents that is related to an increased expression of P2X1, 2 and 7; moreover, we observed a right shift in the dose-response curve to ATP analyzed by Ca2+ microfluorimetry. In this model we also evaluated the effects of Aβ in glutamatergic components and found a decrease in the levels of both NMDAR and AMPAR which can explain the decrease in amplitude of mEPSC, in line with these findings we found a decreased expression of PSD95; interestingly, all the changes induced by Aβ were prevented by the inhibition of P2XR by PPADS or apyrase. In conclusion we can suggest that soluble oligomers of Aβ can disrupt the

main components of excitatory and inhibitory synaptic transmission at pre- and post-synaptic level, and also change the expression and function of purinergic neuromodulation; this can be a new target for the treatment of this pathology and others diseases characterized by increased purinergic transmission.

Title: Impact of 17-beta estradiol (E2) loss on hippocampal synaptic function in an Alzheimer's disease rat model and the role of GluN2B-NMDARs

Authors: ***L. A. SMITH**[1], T. TOWN[2], L. L. MCMAHON[1];
[1]Cell, Developmental, and Integrative Biol., Univ. of Alabama, Birmingham (UAB), Birmingham, AL; [2]Physiol. & Biophysics, Zilkha Neurogenetic Inst., Los Angeles, CA

Abstract: Alzheimer's disease (AD) is the most common form of dementia for those 65 years and older, and interestingly women account for over two-thirds of those affected. Current treatments only target symptoms of the disease. Therefore, there is great need for disease-modifying therapies that can slow or halt disease progression before debilitating symptoms arise. Human imaging data and rodent studies show that pre-symptomatic alterations in synaptic efficacy are correlated with increased soluble protein aggregates of amyloid beta (Aβ) and hyperphosphorylated tau (p-tau), and that these soluble aggregates are more toxic to synaptic function than when they deposit as characteristic lesions in the form of amyloid plaques and tau tangles. Soluble Aβ and tau inhibit N-methyl-D-aspartate receptor (NMDAR)-dependent long-term potentiation (LTP) possibly through excessive activation of extrasynaptic GluN2B-containing NMDARs. Previous work in our lab has shown that 17β-estradiol (E2) treatment, the primary ovarian estrogen, increases hippocampal CA1 pyramidal cell spine density, synaptic GluN2B-mediated NMDAR current, LTP magnitude, and learning in surgically menopausal female rats. Here we investigate early synaptic alterations prior to plaque and tangle formation in the novel comprehensive TgF344-AD (Tg) rat model to test the hypothesis that E2 confers its neuroprotective effects in AD at the synapse by enhancing synaptic and decreasing extrasynaptic currents mediated by GluN2B-containing NMDARs. Current data show that at 3 and 6 months of age there is no deficit in excitatory transmission at CA3-CA1 synapses in both males and acutely

ovariectomized (OVX) females. Presynaptic function and AMPA receptor mediated transmission are also unaltered. Additionally, there is no change in the magnitude of LTP in the presence of the GluN2B-subunit selective antagonist Ro25-6981 (RO) in either sex. Interestingly, there is a trend towards increased block of NMDARs by Ro25-6981 in Tg hippocampal slices from OVX females during the tetanus used to induce LTP, possibly suggesting increased activation of extrasynaptic GluN2B-containing NMDARs, consistent with current literature in AD mouse models. On-going studies are characterizing excitatory transmission, contribution of GluN2B-containing NMDARs, synaptic plasticity, and effects of loss and replacement of E2 in OVX female WT and Tg rats on hippocampal synaptic function over the lifespan. Understanding the underlying mechanism of how E2 is neuroprotective at the synapse throughout early AD pathology can inform future design of AD-modifying therapeutics.

Title: Early LTP deficits in 3xTg mice are restored by D-serine

Authors: *J. VERAN[1], A. PANATIER[1], G. BONVENTO[2], S. H. R. OLIET[1];
[1]Neurocentre Magendie, Bordeaux, France; [2]Sci. du Vivant, CEA, Fontenay aux roses, France

Abstract: At early stages of Alzheimer's disease (AD), intracellular accumulation of Aβ leads to cognitive and synaptic transmission impairment. Such deficits are reproduced in the triple transgenic model 3xTG mice in which basal excitatory synaptic transmission and long-term potentiation (LTP) in the hippocampus are significantly impaired, long before plaque deposits. LTP induction at CA3-CA1 synapses depends on NMDA receptors (NMDARs), and we have shown previously that these receptors were gated by glial D-serine. We here investigated whether the synaptic plasticity deficits observed in 3xTg mice at early age could be due to a reduced level of occupancy of NMDAR glycine-binding sites, on which D-serine is binding. To this end we recorded field excitatory postsynaptic potentials (fEPSPs) at CA3-CA1 synapses in acute hippocampal slices obtained from 6-7 months old female mice. As previously described, both input/output relationship and LTP were impaired significantly. We then assessed the level of occupancy of NMDAR co-agonist binding site by applying exogenous D-serine in the bath. The increase in NMDAR-mediated fEPSPs induced by D-serine was larger in 3xTG mice, indicating that the level of occupancy of NMDAR co-agonist site is lower in these animals. Most

importantly, exogenous D-serine rescued completely LTP induction in the 3xTG mice. Altogether, these results suggest that early deficits in AD are associated with a decrease in D-serine in the synaptic cleft.

Title: AMPA-receptor subunit composition determines the susceptibility of synapses and memory to amyloid-beta

Authors: *N. R. REINDERS[1], Y. PAO[2], M. C. RENNER[1], R. MALINOW[2], H. W. KESSELS[1]; [1]Netherlands Inst. of Neurosci., Utrecht, Netherlands; [2]Univ. of California, San Diego, CA

Abstract: Amyloid-β (Aβ) is a prime suspect to cause Alzheimer's disease (AD). Soluble oligomeric clusters of Aβ trigger synaptic depression by reducing AMPA- and NMDA-type glutamate receptor currents, and initiate memory impairment in mouse models for AD. We here show that these Aβ-driven effects depend on AMPA-receptor subunit composition. Hippocampal neurons were resistant against Aβ-mediated spine loss and synaptic depression of both AMPA-receptor and NMDA-receptor currents when they express AMPA-receptor subunits GluA1 and GluA2 but lack the GluA3 subunit. In addition, an Aβ-mediated blockade of LTP was seen in hippocampal slices only when they express GluA3. Furthermore, while APP/PS1-transgenic mice showed significant impairment in contextual fear memories at 6 months of age, fear memories in littermate GluA3-deficient APP/PS1 mice remained unaffected. These experiments suggest that Aβ selectively disrupts synapses that are enriched for GluA3.

Abstract: Alzheimer's disease (AD) is the most common form of age-related dementia. Multiple factors are involved in the disease progression and the etiology of AD is still not well understood. A serine/threonine kinase, glycogen synthase kinase-3 (GSK-3), is an important kinase involved in normal synaptic function. Recent studies have linked two isoforms (GSK-3α and GSK-3β) to histopathological hallmarks of AD. Another serine/threonine and tyrosine kinase, Lin-11- Isl-1-Mec-3 kinase (LIMK-1/2), is believed to participate in various cellular functions including synapse formation and also may play an important role in the progression of AD pathology. This study evaluated the changes in both enzymes in the hippocampus, one of the earliest brain region affected in the progression of AD. Our laboratory has previously shown a significant loss of synapses in the hippocampus in subjects with amnestic mild cognitive impairment (aMCI). The present study tested whether or not changes in these cell signaling proteins occur in a pre-aMCI phase of AD. We analyzed short post-mortem hippocampal tissues obtained from three different cohorts: (1) individuals with low or no AD-type pathology and no cognitive impairment (LP-NCI), (2) individuals with high AD-type pathology and no cognitive impairment (HP-NCI), and (3) individuals with aMCI. Levels of phosphorylated and non-phosphorylated forms of both GSK-3α/β and LIMK-1/2 were assessed in all subjects. Individuals with aMCI manifested a significant increase in phosphorylation of GSK3β compared to both age- and postmortem-matched NCI cohorts. Levels of GSK-3α and LIMK-1/2, both phosphorylated and non-phosphorylated form, remained unchanged across all groups. These results suggest that altered cell signaling kinases (i.e. GSK-3β) are possibly driving synaptic dysfunction and cognitive loss in aMCI, which is believed to be an early stage of AD.

Abstract: Alzheimer's disease (AD) is considered a uniquely human disorder, characterized neuropathologically by beta-amyloid plaques (Aβ) and neurofibrillary tangles (NFTs). While amyloid plaques and tau pathology have been identified in species other than humans, these animals typically present with one type of pathology and lack the cognitive deficits typical of AD. Prior limited research on aged great apes demonstrated widespread Aβ pathology in absence of significant tauopathy. The objective of the current research was to evaluate AD pathology in a large group of aged chimpanzees (n = 20, ages 37-62 years). Immunohistochemical and stereologic techniques were used to map and quantify Aβ plaques (6E10, Aβ42), cerebrovascular amyloid, and tau pathology (AT8, CP13, MC1, PHF1) in postmortem brain samples from three regions affected by AD in humans (i.e., prefrontal cortex, middle temporal gyrus, and hippocampus). Two-thirds of the elderly chimpanzees exhibited at least one form of Aβ pathology (i.e., plaques and vascular), with Aβ-positive vasculature more common than plaques. Three of the oldest chimpanzees (ages 57-62 years) displayed congophilic cerebral amyloid angiopathy (CAA). At least one form of tau pathology (i.e., preNFTs, NFTs, and neuritic tau plaques) was found in all individuals. Overall, preNFTs and NFTs were most numerous in the hippocampus, while neuritic tau plaques were more prevalent in the prefrontal cortex. Two

chimpanzees had significant, potentially non-age related tauopathy. A 39-year-old male presented with NFTs in the prefrontal cortex, lack of nearly any tau pathology in the hippocampus, and absence of Aβ pathology in all three areas. Conversely, a 57-year-old male demonstrated extensive levels of all tau lesion types in each region, with the hippocampus most severely affected, as well as scarce Aβ plaques and CAA. The co-occurrence of Aβ and tau pathology in aged chimpanzees indicates these lesions are not specific to the human brain; however, further correlative analyses with cognitive and behavioral assessments are needed to shed light on whether neurodegenerative diseases, such as AD, are truly human-specific. Future investigations will characterize the composition of tau isoforms (three or four repeats) in preNFTs, NFTs, and tau plaques, examine the potential coexistence of neurodegenerative pathologies, such as Lewy bodies and synaptopathy, and study the association of DNA sequence polymorphisms in the amyloid precursor protein and tau genes with observed neuropathy in elderly chimpanzees.

Title: Aggravated post-traumatic epileptogenesis associates with acquired channelopathy in the perilesional cortex of APP/PS1 mouse model of Alzheimer`s disease

Authors: *D. MISZCZUK[1,2], K. J. DęBSKI[1], H. TANILA[2], K. LUKASIUK[1], A. PITKANEN[2]; [1]Nencki Inst. of Exptl. Biol., Warsaw, Poland; [2]Dept. of Neurbiology, A. I. Virtanen Inst. for Mol. Sciences, Univ. of Eastern Finland, Kuopio, Finland

Abstract: We tested a hypothesis that traumatic brain injury (TBI) in amyloidogenic genetic background leads to aggravated epileptogenesis which is associated with the development of chronic acquired channelopathy. Traumatic brain injury was induced with controlled cortical impact in APP/PS1 mice (n=14) or in their wild type (Wt) littermates (n=17). Epileptogenesis was monitored with video-EEG, and the expression level of voltage-gated ion channel subunits was assessed 16 wk post-TBI using Affymetrix microarrays. Epileptogenesis was affected both by the genotype and TBI. In APP/PS1-TBI group 88% developed epilepsy, in the Wt-TBI group 11% (genotype effect $p<0.01$), and in the APP/PS1-sham group 50% (TBI effect $p<0.05$). The most pronounced effect of genotype and TBI on the expression of ion channel subunits was found in the perilesional cortex as compared to the ipsilateral thalamus or hippocampus. In sham-operated mice, AD-genotype associated with down-regulation of expression of *Kcna6*, *Scn9a* and *Scn4b* and up-regulation of *Scn4a* as compared to Wt mice ($p<0.01$). In mice with TBI, AD genotype associated with up-regulation of *Hcn4* and *Scn7a* and down-regulation of *Kcnv1, Kcnk4* and *Scn9a* as compared to APP/PS1-sham mice ($p<0.01$). Moreover, we found an injury effect as Wt-sTBI mice displayed a decreased expression of *Scn3a* and *Cacna2d1* as compared to Wt-sham group ($p<0.01$). Interaction analysis between the genotype and the injury revealed differences in the alteration in expression of *Kcnt1*, *Scn3a* and *Scn7a*. Interestingly, correlation analysis revealed that the higher the seizure frequency, the lower the cortical expression of *Scn9a* ($r=-0.82$, $p<0.001$), *Scn4b* ($r=-0.67$, $p<0.001$) and *Kcnk4* ($r=-0.64$, $p<0.001$). The present study provides the first comprehensive evidence of the possible contribution of multi-channelopathy on exacerbated post-traumatic epileptogenesis in amyloidogenic genetic background.

Title: The development and characterisation of a high-throughput assay for evaluation of neuronal excitability and synaptic function in neuronal models of Alzheimer’s disease

Authors: *J. K. VIRDEE, Y. SINHA, S. GLOVER, F. FERRERIA, M. O'NEILL, J. WOLAK, D. URSU;
Eli Lilly and Co., Windlesham, United Kingdom

Abstract: Alzheimer’s disease (AD) is the most common form of dementia, currently with over 850,000 people in the UK being diagnosed with AD, a number that is predicted to increase to

over 2 million by 2050 (statistics from UK Alzheimer's Society). The excessive accumulation of amyloid-beta (Aβ) peptide, in particular the oligomeric form, is believed to be the seminal factor in disease causation, with clear effects demonstrated on neuronal viability but with more subtle and sometime difficult to assess disruptions seen on neuronal synaptic function. Understanding the effects of Aβ on neuronal and synaptic function and how novel compounds may restore abnormal synaptic activity in AD is therefore an attractive approach to pursue for identifying novel therapeutic targets. The aim of this study was to establish and validate methodologies for i) generation and characterisation of Aβ oligomers ii) measure overall neuronal cytotoxicity and iii) development of a new assay for evaluating effects of Aβ oligomers on neuronal excitability and synaptic function. Here we describe an assay based on electrically evoked responses to evaluate both neuronal somatic activity as well as synaptic function in cultured neuronal networks in a multi-well plate format. The assay integrates the state of the art screening platform FLIPR® Tetra with customised hardware and software that allows optimum control of electrical stimulation and recording at single well level. The assay utilises a set of bipolar stimulating electrodes that can deliver well defined stimulation protocols (ie voltage, frequency, number of stimuli) to the cultured neurons. The neuronal excitability and synaptic transmission can be measured indirectly by changes in fluorescence of a calcium sensitive dye in regions of interest located either proximal or distal to the stimulation electrodes. The synaptic nature of the assay was validated by screening a number of compounds with known pharmacological profiles as modulators of synaptic activity, acting either at presynaptic terminals (calcium channels, metabotropic glutamate receptors), postsynaptic region (AMPA, NMDA and GABA receptors) or generally acting on neuronal excitability (Nav, Kv ion channels). By using Aβ oligomer preparations characterised by DLS and EM we are showing disruption of neuronal and synaptic activity in the above validated assay following either acute (hours) or chronic (days) application.

Title: Understanding the melanocortin circuit in the mouse hippocampus

Authors: *Y. SHEN[1,2,3], M. TIAN[1,2,3], Y. ZHENG[1,2,3], A. K. Y. FU[1,2,3], N. IP[1,2,3];

Abstract: Hippocampal synaptic plasticity, the modification of the strength and efficacy of synaptic communication among neurons, is a major cellular mechanism underlying learning and memory. Melanocortins, which are the pro-opiomelanocortin-derived peptides originally shown to regulate energy metabolism, have been implicated in learning and memory enhancement. We recently found that melanocortin 4 receptor (MC4R) plays an important role in the regulation of hippocampal synaptic plasticity. Long-term potentiation in the hippocampus was significantly enhanced by *in vivo* MC4R activation and attenuated by MC4R knockdown. To study the circuitry and mechanisms of melanocortins/MCRs involved in hippocampal synaptic plasticity, we mapped the circuitry of pro-opiomelanocortin/MCRs in the mouse hippocampus. We also confirmed hippocampal melanocortin secretion in response to neuronal activity. These findings help to elucidate the hippocampal circuitry involved in learning and memory as well as the functions of the melanocortin system in the human brain; they may also reveal a functional association between brain metabolism and cognition.

Title: Melanocortin 4 receptor signaling modulation ameliorates synaptic dysfunction in Alzheimer's disease models

Authors: *M. TIAN[1,2,3], Y. SHEN[1,2,3], E. Y. L. CHENG[1,2,3], A. K. Y. FU[1,2,3], N. Y. IP[1,2,3]; [1]Mol. Neurosci. Ctr. and State key Laborary, The Div. of Life Science,, N/A, China; [2]Mol. Neurosci. Ctr., The Hong Kong University of Science and Technology, China; [3]State Key Lab. of Mol. Neurosci., The Hong Kong University of Science and Technology, China

Abstract: Amyloid-beta (Aβ) plaque aggregation is the hallmark of Alzheimer's disease (AD); cognitive dysfunctions in the disease are believed to be due to soluble Aβ oligomers that interrupt synaptic plasticity. We previously demonstrated that the G-protein-coupled receptor melanocortin 4 receptor (MC4R), which regulates energy homeostasis, is involved in synaptic plasticity regulation in the mouse hippocampus. The age-related decrease of the expression of the MC4R endogenous agonist α-MSH regulates MC4R signaling in the brains of AD model mice (APP/PS1 mice). Therefore, the present study examined whether the modulation of MC4R signaling ameliorates the synaptic dysfunction or pathology of AD. The MC4R agonist D-Tyr MTII rescued the soluble Aβ oligomer-induced synaptic transmission deficit in cultured hippocampal neurons. Furthermore, treatment with D-Tyr MTII alleviated the Aβ-induced synaptic plasticity impairment (i.e., long-term potentiation) in acute hippocampal slices and APP/PS1 mice. Interestingly, MC4R knockdown in the APP/PS1 mouse hippocampus abolished the rescue effect of D-Tyr MTII, suggesting that MC4R activation is critical for restoring the synaptic functions in AD. Our findings collectively demonstrate that MC4R signaling activation can ameliorate the impaired synaptic plasticity in AD. Thus, MC4R signaling is a potential target for therapeutic interventions for AD.

Title: The EphA4 inhibitor rhynchophylline ameliorates disease pathology in a mouse model of Alzheimer's disease

Authors: ***W.-Y. FU**[1,2,3], B. BUTT[1,2,3], K.-W. HUNG[1,2,3], F. C. F. IP[1,2,3], A. K. Y. FU[1,2,3], N. Y. IP[1,2,3];

Abstract: Alzheimer's disease is a neurodegenerative disease characterized by cognitive dysfunction. We previously demonstrated an unanticipated role of the signaling of EphA4, a receptor tyrosine kinase, in mediating hippocampal synaptic dysfunction in Alzheimer's disease. Furthermore, we have identified a small molecule rhynchophylline that can effectively block EphA4-dependent signaling in neurons, rescuing the impaired long-term potentiation in the APP/PS1 mouse model of Alzheimer's disease. Here, we further demonstrated that rhynchophylline ameliorates the Alzheimer's disease-like pathology in APP/PS1 mice. Soluble Aβ content and the extent of amyloid plaque deposition were significantly reduced in the cortices of APP/PS1 mice orally administrated with rhynchophylline. Intriguingly, rhynchophylline also regulated the microgliosis in APP/PS1 mice, suggesting that the small molecule reduces neuroinflammation. Taken together, rhynchophylline may be developed as a therapeutic intervention for Alzheimer's disease.

Title: Establishing the role of eukaryotic elongation factor-2 kinase (eEF2K) in Alzheimer's disease and relevance for therapies

Authors: ***A. JAN**[1], G. LEPRIVIER[1], S. SOMASEKHARAN[1], M. VANDAL[2], F. CALON[2], M. HAYDEN[3], P. SORENSEN[1];
[1]BC Cancer Agency, Vancouver, BC, Canada; [2]Univ. of Laval, Quebec, QC, Canada; [3]Ctr. for Mol. Med. and Therapeut. (CMMT), Vancouver, BC, Canada

Abstract: Defects in neuronal energy metabolism and synaptic plasticity are thought to underlie cognitive dysfunction and neuronal loss in Alzheimer's disease (AD), and potentially other neurological diseases. The AMP-responsive protein kinase (AMPK), and its downstream target the eukaryotic elongation factor-2 kinase (eEF2K) couple neuronal energy metabolism to neural activity. This mechanism allows for tight regulation of dendritic mRNA translation in register with synaptic activity, and plays a pivotal role in modulating synaptic strength and plasticity. Previously, we have shown that tumor cells exploit the AMPK-eEF2K axis in developing resistance to nutrient deprivation (Leprivier, G. et al, Cell, 2013), and targeting this pathway represents a potential treatment strategy in cancers. Circumstantial evidence suggests that aberrant activation of the AMPK-eEF2K pathway may also be relevant to neurodegeneration in AD. Recent studies have demonstrated that eEF2K activity, measured by the phosphorylation of its substrate eEF2, is enhanced in AD brains. We have carried out detailed analysis in two AD transgenic mouse models (APPPS1 and 3x-Tg AD), and utilized pharmacological and gene silencing approaches in primary neuronal cultures to understand the relevance of AMPK-eEF2K pathway activity on amyloid-β induced deficits in dendritogenesis and oxidative stress. Our results suggest that the AMPK-eEF2K axis may provide a link between aberrant synaptic activity and neurodegeneration in AD, and represents a novel target for developing mechanism based therapies in AD and related dementias.

Title: Liraglutide protects the brains of macaques against synapse loss caused by Abeta oligomers

Authors: *A. F. BATISTA[1], L. FORNY-GERMANO[1], N. M. LYRA E SILVA[1], J. BRITO-MOREIRA[1], M. GRALLE[1], S. BOEHNKE[2], B. COE[2], A. LABLANS[2], C. HOLSCHER[3], S. MARQUES[1], A. BLANCO MARTINEZ[1], W. KLEIN[4], J.-C. HOUZEL[1], S. FERREIRA[1], D. MUNOZ[2], F. DE FELICE[1];

Abstract: Alzheimer's disease (AD) is a debilitating neurodegenerative disorder and a major health problem worldwide. The lack of effective drugs to treat AD stimulates an intense pursuit of disease-modifying therapeutics. However, a major impediment to progress may lie in fundamental differences between humans and animal model species, largely rodents. Disruption of hippocampal insulin signaling has recently been described in the brains of AD patients and animal models of disease, which could contribute to cognitive impairment in this disease. Therefore, drugs that can restore normal insulin function in the central nervous system have been recently suggested as a promising novel approach to treat AD. Here, we evaluated the neuroprotective effects of liraglutide in cynomolgus macaques (Macaca fascicularis) that received intracerebroventricular injections of Aβ oligomers (AβOs). Liraglutide is an anti-diabetic agent that activates pathways common to insulin signaling through stimulation of glucagon-like peptide 1 (GLP-1) receptors. Nine female cynomolgus macaques were used. Three of them were sham-operated and served as controls. We performed intracerebroventricular (i.c.v.) injections of AβOs into six cynomolgus macaques. Two of these monkeys had been pre-treated with daily i.p. injections of liraglutide. Liraglutide administration continued daily until the last injection of oligomers. Brain sections were used for immunohistochemystry to evaluate the levels of synaptic markers. We found that AβOs induced a decrease in synapse number in the primate brain and reduced the levels of NMDA (GluN1 and GluN2B subunits), AMPA (GluA1 and GluA2 subunits) and insulin receptors. Liraglutide attenuated the impact of AβOs on synapses and on plasticity related receptors. These results establish the protective actions of liraglutide in the primate brain and indicates that a primate model of AD may be valuable not only for studying mechanisms responsible for AβOs toxicity, but also for exploring and evaluating new preventive therapeutic strategies for AD.

Title: Enhanced acetylation of tau in Alzheimer's disease causes deficits in synaptic plasticity and memory formation

Authors: *T. E. TRACY[1,2], P. SOHN[1,2], S. MINAMI[1,2], C. WANG[1,2], Y. ZHOU[1], D. LE[1], Y. LI[1], I. LO[1], R. PONNUSAMY[1], B. W. GIBSON[3], L. ELLERBY[3], L. GAN[1,2];

Abstract: Abnormal accumulation of tau in the brain is linked to severe and debilitating cognitive dysfunction in tauopathies such as Alzheimer's disease (AD). In transgenic mouse models of tauopathy, tau causes memory loss associated with disease; however, the mechanisms by which tau affects neuronal function and promotes cognitive decline are unclear. Using mass spectrometry analysis we detected two lysines on tau, K274 and K281, that were acetylated in human AD brain. We then generated two monoclonal antibodies that selectively recognize these acetylated lysines and investigated the levels of acetylated tau (ac-tau) in AD brains. Human AD cases that were clinically diagnosed with severe dementia had a significantly higher proportion of ac-tau in the brain than non-demented cases. We also found that ac-tau was enhanced in the hippocampus of an AD mouse model expressing human wild-type tau (wt-tau). To determine how ac-tau impacts cognition and the brain we made transgenic mice using the prion promoter to drive neuronal expression of human wt-tau or human tau with mutations to substitute K274 and K281 with glutamines (tauKQ) to mimic the structure and neutral charge of acetylated lysines. In a context discrimination task, we found that mice expressing tauKQ displayed a deficit in pattern separation memory, which is encoded by the dentate gyrus. Electrophysiological recordings from acute hippocampal slices revealed that the expression of long-term potentiation (LTP) in dentate granule cells (DGCs) was impaired in tauKQ mice but not wt-tau mice. We found that tauKQ inhibits the postsynaptic insertion of AMPA-type glutamate receptors (AMPARs) during LTP. We next observed that the polymerization of filamentous actin (F-actin) in DGC spines following LTP induction was impaired in tauKQ mice. Application of jasplakinolide, a drug that stabilizes actin polymerization, during recordings restored LTP in tauKQ mice indicating that tauKQ obstructs activity-dependent AMPAR insertion by disrupting actin cytoskeletal dynamics. Furthermore, we found that the loss of KIBRA, a postsynaptic scaffold protein, underlies the synaptic plasticity deficit triggered by ac-tau. Together, our results suggest that aberrant acetylation of tau on K274 and K281 contributes to memory loss and obstructs synaptic plasticity by inhibiting signaling that regulates postsynaptic actin cytoskeletal dynamics.

Title: Dysregulation of eukaryotic elongation factor 1A expression and synaptic plasticity impairments in Alzheimer's disease

Authors: *B. C. BECKELMAN[1], T. MA[2,3,4];
[1]Neurosci. Grad. Program, Wake Forest Sch. of Med., Winston Salem, NC; [2]Intrnl. Med., [3]Dept. of Physiol. and Pharmacol., [4]Dept. of Neurobio. and Anat., Wake Forest Sch. of Med., Winston-Salem, NC

Abstract: Alzheimer's disease (AD) is the most common form of dementia in the elderly and is quickly rising to epidemic status. Meanwhile, the molecular mechanisms associated with the disease are still elusive, which hinders our ability to search for therapeutic targets. Previous studies have suggested that eukaryotic elongation factor 1A (eEF1A) upregulation is critical for maintenance of hippocampal long-term potentiation (LTP), a synaptic model for learning and memory. Further, eEF1A synthesis is controlled by the mammalian target of rapamycin complex 1 (mTORC1) pathway, which has been linked to LTP impairments in certain mouse models of AD. Here, we explored the dysregulation of eEF1A in AD pathophysiology using biochemical and electrophysiological methods. First, we observed that basal eEF1A levels are downregulated in hippocampi of APP/PS1 AD model mice and postmortem human AD patients. In contrast, no AD-related change of eEF1A levels was found in cerebellum. Furthermore, eEF1A upregulation in hippocampal slices associated with chemical-LTP induction was blunted in AD model mice. Lastly, brain-specific knock-down of tuberous sclerosis complex 2 (TSC2), a negative regulator of mTORC1, rescued the deleterious effects of amyloid beta (Aβ) on hippocampal LTP. In summary, our studies demonstrated impairments of neuronal plasticity-related eEF1A regulation, thus, revealing a potential novel therapeutic avenue for AD and other aging-related memory deficits.

Abstract: As suggested by Palop and Mucke (2010), amyloid beta (Aβ) peptides might have a concentration-dependent dual control effect on excitatory synapses: reduced presynaptic efficacy, presynaptic facilitation and postsynaptic depression appear for low, intermediate and high Aβ concentrations, respectively. Pathologically elevated Aβ impair long term potentiation (LTP) and enhances long term depression (LTD) related to the partial block of N-Methyl-D-aspartate (NMDA) and metabotropic glutamate receptor 5 (mGLur5) receptors. A computational model is developed to explain findings and hypotheses. The model (i) describes the induction and maintenance of long term phenomena by combining a calcium dependent models of bidirectional synaptic plasticity (Shouval 2002} of the induction and a simplified phenomenological model of maintenance motivated by Smolen 2012; (ii) takes into account the effects of Aβ. The calcium control hypothesis assumes that a large calcium transient induces LTP, whereas moderate increase in the calcium concentration induces LTD. The process is controlled by the Ω vs calcium concentration function, which determines both the sign and the magnitude of the change of the synaptic strength. To describe the maintenance mechanism a positive feedback effect is incorporated. Here the synaptic weight is set as a product of two variables with separate dynamics: the first represents the amount of phosphorylated AMPA receptors that are functionally incorporated into postsynaptic sites; the second implements the number of receptors available for incorporation. We couple the two timescales by a phenomenological model of a signaling process: the relatively rapid calcium dynamics induces slow protein expression processes to control the LTP/LTD the maintenance (and expression). Introducing a functional spatial dependence for Ω function we model different levels of Aβ accumulation, which induces impairment of synaptic transmission. This spatial dependence implements that pathologically elevated Aβ may indirectly cause a partial block of NMDARs.Depression of excitatory synapses by high Aβ levels requires activation of mGluR- and NMDAR-dependent LTD pathways. Simulation results describe: a.: Aβ induced synaptic facilitation and occlusion of LTD, b., Aβ induced mGluR and NMDAR dependent LTD facilitation, c: Aβ induced LTP impairment. The next open question to be answered is how elevated Aβ and impaired synaptic plasticity implies destabilization of neural network activity and generation of epileptiform activities.

Abstract: MicroRNAs are a group of small non-coding RNAs that regulate gene expression post-transcriptionally. Recent studies have shown that deregulation of specific microRNAs could be involved in the development of Alzheimer's disease (AD). However, few studies exploring the relationship between microRNAs deregulation in AD and synaptic plasticity exist despite the involvement of some microRNAs in synaptic plasticity. Since it is believed that alterations in synaptic function are related to mild cognitive impairment, it is feasible to hypothesize that alterations in plasticity-related microRNAs could underlie AD progression. Here, levels of a small number of microRNAs involved in the regulation of AMPAR function were examined in mice hippocampal cultures, an AD mice model, where we reported previously changes in AMPAR regulation related with early deficits in learning and memory processes, and in human samples. We found increases in miR-181c-5p (~40%), miR-210-3p (>60%) and miR-92a-3p (~25%) expression but not in miR-181a-5p after oAβ treatment in primary hippocampal neurons. Similar changes in miR-181c-5p and miR-92a-3p were confirmed in the entorhinal cortex of APPSw,Ind transgenic mice. However no significant changes were observed in the hippocampus in these mice. Moreover, the analysis of hippocampal human samples at different Braak stages, show an increase in miR-181c-5p and miR-92a-3p levels during AD progression. These findings indicate a possible relationship between miR-181c-5p and miR92a-3p and the reported changes in glutamate receptor levels and early learning and memory deficits in the APPSw,Ind transgenic mice. Our results suggest that those microRNAs involved in synaptic plasticity might be important factors that contribute to AD neuropathology progress.

Title: Oxidative stress and synaptic protein loss in preclinical Alzheimer's disease

Authors: *S. W. SCHEFF[1], M. A. ANSARI[1], E. J. MUFSON[2];
[1]Ctr. Aging, Univ. Kentucky, Lexington, KY; [2]Neurobio., Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Synaptic dysfunction is one of the hallmarks of Alzheimer's disease (AD) and a seminal event leading to amnestic mild cognitive impairment (aMCI). The precise etiology of synaptic failure remains to be identified although there is strong evidence that oxidative stress, which occurs early in the disease process, may play an important role. Detailed neuropathological analysis and quantitative imaging has shown that the medial temporal lobe (hippocampus, entorhinal cortex, transentorhinal cortex) is one of the earliest brain regions affected in the disease progression. These studies suggest a possible protracted preclinical phase of the disease. We have already shown a loss of synapses in the hippocampus in the aMCI phase. The present study was designed to test whether or not synaptic change occurs in possibly a pre-aMCI or preclinical stage of AD. Human short post-mortem hippocampal tissue was obtained from three different cohorts: (1) individuals with low or no AD-type pathology (LP) and no cognitive impairment (NCI), (2) individuals with high AD-type pathology (HP) and NCI, (3) individuals with aMCI. Changes in several different key synaptic proteins were analyzed along with possible changes in markers of oxidative stress. Compared to the age- and postmortem-matched LP-NCI cohort, individuals with HP-NCI and aMCI manifested a significant increase in numerous markers of oxidative stress. The hippocampal analysis also revealed a significant decline in key synaptic proteins. Elevated oxidative stress strongly correlated levels of the different synaptic proteins. As the oxidative stress increased, the level of synaptic proteins decreased. These results support the idea that in the preclinical stage of the disease, there is already a defect in synaptic structure that may be related to levels of oxidative stress. The fact that the HP-NCI group continues to manifest adequate cognitive ability may be evidence for cognitive reserve in this cohort.

Title: Soluble Aβ oligomers disrupt homeostasis of synaptic vesicle pool among synapses by inhibiting inter-boutonal synaptic vesicle movements

Authors: D. PARK[1], M. NA[2], *S. CHANG[3];
[1]Dept. of Physiol. and Biomed. Sci., [2]Dept. of Physiol. & Biomed. Sci., [3]Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Soluble Aβ oligomer (oAβ) has recently been recognized as a major causative factor in the synaptic dysfunction associated with Alzheimer's disease (AD), yet the molecular mechanisms concerning its presynaptic regulation remain poorly understood. Here, using a quantum-dot based individual synaptic vesicle (SV) probe, we found that acute treatment of cultured rat hippocampal neurons with nanomolar concentrations of oAβ dramatically reduced the interboutonal SV trafficking, without affecting mitochondria transport and the integrity of microtubule structures. Neurons derived from AD transgenic mice also showed defected interboutonal trafficking. We further found that oAβ increased presynaptic Ca2+ levels and subsequent phosphorylation of synapsin. STO-609, blocked oAβ-induced synapsin phosphorylation, and neutralized the effect of oAβ. oAβ treatment induced significant heterogeniety of SV pool size among synapses. Our results indicated that oAβ increases presynaptic Ca2+, which resulted in synapsin phosphorylation, releasing SV and actin from synapsin and subsequently inhibiting interboutonal SV trafficking. By disrupting the SV reallocation among synapses, oAβ may disable neurons from adjusting synaptic weights among synapses that could contribute to homeostatic presynaptic plasticity.

Title: Early synaptic deficits in Alzheimer's disease involve neuronal adenosine A2A receptors

Authors: *S. VIANA DA SILVA[1,2], M. G. HABERL[3], P. BETHGE[4], C. LEMOS[5], A. FRICK[3], V. NÄGERL[4], R. A. CUNHA[5], C. MULLE[4];

Abstract: Alzheimer's Disease (AD) is a progressive neurodegenerative disease characterized clinically by progressive memory loss eventually resulting in dementia. Over the course of the AD amyloid-beta (AB) deposition forms insoluble amyloid plaques but synapse loss is known be better correlated with the progression of the disease. Although the exact role of AB is not fully understood, recent evidence suggests that subtle alterations of synaptic transmission precede neuronal degeneration in the AD. Early disturbance of synaptic processes involved in learning and memory have been reported in several transgenic mouse models. Synaptic plasticity in the autoassociative network of recurrent connections among hippocampal CA3 pyramidal cells is thought to enable episodic memories storage. At the early onset of cognitive deficits in a mouse model of Alzheimer's disease (AD), associative long-term synaptic potentiation (LTP) is abolished in CA3 pyramidal cells. This is caused by activation of up-regulated neuronal adenosine A2A receptors (A2AR) rather than by dysregulation of NMDAR signaling or structural synaptic modifications. Neutralization of A2AR by acute pharmacological inhibition, or downregulation driven by shRNA interference in a single postsynaptic neuron restore associative CA3 LTP. Accordingly, treatment with A2AR antagonists reverts short-term memory deficits.

Title: Adenosine A2A receptor blockade reverts installed deficits of hippocampal-dependent memory and synaptic plasticity in animal models of Alzheimer's disease

Authors: *R. A. CUNHA[1], J. P. LOPES[2], C. LEMOS[2], A. M. CARVALHO-DA-SILVA[2], A. PLIASSOVA[2], F. Q. GONÇALVES[2], N. J. MACHADO[2], P. M. CANAS[2], P. AGOSTINHO[2]; [1]CNC -Center For Neurosci. and Cell Biol., Coimbra, Portugal; [2]CNC-Center for Neurosci. and Cell Biol., Coimbra, Portugal

Abstract: Chronic consumption of caffeine prevents age-related memory dysfunction and is inversely correlated with the incidence of Alzheimer's disease (AD) and animal models confirmed this prophylactic benefit of caffeine (J Alzheimers Dis 20:S95). In accordance with the evidence that caffeine mostly acts through the antagonism of adenosine receptors at non-toxic doses, animal studies allowed defining that selective antagonists of adenosine A2A receptors (A2AR) mimic these neuroprotective effects of caffeine (J Alzheimers Dis 20:S95). The increased density of A2AR upon memory dysfunction, together with the ability of A2AR agonists or activation of A2AR transduction systems to trigger memory impairment and disrupt hippocampal long-term potentiation (LTP, the purported neurophysiological basis of memory) further suggest a causal role for A2AR over-functioning as a trigger of memory impairment. However, it has not been established if A2AR blockade can also revert pre-installed memory deficits. This was first tested in adult mice with memory impairment (object displacement, modified Y-maze), 15 days after exposure to β-amyloid peptides (Aβ1-42, 2 nmol, icv), where A2AR were up-regulated in particular in glutamatergic terminals that undergo selective degeneration (Neuropharmacol 76:51). Slices from these Aβ-treated mice display a reduced LTP in CA1 synapses. Notably, a 30 min superfusion with the A2AR antagonist, SCH58261 (50 nM), reverted LTP amplitude deficits to values similar to sham-operated mice without memory impairments. In another AD animal model (3xTg mice), memory impairment was observed at 4.5 months, which was accompanied by a lower LTP amplitude in the CA1 area together with a decreased density of synaptic markers in the hippocampus (synaptophysin, SNAP25 and vGluT1, but not vGAT). These 3xTg mice also displayed an increased density of A2AR in hippocampal synaptic membranes. Notably a 3-weeks treatment with SCH58261 (0.1 mg/kg ip, daily) reverted the deficits of memory performance of 3xTg mice, without altering the 'normal' memory performance of WT mice. Furthermore, slices from SCH58261-treated mice displayed an LTP amplitude similar to that found in WT mice and larger than that found in vehicle-treated 3x-Tg mice. Likewise, the decrease of synaptic markers in the hippocampus of vehicle-treated 3xTg mice was not present in SCH58261-treated 3xTg mice. These results further re-enforce the key role of A2AR in the emergence of the early features of AD and prompt the suggestion that A2AR antagonists might not only be a prophylactic but also a promising therapeutic strategy to manage early AD.

Title: Sigma-1 receptor involvement in an animal model of Alzheimer’s disease

Authors: ***M. A. SNYDER**, K. MCCANN, M. M. J. LALANDE, R. BERGERON; Ottawa Hosp. Res. Inst., Ottawa, ON, Canada

Abstract: Background: Alzheimer’s disease (AD) is characterized by the progressive loss of neurons in the cortex and hippocampus, leading to cognitive decline. While a small percentage of AD is hereditary, the vast majority of cases are sporadic, composed of both genetic and non-genetic risk factors. Despite decades of research, mostly focused on the amyloid beta (Abeta) synthesis pathway, there is still no cure and current therapies fail to significantly alter the disease course. Thus, new targets for therapeutics are desperately needed. One intriguing area of investigation has focused on the sigma 1 receptor (Sig1R). Sig1Rs are proposed to play a role in the pathogenesis of AD for a number of reasons: 1) genetic polymorphisms of the Sig1R confer risk for AD; 2) Sig1R expression is reduced in AD; 3) Sig1R agonists are neuroprotective and anti-amnesic in AD mouse models; and finally 4) Aricept, the most prescribed drug for AD patients, has nanomolar affinity for Sig1R. Together these results led us to question whether loss of Sig1R function is involved in the underlying etiology of AD. **Rationale and Hypothesis:** The role of Sig1Rs in regulating calcium homeostasis under cellular stress is particularly interesting given the importance of calcium homeostasis for proper cell functioning. Moreover, alterations in calcium homeostasis are observed during AD and normal aging. We hypothesize that loss of Sig1R will exacerbate the cognitive and synaptic deficits in AD by potentiating perturbations in calcium homeostasis. To verify our hypothesis we used an *in vivo* knockout (KO) mouse model, the Sig1R KO mice. **Preliminary data:** We first explored Sig1R’s ability to regulate calcium using whole-cell electrophysiology and examining the post-burst afterhyperpolarization (AHP). This paradigm is often used as a proxy for changes in calcium homeostasis. We found that the Sig1R agonist (+) pentazocine increases the AHP. We next explored how loss of Sig1R affects calcium regulation, physiology, and behavior in an AD mouse model. We used the $Abeta_{25-35}$

infusion model as it recapitulates the process of sporadic AD, including impairments in learning, synaptic plasticity, Abeta plaque deposits, and cell loss in the hippocampus. Wild-type (WT) and Sig1R KO mice were infused intracerebroventricularly with $Abeta_{25-35}$. We found that $Abeta_{25-35}$ impairs performance on spontaneous alternation in the Y maze, reduces the magnitude of long-term potentiation, reduces neuronal excitability, and increases the AHP in Sig1R KO compared to WT. Future experiments will determine how calcium homeostasis is altered and whether reversing changes to calcium will prevent changes to physiology and behavior.

Title: Effect of the pentraxins on neurons and microglia in the CNS

Authors: *T. BENWAY, D. M. CUMMINGS, E. FOSTER, W. LIU, M. V. YASVOINA, F. A. EDWARDS, D. A. SALIH;
Univ. Col. London, London, United Kingdom

Abstract: The pentraxins are neuromodulators that are linked to Alzheimer's disease (AD) (for review, Osera et al. Ageing Res. Rev. 11:189, 2012). In particular, neuronal pentraxin 1 (NPTX1) mediates neurite degeneration induced by amyloid-β when applied to neurons in culture (Abad et al. J.Neurosci. 26:12735, 2006) and NPTX2 has been shown to regulate inflammation, a key process that is dysregulated in AD (Miskimon et al. J.Neuroimmunol. 274:86, 2014). At the synapse, NPTX1, NPTX2 and the NPTX receptor (NPTXR) interact to play a key role in plasticity by clustering AMPA receptors (O'Brien et al., J.Neurosci. 22:4487, 2002). We have studied effects of neuronal pentraxins using patch clamp recording of wild type mouse hippocampal CA1 neurons in organotypic slices. Application of nanomolar concentrations of any one of the human neuronal pentraxins over 7 days reduced paired-pulse ratios of Schaffer collateral synapses, in a dose-dependent manner. This indicates an increase in glutamate release probability, with different potencies of the three pentraxins: NPTX1>NPTXR>NPTX2. Interestingly, the increased probability of release is similar to that observed in transgenic mice expressing human genes that cause familial AD (Cummings et al., Brain in press July, 2015). In agreement with Abad et al. (2006) our preliminary results confirm

that NPTX1 overexpression inhibits the capability of neurons to form complex dendritic processes *in vitro*. Interestingly our recently published database www.mouseac.org indicates changes in gene expression of the neuronal pentraxins at different ages in two different dementia-related mouse models (human APPswe+PSEN1M146V or TauP301L, Matarin et al., Cell Rep 10:633-644 (2015). In relation to the role of inflammation in AD, we have shown that the NPTXR is expressed in the BV2 microglia cell line. Current research aims further to characterize the involvement of neuronal pentraxins in the immune response by using organotypic hippocampal cultures, where a greater extent of brain physiology can be examined. Also, given that NPTX1 forms complexes at the synapse with both NPTX2 and NPTXR, we are using overexpression studies to gain more information about the interactions of these neuronal pentraxins with each other and with peripheral pentraxins that have also been suggested to have a role in AD (see Osera et al., 2012 for review). All work with animals carried out in accordance with the UK Animals (Scientific Procedures) Act 1986.

Title: Rapid modulation of protein expression in the rat hippocampus following deep brain stimulation of the fornix

Authors: ***E. GONDARD**[1], H. N. CHAU[1], A. MANN[1], T. S. TIERNEY[2], C. HAMANI[1,3], S. K. KALIA[1], A. M. LOZANO[1];
[1]Neurosurg., Toronto Western Hosp. - Univ. of Toronto, Toronto, ON, Canada; [2]Brigham and Women's Hospital, Harvard Med. Sch., Boston, MA; [3]Res. Imaging Centre, Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

Abstract: Background: The forniceal area is currently being evaluated as a target for deep brain stimulation (DBS) to improve cognitive function in patients with Alzheimer’s disease. The molecular changes at downstream targets within the stimulated circuit are unknown. Objective: To analyze the modulation of hippocampal protein expression following one hour of fornix DBS in the rat. Methods: Animals underwent bilateral forniceal DBS for one hour and sacrificed at different time-points after the initiation of the stimulation (1h, 2.5h, 5h, 25h). Bilateral hippocampi were isolated for western blot analyses. Results: Forniceal DBS led to a dramatic

elevation of cFos post-stimulation, suggesting that forniceal DBS activates the hippocampus. There was also a significant increase in candidate proteins including several trophic factors, such as brain derived neurotrophic factor (BDNF) and vascular endothelial growth factor (VEGF) but not glial cell-derived neurotrophic factor (GDNF). There was in addition, increased expression of the synaptic markers growth associated protein 43 (GAP-43), synaptophysin and α-synuclein. No changes were observed at the studied time-points in Alzheimer's-related proteins including amyloid precursor protein (APP), tau, phosphorylated tau (ptau), or selected chaperone proteins (HSP40, HSP70 and CHIP). Conclusions: Forniceal DBS triggers hippocampal activity and rapidly modulate the expression of neurotrophic factors and markers of synaptic plasticity known to play key roles in memory processing. The clinical effects of DBS of the fornix may, in part, be mediated by producing changes in the expression of these proteins.

Abstract: Alzheimer's disease (AD) is a neurodegenerative disease and nowadays the most common cause of dementia. AD is anatomically characterized on the macroscopic level by brain atrophy and on the microscopic level by amyloid plaques due to increased beta amyloid levels in the brain. The earliest clinical signs of the disease however are memory loss and cognitive impairment. These functional alterations are thought to precede the anatomical hallmarks of the disease and are currently not well understood in molecular and cell physiological terms. In this study we used the $APP_{swe}/PS1_{dE9}$ (APP-PS1) transgenic mice to study the potential causes of initial memory loss and cognitive decline in AD. We found that 3 months old APP-PS1 mice lack amyloid plaques in the brain, but do show an impairment in hippocampus-dependent spatial memory, which is accompanied by impaired hippocampal LTP induction and an upregulation of synaptic extracellular matrix (ECM) proteins. Intra-hippocampal infusion of the ECM degrading

enzyme chondroitinase ABC (chABC) rescued both memory and LTP impairments. To understand the mechanisms behind this chABC-mediated rescue of synaptic plasticity we are currently analysing the molecular composition of the hippocampal ECM of APP-PS1 and wildtype mice. We found that chABC treatment of the hippocampal slices releases potential novel ECM-associated proteins. Comparative analysis in APP-PS1 and wildtype mice of chABC-induced protein release *in vitro* and chABC-induced effects on synaptic ECM composition *in vivo* may result in the discovery of potential new drug targets for treatment of early cognitive impairments in AD.

Abstract: Precuneus, a component of the neocortical default mode network, contributes to episodic memory function which is disrupted early in Alzheimer disease (AD). However, the relationship between precuneus neuropathology, including synaptic alterations, and cognitive decline in AD is unclear. A recent electron microscopy study reported that numbers of total synapses in precuneus lamina III were stable in mild cognitive impairment (MCI) and reduced in AD, but were not correlated with cognitive performance (Scheff, 2013). Here, we applied unbiased stereologic principles with quantitative confocal microscopy to analyze spinophilin immunofluorescent dendritic spines in lamina III of precuneus from 27 Rush Religious Order Study participants who died with clinical diagnosis of no cognitive impairment (NCI, MMSE 26-30), MCI (MMSE 22-30) or early AD (MMSE 17-28). Density and immunofluorescence intensity of spinophilin-positive dendritic spines were compared among the three clinical groups

and correlated with cognitive measures (MMSE, global cognitive and episodic memory tests) and precuneus neuropathology burden, assessed as percent area covered with 6-CN-PiB positive plaques or PHF1-immunoreactive p-Tau pathology. We observed that in the precuneus from AD cases, immunofluorescence intensity of spinophilin-positive dendritic spines was lower compared to the MCI (but not the NCI) group, while a reduction in spine densities did not reach statistical significance. Across all cases in the study, lower values of spinophilin-positive dendritic spine measures correlated significantly with lower MMSE scores. Lower spinophilin immunofluorescence intensity also correlated significantly with poorer global cognitive and episodic memory test scores. Precuneus 6-CN-PiB positive plaque burden was greater in AD than in the NCI (but not the MCI) group, and across all cases it correlated significantly with global cognitive and episodic memory scores. Precuneus PHF1 pathology burden was not different among the clinical groups and did not correlate with cognitive measures. Measures of spinophilin-positive dendritic spines in the precuneus did not correlate with 6-CN-PiB positive plaques or tau positive pathology burden. Our results demonstrate that cognitive decline in AD is associated with reduced dendritic spines and increased PiB binding in the precuneus, but the two measures did not appear to be related. Perhaps, the observed post-synaptic alterations are due to non-fibrilized (oligomeric) forms of Aβ and/or tau, invisible to currently available PET radiotracers for detecting amyloid pathology *in vivo*.

Title: Chronic deep brain stimulation enhances learning in young mice

Authors: ***A. MANN**[1], C. HAMANI[1,2], A. M. LOZANO[1];
[1]Neurosurg., Toronto Western Hospital-UHN, Toronto, ON, Canada; [2]Res. Imaging Centre, Ctr. for Addiction and Mental Health,, Toronto, ON, Canada

Abstract: Deep brain stimulation (DBS) is a well-established method of focally and titratably modulating neural activity in patients with several disease processes, including movement disorders, psychiatric illness, and pain. Despite its widespread and successful use in Parkinson's disease, and promise in Alzheimer's disease, much of the mechanisms by which DBS exerts its

effects remain unknown. We have previously shown that acute DBS can modulate hippocampal inputs and increase neurogenesis in rodent models. To partially mimic and better model DBS conducted in clinical settings, we assessed the impact of chronic DBS in naïve young mice. We used 2-month old C57bl/6 mice and bilaterally implanted electrodes in the entorhinal cortex (EC). Mice were stimulated for 7 hours per day with 50 μAmp using a frequency of 130 Hz and pulse width of 90 μSec, for 25 days. After 25 days of stimulation mice were assessed for changes locomotor activity in the Open Field and learning and memory using the Morris water maze (MWM). We found that chronically stimulated mice were significantly faster at learning the MWM task when compared to Control mice. However, no significant difference was seen during the probe test. In addition, no differences were observed in the Open Field. This is the first study to show that 25 days of EC stimulation improves learning behaviour through direct activation of the hippocampus.

Title: Amyloid Beta co-localizes with dopamine beta hydroxylase in dense core vesicles of cortical noradrenergic terminals: anatomical evidence for putative regulated co-secretion

Authors: *J. ROSS[1], B. A. S. REYES[1], A. SAUNDERS[2], E. J. VAN BOCKSTAELE[1]; [1]Pharmacol. and Physiol., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Biol., Drexel Univ. Col. of Arts and Sci., Philadelphia, PA

Abstract: Over 5 million Americans are currently suffering from Alzheimer's disease (AD), the most common cause of dementia. Currently, AD has no effective treatment and represents a substantial multi-billion dollar cost burden to the health care system. AD is a neurodegenerative disorder classically characterized by histological features including amyloid beta (Aβ) peptide aggregates known as senile plaques, and hyper-phosphorylated tau protein aggregates known as neurofibrillary tangles (NFT). One of the earliest regions to become dysregulated in AD is the locus coeruleus (LC), the dorsal pontine nucleus that provides the neurotransmitter norepinephrine (NE) to almost all levels of the neuraxis. The dysregulation of the LC-NE system is thought to contribute to multiple aspects of AD pathogenesis. For example, it has been shown that degeneration of the LC and subsequent decreases in NE create a permissive environment for Aβ-induced inflammation. While the detrimental effects of LC degeneration have been the

subject of intense investigation, there are still extensive gaps in our knowledge regarding the interaction of NE in terminal regions of the LC and Aβ at the synapse. *In vitro* studies in neuron-like chromaffin cells have localized Aβ, BACE, and gamma secretases to large dense core vesicles (LDCVs) (Toneff et al., 2013, Peptides, 46:126-35) and further, have demonstrated regulated co-secretion of Aβ with catecholamine neurotransmitters also present within these vesicles. In the present study, we examined the cellular substrates for interactions between Aβ and dopamine beta hydroxylase (DBH), a marker of noradrenergic axon terminals in the rat frontal cortex (FC) using light, immunofluorescence and electron microscopy. Three antibodies for Aβ have been used to evaluate the distribution of various isoforms of the peptide within noradrenergic terminals. Our preliminary immunofluorescence data show co-localization of Aβ and DβH with similar distribution between antibodies, further validating the presence of Aβ in noradrenergic terminals. Using high resolution immunoelectron microscopy, semi-quantitative preliminary analysis revealed that 19% of DBH-containing axon terminals (54/281) also exhibited Aβ-immunogold silver particles, of which approximately 68% are associated with dense core vesicles (37/54). Aβ is also localized to approximately 13% of somatodendritic processes (42/323), of which approximately 14% (6/42) are post-synaptic to NE-containing axon terminals. An on-going study aims to further characterize the presence of Aβ in the LDCVs of noradrenergic projections using chromogranin A, a marker for the LDCV.

Title: Defective glucocerebrosidase in GBA mutant Parkinson's disease fibroblasts is rescued by chemical chaperone ambroxol through modulation of lysosomal factors

Authors: *F. BLANDINI, C. GHEZZI, R. ZANGAGLIA, G. LEVANDIS, C. PACCHETTI, G. AMBROSI;
Ctr. for Res. in Neurodegenerative Dis., Natl. Neurolog. Inst. C.Mondino, Pavia, Italy

Abstract: Introduction: Heterozygous mutations in GBA gene, encoding for lysosomal enzyme glucocerebrosidase (GCase), are a major risk factor for sporadic Parkinson's disease (PD) [1]. Defective GCase has been recently reported in fibroblasts of GBA-mutant PD patients and

pharmacological chaperone ambroxol has been shown to correct such defect [2]. A number of endogenous elements support GCase activity, especially transporter and lysosomal receptor LIMP2 and activator saposin (Sap) C, which have been suggested as possible disease modifiers in PD [3]. Objective: our aim was to further investigate GCase activity, associated lysosomal and proteasomal factors at baseline and after ambroxol administration in fibroblasts from sporadic PD patients, with or without heterozygous GBA mutations, and healthy subjects. Methods: We assessed protein levels of GCase, LIMP2, Sap C and parkin - a central element in PD and cellular proteostasis - by western blotting. We measured activities of GCase and cathepsin D, responsible for Sap C cleavage from precursor prosaposin, using ELISA assays. All analyses were carried out in basal conditions and following exposure to ambroxol. Results: GCase activity was reduced in fibroblasts from GBA-mutant patients and ambroxol corrected this defect, thereby confirming previous results. Ambroxol increased cathepsin D activity, GCase and Sap C protein levels in all groups and LIMP2 protein levels in GBA-mutant PD fibroblasts. Parkin levels were slightly increased only in the PD group without GBA mutations and were not significantly modified by ambroxol. Conclusion: Our study confirms that GCase activity is deficient in GBA-mutant PD patients, further indicating that fibroblasts are a good model to investigate proteolytic dysfunction. Moreover, our study shows that ambroxol-induced rescue of GCase activity is associated with enhanced expression of LIMP2 and Sap C; ambroxol does not interfere with parkin, confirming that this chemical chaperone selectively modulates lysosomal pathways that may be targeted for the development of innovative therapeutic strategies.

Title: Differential neuronal vulnerability by α-synucleinopathy in the human anterior olfactory nucleus in Parkinson's disease

Authors: *I. UBEDA-BANON, A. FLORES-CUADRADO, D. SAIZ-SANCHEZ, C. DE LA ROSA-PRIETO, A. MARTINEZ-MARCOS;
Fac. Med. Ciudad Real-Crib Univ. Castilla-La Mancha, Ciudad Real, Spain

Abstract: Parkinson's disease (PD) is one of the most prevalent neurodegenerative disorders, mainly idiopathic and with palliative treatment. Neuropathologically, it is a proteinopathy with aggregates of ubiquitin and α-synuclein called Lewy bodies and neurites. These deposits appear in a predictable sequence of six stages beginning in olfactory structures, particularly in the anterior olfactory nucleus. Recently, it has identified a preclinical (prodromal) period that would begin even decades before symptoms lead to neurological diagnosis, which opens a promising therapeutic window. This period would be characterized by early symptoms such as olfactory deficits that could correlated with neuropathological staging. Further, neurophatological spreading could occur in a prion-like manner through axons and transynaptically. The aim of this study has been, therefore, study the differential vulnerability of neuronal populations induced by α-synuclein in the different divisions of the anterior olfactory nucleus (retrobulbar, cortical anterior medial, cortical anterior lateral, cortical posterior medial and cortical posterior lateral subdivisions). Human neurological tissue from Parkinson's patients (stages 4-5) and healthy age-matched controls were used. Samples and data from patients included in this study, who gave written informed consent, were collected, processed and provided by the IDIBAPS, BTCIEN and BIOBANC-MUR integrated in the Spanish Biobanks Network and were processed following standard operating procedures with appropriate approval of the Ethical and Scientific Committees. Neuronal markers have been used to determine cell loss. Triple immunofluorescence of calretinin, parvalbumin and α-synuclein or calbindin, somatostatin and α-synuclein plus DAPI were carried out to analyze the differential vulnerability of interneuron populations. Neuronal confocal images were used to quantify potential cell loss and co-localization using Zen software from Zeiss. Our results show differences in vulnerability and co-localization of different cell types in the various divisions of the human anterior olfactory nucleus in PD. These results could help to understand neural substrates of non-motor symptoms such as anosmia and how this proteinopathy could propagate through the olfactory system.

Title: α-synucleinopathy and differential vulnerability of interneurons in the human amygdala and hippocampus

Authors: A. FLORES-CUADRADO, I. UBEDA-BANON, D. SAIZ-SANCHEZ, C. DE LA ROSA-PRIETO, *A. MARTINEZ-MARCOS;
Fac. Med. Ciudad Real, CRIB Univ. Castilla-La Mancha, Ciudad Real, Spain

Abstract: Olfactory dysfunction, anhedonia and dementia are non-motor symptoms involved in Parkinson's disease (PD). These symptoms might be correlated to the appearance of Lewy bodies and neurites (ubiquitin and alpha-synuclein aggregates) in particular brain areas according to six stages of Braak's neuropathological description. The olfactory bulb, the anterior olfactory nucleus and the dorsal motor nucleus of the vagus nerve are involved at stage 1. However, the amygdala and the substantia nigra are involved at stage 3. Previous to cortical spreading, Lewy bodies appear in the hippocampus at stage 4. It has been described that oxidative stress and calcium-induced excitotoxicity are involved in PD cell death. Apart from pyramidal projection neurons, a number of interneuron subpopulations have been described in the amygdaloid complex and hippocampus. These subpopulations have been characterized based on their expression of calcium-binding proteins such as calretinin, calbindin and parvalbumin and neuropeptides such as somatostatin. The goal of this work has been to analyze the α-synucleinopathy and the differential vulnerability of interneuron populations in the amygdala (cortical, central and basolateral nuclei) and hippocampus (CA3, CA2, CA1 and dentate gyrus). In addition, we evaluated if there are differences between rostral and caudal levels and stages in these particular brain areas. We have analyzed 5 PD post-mortem samples at different stages: 2 (stage 3), 1 (stage 4), 2 (stage 5). Samples and data from patients included in this study, who gave written informed consent, were collected, processed and provided by the IDIBAPS, BTCIEN and BIOBANC-MUR integrated in the Spanish Biobanks Network and were processed following standard operating procedures with appropriate approval of the Ethical and Scientific Committees. α-synuclein and interneuron markers positive-cells were quantified using immunofluorescence procedures. Three photographs per area and multiple Z-stacks were taken in confocal microscope. Binarization and threshold were applied in all pictures using ImageJ software. Co-localization between alpha-synuclein and interneurons were carried out using Zen Software Ortho tool. We observed that Lewy bodies were abundant at stage 3 whereas Lewy

neurites appeared at stage 4 and 5 in CA2. Lewy neurites in basomedial amygdaloid nuclei were higher than other amygdaloid nucleus. This analysis could be helpful to understand given non-motor symptoms of PD as well as mechanism of α-synucleinopathy spreading along the temporal lobe.

Title: Activity-dependent neuroprotective protein expression in nigral dopaminergic neurons in sporadic Parkinson's disease

Authors: *Y. CHU, Y. HE, J. H. KORDOWER;
Rush Univ. Med. Ctr., Chicago, IL

Abstract: Activity-dependent neuroprotective protein (ADNP), a vasoactive intestinal peptide (VIP) regulated gene, is essential for brain formation and function. Mutations in ADNP gene are associated with neurodegenerative diseases. It is possible that intracellular alpha-synuclein inclusions, occurring in the context of neurodegenerative diseases, may be due to, or may cause, down-regulation of ADNP expression. The present study investigated alterations of ADNP in dopaminergic neurons in patients with sporadic Parkinson's disease (n =10) and age-matched controls (n=9). Co-localization analyses revealed that ADNP immunoreactivity was severely reduced in both neuromelanin (NM)-laden neurons with or without alpha-synuclein aggregations in PD. Quantitative immunofluorescence intensity measurements in NM-laden nigral neurons further demonstrated that the optical density of ADNP levels was significantly decreased in neurons with (370.79±71.44; $P < 0.01$) and without (388.51±77.30; $P < 0.01$) alpha-synuclein inclusions in Parkinson's disease relative to the age-matched controls (1216.92±51.58). There was no difference between NM-laden nigral neurons with present or absent alpha-synuclein inclusions ($P > 0.05$). Evaluation of ADNP levels with the symptoms of Parkinson's disease progress (H&Y scale) revealed that there were no differences ($P> 0.05$) among H&Y stages II-V, suggesting that reduction of ADNP expression is an early alteration during Parkinson's disease progress. Correlation analyses demonstrated that the decline in ADNP levels was linear with reduction of kinesin heavy chain levels ($r = 0.66$; $P < 0.01$) and dynein light chain tctex type 3 ($r = 0.85$; $P <0.001$). These preliminary data demonstrated that decreased ADNP is independent of alpha-synuclein inclusions, correlated alteration of axonal transport motor protein, and an early event in the pathogenesis of Parkinson's disease.

Abstract: In some patients with Parkinson's disease (PD), variations of the Leucine-rich repeat kinase 2 (LRRK2) gene have been associated with the development of the disease. Patients with PD exhibit specific deficits when performing anti-saccades, an inhibitory task that requires looking in the mirror location of a peripheral visual stimulus. These deficits include longer reaction times, increased direction errors (erroneously looking at the stimulus), and hypometric saccades. We conducted an interleaved pro- and anti-saccade task with age-matched controls, idiopathic PD patients, and LRRK2 mutation carriers either before (non-manifesting) or after they manifest PD (manifesting carriers). The pro-saccade task (look at the peripheral stimulus) assesses the basic sensory-motor processing of eye movements via automatic tendencies to look at salient visual stimuli, whereas the anti-saccade task assesses the inhibition of this automatic response and generation of a voluntary command to look in the mirror location. Interestingly, preliminary analysis revealed that carriers of pathogenic LRRK2 genetic mutation, who have not yet developed Parkinsonism, had anti-saccade deficits similar to PD patients. More specifically, non-manifesting carriers had longer reaction times during the anti-saccade task, resembling the PD patient group. Unsurprisingly, manifesting carriers performed similarly to patients with Parkinson's without the LRRK2 gene mutation in both reaction times and error measures. Further analysis is essential to identify more pre-symptomatic behavioural biomarkers of PD that accurately predict disease and thus lead to earlier PD detection.

Title: Parkinson's and Crohn's disease-associated LRRK2 mutations and LRRK2 inhibitors alter type II interferon responses of human peripheral blood monocyte *ex vivo*

Authors: *T. IKEZU[1], H. ASAI[2], S. IKEZU[2], B. WOLOZIN[2], F. FARRAYE[2], Z. WSZOLEK[3]; [1]Pharmacol. and Neurol., [2]Boston Univ. Sch. of Med., Boston, MA; [3]Mayo Clin., Jacksonville, FL

Abstract: The Leucine Rich Repeat Kinase 2 (LRRK2) is a causative gene of familial Parkinson's disease (PD). In addition, the M2397 allele of M2397T polymorphism in LRRK2 gene is genetically associated with sporadic Crohn's disease. LRRK2 is highly expressed in neurons in the central nervous system and in human peripheral blood mononuclear cells (PBMCs), especially CD14+ monocytes. Recent studies suggest that LRRK2 transcription is potently induced by type II interferon (IFN-γ and suppresses the activity of the transcription factor Nuclear Factor of Activated T cells (NFAT) in human immune cells. The putative role of LRRK2 in immune function raises the possibility that LRRK2 contributes to PD by altering brain inflammatory response. We hypothesize that IFN-γ induces LRRK2 gene expression, which inhibits NFAT activity, leading to a resolution of IFN-γ-mediated inflammation, and this may be altered in human monocytes derived from PD or CD patients by LRRK2 mutations. A total of 50 CD and 50 control cases and 15 PD with LRRK2 mutation cases and 20 PD without LRRK2 mutation cases are recruited. We have isolated live CD14+ human monocytes from recruited PD, CD and control cases for *ex vivo* IFN-γ stimulation. We found that IFN-γ potently enhanced gene expression of pro-inflammatory molecules and LRRK2 itself. Interestingly, specific LRRK2 inhibitors (CZC-25146 and GSK-2578215A) show further enhanced the gene expression, whereas FK506, a NFAT inhibitor, suppressed all the gene induction. M2397 LRRK2 CD risk allele group show enhanced IFN-γ responses in CD but not in control cohort. Monocytes isolated from PD cases with G2019S and R144C LRRK2 mutations show significantly suppressed IFN-γ responses, whereas monocytes from sporadic PD cohort are similar to the ones from control cohort. Interestingly, none of M2397 allele homozygotes are present in the PD cases with G2019S or R144C LRRK2 mutation. These data demonstrate that PD-linked and CD-associated LRRK2 mutations are significant modifiers of innate immune response and potentially important for the immunopathogenesis of PD and CD.

Title: microRNAs as progression biomarkers for Parkinson's disease

Authors: *S. KHOO;
Grand Valley State Univ., Grand Rapids, MI

Abstract: Parkinson's disease is the second most common neurodegenerative disorder. There is no cure nor definitive diagnosis of this progressive disease. When patients are first diagnosed, they are usually in a moderately advanced stage, which is a major roadblock for early therapeutic intervention. Hence, development of objective biomarkers for diagnosis and progression is essential to impact management and treatment of this devastating disease. Previously, we identified a panel of microRNAs (miRNAs) from plasma that can differentiate PD from healthy controls. Here, we evaluate the miRNA expression changes in PD patients over time and assess their potential as biomarkers to track PD progression. 30 plasma samples (15 fast and 15 slow progressors) with baseline (0 mo.) and endpoints (6-23 mo.) were processed and quantitative real-time PCR was performed. We found a subset of miRNAs showing statistically significant difference between baselines and endpoints, as well as between slow and fast progressors. This preliminary results suggest that miRNAs have great potential to serve as progression biomarkers for PD. This research project is funded by the Michael J. Fox Foundation for Parkinson's Research using the DATATOP samples.

Title: Examination of iron-management proteins in Parkinson's disease patients

Authors: *A. M. SNYDER[1], J. R. CONNOR[1], C. STETTER[2], L. KONG[2], M. M. LEWIS[3], X. HUANG[3];
[1]Neurosurgery, MC H110, [2]Publ. Hlth. Sci., [3]Neurol., Penn State Univ. Coll Med., Hershey, PA

Abstract: Increased iron deposition in the brains of patients with Parkinson's disease (PD) has long been reported, yet the role of iron in disease progression or the management of iron in the parkinsonian brain remains to be elucidated. Key proteins that work synergistically to regulate iron uptake and storage are transferrin and ferritin, respectively. Ferritin has the capability of sequestering 4500 atoms of iron and is comprised of H- and L- subunits. H-ferritin is if particular interest in Parkinson's disease because it converts bio-reactive ferrous iron to relatively inert ferric iron. Data from autopsy tissue suggest that H-ferritin levels are decreased in Parkinson's disease specimens, but H-ferritin levels in the central nervous system, as reflected by cerebrospinal fluid (CSF), or in the periphery are unknown in the living PD patient. The overall goal of our work is to establish a biomarker profile to better understand the role of iron in Parkinson's disease pathophysiology. We hypothesize that ferritin levels, particularly those of H-ferritin, will be informative in understanding disease progression. We examined proteins of iron management in serum and CSF from PD patients and controls. No differences were detected in serum transferrin or ferritin between PD and control groups. H-ferritin levels in serum or CSF were not changed when all PD patients were treated as one group. However, when PD patients were sub-divided into disease duration categories of less than one year, one to five years, five to ten years, and over ten years, an important correlation between serum and CSF H-ferritin levels emerged. Patients with disease duration less than one year reflected the positive correlation between serum and CSF H-ferritin levels that is observed in controls. The data from PD patients with disease duration of one to five years showed a negative correlation between H-ferritin in serum and CSF. Patients beyond five years did not show a correlation between serum and CSF H-ferritin levels. These data suggest that iron management is not causative of PD pathology but does signify a shift in iron homeostasis two to five years after PD diagnosis. Investigation is ongoing to determine if H-ferritin levels have prognostic value for determining rate and severity of disease progression.

Title: Specific changes of serum proteins in Parkinson's disease patients

Authors: *X. WANG[1], Y. SUN[2], B. CHEN[3], W. LU[2];
[1]Inst. Materia Med., Beijing, China; [2]Inst. of Materia Medica, Beijing, China; [3]Xuanwu Hosp., Beijing, China

Abstract: Recently we demonstrated that the protein ITI-H4 (inter-alpha-trypsin heavy inhibitor) and Apo-A-IV were specific changed in the serum of Parkinson disease patients (Lu *et al*, *Plos One*, 2014). It was interesting that each protein was found existing two subunits in serum. The full size (120 kDa) ITI-H4 was increased and the fragmented ITI-H4 (35 kDa) was decreased in PD patients. Meanwhile, the subunit A of Apo-A-IV (46 kDa) was not changed in PD group, but the subunit B (26 kDa) was significantly decreased. Above data was obtained from 20 PD patients and 20 health people. In order to further demonstrate and validate the results, we observed the changes of both proteins in 180 PD patients and investigated the regulation of the two proteins in the present study. The blood samples were collected from PD patients aged 50 - 75 and they were diagnosed PD in 5 years. The control blood samples were collected from the health people with the same age range. The serum proteins of ITI- H4 and Apo-A-IV were semi-quantity determined by using western blot method. It was showed that the expressions of full-long ITI-H4 (120 kDa) increased 29% and the 35 kDa fragment was decreased 18% in PD group compared with control group. The ratio of 120 kDa/35 kDa was enhanced 68% in PD patients compared to control. The expression of subunit A (46 kDa) of Apo-A-IV was no difference between PD and control groups. However, the 26 kDa subunit (subunit B) was decreased by 48% in PD patients. Our results are accordant with our previous finding. The regulatory mechanisms of both proteins were also investigated in this study. The two proteins and the subunits might be used as blood biomarkers of PD. They are also important in studies of pathogenesis and the pathophysiology of PD.

Title: Study of the CD163 receptor in Parkinson's disease: A prospective Biomarker?

Authors: *M. ROMERO-RAMOS[1], K. SHRIVASTAVA[1], D. BERG[2], H. J. MØLLER[3]; [1]NEURODIN, Dept. Biomedicine, Aarhus Univ., Aarhus C, Denmark; [2]Dept. of Neurodegeneration, Ctr. of Neurology, Hertie Inst. for Clin. Brain Res., Tuebingen, Germany; [3]Clin. Biochem., Aarhus Univ. Hosp., Aarhus, Denmark

Abstract: Neuropathological processes in Parkinson's disease (PD) are related to abnormalities of the presynaptic protein alpha-synuclein (AS), whose aggregation leads to the formation of amyloid fibrils in Lewy bodies, the pathological hallmark of PD. CD163 is a scavenger receptor normally expressed on peripheral monocytes/macrophages and whose expression is altered upon inflammation. Shedding of the CD163 from the cell surface occurs in human monocytes/macrophages and produces a soluble CD163 (sCD163) plasma protein. This shedding process occurs, at least partly, through a TLR4/Adam17 mediated signal. Interestingly, a positive correlation is seen between the sCD163 plasma level and the severity of various pathologies. Previous studies from our group showed an increased infiltration in brain of CD163+ cells and that CD163+ monocyte/macrophages may be used as tool to achieve neuroprotection in the 6-OHDA rat PD model. We hypothesized that there are changes in peripheral CD163 population and/or shedding of the protein during PD. To address this, we are analyzing expression of CD163 in peripheral blood mononuclear cells by cytometry and the levels of sCD163 by ELISA in patient serum and CSF samples. So far, we have observed an increase in sCD163 in CSF and serum of PD patients when compared to healthy control group and there was a gender effect with females showing higher sCD163 than males. We are currently studying the CD163+ cell population in PD patients as well as the possible influence of AS in the CD163 expression and/or shedding. Our results aim to further evaluate the CD163 population as a therapeutic target in PD as well as to assess the potential value of the sCD163 as a putative biomarker for PD.

Abstract: The biology underlying the development and progression of Dementia with Lewy Bodies (DLB) pathology remains unclear. In this work we have applied next generation sequencing to analyze gene expression patterns altered by DLB pathology in anterior cingulate cortex - a brain region affected by DLB pathology. Gene network analysis was performed to assess pathways and gene-gene interactions, relevant to DLB etiology. Analysis of RNA profiles, using Ampli-seq panel of 20812 genes with ion torrent sequencing, was performed in brain samples from 12 DLB subjects and 10 age-matched controls. Analysis of differential gene expression revealed 109 genes down-regulated and 218 up-regulated in DLB samples. These groups included genes associated with neurological disorders, inflammatory response and cell death, such as adenosine A2a receptor, transforming growth factor beta 1, and chemokine receptor 4. To identify gene clusters associated with the disease we used a systems-biology approach based on weighted gene co-expression network analysis. The analysis revealed differences in co-expression patterns of genes associated with processes and pathways relevant to DLB pathology such as axonal degeneration or neuroinflammation. Our study provides a comprehensive picture of gene co-expression patterns in DLB derived from transcriptional changes in a disease-affected region of the brain. These findings provide a framework for functional studies of gene-gene interactions in DLB.

Title: Angiogenic biomarkers in Parkinson's disease dementia: clinical-biochemical-pathological correlations

Authors: *V. FRANCARDO[1], S. JANELIDZE[2], G. SERRANO[3], T. BEACH[3], C. KONRADI[4], O. HANSSON[2,5], M. CENCI[1];

[1]Lund Univ., Lund, Sweden; [2]Dept. of Clin. Sci., Malmö Univ., Malmö, Sweden; [3]Banner Sun Hlth. Res. Inst., Sun City, AZ; [4]Dept. of Pharmacol., Vanderbilt Univ., Nashville, TN; [5]Memory Clinic, Skåne Univ. Hosp., Lund, Sweden

Abstract: Studies performed in a large number of neurological diseases have revealed an association between altered perfusion and maladaptive angiogenesis in disease-affected brain regions. This maladaptive response is usually accompanied by neuroinflammation, and may contribute to neurodegeneration. These processes have been well documented in Alzheimer´s disease, where cortical microvascular dysfunction is an early event. It is currently unknown whether similar processes accompany the development of dementia in Parkinson´s Disease (PD). This hypothesis seems compatible with the results of functional imaging studies, which have shown reductions in both local blood flow and glucose uptake in the cerebral cortex in in PD patients affected by dementia. The aim of this study was to explore the occurrence of maladaptive angiogenesis in PD dementia. To this end, we measured levels of angiogenic cytokines in samples of cerebrospinal fluid (CSF) from three different cohorts of PD patients, with or without dementia, and non-PD controls. We obtained post-mortem samples of temporal cortex (middle temporal gyrus) from one of these cohorts. In these samples, we examined the density of microvessels (immunostained for CD34) and their expression of nestin, a marker of reactive endothelium that is upregulated during active angiogenesis. On adjacent sections, we measured the total number of neurons (immunostained for NeuN). The results of CSF analysed showed significantly higher levels of Vascular Endothelial Growth Factor (VEGF) and Placental Growth Factor (PlGF) in PD patients compared to controls, whether or not the patients had been affected by dementia. In brain cortical tissue, microvessel density was larger in PD patients with dementia than in the non-demented PD and control groups. There was also a trend towards nestin upregulation in the former group, which did not however reach significance. The counts of NeuN-positive cells (neurons) did not reveal any difference between the groups. The promising results obtained in this study call for further investigations on the role of cortical microvascular pathology and angiogenic responses in the development of PD dementia.

Title: Natural history of rigidity in Parkinson's disease

Authors: *R. XIA[1], A. MUTHUMANI[2], Z.-H. MAO[3], D. POWELL[4];
[1]Dept of Physical Therapy, Univ. of St. Mary, Leavenworth, KS; [2]Dept. of Engin., Montana State Univ., Bozeman, MT; [3]Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [4]Dept. of Physical Therapy, Campbell Univ., Buies Creek, NC

Abstract: Parkinson's disease (PD) is a chronic neurodegenerative disease with a relentlessly progressive course. Rigidity is one of the clinical hallmark symptoms associated with PD, and defined as an increased resistance to passive movement throughout an entire range of motion. Recent studies indicate that rigidity is the result of both increased muscle reflex responses (neural component) and altered mechanical properties of muscle fibers (non-neural component). Emerging evidence from clinical and imaging studies has suggested that rigidity progresses fastest among the hallmark symptoms of PD. The purpose of this study was to examine the relationship between disease history and the neural and non-neural contributions to rigidity in PD. Twelve subjects with idiopathic PD, with a disease duration from one to 13 years, participated in a study protocol, following an overnight withdrawal of dopamine-replacement therapy. Torque resistance of the more affected wrist joint was measured during passive flexion and extension movements in patterns of pseudorandom binary sequences. To differentiate the neural and non-neural components, a parallel-cascaded system identification technique was applied. Pearson correlation coefficients were calculated to quantify the correlations of disease duration with neural and non-neural contributions to rigidity, respectively. Relationship between subjects' age and rigidity was also evaluated. Analyses revealed significant correlations between disease history and neural rigidity ($r = 0.703$, $p = 0.01$) and between disease history and non-neural rigidity ($r = 0.735$, $p = 0.006$). No correlation was observed between age and either neural ($r = 0.243$) or non-neural ($r = 0.235$) rigidity. Our findings show that the longer the disease duration, the greater rigidity was, regardless of subject's age. Clinical Relevance: The quantitative evaluation obtained from this study supports the natural history of disease progression assessed by clinical observation. Non-pharmacologic therapeutic intervention such as manual stretching and relaxation technique shows potential in managing abnormal muscle tone. Future research is directed to determine whether such interventions are effective in managing the progression of parkinsonian rigidity.

Title: Visuomotor control in patients with Parkinson's disease

Authors: *J. CHEN[1], S.-L. HO[2], M.-C. LEE[3,4], S.-K. CHANG[2], Y.-Y. PANG[2], L. LI[1]; [1]Dept. of Psychology, The Univ. of Hong K, Hong Kong, Hong Kong; [2]Div. of Neurology, Univ. Abstract: Previous studies have suggested that the deteriorated visuomotor control in patients with PD (Parkinson's disease) is due to deficits in various aspects of the sensory-motor processing rather than motor control itself. In the current study, by taking a control-theoretic approach, we systematically examined how PD and antiparkinsonian medication affect visuomotor control and the underlying sensory-motor system. We tested 20 PD patients in both ON and OFF medication states and 20 demographically matched healthy controls with a commonly used manual control task. Specifically, in each 95-s trial, participants were instructed to use a joystick to control a randomly moving target to keep it centered on a computer display. We found that although antiparkinsonian medication improved visuomotor control in PD patients, they still showed significantly decreased control precision (measured by RMS error) and response amplitude (gain) as well as increased response delay (phase lag) compared with healthy controls. Our model-driven analysis revealed that PD impairs the responsiveness and the predicting ability of the sensory-motor system as well as the stability of the neuromuscular system. Taking antiparkinsonian medication improves the responsiveness of the sensory-motor system. More importantly, it improves the ability of the sensory-motor system to use the target velocity information to predict the target position error and generate lead control ahead of time up to the level of healthy controls. However, taking antiparkinsonian medication does not improve the stability of the neuromuscular system. These results support the claim that the effect of antiparkinsonian medication on visuomotor control is mainly through improving visual-stimulus-dependent sensory-motor processing. The present study provides the first quantitative examination of the effects of PD and antiparkinsonian medication on the sensory-motor system underlying visuomotor control. The findings have practical implications for developing sensitive assessment tools to evaluate the efficacy of different therapies for PD and preliminary screening and training tools for fitness-to-drive in PD patients.

Title: Rhythmic auditory cues shape neural network plasticity underlying motor control in Parkinson's disease

Authors: ***M. H. THAUT**[1], K. BRAUNLICH[2], B. KLUGER[3], G. MCINTOSH[4], C. SEGER[2]; [1]Ctr. for Biomed. Res. in Music, Colorado State Univ., Fort Collins, CO; [2]COLORADO STATE UNIVERSITY, FORT COLLINS, CO; [3]UNIVERSITY OF COLORADO, DENVER, CO; [4]UNIVERSITY OF COLORADO HEALTH, FORT COLLINS, CO

Abstract: It is well established that rhythmic auditory cues can improve gait and other motor behaviors in Parkinson's disease (PD) and other disorders. However, the neural systems underlying this therapeutic effect are largely unknown. It is well known that the basal ganglia subserves important functions in rhythmic motor timing. However, since PD is characterized by basal ganglia dysfunction, the question arises how rhythmic auditory cues facilitate motor control in PD: putatively, by either maximizing residual basal ganglia function or by shaping a 'bypass' network, e.g., by involving cortico-cerebellar circuits. To investigate this question we scanned people with Parkinson's disease (Hoehn & Yahr level 3) and healthy controls using fMRI. Subjects performed a rhythmic motor behavior (right hand finger tapping) with and without simultaneous audiovisual rhythmic cues at two different speeds.In the Parkinson's group, the presence of simultaneous rhythmic cues during tapping was associated with greater activity in a large neural network including the anterior cingulate and medial frontal regions, bilateral middle frontal gyri, bilateral parietal lobe and insular cortices, and cerebellum and body of the caudate nucleus. A graph theoretical analysis showed a greater functional connectivity between motor regions (left pre and postcentral gyrus, SMA) and between these motor regions and the visual and auditory cortex in the Parkinson's group when simultaneous audiovisual rhythmic cues were present. We interpret our results as indicating that the temporal rhythmic sensory information is driving multiple compensatory mechanisms by shaping an 'assist' network for the basal ganglia consisting of increased activation in cortico-cerebellar regions. This 'assist' network was not seen in PD subjects tapping without rhythmic cues and in healthy subjects with and without rhythmic cuing.

Title: BDNF-TrkB signaling in lymphocytes of patients with Parkinson's disease increases after a four-week intensive rehabilitation treatment

Authors: *C. FONTANESI[1,2,3], S. KVINT[3], G. FRAZZITTA[4], R. BERA[4], D. FERRAZZOLI[4], A. DI ROCCO[5], H. REBHOLZ[3], E. FRIEDMAN[3], G. PEZZOLI[6], A. QUARTARONE[3,7], H.-Y. WANG[3], M. F. GHILARDI[3];

Abstract: In a combined animal and human study, we have previously shown that a five-day treatment that enhances cortical plasticity also facilitates brain-derived neurotrophic factor (BDNF)-tyrosine receptor kinase B (TrkB) signaling and increases activated TrkB and N-methyl-D-aspartate receptor (NMDAR) association in both the cortex and the peripheral lymphocytes. Patients with Parkinson's disease (PD) in general show decreased cortical plasticity, as demonstrated by electrophysiological and behavioral studies. Here we test the hypothesis that an exercise program that improves motor function and seems to slow down symptoms' progression can enhance BDNF-TrkB signaling in lymphocytes. Sixteen patients with PD underwent a four-week Multidisciplinary Intensive Rehabilitation Treatment (MIRT), which included aerobic training, physical and occupational therapy. Blood was collected before, after two- and four-week MIRT. Lymphocytes were isolated to examine BDNF-TrkB signaling induced by incubation with recombinant human BDNF. TrkB signaling complexes, extracellular-signal-regulated kinase-2 and protein-kinase-B were immunoprecipitated; content of immunocomplexes was determined by Western blotting. After MIRT, all patients showed improvement in motor function ($p< 0.01$) as shown in previous studies. TrkB interaction with NMDAR and BDNF-TrkB signaling increased in peripheral lymphocytes at receptor, intracellular mediators and downstream levels ($p< 0.001$). Moreover, the increases in BDNF-TrkB signaling and TrkB-NMDAR interaction were significantly correlated with the decrements in UPDRS II and total scores. We conclude that MIRT promotes changes of the immune function in PD. The reduced severity of PD symptoms together with enhanced lymphocyte BDNF-TrkB signaling further suggests that the immune system might play a role in neurorestoration and recovery of function. We finally speculate that, as BDNF-TrkB signaling in cortex and lymphocyte are partially correlated, MIRT might also increase cortical plasticity.

Title: Evaluation of anti-alpha-synuclein autoantibody affinity in Parkinson's disease and multiple system atrophy

Authors: *T. BRUDEK[1,2], J. FOLKE[1], K. WINGE[3,2], K. FOG[4], B. PAKKENBERG[1], L. ØSTERGAARD PEDERSEN[4];
[1]Res. Lab. For Stereology and Neuroscienc, Copenhagen, Denmark; [2]Bispebjerg Movement Disorders Biobank, Copenhagen, Denmark; [3]Dept. of Neurol., Bispebjerg and Frederiksberg Hosp., Copenhagen, Denmark; [4]H. Lundbeck A/S, Valby, Denmark

Abstract: Objectives: To investigate the properties of naturally occurring anti-α-syn antibodies in plasma from patients with Parkinson's Disease (PD) and Multiple System Atrophy (MSA). Background: PD and MSA are progressive brain disorders caused by loss of nerve cells in specific areas of the brain. This loss causes problems with movement, balance and/or autonomic functions of the body. Compared to PD patients, patients with MSA have more widespread brain pathology, shorter survival, and poor treatment response. Aggregation of filamentous α-synuclein (α-syn) is thought to play a key role in both disorders. Naturally occurring autoantibodies (NAbs) probably act in eliminating circulating proteins, before they can elicit a damaging response. Presence, but not specificity (our pilot study) of anti-α-syn NAbs has previously been repeatedly investigated in PD. However, the reported level differences in plasma-borne NAbs directed against the putatively most important self-antigen in PD and MSA, α-syn, have been inconsistent. Thus, little is known still about the specific properties of anti-α-syn NAbs in PD and MSA. Methods: We have investigated the affinity of anti-α-syn NAbs in plasma samples from 46 PD patients, 18 MSA patients and 41 age-matched normal controls using competitive enzyme-linked immunosorbent assay (ELISA) set-up. The key event of a competitive reaction results from occupation of antibody binding sites with increasing concentrations of free antigen (α-syn) and a subsequent measurement of free antibodies on plates with immobilized antigen (α-syn). Moreover, using similar competition assay, we assess cross-reactivity of the anti-α-syn NAbs toward β-, and γ-synucleins in MSA and PD vs healthy controls. Results: Our data indicate that the frequency of PD patients with high affinity phenotype is lower compared to healthy controls, whereas MSA patients practically do not express the high affinity phenotype of plasma anti-α-syn antibodies. The preliminary data from the cross reactivity assay suggest declined cross reactivity of anti-α, β-, and γ-syn NAbs in both neurodegenerative disorders. Conclusions: Our results indicate that the PD and MSA patients have lower titer of high-affinity anti-α-syn antibodies and thus lower ability for immune clearance of toxic α-syn species/oligomers. This affinity aberration may be a new mechanism of impaired clearance of cerebral α-syn and have important implications for the development of immune-based therapeutic strategies.

Title: Deregulation of HNF4A and PTBP1 in Parkinson's disease

Authors: ***C. WAN**[1], A. B. WEST[2], A. B. RAWLINS[3];
[1]Univ. of Alabama At Birmingham, Birmingham, AL; [3]Neurol., [2]Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Parkinson's disease (PD) affects more than one million Americans, not excluding those that have yet to be officially diagnosed. As the number of PD patients increases from year to year, efforts to find biological markers that precede the clinical onset of PD have increased, so that preventative therapies for patients in the earlier stages of the disease may be implemented. Previously published studies, using a small sample size with limited clinical phenotyping, have indicated that the up-regulation of hepatocyte nuclear factor 4 alpha (HNF4A), part of the nuclear receptor family of transcription factors, and the down-regulation of polypyrimidine tract binding protein 1 (PTBP1), which functions in mRNA processing, may be exaggerated in the blood of PD patients (Santiago and Potashkin, PNAS 2015). Through quantitative PCR assays, we compare the levels of HNF4A and PTBP1 in blood collected in the Parkinson Disease Biomarkers Program (PDPB). Our study involves 200 PD patients and 200 healthy controls, matched for race, ethnicity, age, and gender. We further investigate the change in regulation of the two genes in correlation to PD severity and other clinical metrics associated with the extensive phenotyping in the PDBP. These data will help establish whether HNF4A and PTBP1 might be useful in the diagnosis and prognosis of Parkinson disease.

Title: Increase of red blood cell putrescine detected by cze-lifd in Parkinson's patients

Authors: L. R. BETANCOURT, P. V. RADA, G. A. CEBALLOS, H. F. ARAUJO, *L. F. HERNANDEZ;
Univ. de los Andes, Merida, Venezuela, Bolivarian Republic of

Abstract: Polyamines are modulators of cell functions such as cell proliferation and differentiation and they are involved in many pathological conditions associated to neurodegenerative diseases. Alterations in the expression and activity of polyamine metabolic enzymes have been reported in schizophrenia, affective disorders, anxiety, suicidal behavior and Parkinson disease (PD).We report a new technique to measure putrescina based on CZE-LIFD and an increase of blood putrescine in PD patients. We took a 2.8 micromolar solution of thiocarbamyl-putrescine and diluted it ten times in 20 mM carbonate buffer to obtain 1.4 μM, 0.7 μM, 350 nM, 175 nM, 87.5 nM, 43.7 nM, 21 nM, 10 nM and 5 nM concentrations. The standards and the samples were run in a fused silica, 25 micrometers ID capillary filled with 40 mM Sodium Dodecyl Sulphate and 20 mM Sodium Tetraborate buffer. There was a linear relation between concentration and signal amplitude in the whole range of concentrations (R= 0.998) and in the 5 lower concentrations (R= 0.995). The lowest concentration (5 nanoM) produced a signal to noise ratio of 10:1. We found a significant increase of putrescine in the red blood cells and a non-significant increase of putrescine in plasma of PD patients as compared to matched control ($p<0.04$ and $p<.14$) respectively. These findings support a pathophysiological mechanism for PD and have great potential to provide a marker of PD.

Title: Paradoxical changes in intrinsic motoneuron excitability between flexors and extensors in Parkinson's disease

Authors: *J. M. WILSON[1], C. K. THOMPSON[2], L. C. MILLER[1], C. MACKINNON[3], C. J. HECKMAN[2];
[1]Physical Therapy & Human Movement Sci., [2]Physiol., Northwestern Univ., Chicago, IL;
[3]Neurol., Univ. of Minnesota, Minneapolis, MN

Abstract: Alpha-motoneurons (MNs) possess active membrane properties that significantly influence their capacity for synaptic amplification and self-sustained firing. These properties are facilitated by persistent inward sodium and calcium currents (PICs) in the MNs that are principally dependent on the presence of serotonin and norepinephrine from the brainstem. In Parkinson's disease (PD), degeneration of the caudal raphe nuclei and the locus coeruleus occur relatively early in the disease, suggesting a loss of serotonergic and noradrenergic drive to the spinal cord may contribute to observed abnormalities in muscle activation patterns via alterations in PICs and subsequent changes in MN excitability. In addition, individuals with PD show greater strength deficits and EMG abnormalities in extensors over flexors, suggesting that a loss of MN excitability may be greater in extensor MNs than flexor MNs. We assessed MN intrinsic excitability in upper limb flexors and extensors of mild-moderate PD patients (OFF-state) and healthy controls by recording spike trains of MNs during isometric trapezoid contractions to 10% MVC. We then used a lower-threshold "reporter" unit as an index of descending common drive to a higher-threshold "test" unit, deriving a value known as the delta-F as an estimate of intrinsic excitability of the test unit (Gorassini et al. 2002). As expected, we found that the delta-F in PD was significantly lower than controls in extensors, but were surprised to find that the delta-F in flexors was nearly two-fold higher in PD compared to controls. PD patients also exhibited a greater occurrence of self-sustained firing behaviors indicative of increased PICs. Possible reasons for these results are discussed, including the potential role of reciprocal inhibition and the possibility of constitutively-active PICs in the absence of monoaminergic drive. The present work provides evidence that spinal MNs may actively contribute to PD symptoms via a loss of non-dopaminergic spinal neuromodulators, thus reframing PD motor deficits as having both supraspinal and spinal components.

Title: Bimanual synchronized finger tapping in young and elderly subjects

Authors: *F. JUNG[1], P. LÖHRER[1], I. WEBER[1], F. NETTERSHEIM[1], T. A. DEMBEK[1], E. A. PELZER[2], C. HUBER[1], M. TITTGEMEYER[2], L. TIMMERMANN[1];

Abstract: Coordination of bimanual hand and finger movements is crucial for daily activities and controlled by the supplementary motor area, the premotor and prefrontal cortex. Even though brain areas responsible for the execution of bimanual movements are largely discovered, their causal interplay is not well understood. Apart from a general investigation of hierarchical coupling within a core motor network, we investigated changes occurring during physiological aging since motor functions are known to decline with age. While in general, elderly subjects show an age-related slowing and decrease of performance accuracy, they were shown to perform equally well as young subjects during temporally synchronized, "in-phase" movements yet exhibiting problems with the execution of unsnchronized „anti-phase" movement. In order to unravel these age-related changes in bimanual coordination and potential differences in coupling of brain areas, a complex "anti-phase" finger tapping task was designed. Subjects learned a sequence of finger movements that should be executed while, at the same time, the other hand was used to tap a different sequence. Simultaneously, a surface EEG with 128 electrodes from 23 young (mean age: 25 ± 2) and 28 elderly (mean age: 61 ± 7) subjects was recorded. Behavioral analysis demonstrated that elderly subjects made significantly more mistakes (mean old: 34.36 %; mean young: 20.46 %, $p = 0.003$) and needed more time (mean old: 3.19 s; mean young: 2.27 s, $p < 0.001$) than young subjects. Additionally, the analysis of electrophysiological data revealed differences in event-related potentials (ERPs) averaged time-locked to the "go" stimulus: If the learned rule was performed with the right, i.e. the dominant hand, ERPs for young and old subjects differed between 500 and 750 ms after stimulus onset, with old subjects showing more positive potentials. Significant differences between both groups were found mainly on the right hemisphere above the postcentral sulcus and the angular gyrus. Preliminary analysis showed that ageing not only affects behavior with respect to changes in a general speed-accuracy tradeoff but also electrophysiological processing during bimanual coordination. A successive network analysis using Dynamic causal modelling (DCM) for evoked responses will uncover differences

in the coupling of brain areas between young and elderly subjects and enable us to better understand physiological changes occurring in the aging brain.

Title: Repetitive finger movement and quality of life in persons with Parkinson's disease

Authors: *J. UZOCHUKWU, R. WILLE, E. L. STEGEMÖLLER;
Iowa State Univ., Ames, IA

Abstract: The performance of repetitive finger movements is a clinical tool used to assess the severity, progression, and treatment efficacy of Parkinson's disease (PD). Studies have shown that when some persons with PD performed acoustically cued repetitive finger movements at rates near to and above 2 Hz, participants exhibited increased movement rate, reduced movement amplitude, and loss of phase accompanied by frequent hesitations. The effect of this movement impairment on quality of life (QOL) of people with PD is unknown. As such, the purpose of this study was to examine the QOL ratings of people with PD who demonstrate impairment of repetitive finger movement compared to those who do not. Fifty-one participants (mean age = 69 ± 10; 24 male, 27 female) with PD completed an acoustically cued repetitive finger movement task. The acoustic cue incremented from a rate of 1 Hz to 3 Hz in 0.25 Hz. Participants also completed the Parkinson's Disease Questionnaire - 39 (PDQ-39) as a measure of QOL. Based upon performance on the repetitive movement task (differences in movement rate and movement amplitude), participants were divided into groups of with and without impairment. Group differences were analyzed across individual domains on the PDQ - 39. Results revealed no significant differences between groups on index and individual domain scores on the PDQ - 39. However, those with repetitive finger movement impairment showed a trend of having higher scores across all domains of the PDQ - 39 compared to the non-impaired group. The higher scores were indicative of poorer QOL. These results suggest that repetitive finger movement impairment has a negative impact on perceived QOL in people with PD. A larger sample size of participants who demonstrate this impairment is needed to fully characterize differences among groups of people with PD that demonstrate repetitive finger movement impairment and those that do not.

Title: The implication of basal ganglia α7 nicotinic acethylcholine receptors (nAChr) in MPTP-lesioned monkeys and Parkinsonian patients with motor complications

Authors: N. MORIN[1], M. MORISSETTE[1], L. GRÉGOIRE[1], A. RAJPUT[2], A. H. RAJPUT[2], *T. P. DIPAOLO[1];
[1]Ctr. de Recherche de CHUQ-CHUL, Quebec, QC, Canada; [2]Div. of Neurol., Univ. of Saskatchewan, Royal Univ. Hosp., Saskatoon, SK, Canada

Abstract: In Parkinson's disease levodopa (L-Dopa) is the main symptomatic therapy to alleviate basal ganglia dysfunctions. However, chronic L-Dopa administration leads to motor complications, including L-Dopa-induced dyskinesias (LID) that represent a major therapeutic challenge in the management of Parkinson's disease treatment. The ability of nicotine and nicotinic receptor agonists to alleviate LID in parkinsonian animal models suggests an important role of the cholinergic system in the pathophysiology of LID. The most common subtypes of nicotinic acethylcholine receptors (nAChr) in the striatum are α4β2, α6β2 and α7. The α4β2 and α6β2 nAChr subtypes are reported to be implicated in the reduction LID and recent evidences support also an implication of the α7 nAChr subtype in LID. Indeed, we have shown that an α7 nAChr partial agonist reduced the intensity of LID in monkeys lesioned with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). In the present study, we investigated α7 nAChr specific binding by autoradiography, with the ligand [125I]α-bungarotoxin, in post-mortem brains of parkinsonian patients and MPTP monkeys. MPTP monkeys were treated for one month with L-Dopa and developed LID while those treated with L-DOPA and MPEP, a specific antagonist of the metabotropic glutamate 5 (mGlu5) receptor, developed significantly less intense LID. Normal control and saline-treated MPTP monkeys were also included in the study. In the brains of parkinsonian patients who developed LID, α7 nAChr specific binding was elevated in the caudate nucleus and putamen while it was unchanged in the two segments of the globus pallidus. In patients without motor complications, α7 nAChr specific binding was elevated only in the caudate nucleus. Moreover, in parkinsonian patients with no LID but who experienced wearing-off, α7 nAChr specific binding in the caudate nucleus and putamen was lower than was observed in patients with LID. In monkeys, nAChr specific binding was elevated in the caudate nucleus and putamen as well as in the globus pallidus of dyskinetic monkeys as compared to controls and

MPTP monkeys treated with saline. Interestingly, MPTP monkeys treated with L-Dopa and MPEP had their nAChr specific binding similar to those in intact control animals. Moreover, positive linear correlations between dyskinesia scores of the monkeys and their [125I]α-bungarotoxin specific binding levels were observed in the caudate nucleus, putamen, and the globus pallidus. These findings support a possible involvement of α7 nAChr in LID and targeting this receptor could be an interesting therapeutic strategy to alleviate motor complications in Parkinson's disease.

Title: Human dopaminergic neurons used in an *in vitro* model of Parkinson's disease

Authors: *M. ROACH[1], K. GOMES[1], R. MALAVARCA[1], K. COOK[2], S. CHVATAL[2]; [1]PhoenixSongs Biologicals, Inc., Branford, CT; [2]Axion BioSystems, Atlanta, GA

Abstract: Parkinson's Disease (PD) is a chronic neurodegenerative disease, affecting approximately 1 million individuals in the US alone which is more than people diagnosed with multiple sclerosis, muscular dystrophy and Lou Gehrig's disease combined.. Parkinson's disease results in the loss of dopamine neurons (DA-neurons) that innervate the striatum. These dopamine neurons regulate the activity of a cortico-striatal-pallidal-thalamo-cortical (basal ganglia) circuit that controls the initiation and execution of motor and cognitive patterns. The loss of dopaminergic regulation of this circuit accounts for the development of the cardinal motor symptoms of the disease as well as many of the cognitive sequelae. Currently, a robust *in vitro* model of functional DA-neurons does not exist although many laboratories are trying to develop one. Therefore we set out to develop a robust *in vitro* Parkinson's model using stem cell-derived dopaminergic neurons at a scale that will be compatible with high throughput screens (HTS). Here we report development of a new PD model using human neural stem cells lineage committed to differentiate into a neural population where >60% of the neurons are TH+ mature functional DA-neurons that remain functional beyond 60 days in culture. Data reported will include standard MPP+ assays and neural network activity measured on multi-electrode arrays MEAs.

Title: Using a modified cannula delivery system to implant sural nerve grafts into the rhesus macaque midbrain

Authors: J. E. QUINTERO[1,2], E. S. FORMAN[2], Y. AI[2], A. K. EVANS[2], R. M. WEEKS[2], F. POMERLEAU[2], P. HUETTL[2], *L. H. BRADLEY[3], R. GRONDIN[2], Z. ZHANG[2], G. GERHARDT[1,2,4], C. G. VAN HORNE[1,2,4];
[1]Brain Restoration Ctr., [2]Anat. & Neurobio., [3]Anat. and Neurobio., [4]Neurosurg., Univ. of Kentucky, Lexington, KY

Abstract: Parkinson's disease (PD) is a progressive neurodegenerative disorder characterized by a loss of dopaminergic function. There is currently no effective treatment to slow or prevent its progression. Studies have shown that neurotrophic factors can promote dopaminergic function in areas like the substantia nigra, which is affected in PD. It has also been shown that Schwann cells in peripheral nerves might be a source of growth factors, including GDNF, NDF, BDNF, and NT-3. An FDA-approved Phase I clinical trial is currently ongoing at the University of Kentucky to assess the safety and efficacy of implanting an autologous sural nerve graft into the substantia nigra of patients with PD. While functional improvements have been seen in these participants post-implantation, how the sural nerve graft interacts with the surrounding brain tissue is unclear. To address this knowledge gap, similar procedures were performed in two normal, adult female rhesus macaques to study the histological and neurochemical effects from the implanted nerve grafts into the substantia nigra. A modified cannula/stylet assembly and modified Nexdrive system were implemented. First, the tip of a stainless steel 18G cannula/stylet was cut to have a tapered blunt end. Then, a 1 x 5mm side window was created, 4mm from the cannula tip to load the sural nerve tissue. Next, a Nexdrive system was adapted to hold the cannula while allowing both the cannula and stylet to be individually locked down for insertion into the brain parenchyma. MRI-guided sural nerve grafts were performed in both animals without post-surgical complications. Animals were monitored for 8 weeks post-implant for changes in motor function and/or body weight, at which point they were necropsied and brain tissue collected for analysis. No significant changes in body weight or locomotor activity were observed over the course of the study. Histological analyses indicated sural nerve tissue delivery to the substantia nigra with tyrosine hydroxylase (TH) immunoreactive cells innervating the graft. Neurochemical analyses showed that in the ipsilateral side to the graft, dopamine content in the caudate was 21400 ± 1290 ng/g and in the putamen was 19800 ± 4660 ng/g while in the

contralateral side the caudate was 12400 ± 2180 ng/g and in the putamen was 12800 ± 2950 ng/g (mean ± SD). We conclude that our modified surgical hardware can be safely used to successfully deliver sural nerve tissue to the rhesus midbrain to further understand the associated mechanisms of action and support further clinical development of this promising therapy.

Title: Analysis of cellular morphology, growth dynamics and autophagic mechanisms in primary skin fibroblasts from individuals diagnosed with sporadic Parkinson's disease

Authors: *A. J. FLORES[1,2], M. J. CORENBLUM[2], C. CURIEL[3], S. J. SHERMAN[2], L. MADHAVAN[2,4];

Abstract: Human primary skin fibroblasts are easily accessible peripheral cells that have Parkinson's disease (PD)-relevant biochemical and gene expression profiles, and constitute a system which reflects the chronological and genetic aging of patients to form a patient-specific model of the disease. Recent data suggest that cytoskeletal and metabolic alterations play a role in the PD degenerative process. Because cytoskeletal and metabolic dynamics are also important determinants of cellular morphology, we systematically analyzed the morphological features and growth dynamics of primary fibroblasts generated from skin biopsies of individuals diagnosed with late-onset PD, as well as age-matched control subjects. Under phase contrast conditions, control and PD fibroblasts apparently differed with respect to spatial growth patterns, and cell size and shape. Therefore, to clearly visualize morphology, dermal fibroblasts were stained with a fluorescent phalloidin F-actin probe, and analyzed for five different shape and size parameters using CellProfiler software. In particular, comparisons of cell area, perimeter and minimum and maximum diameters revealed that fibroblasts from PD patients were significantly smaller than control fibroblasts. Additionally, PD fibroblasts displayed a significantly higher form factor, indicating that they were more circular than control fibroblasts. In terms of growth dynamics,

comparisons between control and PD cell lines showed no significant differences in cell viability, time to reach 90% confluence, nor in total cell count at 90% confluence. However, a trend towards higher cell count and greater time to reach 90% confluence, was noted in the PD fibroblasts. Additionally, immunocytochemical analysis revealed that fibroblasts from Parkinson's subjects had significantly higher expression of the PD-relevant protein alpha-synuclein (α-synuclein) than control fibroblasts, as reflected by higher intensity of α-synunclein staining per cell. Given that α-synuclein is degraded via chaperone-mediated autophagy (CMA, a selective form of autophagy), and also that aberrant α-synuclein may act as a CMA inhibitor, as a next step, we have begun to analyze autophagy-related mechanisms, in the patient fibroblasts. These studies provide a foundation for investigating PD-relevant structural and autophagic alterations in a patient-specific manner, and will complement future assessments in induced pluripotent stem cell (iPSC)-derived midbrain dopaminergic neurons generated from skin fibroblasts of PD subjects.

Title: Investigating cortico-basal-ganglia neural dynamics with optogenetic stimulation in hemi-Parkinsonian rats

Authors: Z. YU[1], R. DARIE[1], J. PERGE[2], W. ASAAD[2,3], A. V. NURMIKKO[1], *I. OZDEN[1]; [1]Sch. of Engin., [2]Dept. of Neurosci., Brown Univ., Providence, RI; [3]Deparment of Neurosurg., Brown Univ. Alpert Med. Sch. and Rhode Island Hosp., Providence, RI

Abstract: Deep brain electrical stimulation (DBS) is an effective treatment for severe Parkinson's disease (PD), While DBS leads to alleviation of PD motor symptoms and suppression of abnormal beta oscillations (13-30 Hz) in the cortico-basal-ganglia system (CBGS), some motor deficits typically persist. Ongoing efforts to improve the efficacy of DBS are partly hampered by an incomplete understanding of the mechanisms of DBS and by the ambiguities associated with the effect of electrical stimulation. Optogenetics, with its cellular

specificity, offers a unique opportunity to investigate PD pathophysiology and to develop a more potent alternative to electrical DBS. Accordingly, we aim to investigate neural mechanisms of therapeutic action of electrical and optogenetic DBS by using microelectrode array (MEA)-based recordings of motor cortical activity, together with simultaneous recordings from and optogenetic stimulation at deep brain nuclei (e.g. subthalamic nucleus (STN) and globus pallidus (GP)). Here we present our preliminary data based on 6-OHDA induced hemi-Parkinsonian (hemi-PD) rats. We surveyed four behavioral paradigms, namely adjusting step (AS) test, amphetamine induced rotation (AIR), harnessed treadmill running (HTR), and limb use asymmetry (LUA) to quantify the extent of hemi-PD behavior. Our data confirms presence of motor deficits such as akinesia, LUA and AIR bias in hemi-PD rats. Electrical DBS of STN improved these motor deficits to some extent (reduced AIRs and increased number of steps in HTR), but not completely. Based on existing hypotheses about sources of abnormal activities in the CBGS, we tested potential target sites for optogenetic DBS. As a first target, optogenetic suppression of STN neurons through a step-function inhibitory virus, SwiChRCA, showed similar therapeutic effects as to the case of electrical DBS (drop in AIRs). Other target sites for optogenetic DBS include external and internal globus pallidi. To characterize the neural mechanisms of these interventions, we implanted 6x6 MEAs into the normal and lesioned motor cortices of hemi-PD rats. Our preliminary data confirmed presence of excess beta oscillations in the lesioned-side motor cortex. However, the oscillations were not synchronized throughout the whole motor cortex but intermittently appeared at different locations at different times. As various optogenetic stimulation sites might impact motor cortical activity and behavior differently, we will aim to develop a temporally coordinated multisite stimulation paradigm for constructively integrating the specific therapeutic effects of each type of stimuli.

Title: Sensory integration in the dopamine-depleted striatum

Authors: *M. KETZEF, A. BONITO-OLIVA, G. SPIGOLON, G. FISONE, G. SILBERBERG;
Karolinska Inst., Stockholm, Sweden

Abstract: Parkinson's disease (PD) is primarily characterized as a movement disorder, resulting from the loss of dopaminergic innervation particularly to the striatum (ST). PD patients and model animals often exhibit sensory impairments alongside with motor symptoms, yet little is known about them. We characterized the bilateral sensory integration in the dopamine (DA) depleted ST using in-vivo whole-cell patch-clamp recordings in anaesthetized mice, unilaterally injected with 6-hydroxydopamine in the medial forebrain bundle (MFB). Recordings were obtained from the striatum of the lesioned hemisphere during spontaneous activity and during ipsi- and contralateral whisker deflection. Direct and indirect pathway medium spiny neurons (MSNs) were identified either by co-localizing labeled neurons in D1/D2-GFP mice post-hoc, or by "online" optogenetic stimulation using an "optopatcher" during whole-cell recordings. In DA depleted animals, direct pathway (D1 expressing) MSNs responses to contralateral and bilateral whisker deflection were reduced in amplitude and rising slope and had delayed peak latency compared to controls. Delayed and reduced contralateral responses thus appeared more similar to ipsilateral ones, thereby rendering D1 MSNs indistinguishable from D2 MSNs. Chronic levodopa administration in lesioned mice recovered D1 MSNs responses to contralateral stimulation. Our results suggest that sensory deficits following DA depletion are caused primarily by selective attenuation of tactile responses in direct pathway MSNs.

Title: Beta frequency oscillations are neither necessary nor sufficient for emergence of Parkinsonian symptoms in rats

Authors: *C. BEHREND[1,2], D. T. BROCKER[1], W. M. GRILL[1,3,4];
[1]Biomed. Engin., [2]Sch. of Med., [3]Neurobio., [4]Surgery, Duke Univ., Durham, NC

Abstract: In studying the pathophysiological mechanisms of Parkinson's disease (PD) a particular focus has been placed on determining the significance of synchronized oscillatory burst firing at frequencies of 13-30Hz (termed "beta band"). Correlative evidence has suggested a relationship between beta band oscillations observed in local field potentials (LFPs) and symptoms of bradykinesia and akinesia. We tested the hypothesis that a causal relationship exists between synchronized, beta frequency oscillations in cortical-basal ganglia circuits and the development of bradykinesia/akinesia in PD. We designed novel temporal patterns of deep brain stimulation to mimic the oscillatory bursting activity in the beta frequency band observed in parkinsonian patients and rats. First, we applied these beta frequency patterned stimulus trains (BPTs), along with continuous frequency controls, to a model of the intact basal ganglia to quantify the effects on simulated neural activity. BPTs preferentially increased beta band oscillatory power in model GPi neuron activity as compared to continuous low and high frequency controls. Second, we applied BPTs and continuous frequency controls unilaterally to the subthalamic nucleus (STN) in intact rats using implanted stimulating electrodes and measured the effects on akinesia using the bar test. We also recorded electrocorticograms (ECoG) from primary motor cortex (M1) and LFPs from globus pallidus (GP) to determine the effects of STN stimulation on neural activity. All stimulation patterns evoked stereotyped, polyphasic potentials in M1 and GP at the burst or continuous frequency, implying an increase in signal power generated by stimulation. However, no significant difference was found in length of time on the bar among stimulation patterns or compared to no stimulation controls. We repeated these experiments after administration of raclopride, a selective antagonist of D2 receptors. Raclopride administration alone resulted in a statistically significant difference in length of time spent on the bar but did not enhance any stimulation pattern specific differences in bar test performance. Neural recordings pre- and post-raclopride administration revealed no significant difference in the total percent of spectral power within the beta band in either M1 ECoG or STN LFPs. Taken together, these results suggest that beta frequency oscillations may not be necessary or sufficient for the generation of symptoms of bradykinesia/akinesia in PD.

Title: Motor and cognitive functions of striatal cholinergic interneurons in Parkinson's disease: optogenetic and pharmacological approaches

Authors: ***S. ZTAOU**[1], M. LIBERGE[1], N. MAURICE[2], F. JOUEN[2], L. KERKERIAN-LEGOFF[2], C. BEURRIER[2], M. AMALRIC[1];
[1]Aix Marseille Univ. - CNRS UMR 7291, Marseille Cedex 03, France; [2]Aix-Marseille University, CNRS UMR7288, Marseille cdx3, France

Abstract: Disturbance in the central muscarinic cholinergic system has been implicated in several neurodegenerative pathology. In Parkinson's disease (PD), anticholinergic (ACh) drugs were the first widely accepted drugs before the discovery of L-DOPA. Their precise mechanism of action is still not clear, although it is believed that they work by correcting the imbalance between striatal dopamine and acetylcholine activity. Here, we examined the involvement of striatal ACh interneurons in motor and cognitive functions by manipulation of striatal cholinergic activity using optogenetic and pharmacologic approaches. In transgenic mice specifically expressing halorhodopsin (eNpHR) in cholinergic neurons, photostimulation of striatal ACh interneurons in unilateral 6-OHDA lesioned mice inhibited ACh neuronal activity and reduced the asymetric motor symptoms (postural asymmetry and turning bias). To further investigate the muscarinic cholinergic subtypes involved in these beneficial effects, systemic and intrastriatal injections of telenzepine and tropicamide (M1 and M4 receptor antagonists, respectively) were tested in the same PD model. The beneficial effect on motor symptoms were reproduced by blocking either M1 or M4 mACh receptors in the dorsal striatum. To decipher the mechanisms of ACh action on striatal post-synaptic M4 receptors, additional experiments were performed with mutant mice that lack M4 receptors only in D1 dopamine receptor-expressing cells. As cognitive and neuropsychiatric symptoms are increasingly recognized in PD, we also examined the role of striatal ACh interneurons in these deficits in a bilateral partial model of PD. Blockade of striatal ACh interneurons activity by eNpHR photostimulation or by M1 and M4 receptor antagonists was tested on elevated plus maze, spatial object recognition and social recognition tests. The present results indicate that cholinergic modulation of the dorsal striatal circuit, particularly M1 or M4 receptor subtypes, plays a pivotal role in the regulation of motor, cognitive and emotional symptoms in PD. Abstract: Parkinson's disease (PD) is a neurodegenerative disease characterized by a progressive and specific degeneration of A9 dopaminergic neurons of the substantia nigra, leading to the classic motor and cognitive deficits. Several studies have shown that cholinergic activity in the striatum regulates the release of dopamine (DA) through the action of nicotinic receptors (nAChRs) which are expressed in dopaminergic nerve terminals. Since the normal activity of striatal neurons depends on the balance between DA and ACh, disruptions in this signaling may contribute to the development of PD. The aim of the present research is to investigate the biochemical changes in the cholinergic system during different survival periods in a mouse model of PD, in order to study the possible striatal cholinergic modulation and the performance of these animals in a memory test. Anaesthetized adult C57Bl6 mice were submitted to unilateral injection of 6-OHDA (2 µl at a rate of 0.5 µl/5 min) into the left medial forebrain bundle using stereotaxic procedures. 1, 2 or 4 weeks after surgery, 6-OHDA and SHAM groups were submitted to the rotational test induced by apomorphine (0.5 mg/kg, ip) and to the object recognition test, to estimate the ability of the animal to distinguish a new object from a familiar one. The amount of time taken to explore the new object provides an index of recognition memory for the investigation of learning processes. Then, the mice were euthanized and striatum used to biochemical assay. Our results showed a modulation of Ach turnover. Moreover, we also detected a reduction in α6 subunit content. Conversely, α7 and β2 subunits content had a progressive increase that was accompanied by improvements in motor behavior. Behavior analyses showed that 6-OHDA mice were not able to distinguish pairs of objects with subtle structural differences. 6-OHDA mice with 2 weeks after lesion surgery showed the worst results in this test, while the animals with 4 weeks showed a partial improvement. Altogether, these data suggest that the availability of ACh may be involved in the remodeling of nAChRs as a result of the dopaminergic loss, what might contribute to partial improvement in a discriminative learning and motor behavior observed in our animals.

Title: Dopamine manipulation disrupts delta/theta activity in medial frontal cortex during cognitive tasks in humans and rodents

Authors: ***R. N. RUGGIERO**[1], K. PARKER[1], Y. KIM[1], J. KINGYON[1], J. CAVANAGH[2], N. NARAYANAN[1];

Abstract: Abnormal changes in dopamine in the cerebral cortex are characteristic of a series of human neurological disorders such as schizophrenia, ADHD and Parkinson's disease. These conditions are well known to present profound cognitive process alterations. It is still unknown how altered dopamine signaling influences cortical processing. We study this question by manipulating cortical dopamine signaling and studying field potentials in the medial frontal cortex using different approaches. First, we investigated patterns of EEG oscillations during elementary cognitive tasks in humans with Parkinson's. We also used pharmacological tools to block medial frontal dopamine neurotransmission in rodents. Finally, to specifically and selectively manipulate dopamine neurons in the midbrain, we used transgenic mice in which cre-recombinase is expressed only in neurons expressing tyrosine hydroxylase. We injected AAV-LoxP-ChR2 and implanted optical fibers in the VTA, and a recording electrode array in the medial frontal cortex. We record medial frontal neuronal ensembles as we optogenetically change the firing rate of these neurons in rodents performing a fixed interval timing task. Our preliminary results indicate that humans with Parkinson's disease and rodents with disrupted medial frontal dopamine have attenuated 4 Hz oscillations triggered by instructional stimuli during cognitive tasks. We also demonstrate that these oscillations depend on D1 dopamine signaling. These results indicate how dopamine affects media frontal activity influencing cognition. Such findings help to better understand how information processing can be modified in ADHD, schizophrenia and Parkinson's disease.

Title: Movement and striatal activity in the development of L-Dopa-induced dyskinesias

Authors: ***S. L. ALBERICO**[1,2], Y. KIM[2], S. J. GROSS[1], N. S. NARAYANAN[2];

Abstract: Parkinson's disease is most commonly treated with the dopamine precursor L-Dopa. Although L-Dopa is effective, a major limitation is that long-term use leads to L-Dopa-induced dyskinesias (LIDs). The mechanism of LIDs remains unknown. Here, we studied the development of LIDs in a mouse model. We injected 6-OHDA into the medial forebrain bundle and implanted microwire electrode arrays in the striatum as well as hardware to track movements. We tested the hypothesis that during LIDs the correlation between movement and striatal neural activity is disrupted. Following dopamine depletion, LIDs were developed with daily injections of L-Dopa (20 mg/kg, i.p.) for 14 days. During the development of LIDs, animal movement was tracked with high temporal and spatial resolution using infrared tracking and accelerometers. Simultaneously, we recorded from neuronal ensembles in the striatum. Previous research demonstrated that the firing rate of neurons in the substantia nigra significantly correlated either positively or negatively with x or y positions. Our striatal data are consistent with this finding. Moreover, our preliminary data suggest that striatal activity and movement correlate less in sessions where LIDs are present. Additionally, animals depleted of dopamine and serotonin exhibit less LIDs. We are currently exploring this phenomenon by pharmacologically inhibiting serotonergic neurons with 8-OH-DPAT, which has been used successfully to decrease LIDs in rats. These data could lead to a deeper understanding of the mechanism of LIDs.

Title: Pathway-specific remodeling of thalamostriatal synapses in Parkinsonian mice

Authors: *P. R. PARKER[1], A. C. KREITZER[2];
[1]Neurosci., UCSF GIND, San Francisco, CA; [2]UCSF/Gladstone Inst., San Francisco, CA

Abstract: Suppression of movement in Parkinson's disease (PD) is thought to arise from increased efficacy of the indirect pathway basal ganglia circuit, relative to the direct pathway. However, the underlying pathophysiological mechanisms remain elusive. To examine whether changes in the strength of synaptic inputs to these circuits contribute to this imbalance, we obtained paired whole-cell recordings from striatal direct- and indirect-pathway medium spiny neurons (dMSNs and iMSNs) and optically stimulated inputs from sensorimotor cortex or intralaminar thalamus in brain slices from control and dopamine-depleted mice. We found that dopamine depletion selectively decreased synaptic strength at thalamic inputs to dMSNs, suggesting that thalamus drives asymmetric activation of basal ganglia circuitry underlying parkinsonian motor impairments. Consistent with this hypothesis, *in vivo* chemogenetic inhibition of intralaminar thalamic neurons reversed motor deficits in dopamine-depleted mice. These results implicate thalamostriatal projections in the pathophysiology of PD and support interventions targeting thalamus as a potential therapeutic strategy.

Abstract: The pathophysiology of Parkinson's disease (PD) and L-DOPA induced dyskinesias (LID) is associated with dysfunctional neuronal activity in several nuclei of the basal ganglia. Also high level of oscillatory activity and synchronization have been described, both intra and inter the basal ganglia nuclei and the cerebral cortex. However, the relevance of these alterations in the motor symptomatology associated to two different stages of parkinsonism is not fully understood. Recently, we have shown that the subthalamic neuronal activity correlates with axial dyskinetic movements and that subthalamic nucleus (STN) lesion partially reduces dyskinesia severity as well as the expression of some striatal molecular modifications (Aristieta et al., 2012, Plos one 7; e42652-e42652). In the present study we further investigate the electrophysiological changes and the role of the STN in parkinsonism and LID. Neuronal activity of the substantia nigra reticulata (SNr), the STN and cerebral cortex were recorded from 6-OHDA lesioned and dyskinetic rats. Results show that the firing rate of SNr neurons from dyskinetic animals was increased with respect to values obtained in intact and 6-OHDA lesioned rats. Moreover, there was a significant correlation ($p<0.01$) between the mean firing rate of SNr neurons and the severity of the dyskinetic movements (limb and orolingual subtypes). We also found a significant correlation between the firing activity of SNr and STN neurons recorded from dyskinetic rats. In addition, 6-OHDA lesioned animals showed low frequency band oscillatory activity and synchronization both, within the nucleus and with the cerebral cortex, regardless the chronic treatment with L-DOPA. The degree of synchronization and oscillatory activity in parkinsonian and dyskinetic rats was higher with respect Altogether, these results indicate that SNr neuronal firing activity is relevant in dyskinesia and may be driven by STN hyperactivity. On the other hand, oscillatory activity and synchronization seem to be more important in PD since they are not influenced by prolonged L-DOPA administration. Supported by GIC IT747-13. There is no conflict of interest.

Title: Muscarinic dependent cholinergic modulation of striatal beta oscillations

Authors: *K. KONDABOLU[1], E. A. ROBERTS[2], M. BUCKLIN[2], M. M. MCCARTHY[2], N. KOPELL[2], X. HAN[2];

Abstract: Parkinson's disease is characterized by degeneration of mid-brain dopaminergic neurons that project to the striatum. In animal models of dopamine depletion, striatal cholinergic tone is elevated and is coincident with enhanced pathological beta oscillations (15-30Hz) within the cortico-basal ganglia-thalamic circuit. Recently, we have demonstrated that infusion of cholinergic agonist in the striatum generates exaggerated beta oscillations - consistent with our computational model - suggesting that striatal circuitry possessed the ability to generate beta oscillations. In the current study, we utilized optogenetics to directly activate striatal cholinergic interneurons, and demonstrate that increased cholinergic tone is sufficient to produce beta oscillations within the striatum. We also show that these beta oscillations can propagate to the motor cortex in a cortical layer dependent manner, with the deeper layers having the greatest increase in beta power. Furthermore, we demonstrate that the muscarinic receptors, but not the nicotinic receptors are critical for generation of beta oscillations. Together, our results provide direct evidence for striatal cholinergic interneurons ability to generate propagating beta oscillations through activating muscarinic receptors.

Title: High striatal cholinergic tone attenuates theta-gamma coupling in M1 and striatum

Authors: *M. ROMANO[1], B. PITTMAN-POLLETTA[2], M. MCCARTHY[2], K. KONDABOLU[3], N. KOPELL[2], X. HAN[3];

Abstract: Locally synchronous neuronal firing generates cognitive rhythms, some of which have been associated with movement disorders. Rhythms might not only serve as means of communication between different brain regions, but might also influence rhythms of other frequencies. In a recent study, theta (4-8 Hz) rhythms were shown to phase modulate gamma (30-100 Hz) both within the motor cortex (M1) and within the striatum while mice were running (von Nicolai 2014). This suggests that theta-gamma coupling within M1 and within striatum may have roles in movement. Here we show that increased cholinergic tone in striatum decreases this phase-amplitude coupling in both of these regions. We simultaneously recorded local field potentials from M1 and dorsolatereral striatum in Chat-ChR2 mice, with channelrhodopsin expressed in striatal cholinergic interneurons. We used wavelets to extract amplitudes and phases, and used a modulation index (MI) to measure cross-frequency coupling between low bands of 0.5-30 Hz and phase-modulated bands of 8-200 Hz. We find a decrease in coupling compared to non-stimulation time periods between low theta (~4 Hz) and high gamma (~75 Hz) in M1 with stimulation of the striatal cholinergic interneurons. A similar trend of phase-amplitude coupling was also seen in striatum. However, we also found an increase over control in theta-gamma coupling in both M1 and striatum during the time periods between stimulation. Such an increase may be a response to rebound of dopamine in striatum (López-Azcárate 2013). These results have importance as the state of striatal cholinergic tone is relevant to Parkinson's disease, a disease in which bradykinesia (slowness of movements) is a characteristic symptom. Increases in beta and decreases in gamma are characteristic oscillatory changes seen in the Parkinsonian state, which can be produced by increasing cholinergic tone in striatum (McCarthy 2011). Title: Striatal cholinergic and dopaminergic tone modulate distinct beta band sub-frequencies in the cortical-basal ganglia-thalamic loop

Authors: *A. QUACH, B. R. PITTMAN-POLLETTA, N. KOPELL, M. MCCARTHY, X. HAN;
Boston Univ., Boston, MA

Abstract: Enhanced oscillations in the beta frequency band (8-30 Hz) are a characteristic neural signature observed in the cortical-basal ganglia-thalamic (CBT) loop of Parkinson's disease (PD) patients. While beta oscillations have been shown to be correlated with parkinsonian motor symptoms, the mechanisms underlying the generation and propagation of beta oscillations in PD are not well-understood. We have previously shown both computationally and experimentally that increased cholinergic activation in the striatum can lead to enhanced beta oscillations in normal, non-parkinsonian mice (McCarthy et al, 2011). Here, we infused the acetylcholine agonist carbachol into the striatum of normal adult mice to produce beta oscillations and recorded simultaneously from the striatum and the subthalamic nucleus (STN) or the motor cortex (M1). We found that striatal carbachol-induced beta oscillations can propagate to STN and M1. However, STN and M1 manifest distinct oscillation patterns at different sub-frequencies within the beta band. Broadband beta oscillations increased in STN, but only the highest beta band sub-frequency (18-25 Hz) in M1 increased. We then optogenetically silenced excitatory neurons in deep layers of M1, and observed a reduction only in low beta (8-13 Hz) in M1 but no change in the striatum, suggesting that in the exaggerated cholinergic state, striatal beta oscillations are independent of cortical input and that only low beta in M1 is dependent on the activity of cortical excitatory neurons. Finally, we compared these results to recordings from M1 and striatum in a 6-hydroxydopamine (6OHDA) model of PD. The exact same pattern of beta sub-band elevation was observed in the 6OHDA mice as in the carbachol-infused mice with the exception of the low beta band in M1, which was elevated with 6OHDA but not with carbachol. Additionally, optogenetic silencing of M1 excitatory neurons paradoxically increased low beta in M1 in the 6OHDA mice and decreased all sub-bands of beta in striatum. Together, our results provide direct evidence that cholinergic and dopaminergic tone differentially modulate

propagating beta oscillations within the CBT loop. At least two beta oscillators were observed in the motor cortex with the low sub-frequency beta oscillator strongly dependent upon M1 local circuitry whereas the high sub-frequency beta oscillator strongly modulated by basal ganglia circuits. Dopamine depletion and cholinergic upregulation created similar patterns of striatal beta oscillation patterns, but differentially impacted striatal responses to M1 inputs.

Title: A possible mechanistic link between beta oscillations and bursting in the Parkinsonian basal ganglia

Authors: *M. M. MCCARTHY, B. R. PITTMAN-POLLETTA, A. QUACH, X. HAN, N. KOPELL;
Boston Univ., Boston, MA

Abstract: Increased neuronal busting and increased oscillatory activity in the beta frequency (8 - 30 Hz) range are two prominent electrophysiological characteristics of the parkinsonian basal ganglia. It is currently unknown if there is a mechanistic link between them. Here we use a combination of experimental and computational techniques to investigate the possibility of a direct association between bursting and beta oscillations in basal ganglia. We have previously shown that increased striatal cholinergic tone, a condition relevant to Parkinson’s disease, reliably and reversibly produces exaggerated beta oscillations in the basal ganglia of normal mice. Here we find that high striatal cholinergic tone not only increases the power of beta oscillations but also changes the phase relationships in the beta frequency range between basal ganglia nuclei, specifically between the striatum and the subthalamic nucleus (STN). Striatal beta oscillations generally phase lead STN beta oscillations under conditions of normal striatal cholinergic tone. In contrast, under conditions of high striatal cholinergic tone, STN phase leads striatum over a wide region of the beta frequency band (13 - 23 Hz). We use computational models to examine the effect of this beta frequency phase shift on the output nucleus of the basal ganglia, the internal segment of the globus pallidus (GPi), which receives input from both striatum and STN. We find significantly increased bursting in GPi when STN input precedes

striatal input. This is due to a relatively high rate of coincident spiking between GPi and STN and thus increased activation of NMDA-mediated currents in GPi. In contrast, when striatal input precedes STN input, GPi neurons are hyperpolarized during the time of arrival of STN input, which effectively prevents NMDA-induced bursting in GPi. These results suggest a potential mechanistic link between beta oscillations and neuronal bursting in GPi under conditions of high striatal cholinergic tone. They further suggest the beta phase difference between the striatum and the STN, as opposed to the power of the beta oscillations, may be more immediately linked to the dysfunction associated with the beta oscillations in the parkinsonian basal ganglia.

Title: Enhanced cortico-striatal beta oscillations and synchrony mediated by optogenetic increase of striatal cholinergic tone

Authors: *E. A. ROBERTS, K. KONDABOLU, M. ABDULKERIM, M. M. MCCARTHY, N. KOPELL, X. HAN;
Boston Univ., Boston, MA

Abstract: Amplified beta frequency (13-30Hz) oscillations in the cortico-basal ganglia-thalamic (CBT) loop are characteristic of Parkinson’s disease (PD). Enhanced beta spectral power is known to correlate with bradykinesia and akinesia symptoms in PD patients. Another feature of PD is increased beta synchrony between the basal ganglia and cerebral cortex. Clinically, dopamine replacement and basal ganglia deep brain stimulation attenuate beta power and

cortical-basal ganglia synchrony, leading to improvements in bradykinesia and akinesia. Since anticholinergic medication has also been used in humans to reduce PD tremor, it is not surprising that animal models of Parkinson's disease demonstrate augmented striatal cholinergic tone. Previous studies from our group demonstrated that injection of a cholinergic agonist into striatum leads to increased beta power, suggesting that striatum can generate beta oscillations. However, it was undetermined if these cholingerically mediated beta oscillations propagated through the CBT loop. To investigate this, we optogenetically activated striatal cholinergic interneurons in mice while simultaneous recording from the striatum as well as the motor cortex using a laminar probe. Optogenetic increase in cholinergic tone produced beta oscillations in the striatum that propagated to motor cortex in a cortical depth dependent manner. This was accompanied by a simultaneous increase in beta coherence between these structures. Behavioral activity of mice was monitored in a separate activity chamber to confirm that these beta oscillations affected locomotion. We observed a laser induced decrease in locomotion that was restored back to baseline activity after laser offset. These results demonstrate that optogenetically increasing striatal cholinergic tone, a state relevant to PD, produces pathophysiological oscillations and behavior typical of PD.

Title: Spiking neuron model of the basal ganglia for the generation of Parkinsonian pathological oscillations

Authors: *O. SHOUNO[1,2], K. DOYA[2];
[1]Honda Res. Inst. Japan Co Ltd, Saitama, Japan; [2]Okinawa Inst. of Sci. and Technol. Grad. Univ., Tancha, Onna-son, Okinawa, Japan

Abstract: Parkinson's disease is a disorder of movement caused by dopamine depletion in the basal ganglia. Abnormally synchronized neuronal oscillations between 8 Hz and 15 Hz in the basal ganglia are implicated in motor symptoms of Parkinson's disease. However, how these abnormal oscillations are generated and maintained still remains unveiled. Based on recent experimental evidence (Atherton et al., 2013), we propose a hypothesis that the short-term plasticity of the synapses between the subthalamic nucleus (STN) and the external segment of the globus pallidus (GPe), as well as post-inhibitory rebound bursting of STN neurons, generate parkinsonian oscillations and that the cortical oscillatory feedback input to the STN can amplify

the oscillation. To test this hypothesis, we develop a spiking neuron model of the STN-GPe circuit and performed systematic search in the model parameter space to reproduce BG neuronal activities in normal and parkinsonian states (Tachibana et al., 2011). Simulation results revealed that the mean firing rates, oscillation frequency, and the enhanced bursting rate of parkinsonian oscillation are reproduced by reduced excitability of GPe neurons and increased strength of GPe-to-STN synaptic connections. The reduced activity of GPe neurons can be caused by reduced autonomous activity of GPe neurons (Chan et al., 2011) or increased inhibitory input from striatal D2R expressing neurons under dopamine depletion. The increased GPe-to-STN inhibitory connection, combined with its short-term depression property, triggers stronger rebound burst activities of STN neurons. Furthermore, oscillatory cortical feedback input to the STN amplifies 8-15 Hz oscillation if the feedback delay of the GPi-thalamus-cortex-STN loop is within 60-80 ms, while increased tonic excitatory cortical input to the STN can suppress the oscillations. These observations will be the basis for identifying new targets for the therapy of Parkinson's disease, such as deep brain stimulation.

Title: Phase coupling between neural populations in Parkinson's disease

Authors: ***H. CAGNAN**[1,2], A. SHAROTT[2], N. MALLET[3], P. MAGILL[2], P. BROWN[2];
[1]Univ. Col. of London, London, United Kingdom; [2]Univ. of Oxford, Oxford, United Kingdom; [3]Univ. of Bordeaux, Bordeaux, France

Abstract: Phase coupling between neural populations is believed to shape information flow and determine system performance. In Parkinson's disease (PD) the motor circuit exhibits excessively synchronized rhythmic activity patterns. These activity patterns are correlated with PD motor symptoms such as bradykinesia, rigidity and tremor, suggesting that excessive synchrony could underlie impaired motor system performance. Using simultaneously recorded local field potential (LFP) recordings from the subthalamic nucleus (STN) and the globus pallidus (GP), we investigated the neural processes underlying excessive synchronisation and its termination in PD [Cagnan et. al. Brain, 2015 (doi: 10.1093/brain/awv093)]. Local beta activity in each nucleus varied in amplitude according to the phase alignment between the nuclei, and according to how long such phase alignment was sustained. LFPs were more likely to align at

phases that amplified local beta synchrony when patients were off as opposed to on dopaminergic therapy, and did so for longer, thereby promoting beta activity. Dopaminergic stimulation shifted the motor circuit from prolonged periods of phase locking enhancing beta synchrony, associated with PD motor symptoms, to more dynamic phase coupling and improved motoric function. Here we corroborate the above findings in the 6-OHDA lesioned rodent model of PD, extending them to multi-unit activity and establishing the frequency specificity of phase alignment effects. Critically, by focusing on multiunit activity rather than LFP activity, we have the spatial resolution to establish that local amplitude amplification also entails progressively more spatially extensive intranuclear synchronization. Together our findings demonstrate the dynamic interaction between internuclear phase alignment and intranuclear synchronization, and its control by the neuromodulator dopamine in the basal ganglia circuit.

Title: Gamma band favors levodopa-induced dyskinesia: an *in vivo* study on freely-moving rats

Authors: V. D'ANGELO[1], *A. STEFANI[1], A. SALVADÉ[2], A. KAELIN[2,3], S. GALATI[2]; [1]Univ. Tor Vergata, Rome, Italy; [2]Neurocenter of Southern Switzerland, Torricella-Taverne, Switzerland; [3]Movement Disorders Ctr., Bern, Switzerland

Abstract: An enhanced β band (βB) oscillatory neuronal activity features basal ganglia discharge in Parkinson’s disease (PD), as evaluated during stereotactic neurosurgery in humans as well as in disease rodent’s models. Far from fully elucidated is whether higher βB partecipates to the behavioral pathogenesis or represents a mere correlative hallmark. A less explored phenomenon regards the putative contribution of the γ band (γB) activity to PD pathophysiology. We have monitored these frequency bands thorugh weekly histological and electrophysiological assessments (from unilateral globus pallidus - GP - and bilateral frontal cortex) in freely moving rats, following traditional unilateral 6-HPDA lesioning; hence, we acquired parameters right after denervation, after 2-4-6 weeks, and after levodopa therapy (in groups exhibiting or not severe involuntary movements). It was detected a significant increase of the βB (18-30 Hz) activity within the first week after the toxin injection, while γB remained quite constant. Notably, the increase βB discharge affected also cortex contralateral to the lesion. Dopaminergic treatment influenced in opposite ways the two examined bands, reverting βB but increasing the expression of the γB in those animals manifesting dyskinesia. If, on one hand, βB activity increased parallel

to the emerging of PD akinesia and impaired TH-staining, on the other hand the occurrence of dyskinesia correlated strongly with γB activity. We are suggesting that, albeit a *normal* γB exerts a physiological pro-kinetic role, an exhuberant cortical γB influences the unmasking and intensity of dyskinesia.

Title: Neuronal, glial and neural stem cell marker expression in mesenchymal stem cells from R6/2 (transgenic mouse model of Huntington's disease)

Authors: *C. B. KAYA[1], M. LU[2], K. L. RETERSTORF[3], T. S. WHITE[4], G. DUNBAR[2], J. ROSSIGNOL[5];

Abstract: Current research data on the use of stem cells as cell replacement therapy for neurological diseases show inconsistent results on whether mesenchymal stem cells (MSC) are capable of neuronal, glial and/or neural progenitor differentiation during subsequent *in vitro* culturing in the absence of complex induction media. Bone marrow-derived MSCs isolated from R6/2 transgenic mouse model for Huntington's disease and its wild-type counterpart, were isolated, cultured and analyzed by flow cytometry, immunocytochemistry and qRT-PCR. Preliminary data show varying, positive expression of neuronal, glial, neural progenitor and basal MSC markers. Such discrepancies in MSC, glial, neural progenitor and neuronal biomarker expression across passages, and between wild-type and Huntington's Disease-positive MSCs implies feasibility of isolating a putative multipotent adult progenitor (MAP-MSC) cell population in MSCs that are predisposed to neuronal, glial and/or neural progenitor

differentiation. Naïve MSCs are therefore, found to be 'differentiation-ready'. Selecting for such subpopulations of MSCs, directed to have a particular neural lineage without the need for any induction or differentiation media, may enhance stem cell transplantation studies for neurodegenerative diseases and also allow for a faster turnaround from isolation to transplantation, and thus offering better transplantation survivability.

Title: Huntingtin mRNA 3′UTR isoform abundance changes in a mouse model of Huntington's disease

Authors: *L. ROMO[1], E. PFISTER[1], A. ASHAR-PATEL[2], M. MOORE[2], N. ARONIN[1]; [1]Med., [2]RNA Therapeut. Inst., Umass Med. Sch., Worcester, MA

Abstract: Huntington's disease is a devastating neurodegenerative disorder caused by an expanded glutamine repeat within exon 1 of the huntingtin (HTT) gene. The wild-type and mutant allele are expressed as two alternatively polyadenylated (APA) mRNA isoforms with tissue-specific abundance. Isoforms differ only in the length of their 3′ untranslated region (3′UTR), and both are processed into the HTT protein. Recent findings indicate mutant and wild-type mRNA exhibit different localization and stability. These differences may be due to alternative processing of mutant and wild-type mRNA into different isoforms. Here, we aimed to determine if the abundance of HTT 3′UTR isoforms changes in a model mouse. Quantitative PCR assessed the abundance of the HTT long 3′UTR isoform mRNA in male Yac18-/- and Yac128-/- mice after normalization to total HTT. These mice lack endogenous HTT but harbor the full-length human HTT gene with either expanded 128 (Yac128) or wild-type 18 (Yac18) glutamine repeats. We found Yac128 mouse tissues contain a significantly higher abundance of long HTT isoform than Yac18 mouse tissues. To determine if this change was specific to HTT, we performed next generation polyadenylation (polyA) site sequencing on Yac18 or Yac128 mouse cortex. Of 1,466 genes with two detected 3'UTR polyA sites, none exhibit significantly ($p<0.01$) different isoform ratios between Yac128 and Yac18 cortex. Interestingly, despite reported transcriptional dysregulation in symptomatic disease, only 82 mRNAs out of 11,469 show significant changes in polyA mRNA expression. The difference in total HTT expression

between Yac128 and Yac18 mice was less than the difference in HTT long isoform expression, implying the shift to the long HTT isoform in Yac128 mice is not solely explained by transcriptional changes. These data indicate disease-associated changes in HTT isoform abundance are unique to HTT, suggesting they are due to a cis element rather than a change in an APA global regulator. It remains unclear what HTT cis element dictates the observed changes in 3′UTR mRNA isoform abundance, although the promoter-exon1 region is a likely candidate given its role in polyA factor assembly and site selection as well as its disruptive glutamine repeat. These studies reveal differences in HTT mRNA isoform abundance in mouse models of HTT. Our preliminary data suggests these differences also occur in human disease brain. If so, differences in HTT mRNA 3′UTR isoform abundance could explain different stability and localization of the mutant and wild-type allele, and the long 3′UTR will be the ideal target for small RNAs aiming to degrade mutant but not wild-type HTT mRNA.

Title: Assessment of demyelination/remyelination responses in cuprizone-treated YAC128 Huntington’s disease mice

Authors: *R. TEO[1], C. FERRARI BARDILLE[1], A. TAN[1], M. R. HAYDEN[1,2,3], M. A. POULADI[1,3];

Abstract: Huntington disease (HD) is an autosomal dominant neurodegenerative disorder characterized by motor, cognitive, and psychiatric disturbances. While generally considered a grey matter disease, early and progressive white matter (WM) atrophy is a well-recognized feature of HD. Abnormalities in WM and myelination have also been observed in a number of animal models of HD. Despite this, the aetiology of WM pathology in HD remains largely unexplored. The capacity to generate new oligodendrocytes and new myelin under normal conditions and in response to injury are essential to maintain WM health and function. Whether these processes are impaired in HD has not been addressed. In this study we employed

cuprizone-induced demyelination to characterize the demyelination and remyelination responses in the transgenic YAC128 mouse model of HD. The YAC128 HD mice exhibit phenotypes that mimic many features of human HD including progressive motor, cognitive, affective deficits as well as selective striatal atrophy and white matter abnormalities. To induce demyelination, YAC128 mice and littermate controls were treated with 0.2% cuprizone for 6 weeks starting at 2 months of age. To allow remyelination, cuprizone treatment was withdrawn and the animals were allowed to recover for 6 weeks. Assessment of oligodendroglial (CAII-, GSTpi-, and NG2-positive), microglial (Iba-1-positive), and astrocytic (GFAP-positive) cell counts indicates altered demyelination/remyelination responses in the YAC128 HD mice compared to littermate controls. Gross and ultra-structural myelination characteristics are being examined using myelin basic protein staining and electron microscopy analysis, respectively. Taken together, these studies shed light on remyelination capacity, a process important in the maintenance of white matter integrity, in the HD context.

Abstract: Huntington’s disease (HD) is a rare neurodegenerative disease caused by an autosomal dominant mutation on the huntingtin gene (*HTT*). Despite ubiquitous expression of the mutant *HTT,* a selective vulnerability of medium-sized spiny neurons (MSN) of the striatum is observed. Recent data have suggested the implication of non-neuronal cells in the disease, in particular astrocytes, which have essential roles in many neuronal functions including ion regulation or energetic modulation. These observations underline the need to better characterize neuron-astrocyte interactions specifically in HD. Several transgenic mouse models of HD are available but modulation of mutant *HTT* expression to reach a cell-type specific pathology is

hardly achieved due to their variability in terms of genetic background and transgene constructions. An alternative strategy consists to model the disease using cell-type specific viral vectors expressing mutant *HTT* in the striatum. In particular, Adeno-Associated Viruses (AAV) offer the possibility to shift their tropism from neurons to astrocytes using specific capsids and cell-type specific promoters. In this study, we characterized several viral-mediated HD models using an AAV2/5 to express a short mutant *HTT* fragment under the control of a neuronal or an astrocytic promoter. We first show that the combination of AAV2/5 and the chicken β actin (CBA) promoter or Gfa2(b)3 promoter leads to a high expression of a reporter gene specifically in striatal neurons or in astrocytes, respectively. We replaced this reporter gene by a cassette expressing the first 171aa of the *HTT* with 82 or 18 CAG to study the contribution of each cell population to HD. Expression of mutant HTT selectively in neurons leads to progressive motor alterations and increased anxiety, whereas expression in astrocytes leads to a less severe phenotype. We furthermore characterized several cellular and molecular hallmarks and their evolution in these two models. Two profiles of huntingtin aggregation were observed between the neuronal and the astrocytic model, leading to specific cellular dysfunctions. We are currently using co-injections to express mutant *HTT* both in neurons and in astrocytes to evaluate the potential synergistic effect of the mutant protein in both cell types. In this study, we were able to make a direct comparison between neuron-specific, astrocyte-specific or more global expression of mutant *HTT* to better understand neuron-astrocyte interactions, and their respective contribution to behavioral and cellular alterations in HD.

Title: Neurophysiological correlates of motivation and timing in a mouse model of Huntington’s disease

Authors: ***N. E. ZLEBNIK**, E. A. COLE, I. GILDISH, D. P. COVEY, J. F. CHEER;
Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Huntington’s disease (HD) is an inherited neurodegenerative disorder caused by a polyglutamine expansion in the huntingtin gene and results in the progressive loss of striatal and cortical neuropil. Striatal neurodegeneration occurs first and mainly affects the indirect pathway

of the basal ganglia, causing dyskinesia followed later by akinesia. However, the marked motor impairments characteristic of HD may often be preceded by motivational and cognitive dysfunction. Recent studies report altered function at dopamine terminals in in HD patients and rodent models, but how this relates to motivational and cognitive deficits is unclear. In order to characterize mesolimbic system dynamics in HD progression, extracellular electrophysiological recordings were collected at multi-electrode arrays implanted in the nucleus accumbens of wild-type (WT) and Q175 knock-in mice during tasks of motivation (progressive ratio) and timing (fixed-interval 30). While reward-encoding single units exhibited similar patterns in both genotypes, session-wide power distribution significantly differed across several frequency bandwidths and in reward-evoked power specifically in the gamma bandwidth. These results suggest the nucleus accumbens may be one brain locus with sufficient predictive power to function as a neurophysiological biomarker of the motivational and cognitive impairments inherent to HD.

Abstract: Huntington’s disease (HD) is a neurodegenerative disorder caused by a pathological CAG expansion at the 3’ end of the first exon of the huntingtin gene (*HTT*). Currently, there is no efficient treatment for HD. Editing of the mutant *HTT* gene with the Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR) system represents a new and promising approach. Recognition of the *HTT* target sequence by a single-guide RNA sequences (sgRNA) and the Cas9 protein is inducing DNA double-strand breaks (DSB), which activate endogenous

cellular repair pathways. Non-homologous end joining (NHEJ) will introduce small insertions/deletions (indels) that alter the reading frame of *HTT* gene while homologous directed repair (HDR) is activated in the presence of a DNA template. Both approaches would lead to a definitive loss of mutant *HTT* expression. To validate the approach and optimize the delivery of the CRISPR system with viral vectors, we first targeted artificial sequences containing fluorescent reporter genes in HEK 293T cells. Furthermore, targeting of a genomic integrated reporter gene in neurons and in astrocytes resulted in an efficient gene disruption and was associated with a loss of fluorescence *in vitro* and in the mouse striatum. We developed multiple strategies to disrupt the mutant *HTT* gene. Quantification demonstrated a high rate of indels, leading to a strong reduction of HTT protein in HEK 293T cells, mouse cortical neurons and human iPSC-derived neurons. Blocking *HTT* expression in cellular HD models improved several physiopathological parameters. We are currently evaluating the impact of allele or non-allele specific mutant *HTT* editing in human neurons from HD patients. Altogether, these data demonstrate the potential of the CRISPR technology as therapeutic strategy for HD.

Title: Changes in structure and function of diaphragm neuromuscular junctions from BACHD mouse model for Huntington’s disease

Authors: *C. GUATIMOSIM[1], B. ARAGAO[1], H. RODRIGUES[1], P. VALADAO[1], W. CAMARGO[2], L. NAVES[2], F. RIBEIRO[3];
[1]Univ. Federal De Minas Gerais, ICB, Dept. De Morfologia, Belo Horizonte, Brazil; [2]Univ. Federal de Minas Gerais, ICB, Dept. de Fisiologia e Biofisica, Belo Horizonte, Brazil; [3]Univ. Fedearl de Minas Gerais, ICB, Dept. de Bioquimica e Imunologia, Belo Horizonte, Brazil

Abstract: Huntington's disease (HD) is a neurodegenerative disorder characterized by a progressive decline of motor and cognitive functions. It is caused by a polyglutamine expansion in the huntingtin (htt) protein which then leads to neuron degeneration involving multiple neuronal compartments that span both the central and peripheral nervous system. At the synaptic level, htt binds to synaptic vesicles and interacts with several proteins associated with vesicular transport. Therefore, it is suggested that the mutant htt may interfere with the release of neurotransmitters causing synaptic dysfunction. In this work, we looked at alterations in diaphragm muscle neuromuscular junctions (NMJs) from BACHD mouse model for HD. This mouse model represents a new and robust *in vivo* paradigm for studying the pathogenesis of HD. For optical analysis, NMJs were stained with FM1-43fx and α-bungarotoxin to visualize both pre and post-synaptic elements, respectively. Confocal microscopy optical analysis showed a decrease in the number of synaptic elements and fluorescence intensity in NMJs from BACHD diaphragms compared to WT. We next analyzed pre-synaptic activity and we observed that synaptic vesicle exocytosis was impaired in NMJs from BACHD diaphragms. Ultrastructural analysis revealed significant changes in the form and sizes of the synaptic vesicles in BACHD diaphragm NMJs that could contribute to impaired exocytosis. Additionally, electrophysiology recordings revealed a decrease in the amplitude of miniature endplate potentials (MEPPs), indicating a significant reduction in the acetylcholine quantal content in synaptic vesicles from BACHD diaphragm NMJs. Our data so far suggest a function impairment in BACHD diaphragm NMJs that might occur in other muscles and then play a role in the motor defects seen in HD. These results may contribute to a better understanding of peripheral cholinergic dysfunction in this neurodegenerative disease.

Title: Intravascular AAV9-EAAT2 upregulates corticostriatal EAAT2 in the Q175 mouse model of Huntington's disease

Authors: *G. V. REBEC, C. RANGEL-BARAJAS, K. D. BUNNER, S. J. BARTON; Program Neurosci & Dept. Psychological & Brain Sci.,, Indiana Univ., Bloomington, IN

Abstract: Dysregulation of glutamate transmission is a key feature of Huntington's disease (HD), a dominantly inherited condition typically characterized by progressively worsening cognitive and motor symptoms as well as dysfunction and eventual loss of neurons in corticostriatal circuits. In the striatum of HD patients and transgenic mice that model HD, there is a down regulation of the major glutamate transporter, excitatory amino acid transporter 2 (EAAT2) in humans and glutamate transporter 1 (GLT1) in mice. Reversal of this effect by systemic injection of ceftriaxone, a beta-lactam antibiotic, increases glutamate uptake and improves the behavioral phenotype in HD mice, but only for a relatively short period. A meaningful therapeutic approach to HD, however, requires a long-lasting change in EAAT2. Moreover, because the pathology is widespread throughout the corticostriatal system and may affect other brain regions as well as peripheral tissue, a global treatment strategy is required. Here, we tested the approach of using intravascular administration of adeno-associated virus serotype 9 (AAV9), which crosses the blood-brain barrier, to express EAAT2 . To determine if intravascular AAV9 can transduce cortical and striatal cells, we injected recombinant AAV9 expressing green fluorescent protein (GFP) into the tail vein of adult, heterozygous Q175 knock-in mice (HET) and wild-type (WT) controls. AAV9-GFP was diluted to a working titer of 1x1013 vg/ml and administered in a volume of 0.1 ml. At 6-8 weeks post-injection, robust transduction patterns were evident in neurons and glia in both cortical and striatal tissue of HET and WT mice. Double label immunofluorescence staining with glial fibrillary acid protein (GFAP) confirmed transduction of astrocytes, the primary cellular location of EAAT2/GLT1. To assess EAAT2 expression, HET and WT mice received tail vein injection of AAV9-EAAT2, provided by Dr. Brian Kaspar (Nationwide Children's Hospital, Ohio State University, Columbus, OH). Density analysis of cortical and striatal western blots indicated a significant increase in EAAT2 expression in both HETs and WTs relative to untreated mice. Collectively, these results validate the use of AAV9 as a delivery tool for EAAT2 up-regulation that can be part of a comprehensive treatment strategy for HD.

Title: RNA interference therapy in mice subjected an experimental model of Huntington's disease

Authors: *R. AVILES REYES[1,2], D. SANCHEZ[1], S. CABRERA[1], S. ANDRADE[1], P. PALACIOS[1];
[1]Pontificia Univ. Católica Del Ecuador, Bioanalisis School, Ecuador; [2]Secretaria Nacional de Educación Superior, Ciencia, Tecnología e Innovación, Quito, Ecuador

Abstract: Huntington's disease (HD) is a late-onset and progressive neurodegenerative disorder that is caused by aggregation of mutant huntingtin protein which contains expanded-polyglutamine and it produce effect on motor control, muscles and leads to cognitive decline and psychiatric disorders. HD is wellknown pathology associated with trinucleotide repeat expansions (CAG) caused by slippage during DNA replication. As a result of the repetitive nature of DNA sequence in these regions, there may be formation of "loop out" structures during DNA replication while maintaining complementary base pairing between the parent strand and daughter strand being synthesized. RNA interference is a biological process currently being studied as a potential therapy for Huntington's disease. RNA interference (RNAi) is a natural, selective method of turning off genes, which can be induced by the production of small interfering RNAs (siRNAs) formed by a guide strand and a passenger strand. In this study we induce neurochemical injury to inoculate 1.2 µl of Q-A solution during ten days. The lesions assessments were done after 1; 3; 6; 9 doses of neurochemical damage; other animal groups were subjected to RNAi + *in vivo* fectamine and the controls of these animals were inoculated 0.9 Saline Solution; then GFAP and HTT immunohistochemistry; Hematoxylin / Eosin staining in striatum area was evaluated to test neurons and astrocytes reaction; western blot analyses of GFAP were developed and weight body mice was assessed. The results showed decrease of neuronal number and astrogliosis prominent in striatum area, furtheremore a significant weight loss of animals subjected to neurochemical experimental model. Interestingly, the treatments inoculated RNAi, presented minor astrogliosis, increase neuronal cells and enhanced the body weight. In conclusion, this research support the evidence of RNAi theraphy is capable to interfere with development of Huntington disease.

Title: Striatal local field potential Activity in the Q175 knock-in mouse model of Huntington's disease during plus-maze motor activity

Authors: *C. RANGEL BARAJAS, K. D. BUNNER, S. J. BARTON, G. V. REBEC; Psychological and Brain Sciences, Program in Neurosciences, Indiana Univ., Bloomington, IN

Abstract: Huntington's disease (HD), a dominantly inherited condition characterized by progressively worsening cognitive, emotional, and motor symptoms, is caused by an expanded CAG repeat (Q) in the gene that encodes for the huntingtin protein (HHT). In knock-in (KI) mouse models, the expanded CAG repeat is contained within the native HHT, closely mimicking the genetic condition of HD patients. Using the KI mouse model with 175-CAG repeats (Q175), we studied motor performance in a rotarod task as well as local field potential (LFP) activity in the striatum, a primary target of HD pathology, during approach and exit of the choice point or center of a four-arm, plus-shaped maze. Both heterozygous (HET) and homozygous (HOM) Q175 mice showed significantly shorter latency to fall in rotarod motor performance ($p<0.001$ and $p<0.0001$, respectively) compared to wild type (WT) mice. This impairment was genotype- and age-dependent. The number of arm choices in the plus maze was dramatically lower in HOM mice relative to both WT and HET ($p<0.0001$), suggesting that HOM mice were less active during plus-maze performance. Interestingly, HET mice showed significantly lower probability of turning compared to WT or HOM mice ($p<0.05$) and the effect was age-related, suggesting that age may underlie behavioral inflexibility in HET mice. Striatal LFP activity in the maze was also differentially related to genotype. Power spectral density analysis showed an increase in theta frequency (4-7 Hz) in HOM mice compared to HET and WT in the 1s before entry into the choice point, while an increase in delta frequency (1-4 Hz) was found in HET mice compared to WT or HOM in the 1s after the turning decision. Together, these data suggest that the Q175 HD model not only shows age-related deficits in motor performance, but also modulation of striatal LFP activity in relation to turning choice in the plus maze. Title: Role of p75 neurotrophin receptor in the Q175 mouse model of Huntington's disease

Authors: *A. WEHNER[1], A. MILEN[2], R. L. ALBIN[2], B. A. PIERCHALA[2];
[1]Biol. and Materials Sci., Univ. of Michigan-Ann Arbor, Ann Arbor, MI; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Huntington's disease (HD) is a dominantly-inherited neurodegenerative disorder characterized by a constellation of motor, cognitive, and psychiatric symptoms. Striatal medium spiny neurons (MSNs), one of the most affected populations, are dependent on brain-derived neurotrophic factor (BDNF) anterogradely transported from the cortex for proper function and survival. Recent studies suggest both receptors for BDNF, TrkB and p75, are improperly regulated in striata of HD patients and mouse models of HD. While BDNF-TrkB signaling almost exclusively promotes survival and metabolic function, p75 signaling is able to induce survival or apoptosis depending on the available ligand and associated co-receptor. We investigated the role of p75 in the Q175 knock-in mouse model of HD by examining the level and activation of various downstream signaling molecules, as well as receptor components and effectors that associate with p75. Additionally, we examined these same signaling pathways and histopathological changes in $Q175^{WT/WT};p75^{+/+}$, $Q175^{WT/HD};p75^{+/+}$, $Q175^{WT/HD};p75^{-/-}$, and $Q175^{WT/WT};p75^{-/-}$ mice to determine if p75 and/or TrkB represent promising therapeutic targets. In $Q175^{WT/HD};p75^{+/+}$, we see an increase in activation of both Akt and NFkB in the striatum at 5 months of age compared to $Q175^{WT/WT};p75^{+/+}$, and this increase is lost in $Q175^{WT/HD};p75^{-/-}$. We see no change in activation of apoptotic pathway signaling at 5 months of age in any genotype examined. Additionally, $Q175^{WT/HD};p75^{-/-}$ show a marked decrease in DARPP-32 expression in the striatum both by western at 5 months of age and by immunohistochemistry at 7 months of age. This decrease is not seen in $Q175^{WT/HD};p75^{+/+}$. Our data suggest that p75 may play an early role in augmenting pro-survival signaling during striatal development, and disruption of this signaling may exacerbate pathology in Q175 mice.

Title: Abnormalities in the dendritic branching of cholinergic interneurons and their thalamostriatal input in the Q140 knock-in mouse model of Huntington's disease

Authors: *Y. DENG, A. REINER;
Univ. of Tennessee HSC, Memphis, TN

Abstract: Premanifest HD individuals are mildly impaired in the initiation and/or execution of motor tasks. The basis of these symptoms is uncertain, as little or no neuron loss in the motor striatum has been reported in premanifest HD. Loss of cerebral and striatal white matter and reduced striatal activation during behavioral tasks has been reported, suggesting that input loss may contribute to early symptoms. In a prior study, we found that thalamostriatal axodendritic terminals are lost as early as 1 month of age in heterozygous premanifest Q140 HD mice, i.e. prior to striatal neuron loss (Deng et al., Neurobiol Dis 2013). As cholinergic interneurons are a prominent target of thalamic axodendritic terminals, we examined the thalamic input to striatal cholinergic interneurons in heterozygous Q140 males at 1 and 4 month. We used VGLUT2 immunolabeling to identify thalamostriatal terminals, and choline acetyltransferase (ChAT) immunolabeling to identify cholinergic interneurons. Stereological neuron counts showed that cholinergic perikarya were normal in abundance in Q140 mice, while Sholl Analysis revealed that their dendritic arborizations were fewer and their dendritic length was significantly decreased. Consistent with the LM evidence of dendritic arbor loss, EM analysis revealed that the abundance of ChAT+ dendritic profiles per unit area was also decreased significantly in Q140 striata. EM double-label studies showed that the abundance of VGLUT2+ axodendritic terminals making synaptic contact with ChAT+ dendrites per unit area of striatum was decreased by 40% in Q140 mice at 1 and 4 months. The loss of dendritic territory was commensurate with the overall loss of thalamic terminals on cholinergic dendrites. Thus, the density of the thalamic input to cholinergic neurons was largely unaltered in Q140 mice, although the number of terminals having input to any one neuron appeared to be less. These changes in thalamic input to striatal cholinergic interneurons may yield reduced excitatory drive to them. Physiological data on the influence of cholinergic interneurons on striatal direct versus indirect pathway neurons suggest this deficiency could contribute to early motor abnormalities (Smith et al., J Neurosci 2011).

Title: A small molecule p75 neurotrophin receptor ligand reduces Huntington's disease phenotypes in R6/2 and BACHD mice

Authors: *D. A. SIMMONS[1], N. P. BELICHENKO[1], S. SEMAAN[1], E. FORD[1], M. MONBUREAU[2], S. AIYASWAMY[1], C. M. HOLMAN[1], C. CONDON[1], M. SHAMLOO[2], S. M. MASSA[3,4], F. M. LONGO[1];

Abstract: Huntington's Disease (HD) is caused by an expanded polyglutamine tract in the huntingtin protein. Mutant huntingtin triggers numerous degenerative processes including loss of neurotrophic signaling, primarily attributed to reduced brain-derived neurotrophic factor (BDNF) signaling via its TrkB receptor, and increased deleterious signaling, to which the p75 neurotrophin (NTR) receptor contributes importantly. p75NTR signaling can be initiated by neurotrophins, including BDNF, and can foster either death or survival depending on the cellular context and presence of Trk receptors. Striatal p75NTR is increased while TrkB receptors are decreased in HD patients and mice and this skewed ratio was shown to up-regulate p75NTR's degenerative signaling. This increased p75NTR signaling has been shown to mediate the structural and functional synaptic plasticity deficits in HD. Thus, p75NTR is an enticing therapeutic target for HD, especially if its degenerative signaling is inhibited while its pro-survival signaling is increased. These desired effects are produced by a first-in-class small molecule p75NTR ligand, LM11A-31, developed in our laboratories. To evaluate the effectiveness of LM11A-31 against HD-related behavioral deficits and neuropathology, we administered LM11A-31 (50 mg/kg, oral gavage, once daily, 5-6 days/week) to R6/2 and BACHD mice. LM11A-31 restored striatal Akt signaling while normalizing increased PTEN, reduced the area and/or number of huntingtin aggregates in the striatum, cortex and hippocampus, and extended the survival of R6/2 mice by 18% compared to those given vehicle. The compound decreased inflammation in the striatum of both R6/2 and BACHD mice and reduced deficits in dendritic spine density of striatal medium spiny neurons and hippocampal CA1 pyramidal neurons. R6/2 mice treated with LM11A-31 showed improvements in motor behavior in an activity chamber and in their home cage. Furthermore, gait disturbances, anxiety-like behavior, and deficits in associative learning and memory were ameliorated by LM11A-31 treatment in BACHD mice. Taken together these results provide the first validation that p75NTR, a receptor critically positioned in survival and neurodegenerative signaling, might serve as an effective therapeutic target for HD. LM11A-31 has successfully completed Phase I safety and pharmacokinetic clinical trials in normal subjects and is therefore a viable candidate for HD clinical testing.

Title: Retinal degeneration in Huntington's disease

Authors: *M.-S. LIN[1,2], Y. CHERN[1,2];
[1]Inst. of Biomed. Science, Academia Sinica, Taipei City, Taiwan; [2]Natl. Yang Ming Uinervisity, Taipei City, Taiwan

Abstract: Huntington’s disease (HD) is the neurodegenerative disease resulted from abnormal CAG-expended Huntingtin (htt) gene. The accumulation of mutant Huntingtin protein (mHTT) is associated with neuronal death in the striatum and cortex, and subsequently give rise to multiple syndromes including motor dysfunction, and cognitive and memory impairment. Besides the impairment in the brain, HD-related pathology in the retina is less investigated and understood. Retinal dysfunction and synaptic remodeling were reported earlier in a HD mouse model (R6/1). However, the major type of retinal neurons affected by mHTT during disease progression, and the underlying pathway for such retinal dysfunction in HD remains unclear. In the present study, longitudinal changes of photosensitive neurons (the Rod and cone photoreceptors and the intrinsically photosensitive retinal ganglion cells) and non-photosensitive interneurons were observed. We also characterized the possible involvement of several important transcription factors in the retinal gene regulatory network using a HD mouse model (R6/2). Our results showed that at the late stage of HD (12 weeks old), the expression of rhodopsin was relocated to rod photoreceptor cytosol in the outer nuclear layer (ONL). Progressive decreases in the transcripts of rhodopsin and rod arrestin were also observed. Importantly, cone photoreceptors developed a more severe and earlier degenerative phenotype than rod photoreceptors. The level of S-opsin, M-opsin, and cone arrestin transcripts were down-regulated earlier than rod genes during disease progression. Besides photoreceptor, Brn3a(+) RGCs and rod bipolar cells was slightly affected in R6/2 retina. Interestingly, CRX, Nrl, Nr2e3 and TRβ2, important

transcription factors for photoreceptor differentiation, are progressive decreased in R6/2 retina compared to other transcription factors related to late cell fate determined. Collectively, we demonstrated that the photosensitive neurons are vulnerable to the expression of HD, and dysregulation of gene-regulatory network may attribute to this retinal neuropathy of HD.

Title: Investigating behavior-related changes in striatal firing patterns in the Q175 knock-in mouse model of Huntington's disease

Authors: ***K. D. BUNNER**[1], C. RANGEL-BARAJAS[2], B. M. MCCORMICK[2], S. J. BARTON[2], G. V. REBEC[2];

Abstract: Huntington's disease (HD) is a genetically inherited neurodegenerative disorder characterized by progressively worsening cognitive, emotional and motor symptoms. While the mutated huntingtin protein is found throughout the brain, the main neuropathology involves the dorsal striatum and cerebral cortex. Several animal models have been developed to improve our understanding of HD progression, and each animal model has a different neurological time course making it important to determine behavioral as well as neuronal changes corresponding to the early and/ or late stages of the disease. In this study, nest-building and open-field behavior were assessed in both homozygous (HOM) and heterozygous (HET) Q175 mice compared to wild-type (WT) controls. Nest building was assessed weekly and open field was assessed monthly starting at 28-30 weeks of age. Both the amount of building materials used and quality of the nest was significantly decreased in HOM and HET mice compared to WT controls, with HETs occupying an intermediate position. In the open field, HOMs were significantly less active than HETs as well as WT controls. Chronically implanted micro-wire bundles were used to make simultaneous assessments of open-field spiking patterns in dorsal striatum. We found a significant decrease in burst firing in both HOMs and HETs relative to WT. Our results indicate an age-related progression of multiple neurobehavioral signs in the Q175 model that parallel our findings in both truncated (R6/2) and full-length (YAC and BACHD) mouse models of HD. Moreover, preliminary analysis of our age-progression data in HET mice indicate a change in

striatal electrophysiology before overt symptom expression, suggesting that striatal dysfunction may precede onset of the subsequent behavioral phenotype.

Title: Respiratory activity and calcium uptake capacity in brain mitochondria from R6/2 mice, a model of Huntington's disease

Authors: *J. HAMILTON[1], J. J. PELLMAN[1], T. BRUSTOVETSKY[1], N. BRUSTOVETSKY[1,2];

Abstract: Huntington's disease (HD) is a hereditary neurodegenerative disorder characterized by severe motor and cognitive abnormalities. HD pathogenesis is linked to a mutation in a protein called huntingtin that is normally involved in developmental processes. In healthy individuals, the N-terminus of huntingtin possesses a polyglutamine stretch containing less than 35 glutamines. The mutant huntingtin (mHtt) protein has an elongated polyglutamine stretch at the N-terminus that correlates with the development of HD. The mechanism by which mHtt causes HD is unknown. Some investigators previously reported that mHtt suppresses mitochondrial respiratory activity and decreases mitochondrial Ca2+ uptake capacity. However, other investigators have found neither an impairment in respiration of isolated mitochondria and neurons derived from HD mice nor a decrease in Ca2+ uptake capacity in mitochondria isolated from the brains of HD mice. In the present study, we investigated the effect of mHtt fragments containing a 160 glutamine stretch on respiration and Ca2+ uptake capacity of mitochondria isolated from R6/2 mice, a model of HD. To confirm the presence of the elongated polyglutamine stretch in mHtt fragments, we genotyped every mouse. We evaluated respiratory activity in isolated, purified synaptic and non-synaptic brain mitochondria from 6-8 week old, symptomatic R6/2 mice and age-matched wild-type (WT) mice. We also investigated the effect of mHtt fragments on Ca2+ uptake capacity in synaptic and non-synaptic brain mitochondria isolated from R6/2 mice and WT littermates. In addition, we evaluated respiration in cultured striatal neurons derived from postnatal day 1 R6/2 mice and their WT littermates using Seahorse

XF24 flux analyzer. Mitochondrial Ca2+ accumulation was also assessed in cultured striatal neurons from R6/2 mice and their WT littermates. This has been done by evaluating FCCP-stimulated release of mitochondrial Ca2+ into the cytosol following Ca2+ loading into mitochondria during glutamate-induced increase in cytosolic Ca2+. In experiments with isolated mitochondria, we found no difference in respiratory activity and Ca2+ uptake capacity between mitochondria from R6/2 mice and WT animals. Experiments with cultured striatal neurons demonstrated similar respiratory activity and mitochondrial Ca2+ accumulation comparing neurons derived from R6/2 and WT mice. Thus, our data do not support mHtt-mediated impairment of mitochondrial respiratory activity and Ca2+ uptake capacity assessed either in isolated brain mitochondria or in cultured striatal neurons from R6/2 mice.

Abstract: Glial pathology has been noted to contribute to a broad set of neurodegenerative and neuropsychiatric diseases traditionally considered disorders of solely neuronal dysfunction. Huntington's Disease is a prototypic neurodegenerative disorder, characterized by abnormally long CAG repeat expansions in the first exon of the Huntingtin gene. To define the contribution of glial pathology to Huntington's disease (HD), we established human HD glial chimeras by neonatally engrafting the striata of immunodeficient mice with mutant huntingtin (mHTT)-expressing glial progenitor cells (GPCs), derived from huntingtin mutant human embryonic stem

cells (hESC) or mHTT-transduced human forebrain hGPCs. Mice engrafted with mHTT-expressing (48Q) hESC GPCs manifested significantly worse motor performance than controls chimerized with normal (18Q) hESC GPCs. To assess the basis for this effect, we established human glial chimeras using human fetal striatal GPCs transduced to express the first exon of mutant HTT (73Q and 23Q), and patch-clamped local medium spiny neurons (MSNs). MSNs in the mHTT glial environment manifested higher input resistance, less frequent spontaneous EPSPs, and lower excitation thresholds than those resident with normal (23Q) HTT-transduced glia. We then asked if the converse manipulation, engraftment of normal glia into an HD environment, might slow disease progression in R6/2 (120Q) HD mice. R6/2 mice engrafted with normal hGPCs survived longer than unengrafted R6/2s, and manifested slower motor deterioration, while their MSNs exhibited lower input resistance, more frequent spontaneous EPSPs, and were less excitable. Furthermore, whereas R6/2 mice manifested abnormally high levels of interstitial potassium, chimerization with normal glia restored striatal potassium levels to near normal. These observations suggest a causal role for glia in HD, and indicate that the colonization of diseased striata with wild-type glia may slow disease progression.

Title: Nucleus accumbens dopamine release and motivated behavior are compromised in the Q175 mouse model of Huntington’s disease

Authors: *D. P. COVEY[1], H. M. DANTRASSY[2], I. GILDISH[2], J. F. CHEER[2,3];
[2]Anat. and Neurobio., [3]Psychiatry, [1]Univ. of Maryland, Baltimore, MD

Abstract: Huntington’s disease (HD) is a fatal, neurodegenerative disease caused by a mutation in the HTT gene. Motor abnormalities, including chorea, akinesia and dystonia, represent the classic symptoms that characterize HD. Additionally, cognitive and emotional disturbances affecting memory, attention, executive function and mood are commonly described non-motor symptoms and these may present early in disease progression before the onset of motor abnormalities. Imaging studies in humans and measures of dopamine release in animal HD

models indicate disrupted striatal dopaminergic function as a common manifestation of HD that may precede motor deficits. However, a direct association between compromised but temporally resolved dopamine release measurements and behavior in HD is lacking. Here, we assessed alterations in dopamine release and reward seeking in the heterozygous Q175(+/-) knock-in mouse HD model. Dopamine was monitored in the nucleus accumbens using fast-scan cyclic voltammetry while mice lever pressed for sucrose reward on a fixed interval (FI) 30 s and progressive-ratio (PR) schedule to assess timing and motivation, respectively. Both strains of mice showed similar patterns of responding on the FI task, indicating that timing is not disrupted in this mouse HD model. However, Q175(+/-) mice displayed significantly lower breakpoints on the PR task relative to wild-type controls. Impaired motivation was associated with a decrease in the peak dopamine signal evoked by reward receipt. Genotypic differences in dopamine release increased as trials progressed and cost increased and were significantly different during the final trials of the PR session as animals reached their breakpoint. Moreover, while a strong correlation was observed between peak reward-evoked dopamine release and breakpoint in wild-type controls, no correlation was observed in Q175(+/-) mice, indicating that lower levels of subsecond dopaminergic activity accompany the pursuit of reward. These findings indicate that compromised transduction at dopamine receptors in the nucleus accumbens may contribute to cognitive behavioral deficits, particularly decreased motivation that are commonly observed in HD prior to phenoconversion.

Title: Further evidence of defective sphingolipid metabolism across multiple HD animal models*

Authors: A. DI PARDO, E. AMICO, M. FAVELLATO, S. SCIACCA, F. SQUITIERI, *V. MAGLIONE;
IRCCS Neuromed, Pozzilli, Italy

Abstract: Huntington's disease (HD), the most common dominantly inherited neurodegenerative disorder affecting an estimated 3 to 7 per 100000 people, is characterized by the progressive striatal and cortical neurodegeneration and associated motor, cognitive and behavioral disturbances. The disease causing mutation is an expansion of CAG trinucleotide repeats (>36

repeats) encoding a polyglutamine (polyQ) stretch in N-terminal region of huntingtin (Htt), a ubiquitous protein whose function is still unclear. Expansion of the polyQ stretch endows mutant Htt (mHtt) with toxic properties and results in the development of a broad array of cell dysfunctions including dysregulation of gene expression, reduced synthesis and release of neurotrophins (i.e. BDNF) as well as impaired lipid homeostasis. We have recently demonstrated that metabolism of sphingolipids (gangliosides) is impaired in HD and seems to play a critical role in the susceptibility of neuronal cell to apoptosis. Defective sphingolipid metabolism has been reported also in different other neurodegenerative conditions like Alzheimer and Parkinson diseases supporting the hypothesis that sphingolipid alterations may be critical in the pathogenesis of the neurodegenerative disorders. In this study we investigated the content of different sphingolipids and the expression of some sphingolipid metabolic enzymes in multiple brain area of two different HD animal models. Our findings consolidate and extended the evidence that sphingolipid metabolism is aberrant in multiple HD models. Importantly, we also showed that defects in lipid homeostasis, in particular reduced levels of gangliosides, are detected early in the disease even before any sign of pathology appears in both animal models. Collectively our data clearly suggest that defective sphingolipid metabolism might potentially represent the molecular basis of severe structural and functional alterations normally associated with the disease.

Title: Decrease in maximal, not basal, CMRO2 in R6/2 mouse model of Huntington's disease by ultra-high field 17O magnetic resonance spectroscopy

Authors: ***J. M. DUBINSKY**[1], S. LOU[2], T. LEPAK[2], W. CUI[3], X.-H. ZHU[3], G. OZ[3];
[1]Dept Neursci, [2]Neurosci., [3]Ctr. for Magnetic Resonance Res., Univ. of Minnesota, Minneapolis, MN

Abstract: *In vivo* evidence for brain mitochondrial dysfunction in animal models of HD is scarce. We used the novel 17O magnetic resonance spectroscopy (MRS) technique on R6/2 mice to directly determine rates of oxygen consumption (CMRO2) and mitochondrial function *in vivo*. Maximal CMRO2-max, represents the maximum flux through all of metabolism, from glucose

through electron transport. *In vitro*, maximal respiration is proportional to the concentration of cytochrome oxidase in electron transport and can be used as a measure of mitochondrial capacity. We compared *in vivo* basal and maximal CMRO2 in the presence of dinitrophenol (DNP), using 16.4 T 17O MRS in male HD mice and littermates at 9wk. In addition, we examined the amount respiration decreased in the presence of oligomycin to block oxidative phosphorylation. Utilizing 17O MRS (Cui et al, 2013 JCBFM), the basal oxygen consumption rate did not differ between isoflurane anesthetized R6/2 mice and littermates. At rest, striatal CMRO2-basal of R6/2 mice was 2.49±0.35 μmol/g/min (mean ± stdev, N=9), while that of littermates was 2.67±0.33 μmol/g/min (N=10), indicating comparable mitochondrial output despite onset of motor symptoms in R6/2. CMRO2-max was tested 10 min after systemic injection of DNP, an uncoupler that shunts the proton electrochemical gradient producing maximal mitochondrial respiration. After DNP injection, the maximal CMRO2 in both striatum and cortex of R6/2 mice was significantly lower than that of control mice, indicating a lower spare energy generating capacity. In a separate set of mice, oligomycin injection decreased CMRO2 equally in brains of R6/2 and wild type mice, suggesting oxidative phosphorylation capacity was equivalent at rest. When examining expression levels of representative mitochondrial proteins from *ex vivo* tissue samples, VDAC/actin was significantly higher in striatum than in cortex in WT mice, but not in R6/2. No significant differences were observed in individual electron transport protein expression with respect to VDAC or actin, although trends were noted. A similar pattern was observed for regional differences in cytochrome oxidase activity, with striatal activity exceeding cortical activity in wild type, but not R6/2. In determinations of total oxidized regional proteins by Oxyblot, R6/2 cortical protein oxidation may exceed that of wild type. Together, these data suggest that the R6/2 decrease in striatal CMRO2 may be attributed to a decrease in mitochondria or mitochondrial function and that the cortical CMRO2 decrease may result from constraints upstream in energetic pathways.

Abstract: Glucose metabolism is reduced in the brains of patients with Huntington disease (HD). The mechanisms underlying this deficit, its link to the pathology of the disease, and the vulnerability of the striatum in HD remain unknown. Abnormalities in some of the key mitochondrial enzymes involved in glucose metabolism, including the pyruvate dehydrogenase complex (PDHC) and the tricarboxylic acid (TCA) cycle, may contribute to these deficits. Here, activities for these enzymes and select protein levels were measured in human postmortem cortex and in striatum and cortex of an HD mouse model (Q175); mRNA levels encoding for these enzymes were also measured in the Q175 mouse cortex. The activities of PDHC and nearly all of the TCA cycle enzymes were dramatically lower (-50% to 90%) in humans than in mice. The activity of succinate dehydrogenase increased with HD in human (35%) and mouse (223%) cortex. No other changes were detected in the HD cortex or mouse striatum. In Q175 cortex, there were increased activities of PDHC (+12%) and aconitase (+32%). Increase mRNA levels for succinyl thiokinase (+88%) and isocitrate dehydrogenase (+64%) suggested an upregulation of the TCA cycle. These patterns of change differ from those reported in other diseases, which may offer unique metabolic therapeutic opportunities for HD patients.

Abstract: Abnormalities in mitochondrial function and metabolism are a recurring feature in a wide range of neurodegenerative disorders. Diseases in which these alterations have been documented include diseases caused by the misfolding of proteins with expanded polyglutamine (polyQ) tracts, which include nine known inherited neurological disorders, including Huntington's disease (HD). These disorders are thought to cause neurodegeneration through the toxic-gain-of function of the abnormal protein, and disease severity is closely linked to the number of glutamine repeats. We and others have shown that maintenance of mitochondrial fitness attenuates polyQ-induced proteotoxicity and have shown evidence that suggests that human huntingtin exon 1 gene fragments expressing 103 repeats of polyQ (hHttExQ103) associates with the mitochondrial outer membrane causing mitochondrial dysfunction. However, the complex interplay between mitochondrial function, polyQ toxicity, and disease progression remains to be fully understood. To investigate these questions in a simple setting we have created yeast models of polyQ diseases that allow for the induced expression of specific toxic proteins during yeast chronological lifespan (CLS), a model of neuronal aging. Our results show that in these models, toxicity is significantly attenuated by the enhancement of mitochondrial biogenesis by protecting cellular oxidative phosphorylation (OXPHOS) without altering polyQ oligomerization. Toxicity is also attenuated by caloric restriction, which increases mitochondrial respiration and resistance to stress. To confirm these results in a multicellular organism, we have used a *Drosophila* model of Huntington's disease created by overexpressing exon 1 of the human huntingtin gene (hHttExQ93) with 93 repeats of polyQ. In these models, enhancement of mitochondrial biogenesis by overexpression of DmPGC-1/spargel in the nervous system with a pan-neuronal driver significantly reduced neuronal apoptosis and improved climbing performance at all ages. We have also found similar results in human neuronal stem cells derived from human HD-patient fibroblasts. Our results suggest that therapeutic approaches protecting mitochondrial respiration could reduce polyQ toxicity and delay the development of clinical symptoms in patients.

Title: Genome-wide DNA methylation in mouse models of Huntington's disease: impact of super-enriched environment

Authors: *J.-Y. HWANG[1], M. SUZUKI[2], K.-M. NOH[1], B. L. COURT VAZQUEZ[1], J. M. GREALLY[3], R. S. ZUKIN[1];

Abstract: Huntington's disease (HD) is an inherited, late onset neurodegenerative disorder characterized by progressive motor, psychiatric and cognitive decline. Marked neuronal loss occurs in the cortex and striatum. HD is caused by a polyglutamine (CAG) expansion in the 5' coding region of the gene encoding huntingtin. Environmental enrichment has been shown to delay the onset and progression of motor symptoms and to improve neurological function and cognitive performance in animal models of HD. Epigenetic modifications such as DNA methylation and histone modification are critical to genome reprogramming during brain development, tissue-specific gene expression and global gene silencing in adult mice. Recent findings implicate epigenetic modifications in the progressive neurodegeneration associated with a number of brain diseases. However, the impact of enriched environment on DNA methylation in a transgenic mouse model of HD is, as yet, unclear. Here we show the impact of enriched environment on DNA cytosine methylation in the striatum of R6/2 mice by means of an unbiased, genome-wide screen for abnormal DNA methylation using HELP-tagging, a next generation, quantitative DNA methylation assay. HD and wild-type mice were reared in either a stark or super-enriched environment. Under conditions of stark environment, DNA methylation in the striatum of HD mice was modestly increased relative to that of wild-type littermates. In contrast, striatal DNA from HD mice exposed to a super-enriched environment exhibited overall hypomethylation vs. wild-type mice reared in the same conditions. Bioinformatic analysis reveals that genes exhibiting hypomethylation include those involved in synaptic function and plasticity and/or brain development. We predict that identification of genes and gene networks with altered DNA methylation status in HD will help identify novel targets for therapeutic intervention and accelerate development of novel therapeutic strategies to ameliorate motor and cognitive deficits associated with this debilitating and devastating disease.

Title: Imaging intrinsic connectivity networks in a full-length huntingtin knock-in mouse model

Authors: *T. REN, SR[1,2], H. LU[6], Q. LI[3], P. QI[2], J. ZHANG[3], Y. YANG[6], W. DUAN[2,4,5]; [1]Emergency, Beijing Tiantan Hosp. Capital Med. Universit, Beijing, China; [2]Div. of Neurobiology, Dept. of Psychiatry & Behavioral Sci., [3]Radiology,, [4]Neurosci., [5]Program in Cell. and Mol. Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [6]Neuroimaging Res. Br., Natl. Inst. on Drug Abuse, NIH, Baltimore, MD

Abstract: Huntington's disease (HD) is an autosomal dominant neurodegenerative disease, which results in progressive neuronal degeneration in the neostriatum and neocortex, and associated functional impairments in motor, cognitive, and psychiatric domains. To date, proven neuroprotective strategies remain elusive although there has been a rapid progress in the understanding of the pathogenetic mechanisms. Part of the problem has been that most of the trials have attempted intervening at a time when the degenerative process is already far advanced and hence when it would be difficult even for the most effective therapy to demonstrate any benefit. Through genetic testing, people who will ultimately develop HD can be identified before clinical onset, raising the possibility of initiating therapy in this prodromal period to delay or prevent disease onset. In order to accurately assess the effectiveness of disease-modifying therapies in a group of clinically normal HD carriers, biomarkers that reflect the early cell dysfunction have become of paramount importance. Resting state functional MRI (RS-fMRI) constitutes a novel paradigm that examines spontaneous brain activity in the absence of task, and it enables us to investigate the functional connectivity between brain regions. We conducted a preliminary RS-fMRI functional connectivity study of a full-length huntingtin knock-in mouse model. Independent component analysis of RS-fMRI data identified spatially consistent brain networks in mice as those reported in rats. Further seed-based functional connectivity analysis demonstrated altered network-related activity in selected areas of the default mode network in HD mice, such as reduced connectivity between motor cortex and striatum, as well as between anterior cingulate cortex and thalamus. These preliminary results suggest that a specific subset of brain networks is altered in these HD mice, and encourage further investigation on whether the resting state network changes are representing effects of ongoing neurodegeneration, and whether the altered resting state networks are correlated with behavioral abnormality and synaptic dysfunction in HD. These results, if confirmed with a large cohort of mice, could

potentially provide insights into elucidating the cellular mechanisms responsible for perturbed brain network connectivity, as well as evaluating potential therapeutic interventions in HD.

Title: Loss of the Huntington's disease-associated palmitoylacyltransferase HIP14 in adulthood leads to death due to progressive paralysis and seizures, motor and psychiatric disturbances, and astrogliosis and microglial activation

Authors: *S. S. SANDERS[1], M. P. PARSONS[2], A. L. SOUTHWELL[1], K. K. N. MUI[1], S. FRANCIOSI[1], L. A. RAYMOND[2], M. R. HAYDEN[2];

Abstract: Huntington disease (HD) is caused by a CAG expansion in *HTT* and is characterized by striatal atrophy and motor, cognitive, and psychiatric symptoms. The interaction between mutant HTT and HIP14 (zDHHC17), a palmitoyl acyltransferase for HTT, is disturbed, resulting in reduced palmitoylation of HTT and other HIP14 substrates. *Hip14*-deficient mice recapitulate many features of HD, including striatal atrophy and motor deficits. However, the phenotype is developmental, unlike in HD mice and patients. A model of post-developmental loss of HIP14 was generated to examine the role of HIP14 in neurological deficits and neurodegeneration. This mouse model allows for highly efficient *Hip14* deletion upon tamoxifen administration at 6-weeks of age ($iHip14^{\Delta/\Delta}$). $iHip14^{\Delta/\Delta}$ mice show dramatically reduced survival due to progressive paralysis and seizures beginning 10 weeks after loss of *Hip14.* At 3 months (~7 weeks after loss of *Hip14*) $iHip14^{\Delta/\Delta}$ mice have motor deficits, anhedonia, and increased escape response.

Electrophysiological analysis suggests that *iHip14*$^{\Delta/\Delta}$ mice have striatal dysfunction and an imbalance between excitatory and inhibitory synapses in the hippocampus. *iHip14*$^{\Delta/\Delta}$ mice have increased cortical volume due to early and very striking astrogliosis and microglial activation suggesting a novel role for HIP14 in glial cells. Interestingly, mice deficient in any one of the following palmitoylated HIP14 interacting proteins or HD-related proteins have similar phenotypes to *iHip14*$^{\Delta/\Delta}$ mice: CSP, GLUA2 Q/R editing, KCNMA1, SLC1A3, and Kir4.1. The palmitoylation levels of these proteins will be assessed in *iHip14*$^{\Delta/\Delta}$ mice. This indicates that loss of *Hip14* from conception allows for developmental compensation that cannot take place if *Hip14* deficiency occurs in the adult.

Title: Investigating the effects of conditional caspase-6 deficiency on the YAC128 mouse model of Huntington's disease

Authors: *S. LADHA, D. E. EHRNHOEFER, B. K. Y. WONG, P. RUDDLE, Q. XIA, Y. DENG, D. CHEUNG, S. FRANCIOSI, M. R. HAYDEN;
Univ. of British Columbia, Ctr. For Molecul, Vancouver, BC, Canada

Abstract: Huntington disease (HD) is an autosomal dominant neurodegenerative disorder characterized by motor, cognitive, and psychiatric symptoms. HD is caused by a CAG repeat expansion in the huntingtin (HTT) gene resulting in the production of mutant huntingtin (mHTT). Caspase-6 is a cysteine aspartyl protease that plays a central role in apoptosis and has been implicated in several neurodegenerative diseases. Increased caspase-6 activation is observed in early grade human HD brains and in mouse models of HD and our lab has previously demonstrated that inhibiting caspase-6-mediated cleavage of mutant huntingtin protects against neuropathology and behavioural deficits in a mouse model of HD. Constitutive genetic ablation of caspase-6 in the YAC128 mouse model of HD results in a partial rescue of some features of HD; however, the continued presence of the 586 fragment suggests possible

developmental reprogramming and compensation for caspase-6 function. In order to circumvent this, we are investigating the effects of the genetic loss of caspase-6 in adulthood on the pathogenesis of HD, a strategy that more closely mimics a clinical therapy. To that end, we have created an inducible caspase-6 knockout/YAC128 mouse using the Cre-loxP recombination system. Knockout was induced in male and female mice at six weeks of age by daily intraperitoneal injections of 100mg/kg of tamoxifen for 19 days. This treatment paradigm results in ~50% loss of caspase-6 in the brain and 95-100% loss of caspase-6 in the peripheral tissues. Behavioural characterization of these mice reveals no change in rotarod performance but a delay in the climbing deficit and an improvement in the anxiety phenotype as assessed by the elevated plus maze. Neuropathological assessement shows no differences in striatal volume loss and a significant reduction in corpus callosum volume in mice lacking caspase-6 compared to YAC128 controls. Peripherally, the complete loss of caspase-6 attenuates the overactive inflammatory response observed in YAC128 mice and delays body weight gain. These data suggest that partial loss of caspase-6 in the brain is not sufficient to improve most behavioural and neuropathological phenotypes; however, an assessment of peripheral phenotypes following complete loss of caspase-6 in non-CNS tissues points to an important role for caspase-6 in mediating peripheral inflammation and body weight gain in HD.

Abstract: Hypertension arterial (HTA) is a main risk factor for development cardiovascular disease, cerebrovascular disease and renal failure, which are considered a public health. Reports

indicate that HTA can damage the brain, inducing a brain vascular disease associated with cerebral ischemia in patients at long-term. Consequently this may affect cognitive functions. The cerebrovascular disease affect the functioning of the limbic system, which regulates different both motor and cognitive functions. Besides several reports suggests that prefrontal cortex (PFC) and hippocampus play an important role in the development of the processes of learning and memory. Recent studies indicate that in a model of HTA, which is the spontaneously hypertensive rat (SH), there are some alteration in the dendritic morphology in brain regions such as PFC and hippocampus CA1. This is due to the release of free radicals associated with endothelial damage that induce the development of oxidative stress, which is responsible for neuronal death. It is suggested that the use of antioxidants such as resveratrol, may help prevent oxidative stress and this neuronal damage in a process of HTA, however, this is not yet clear. The aim was to evaluate the effect of administration of resveratrol on the dendritic morphology of the prefrontal cortex and hippocampus of spontaneously hypertensive rats. We use SH male rats of 15 months, which were administered orally with resveratrol (50mg/Kg/day) during 8 weeks. After the brain was removed and processed for Golgi-Cox stain method, to perform morphological analysis of the PFC (layer III and V) and dorsal hippocampal CA1 region. The results of neuronal morphological analysis in PFC and dorsal hippocampus show a neuroprotective effect that prevents alterations induced by HTA, through promote an increase in the dendritic tree for some areas analyzed. The most obvious increase was observed in the dendritic length in PFC; layer III and V, and dorsal hippocampus CA1 region and dentate gyrus. This suggest that resveratrol exerts a neuroprotective effect against the alterations caused by the chronic course of the HTA. (Supported by: CONACyT grants No. 138663 and 129303 to G Flores).

Title: Interfering with progranulin degradation to combat frontotemporal dementia

Authors: *X. ZHOU, Y. WEN, E. GIBBS, W. JIA, M. S. CYNADER;
UBC hospital, Brain Res. Ctr. Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Mutations in progranulin (PGRN) have been found to be a common cause of familial FTLD and the major cause of FTLD with tau-negative ubiquitin positive inclusions. Most mutations result in decreased PGRN expression and PGRN haplo-insufficiency is strongly

associated with FTLD. Sortilin (SORT1), a member of vacuolar-protein-sorting-10-protein (VPS10) family, recently has been found to be a PGRN binding partner. When PGRN binds to the SORT1 receptor, it is rapidly endocytosed and transported to lysosomes for degradation (Hu et al. 2010). Overexpression of SORT1 in cultured HeLa cells dramatically reduces PGRN levels in conditioned media, whereas knockdown of SORT1 increased extracellular PGRN levels. This SORT1 mediated PGRN level increase was also observed in SORT1 knockout mice(Hu et al. 2010). Thus, SORT1-mediated PGRN endocytosis is likely to play a central role in FTLD-TDP pathophysiology. Rather than knocking-out SORT1, we are using small interference peptides to block PGRN binding to the SORT1 receptor on this rapid degradation pathway in order to maintain extracellular PGRN levels. Our preliminary studies using peptide arrays has shown that PGRN can bind to multiple sites on SORT1. Based on the potential binding sites, we generated several deleted mutations of SORT1. To determine the critical PGRN binding domains on SORT1, we used Biacore to analyse real-time binding affinity between those mutants SORT1 with PGRN. Interestingly, one of the binding sites is located in the same domain bound by other pro-neurotrophins such as pro-BDNF and pro-NGF. We speculate that binding of PGRN to SORT1 may prevent apoptosis induced by pro-NTs, through competitive binding. This speculation may explain the requirement of certain levels of PGRN to maintain a healthy brain. Here, we aim to define PGRN binding sites on SORT1, assess the role of this complex in cell death, and create peptide antagonists to block the PGRN- SORT1 interaction as a therapeutic strategy to raise PGRN levels in FTLD.

Title: Pick's disease: characterization of pathology with diverse stains

Authors: *J. BAUN, S. HUTCHINGS, J. BALLARD, C. ZURHELLEN, B. TIPTON, J. KIEFFER, R. C. SWITZER, III;
Neurosci. Associates, Knoxville, TN

Abstract: Pick's Disease (PiD) is a neurodegenerative disease characterized by neuronal cell death in the frontal and temporal lobes of the brain. Symptoms include dementia, changes and difficulty in speech patterns, and many behavioral indicators including anxiety, confusion, attenuated social abilities and disengagement from friends and family. Onset of the disease usually occurs between the ages of 40 and 60, with the average age of onset being 54. We evaluated the pathology post-mortem in the brain of a 68 year old female using various histological and antibody stains. One of the main indicators of the disease is a buildup of amyloid and tau proteins, which was evaluated using Ab 1-42 and AT8 (respectively) as well as other amyloid and tau markers. Several silver stains were also used to detect abnormal pathology. The Campbell-Switzer method revealed amyloid deposits and plaques, which resembled Alzheimer's (AD) pathology but the plaques were far fewer in number in the PiD brain than an average AD brain. A Silver Protein protocol (Wako, cat#283-90241), a modified Bodian stain, revealed both amyloid plaques and neurofibrillary tangles. Thionine Nissl and H&E stains showed swollen, "ballooned" neurons, one of the hallmark indicators of PiD. A hypertrophied glial state was observed with both GFAP (astrocytes) and Iba1 (microglia). The Perl's/DAB stain for ferric iron positively stained glia, and surprisingly also intensely stained many neurons. This battery of stains on near adjacent tissue sections further characterizes the unique pathology of PiD.

Title: Myocilin protects axons from myelin-associated glycoprotein-induced degeneration

Authors: *S. I. TOMAREV[1], H. S. KWON[1], C. JAWORSKI[2], I.-H. YANG[3];
[1]SRGCB, LRCMB, [2]LRCMB, NEI, NIH, Bethesda, MD; [3]Dept. of Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: *Myocilin* (*MYOC*) gene encodes a secreted glycoprotein. Mutations in *MYOC* may lead to juvenile and adult-onset primary open-angle glaucoma. The main goal of this study was

to elucidate possible role of myocilin in axon growth and degeneration using dorsal root ganglion (DRG) and retinal explant cultures as well as *Myoc* null mice.Sequencing of RNA isolated from 2 month-old optic nerves of wild-type and *Myoc* null mice demonstrated changes in components of the signaling pathway governing axon guidance. Addition of 1 μg/ml of purified myocilin to DRG cultures protected neurites from myelin-associated glycoprotein (MAG)-induced degeneration as well as reduced MAG-stimulated growth cone collapse. The direct physical interaction of myocilin and MAG was demonstrated by co-immunoprecipiatation from mouse optic nerve lysates. This interaction as well as the modulation of RhoA-GTPase level by myocilin may contribute to the protective effects of myocilin. Addition of myocilin to P4 mouse retinal explants similarly protected neurites from MAG-induced degeneration and reduction of neurite length. Myocilin provides protective action through interaction with soma or axons alone as was shown by cultivating DRGs in microfluidic two-compartment chambers. Addition of myocilin to the axonal compartment did not lead to changes in the number of axons or their total length compared with untreated samples, but protected axons from MAG-induced degeneration. Addition of myocilin to the axonal compartment induced changes in the levels of several mRNAs in axons as was shown first by PCR array analysis and confirmed by quantitative RT-PCR. We concluded that myocilin protects axons from MAG-induced degeneration and this protection could be achieved through interaction with axons, soma or both.

Title: Emotion recognition in the behavioral variant of frontotemporal dementia: evidence from error patterns analysis and resting-state brain activity

Authors: *S. F. CAPPA[1,2], N. CANESSA[1,2], A. DODICH[3], C. CERAMI[3], G. LETTIERI[3], C. CRESPI[3], S. IANNACCONE[2], A. MARCONE[2], A. FALINI[3,2], D. PERANI[3,2];
[1]IUSS Pavia, Pavia, Italy; [2]San Raffaele Scientific Inst., Milan, Italy; [3]San Raffaele Univ., Milan, Italy

Abstract: Background and aims: Patients with the behavioral variant of frontotemporal dementia (bvFTD) present pervasive social dysfunctions, including deficits in emotion recognition (Diehl-Schmid et al, 2007). Previous evidence suggests a global deficit in the ability to recognize emotional cues, more pronounced for negative emotions, in these patients. This impairment has been previously associated with structural changes in fronto-temporal and limbic regions (Kumfor et al, 2013). To date no studies have investigated the relationship between emotion recognition abilities and resting state activity, which is also abnormal in bvFTD (Whitwell et al, 2011). Materials and Methods: We administered the Italian version of the Ekman 60-Faces test (Dodich et al., 2014) to 18 bvFTD patients (age=68.7±7.90 years, education=10.94±3.93 years) and 26 healthy controls (57.46±7.96 years, education=13.58±3.74 years). All subjects also underwent a functional magnetic resonance imaging (fMRI) session lasting 10 minutes, during which they lied quietly, awake with eyes closed. We used a group Independent Component Analysis (gICA), implemented in the GIFT toolbox (http://mialab.mrn.org/software/gift/), to analyze the relationship between task performance and resting-state metrics in bvFTD patients vs. controls. Results: Compared to controls, bvFTD patients showed an overall deficit in emotion recognition, as well as higher rate of confusion among negative emotions, highlighted by an error-pattern analysis. Resting-state analyses showed abnormal resting state activity in bvFTD, particularly in the anterior portion of the Default-Mode Network (DMN) and in attentional and executive networks. One of these networks, including the dorsomedial prefrontal cortex, inferior frontal gyrus and amygdala, showed a specific relationship between spectral properties and the ability to recognize negative emotions, with both reduced coherent internal activity and a stronger correlation between activity and performance. Conclusion: The analysis of specific resting-state networks represents an intermediate level of analysis between abnormal brain structure and impaired social abilities in these patients, showing an association between emotion recognition deficits and abnormal brain functioning in fronto-limbic regions.

Abstract: Progressive supranuclear palsy (PSP) is the second most common cause of akinetic-rigid movement disorders, and is characterized by gait disturbance and postural instability with falls, supranuclear vertical gaze palsy, and cognitive dysfunction. PSP is a tauopathy with abnormal accumulation of misfolded tau protein in neurons of the midbrain, basal ganglia, brainstem, and cerebrum, contributing to neuronal loss in these regions. While the causes of PSP are unknown, a recent genome-wide association study in autopsy-proven PSP identified 11 single nucleotide polymorphisms (SNPs) associated with increased risk of PSP. There is also clinical heterogeneity in PSP where recent clinical observations suggest a behavioral overlap with behavioral variant frontotemporal dementia (bvFTD), of which tau is the also the underlying pathology in roughly 40% of bvFTD cases. In this exploratory study we evaluate whether SNPs previously associated with PSP are associated with their behavioral features. We evaluated 41 PSP patients on 5 subscales of the Neuropsychiatric Inventory (NPI) and short-form NPI-Q that are typically associated with bvFTD. Our cohort included 34 clinically-diagnosed PSP patients who have highly-probable PSP pathology and 9 autopsy-confirmed PSP patients. Analysis revealed evidence of behavioral changes on all 5 evaluated NPI subscales: apathy (74%), disinhibition (29%), irritability (50%), appetite (44%), and aberrant motor behavior (27%). We then examined genetic associations in 32 of the 43 PSP patients who were genotyped using a customized panel for the 11 PSP GWAS SNPs. Assuming a dominant model of inheritance, we observed an association between rs2493013 (EXOC2) and an increased risk of disinhibition (LR=7.623; p=0.006) and aberrant motor behavior (LR=7.623; p=0.006). We also observed an association between minor allele carriers in rs6687758, an intergenic SNP in Chromosome 1, and an increased risk of apathy (LR=10.08; p=0.001): 100% of homozygous major allele carriers did not exhibit apathetic behavior. All other SNPs did not achieve an association corrected for multiple comparisons. Together, these findings suggest that two SNPs, rs2493013 and rs6687758, may confer an increased risk of behavioral and psychiatric phenotype in PSP. We suggest that future work is required to evaluate the potential genetic risk factors and mechanisms that contribute to the clinical heterogeneity observed in PSP.

Title: Progranulin deficiency delays nerve regeneration and functional recovery following nerve crush injury

Authors: S. BEEL[1], L. DE MUYNCK[1], L. M. J. VAN DEN BOSCH[1], W. L. ROBBERECHT[2], *P. VAN DAMME[2];
[1]Lab. of Neurobiology, Vesalius Res. Center, VIB, Leuven, Belgium; [2]Neurol. Department, UZ Leuven, Leuven, Belgium

Abstract: Frontotemporal dementia (FTD) is the second most common form of early-onset dementia, after Alzheimer's disease. Symptomatic onset of this primary progressive, neurodegenerative disorder is most common between the ages of 40 to 60 years and can be clinically subdivided into one behavioral and two language variants. About 40% of the patients have a familial history and one of the most common forms of familial FTD is caused by loss of function mutations in the gene encoding progranulin (GRN). These mutations lead to a reduction of 50% or more of GRN levels in the blood and cerebrospinal fluid. Therefore, haploinsufficiency seems to be the mechanism of disease in these patients. GRN is a pleiotropic growth factor and its expression in the CNS is limited to neurons and microglia. *In vitro* studies already showed the importance of GRN in neuronal survival and axonal outgrowth. However, an *in vivo* setting would allow for a much better approach to unravel the mechanisms by which GRN exerts its neurotrophic functions in the CNS. Therefore, we generated GRN knockout mice and established a nerve crush model to study axonal regeneration and functional recovery in the absence or presence of GRN. By comparing our crush model to an axotomy model, using the sciatic nerve, we confirmed that our crush injury induces complete degeneration of the distal nerve segments which is important to ensure homogeneous injury across all animals. To study the effect of GRN depletion on nerve regeneration after injury, we performed a crush on the facial nerve of young GRN knockout mice (8 - 12 weeks). Functional recovery was checked on a daily basis by comparing the whisker movement on the injured side to the movement of the contralateral non-injured side and scoring the movement on a scale from 0 to 3 (0 = no recovery; 1 = detectable motion; 2 = significant (but asymmetric) voluntary motion of all whiskers; 3 = symmetric voluntary motion of all whiskers). GRN knockout mice showed a significant delay in recovery compared to non-transgenic littermate controls. Crossbreeding GRN knockout mice with human GRN (hGRN) overexpressing mice made it possible to study if hGRN can substitute for the endogenous mouse GRN. Indeed, the overexpression of hGRN in a knockout background showed a complete rescue of the delayed whisker movement recovery of GRN knockout mice. These observations suggest that GRN is an essential component in the nerve regenerative process and that hGRN can mediate these effects. Further research will be necessary to unravel the precise mechanism underlying this *in vivo* neurotrophic effect of GRN.

Title: Effect of genetic background on the phenotype of chorea-acanthocytosis model mouse

Authors: *H. SAKIMOTO, O. NAGATA, S. YOKOTSUKA, K. ARAI, M. NAKAMURA, A. SANO;
Kagoshima Univ., Kagoshima-Shi, Japan

Abstract: Chorea-acanthocytosis (ChAc) is an autosomal recessive neurodegenerative disorder that is caused by loss of function mutations in the VPS13A gene. Clinically, ChAc is characterized by acanthocytosis in erythrocytes and Huntington disease like various neuropsychiatric symptoms that indicate the existence of phenotypic modifiers. In the previous sturdy, we previously produced ChAc model mice encoding a human disease mutation with deletion of exons 60-61 in Vps13a by gene targeting. The mutant mice that have a hybrid C57BL/6J and 129/Sv genetic background displayed variable phenotypes, strongly suggesting the existence of modifier genes. We backcrossed the ChAc model mice separately onto C57BL/6J, 129S6/Sv, DBA/2J, BALB/c, and FVB/N genetic backgrounds. Osmotic fragility test of erythrocytes and measurement of body weight were performed for these mice. We found a marked increase in the osmotic fragility of red blood cells in the ChAc mutant mice of 129S6/Sv, FVB/N, and C57BL/6J. Statistically significant low body weight against weeks of age was found in ChAc mutant model mouse of FVB/N, 129S6/Sv, and DBA/2J backgrounds. Subsequently, we performed behavioral analyses for the mice of the low body weight strains. The observed abnormal behavioral phenotypes in the ChAc model mice varied according to the strain backgrounds. These results suggest that there may be modifying factors of ChAc symptoms in genes that generate genetic background of each mouse strain.

Title: Motor-related neuronal activity in cerebellar thalamus of Essential Tremor patients

Authors: *D. J. SEGAR[1], S. LEE[2], S. R. JONES[2], W. F. ASAAD[2];
[2]Neurosci., [1]Brown Univ., Providence, RI

Abstract: Introduction: The ventral intermediate nucleus of the thalamus (VIM), a key link between the cerebellum and the sensorimotor cortex, has long been a neuromodulatory target for pathologic tremor. Stimulation of VIM can dramatically reduce tremor in these patients, but the underlying mechanisms by which VIM modulates motor output are poorly understood. Methods: We obtained single neuron recordings in VIM from Essential Tremor (ET) patients during deep brain stimulation (DBS) electrode implant surgery. To assess neuronal responses to movement direction, patients performed a center out joystick task in which they manipulated a joystick to move a cursor on a screen toward a target. Targets appeared individually at one of eight locations around a circle. On some trials, the target jumped to a predictable or a random location just after initiation of movement. Spike responses were recorded at 40 kHz, thresholded, and sorted offline using principal components analysis. Results: Each neuron was tested for task-related responsiveness by comparing baseline firing rates to firing rates cued to particular task-related events using a non-parametric bootstrap. Approximately half of all neurons responded to at least one task-related visual cue or movement, and several were selectively responsive to specific visual cues or movements. Some neurons demonstrated similar responses to both visual and motor events, suggesting that they may be involved in the visual-motor transformation. Other neurons exhibited classical "tuning" to movements in specific directions. A small group of neurons responded significantly more to the appearance of a "jumped" target and the associated movement correction. These neurons may be directly related to the transmission of a motor error correction signal. Conclusions: VIM neurons were actively engaged by our center out joystick movement task, with a substantial number tuned to the direction of the patient’s movement. A few also selectively responded to corrections of movement, supporting a role for the VIM in conveying alterations in motor plans from the cerebellum to the cortex.

Title: Anxiety in Wfs1-deficient mice is probably related to changes in brain cells' ability to cope with endoplasmic reticulum stress

Authors: *A. ALTPERE, S. SÜTT, S. RAUD, R. REIMETS, M. LOOMETS, E. VASAR; Univ. of Tartu, Tartu, Estonia

Abstract: Mutations in WFS1 (Wolfram syndrome 1) gene are associated with rare hereditary disorder called Wolframin syndrome that presents with diabetes, nerve atrophy and several psychiatric disorders. This condition is associated with impaired cell survival, but the exact mechanism of how Wfs1 affects cell survival remains unknown. Wfs1 has been associated with changes in expression level of several endoplasmic reticulum (ER) stress related genes in cell cultures. Prolonged ER stress in turn is associated with cell death. In this study we investigated how Wfs1-deficiency affects mRNA expression of ER stress related genes in brain of naive mice and those that were exposed to elevated plus maze. Namely, we analyzed mRNA expression levels of Grp78, Grp94, total and spliced Xbp1, Atf6α, Chop and Perk in ventral striatum, temporal lobe, hippocampus and prefrontal cortex. We found that there were no differences in mRNA expression level of ER stress related genes in naive Wfs1-deficient mice compared to wild type mice. Difference in expression level of ER stress related genes in brain of Wfs1-deficient mice compared to wild type mice became apparent only after exposure to elevated plus maze and was region specific, with most differences in ventral striatum. For example in ventral striatum mRNA expression levels of Chop and spliced Xbp1 were significantly lower in Wfs1-deficient mice compared to wild type mice after elevated plus maze. Expression level on Grp94 in ventral striatum was significantly higher in Wfs1-deficient mice after exposure to plus maze when compared to naive Wfs1-deficient mice. No such changes were found in ventral striatum of wild type mice. Spliced Xbp1 is shown to be negative regulator of ER stress related apoptosis. No change in spliced Xbp1 mRNA expression after stressful situation may suggest that Wfs1-deficiency alters cells' ability to cope with ER stress and results in apoptosis.

Title: Increased presence of inflammatory proteins within the pontocerebellar tracts in Multiple System Atrophy

Authors: A. B. VALENTI[1], W. T. BOOTHBY-SHOEMAKER[1], B. KATBAMNA[2], *C. F. IDE[1];
[1]Biol. Sci., [2]Speech Pathology and Audiol., Western Michigan Univ., Kalamazoo, MI

Abstract: Multiple System Atrophy (MSA) is an adult onset progressive neurodegenerative disease, characterized by various degrees of Parkinsonism, cerebellar ataxia and autonomic failure. In MSA, the protein alpha-Synuclein (α-Syn) forms misfolded protein aggregates that appear primarily in oligodendrocytes in the white matter tracts of the pons and cerebellum. In other synucleinopathies such as Parkinson's disease, the accumulation of α-Syn is associated with microglial activation, production of inflammatory cytokines and chemokines, and T-cell infiltration (Lee et al., 2010; Brochard et al. 2009). However, little is known about an inflammatory and adaptive immune response in MSA. Previous Affymetrix studies conducted by our lab revealed upregulation of genes involved in an immune response in MSA pons (Langerveld et al, 2007). To further define changes in pons tissue related to MSA, immunohistochemistry (IHC) was performed on transverse sections from MSA and control pons tissues from the New York Brain Bank at Columbia University. IHC analysis showed the upregulation of CD33 (expressed on microglia; associated with the impairment of microglia-mediated clearance of amyloid-beta in Alzheimer's Disease), CD68 (marker of microglia and macrophages), and CD8α (involved in adaptive immune response; cytotoxic T cell marker) in three regions of the pontocerebellar tracts. Our pilot study revealed an increasing trend of CD68 and CD33 expression in the dorsal-most, mid-, and ventral pontocerebellar fiber tracts in MSA pons. The data also showed a significant increase of CD8α expression ($p=0.003$) in the dorsal-most, mid-, and ventral pontocerebellar fiber tracts. These data suggest inflammation may contribute to the neuropathology that occurs in MSA, and that CD33 may limit microglia-mediated clearance of protein aggregates in MSA.

Title: Dorsal genital nerve stimulation reduces incontinence episodes in idiopathic OAB patients

Authors: *J. DONG[1], A. M. RYHAMMER[2], N. J. M. RIJKHOFF[1];
[1]Hlth. Sci. and Technol., Aalborg Univ., Aalborg Ost, Denmark; [2]Dept. of Urology, Pelvic Floor Unit, Aarhus Univ. Hospital, Skejby, Aarhus, Denmark

Abstract: Purpose: Different treatment methods for overactive bladder (OAB) are available, including fluid advice, bladder training, pharmacotherapy, neuromodulation and surgical treatment. Neuromodulation (sacral or tibial nerve stimulation) was established on reducing the symptoms of OAB. However, the drawbacks limit their wide clinical application. Therefore, a new neuromodulation is needed. Previous experiments on animals have revealed a lasting suppression of the parasympathetic micturition reflex after stimulation of the dorsal genital nerve (DGN) 1. The aim of this study is to assess the effect of DGN stimulation on incontinence episodes (IE) using surface electrodes in idiopathic OAB patients. Methods: Two idiopathic OAB patients were recruited. Stimulation was performed using a battery powered handheld stimulator in patient's home. A monophasic square constant current pulse with a width of 200 μs and a frequency of 20 Hz was used. One electrode was placed on the clitoris, and the second electrode was placed 3-4 cm lateral to the clitoris. More details of stimulation can be seen in the study by Worsøe et al. 2. Stimulation was performed twice daily for 15 minutes in each session for a period of 3 weeks. All data (frequency, severity of urgency (none, mild, moderate, severe), number of IE per day) were collected during 4 days baseline pre-stimulation, a 3 weeks home test and 4 days post-stimulation. Results: Until now, two female patients have completed the experiment. The reduction from pre-stimulation to post-stimulation in average IE per day was 86% and 57% respectively. The average IE per day post-stimulation was lower than the average IE during and pre-stimulation in these two patients. Conclusions: Reduction of average IE per day was seen in both patients. If more positive data can be obtained from enough patients, DGN stimulation using surface electrodes might be a potential therapeutic option in management of idiopathic OAB in women resistant to conservative treatment. Title: Low dose aspirin as a prophylactic against the progression of Scrapie in Mice

Authors: *D. N. BRYANT[1], M. A. BENNEYWORTH[2], D. M. SEELIG[3];
[1]Vet. Clin. Sci., Univ. of Minnesota, Saint Paul, MN; [2]Mouse Behavior Core, Dept. of Neurosci., Univ. of Minnesota, Minneapolis, MN; [3]Vet. Clin. Sciences, Col. of Vet. Med., Univ. of Minnesota, St. Paul, MN

Abstract: Transmissible Spongiform Encephalopathies (TSEs) are a group of infectious neurodegenerative diseases that occur in mammals. Our current understanding is that TSE progression involves the conversion of the benign Prion protein (PrP^{C}) into its harmful and infectious counterpart (PrP^{SC}). Increased PrP^{SC} production is associated with a number of consequences, including: PrP^{SC} aggregation, stimulation of pro-apoptotic signaling, gliosis, motor deficits, cognitive deficits and death. Since there is no known cure for TSEs, we wanted to test the hypothesis that acetylsalicyclic acid (ASA or Aspirin) is a primary or secondary prophylactic against the progression of the TSE known as Scrapie. ASA has been shown to protect against PrP^{SC} toxicity *in vitro* via its antiapoptotic effects. C57BL 6 mice were divided into 4 groups of 6-8 mice (males and females). 1. ASA pretreatment, 2. ASA Intervention at behavioral onset of symptoms, 3. scrapie only, 4. No ASA/No scrapie. Group 1 was administered ASA (30ug/ml ad libitum in drinking water) two weeks prior to a single intraperitoneal injection of scrapie inoculum (ME7, 100ul of 5%) to groups 1,2 and 3. Mice remained on ASA for the duration of the study. Since there is little to no data on early motor/behavioral deficits associated with scrapie progression, we performed three behavior assays (Pole Test for bradykinesia, Forelimb Grip Strength and Rotarod for motor coordination) monthly. Baseline motor behavior was assayed after group 1 started ASA but prior to inoculation. Preliminary data suggest that scrapie mice are beginning to show a deficit on the pole test at 52 days post inoculation. Compared to control animals, scrapie mice have increased latency to turn and reach the bottom of the pole. No trend or difference was observed in the Rotarod or grip strength test as of 52 days post inoculation. The progression of scrapie takes approximately 200-250 days in this mouse model system. We will continue to monitor the effect of ASA on motor behavior and survival. ASA intervention will occur when we have statistically significant confirmation of a motor deficit. Finally, we will harvest brains, confirm PrP^{SC} expression and assay apoptotic signaling pathways in terminal mice.

Title: Behavioral and sperm motility analyses of male infertility in Chorea-acanthocytosis model mouse

Authors: *O. NAGATA, H. SAKIMOTO, S. YOKOTSUKA, K. ARAI, M. NAKAMURA, A. SANO;
Kagoshima Univ., Kagoshima Univ., Kagoshima-Shi, Japan

Abstract: Chorea-acanthocytosis (ChAc) is a rare autosomal recessive neurodegenerative disorder caused by loss of function mutations in the vacuolar protein sorting 13 homolog A (VPS13A) gene that encodes chorein. It is characterized by adult-onset chorea, erythrocyte acanthocytosis, and neuropsychiatric symptoms. We previously produced a ChAc model mouse introducing exons 60-61 deletion corresponding to a human disease mutation by a gene targeting technique. The ChAc model mice exhibited male infertility. In the present study, we performed analyses of mating behavior, olfactory behavior, sperm count, and sperm motility in order to elucidate a cause of the male infertility. Sperm motility was siginificantly decreased in ChAc model mice compared with littermate contorols although mating behavior, olfactory behavior, and sperm count analyses showed no significant differences. These results suggests that the male infertility of the ChAc model mouse is caused by asthenozoospermia. Further studies are needed to clarify a molecular role for chorein in sperm motility and its association with ChAc molecular pathogenesis.

Title: Role of yeast Hsp31/DJ1 in Sup35 prion aggregation

Authors: *K. ASLAM, T. HAZBUN;
Purdue Univ., West Lafayette, IN

Abstract: Amyloids are a biochemically well-characterized state of protein aggregation commonly associated with neurodegenerative diseases in mammals and cause heritable traits in *Saccharomyces cerevisiae*. An associated class of amyloid aggregation state includes prions, which are self-replicating, misfolded proteins capable of adopting amyloid aggregates in cells.

Sup35, a translation-termination factor, is one of the original and best-studied prions in yeast. Yeast provides a useful model to study amyloid aggregation including Sup35 prion formation. Yeast Hsp31 is a member of small heat shock proteins that has structural similarity with human DJ1 protein. Previously, we have showed that Hsp31 possesses chaperone properties with protective effects against α-Syn toxicity in yeast. In the present study, we elucidate the mechanism of Hsp31 modulation of prion formation in yeast. We find that Hsp31 inhibits the formation of Sup35 aggregates as determined by fluorescence microscope, flow cytometry and SDD-AGE. Furthermore, overexpression of Hsp31 transiently inhibits the induction of Sup35 prion but has no significant effect over prolonged induction and cannot cure the [PSI^+] prion state. We hypothesize that Hsp31 acts on the early stages of prion formation therefore, it can't cure already formed aggregates. In fact, localization of Hsp31 under fluorescence microscope showed that Hsp31 and Sup35 aggregates do not co-localize; rather Hsp31 is occluded from Sup35 prion aggregates, indicating that Hsp31 acts on substrates prior to the formation of large aggregates. We also find that deletion of HSP31 in [PSI^+] background modulates the level of curing by Hsp104. Further studies are investigating the possible interaction of Hsp31 with early prion and α-Syn oligomers to establish further mechanistic insight in the biological roles of the Hsp31/DJ-1 chaperone family.

Title: Intraoperative recording and computational modeling of modulation of tremor related oscillations in human ventral intermediate nucleus of the thalamus

Authors: *S. LEE[1], D. J. SEGAR[1], W. F. ASAAD[2], S. R. JONES[2];
[2]Neurosci., [1]Brown Univ., Providence, RI

Abstract: Essential Tremor (ET) is the most common movement disorder and is typically characterized by a 4-8 Hz intention tremor, manifested upon voluntary movement toward a target. For severe, medication refractory ET, deep brain stimulation (DBS) of the cerebellar motor thalamus, the ventral intermediate nucleus (VIM), can be an effective treatment to alleviate tremor. The causes and pathophysiology of ET and the mechanisms by which DBS alleviates tremor in these patients are not fully understood. We are integrating intraoperative

electrophysiological recording from VIM in human ET patients performing a center out motor task with biophysically principled computational modeling of cerebellar-thalamic-cortical circuits to help understand the pathophysiology of ET and mechanisms of effective DBS. During DBS lead implant surgery, we recorded extracellular field potential and single unit spike activity from VIM while patients used a joystick to move a cursor on a screen toward a target. The target appeared at one of eight locations on a circle, and upon initiation of movement, the target sometimes jumped to another location in either a predictable or random manner. Patients were required to move the cursor to the target and hold at the target until cued for the end of the trial. We measured reaction times, time to final target, and distance from final target trajectory to quantify performance on the task and correlate with neurophysiology and tremor. We quantified tremor frequency (4-8 Hz) field activity consistent with the tremulous movement and observed increases in tremor activity during movement and maintenance of posture, which was modulated differently for random and predictable trials. Finally, we developed a computational model of cerebellar input into VIM consisting of multicompartment thalamocortical relay (TC) cells, thalamic relay nucleus (TRN) cells, and inhibitory thalamic interneurons to understand how differences in cerebellar input to VIM may modulate tremor activity, with implications for tremulous motor output. In the model, we find that timing and strength of the inhibitory inputs, coupled with T-type and L-type calcium channels in TC and TRN cells, affect how tremor oscillatory activity is manifested in VIM. We discuss the implications of our work for understanding the effects of DBS. Together, our joint data and modeling provides novel detail on multiple aspects of movement-related activity in VIM.

Title: Suppressing an infantile neuronal ceroid lipofuscinosis associated nonsense mutation

Authors: *R. GERAETS[1,2], J. M. WEIMER[1,2], D. A. PEARCE[1,2];
[1]Sanford Sch. of Med. - Univ. of South D, Sioux Falls, SD; [2]Children's Hlth. Res. Ctr., Sanford Res., Sioux Falls, SD

Abstract: Lysosomal storage disorders (LSD) result from deficiencies in either a lysosomal enzyme or membrane protein. A deficiency in the soluble lysosomal enzyme palmitoyl-protein thioesterase 1 (PPT1) causes the LSD known as Classic Infantile Neuronal Ceroid Lipofuscinosis (INCL). Medically, this disease is classified as a rare neurodegenerative disorder with hallmarks of retinopathy, progressive motor and cognitive decline, and premature death. Different genetic mutations in *CLN1* give rise to the PPT1 deficiency. Approximately 25% of patients with INCL have disease causing nonsense mutations in at least one allele; the most common being $CLN1^{R151X}$. The deleterious effect of nonsense mutations can be suppressed using read through compounds (RTCs). RTCs suppress nonsense mutations by promoting non-recognition of premature termination codons, resulting in the production of full length proteins. The objective of this study was to evaluate the effectiveness of RTCs at suppressing the $CLN1^{R151X}$ nonsense mutation. *In vitro* and *ex vivo* models derived from the $CLN1^{R151X}$ mouse were treated with various concentrations of the following RTCs: Gentamicin, Ataluren, RTC-13, and Amlexanox. Patient-derived, immortalized lymphoblasts containing the $CLN1^{R151X}$ mutation were also treated. Changes in PPT1 activity were assessed using a fluorogenic enzyme assay. Results indicate that select RTCs can successfully increase PPT1 activity. Collectively, our findings support further investigation into this therapeutic approach.

Title: Fluctuation analysis of steady gaze in essential tremor

Authors: *J. H. ANDERSON[1,3], J. WILLGING[2], J. ASHE[4,5];
[1]Dept Otolaryngology, [2]Neurol., Univ. Minnesota, Minneapolis, MN; [3]Otolaryngology, [4]Neurol., Minneapolis VA Hlth. Care Syst., Minneapolis, MN; [5]Neurol., Univ. of Minnesota, Minneapolis, MN

Abstract: Some oculomotor abnormalities suggesting cerebellar dysfunction have been identified in essential tremor. Some aspects of pursuit tracking, small amplitude saccades and vestibular reflexes have been studied. Less is known about large amplitude saccades, optokinetic

reflexes, and oscillations during steady gaze. The present study is an effort to quantify variability in eye movements and to characterize the presence of eye jerks/oscillations during steady gaze. The general aim is to identify and characterize the short and long range correlation and self-similarity of fluctuations in gaze over time using a multifractal, de-trended fluctuation analysis (Kantelhardt et al., 2002), MFDFA, of time series data. For this initial work the analysis is applied to recordings during fixation at a straight-ahead, stationary target; while attempting to maintain a straight-ahead position in complete darkness; and during optokinetic stimulation with a constant velocity visual stimulus. The preliminary results show promise for characterizing possible fractal properties of the oculomotor system dynamics, interactions across temporal scales, and how that is manifested in essential tremor. This approach could provide further insight into the underlying pathophysiology affecting the control of gaze in essential tremor.

Title: Morphological changes in the peripheral tissues of Neuronal Ceroid Lipofuscinosis mouse models

Authors: *R. N. LAUFMANN, D. TIMM, J. M. WEIMER;
Children's Hlth. Res. Ctr., Sanford Res., Sioux Falls, SD

Abstract: Neuronal Ceroid Lipofuscinoses (NCLs) are a family of lysosomal storage disorders characterized by visual, motor, and cognitive decline, behavioral deficits, and premature death. Pathologically, NCLs result in an accumulation of autofluorescent material in the lysosome, neurodegeneration, disruptions in lysosomal enzyme function, and robust glial activation. Initial studies from our laboratory have also suggested that, in addition to the defects within the central nervous system, other organs, including the kidney, spleen and thymus, may be severely affected in vLINCL. We hypothesize that these additional factors outside of the CNS contribute to the premature death of our mutant mice. We will present evidence of morphological differences in the periphery between mutant and wild type mice in the spleen and liver, blood analysis data, and evidence for potential biomarkers that could be used to track the progression of the disease. Our

main goal for this project is to see if there are notable differences in the periphery, so that future studies may be focused on using combinatorial treatments for both the CNS and peripheral tissues.

Title: Functional compensation for executive deficits in progressive supranuclear palsy

Authors: *C. A. OLM[1], B. M. KANDEL[2], B. B. AVANTS[2], J. A. DETRE[3], J. C. GEE[2], K. RASCOVSKY[1], M. GROSSMAN[1], C. T. MCMILLAN[1];

Abstract: Progressive supranuclear palsy (PSP) is a neurodegenerative disorder characterized by postural instability, supranuclear gaze palsy and other visual system problems, and cognitive or behavioral deficits. While PSP is most commonly characterized as a movement disorder with primary midbrain atrophy, frontal cortical atrophy has also commonly been observed along with accompanying frontally mediated executive dysfunction. However, PSP is clinically heterogeneous with some patients having more severe executive deficits while others have relatively spared cognitive function. In this study we evaluate whether functional mechanisms may provide compensatory support for executive deficits in PSP and account for some of the previously reported heterogeneity. To evaluate whether there may be functional mechanisms for executive compensation in PSP we performed a multimodal assessment of gray matter using cortical thickness measured with T1 MRI and cortical cerebral blood flow (CBF) measured with pseudo-continuous arterial spin labeling (pCASL). We evaluated 17 clinically-diagnosed PSP patients and 19 demographically-comparable healthy controls. We used a verbal fluency task in PSP patients as a measure of executive function, involving the generation of as many words as possible in one minute that begin with the letter “F”. Based upon the T1 MRI we analyzed cortical thinning in patients relative to controls. From the pCASL images, we calculated CBF

that was corrected for partial voluming to control for cortical thinning. Cortical thinning was found in bilateral inferior and prefrontal cortex and extended to include right insula and superior temporal cortex. Regions of hypoperfusion were widespread throughout frontal cortex and extended to include temporal and parietal cortices. Regions showing hypoperfusion minimally overlapped with regions of reduced cortical thickness as expected since this analysis controlled for gray matter/CSF and gray matter/white matter partial voluming effects. A regression analysis relating verbal fluency performance to corrected CBF revealed two clusters in which higher CBF within bilateral ventrolateral and inferior frontal cortex was associated with better executive function. Together, these findings suggest that increased perfusion in the frontal cortex is associated with increased performance on an executive task and these findings are consistent with other studies implicating these regions in verbal fluency tasks. We interpret this as evidence of functional compensation and suggest that compensatory mechanisms in PSP may account for some of the heterogeneity of cognitive impairments reported in this disease.

Title: The contralateral cortical silent period is not abnormal in primary Restless Legs Syndrome / Willis-Ekbom disease

Authors: *A. CONFORTO[1], G. DO PRADO[2], E. AMARO JR.[3], A. ECKELI[4], S. MAGALHÃES[3];
[1]Hosp. Das Clínicas/São Paulo Univ. and Inst. Israelita De Ensino E P, Sao Paulo, Brazil; [2]Univ. Federal de São Paulo, São Paulo, Brazil; [3]Hosp. Israelita Albert Einstein, São Paulo, Brazil; [4]Univ. de São Paulo - Ribeirão Preto, Ribeirão Preto, Brazil

Abstract: Background: Restless legs syndrome (RLS) is characterized by unpleasant sensations and an irresistible urge to move the lower limbs. A reduction in duration of the cortical silent period (CSP) induced by transcranial magnetic stimulation, believed to reflect activity of GABAB neurons, has been inconsistently reported in RLS. Objectives: 1) To compare the CSP duration, in patients with primary RLS and in healthy subjects; 2) To correlate these measures with severity of RLS symptoms. Patients and Methods: Patients were grouped according to scores in the international RLS severity scale, IRLSS: (light/moderate [IRLSS<20] = RLSLM ;

severe/very severe [IRLSS≥20] = RLSSVS). Resting (rMT) and active (aMT) motor thresholds as well as CSP were measured. We obtained patient and Institutional Review Board (IRB) approval. Mann-Whitney tests were used to compare results in patients and in controls, and to compare results in patients with RLSLM and RLSSVS. Results: Thirty one (25F/6M) patients with primary RLS and 13 healthy subjects were included. Twenty one patients had IRLSS≥20 (RLSSVS) and 10, IRLSS<20 (RLSLM). TMS results were (RLS x controls): rMT (69.2±13.8% x 67.9 ± 13.2%; p=0.78); aMT (54.6±10.4% x 55.3±12.6%; p=0.88); CSP duration (108.7±36.3 milliseconds(ms) x 106.1±36.5 ms; p=0.83). CSP duration was not significantly different between the two groups of patients with different severities of symptoms (RLSLM 112.3±34.7 x RLSSVS 103.0±37.9; p=0.51). Conclusion: These results do not support the hypothesis that GABAB neurons of the primary motor cortex are relevant to RLS pathogenesis.

Sci., Fac. of Medicine, Univ. of Tsukuba, Tsukuba, Japan

Abstract: We identified an aged Japanese macaque (Macaca fuscata yakui; 17 years old) in the Primate Research Institute colony- Kyoto University, who exhibited both parkinsonian (mild to moderate hypokinesia with stooped posture) and cerebellar signs (typically action tremor in all the axial limbs and gait instability). We used a number of investigative methodologies to classify symptom types and define the disease, including a monkey parkinsonism rating scale, EMG- and accelerometer-based classification of movement, simultaneous cortico-basal ganglia-cerebellar local field potential (LFP) recordings, genetic profiling, structural imaging using a high-intensity MRI (7 Tesla), and high resolution PET measurements of α-synuclein and dopamine transporter (DAT) levels. The LFP recording showed increased power in the high beta-frequency range ~ 20-30 Hz, relative to normal control and MPTP treated animals. Whole genome analysis of this monkey and extensive population genomic analysis of 100 macaque monkeys revealed that only this monkey possessed a deleterious homozygous deletion in SHC2 gene, a candidate gene of human multiple system atrophy (MSA). High-intensity MRI imaging showed a potential cruciform signal, like a 'hot cross bun sign', in the pons. Compared with a control subject, the α-synuclein level tended to be increased in the brainstem and cerebellum, while the DAT binding level appeared to be unaffected. In light of the above symptom profiles, we suggest that the animal may suffer from MSA, and provides a novel platform for investigating the causes of and treatments for MSA.

Title: Walking performance and deep brain stimulation in Essential Tremor

Authors: *C. J. HASS[1], J. SKINNER[1], R. ROEMMICH[3], M. TERZA[2], J. ROPER[2], P. ZEILAMAN[2], M. OKUN[2];
[1]Applied Physiol. and Kinesiology, [2]Univ. of Florida, Gainesville, FL; [3]Johns Hopkins, Baltimore, MD

Abstract: Essential tremor (ET) is symptomatically characterized by an action (postural and kinetic) tremor of the upper extremities, but may also involve tremors of the head, voice, trunk, and occasionally the lower extremities. Recent literature has quantitatively detected gait impairments that have been previously reported clinically. For participants with mild ET these impairments include a decreased walking velocity, decreased step length, and increased step

width as compared to healthy aged matched controls. With disease progression gait impairment worsens. Specifically, cadence decreases and a greater percentage of the gait cycle is spent in the double support phase. Deep brain stimulation (DBS) is an effective means of mitigating medication refractory tremor but early evidence suggest that ET DBS patients could possibly develop gait and balance difficulties following surgery. The purpose of this study was to systematically evaluate the effects of DBS on gait performance. Twenty-five participants (16 Male, 67 ± 8 years old) underwent the DBS procedure where stimulating electrodes were inserted unilaterally into the VIM nucleus of the thalamus. Participants were evaluated between 6-12 months post-surgery providing time to optimize the beneficial effects of surgery on tremor. During the post-surgery evaluations, participants were tested in both the DBS turned off (Off DBS - stimulation was turned off at least one hour prior to testing) and DBS turned on (On DBS - stimulation was on for 60 minutes). Retroreflective markers were placed on the participant's bony landmarks in accordance with the Vicon Plug-in-Gait full body marker set. Kinematic performance was collected at 120Hz using a 10 camera motion capture system. Participants performed 10 overground gait trials at self-selected walking speed. Tremor was assessed using the Tremor Rating Scale (TRS). Ten gait variables were compared between the baseline, DBS-on and DBS-off conditions using a one-way repeated measures ANOVA. ON-OFF DBS evaluations were conducted 9±2 months following the baseline pre-DBS evaluation. TRS scores improved following DBS implantation and optimization ($p<0.05$). However, the statistical analyses failed to detect differences in gait speed ($p=.66$), cadence ($p=.85$), stride length ($p=.27$), stride time ($p=.47$), step length ($p=.29$), step time ($p=.83$), step width ($p=.93$), percent of the gait cycle in single support ($p=.93$), double support ($p=.93$) and swing to stance ratio ($p=.92$) across the three time points. Though these findings show across the group DBS did not negatively/positively impact gait, there were patients in the cohort with observable differences post-DBS.

Title: Pseudogene-mediated expression dysregulation contributes to the development of neurodegeneration in a haplotype-specific manner

Authors: *A. E. FURTERER, P. NGUYEN, J. CHEN, M. PRIBADI, F. GAO, M. RAMOS, G. COPPOLA;
UCLA, Los Angeles, CA

Abstract: Tauopathies are a group of neurodegenerative diseases characterized by abnormal aggregation of tau, an abundant microtubule-associated protein, and include Progressive Supranuclear Palsy (PSP), corticobasal degeneration, and forms of frontotemporal dementia and Alzheimer's disease. Rare, causal mutations within the *MAPT* gene that encodes the protein tau have been identified in families. Genetic studies have consistently linked the 17q21.31 region, containing *MAPT*, to neurodegenerative tauopathies, even when causative mutations in *MAPT* cannot be identified. The H1 haplotype at the 17q21.31 locus is the greatest risk factor for PSP and possibly other tauopathies. While the H1 haplotype occurs in ~80% of the healthy controls (the remaining 20% being H2), an estimated 97.1% of PSP patients are H1 carriers [1]. Our group previously reported methylation differences between H1 and H2 individuals, with differentially methylated probes clustering in the 17q21.31 region [2]. Analysis of microarray data from healthy controls indicates specific gene expression differences between H1 and H2 individuals. The most consistent expression change was *MAPK8IP1*, a gene located on chromosome 11. Importantly, homology analysis revealed that the microarray probe for *MAPK8IP1* is cross-reacting with LOC644172, a pseudogene within the 17q21.31 region. Though once considered defunct, certain classes of pseudogenes are now understood to perform important regulatory functions, and have been implicated in complex diseases like cancer and neurodegeneration [3,4]. Pseudogenes who share microRNA binding sites with their parent genes can act as "decoys" that compete with transcripts of the parent gene [and potentially other genes] to generate a subtle microRNA knockdown effect, or alternatively form long double-stranded RNAs that interfere with RNA stability [4]. We investigate how haplotype-associated differential expression of LOC644172 mediates neurodegenerative risk via an interaction between LOC644172 and its parent gene, *MAPK8IP1*, by overexpressing lentiviral vectors containing the sense and antisense forms of LOC644172 in human cell lines as well as induced pluripotent stem cell (iPSC) derived-neurons from patients and healthy controls. We demonstrate that pseudogene overexpression modulates endogenous *MAPK8IP1* expression at the transcriptional and translational levels using RT-qPCR and western blotting, and does so by competing for microRNA binding.

Title: Post-developmental LIS1 knockout in mice produces a lethal phenotype

Authors: *T. J. HINES[1], X. GAO[2], D. SMITH[2];
[1]Biol. Sci., Univ. of South Carolina, West Columbia, SC; [2]Biol. Sci., Univ. of South Carolina, Columbia, SC

Abstract: LIS1 haploinsufficiency causes lissencephaly in humans. Characteristics of lissencephaly are a smooth cortex, enlarged ventricles, cognitive deficits, and increasingly severe seizures. LIS1 is critical for proper cortical development by regulating the microtubule motor, cytoplasmic dynein. Interestingly, LIS1 expression remains high in adult nervous tissue. LIS1 and its binding partner, NDEL1, are important for axonal transport in cultured adult rat sensory neurons. In order to explore the role of LIS1 in adult animals, we are utilizing an actin-driven, tamoxifen-inducible cre recombinase mouse strain crossed to a homozygous floxed LIS1 strain to knock out LIS1 post-developmentally. The mice also express a cre reporter gene that switches from red to green fluorescence when cre becomes active. After tamoxifen injection, the cre reporter is most prominent in brainstem neurons, heart, and skeletal muscle. Cre activity is also observed in scattered astrocytes and cerebellar glia. Mosaic cre activity is observed in other tissues, such as liver, lungs, and kidneys. Brainstem neurons display signs of chromatolysis, which is a symptom of axonal damage. Dorsal root ganglion neurons cultured from these mice have more axonal swellings than controls and show defects in retrograde transport. After LIS1 knockout, the mice become very lethargic, exhibit hind leg clasping, and die within five days of tamoxifen injection. Control animals, which include vehicle-only injections or tamoxifen injected animals with either no cre or no floxed LIS1 alleles, show no observable phenotypes. While these results demonstrate the importance of Lis1 in adult animals, the precise cause of death is unknown. We have ruled out a vital role for Lis1 in cardiomyocytes and are investigating potential sources of declining health using urinalysis, electrocardiogram, and monitoring blood glucose levels. Our current model is that defective axon transport in brainstem cardiorespiratory neurons leads to widespread failure of autonomic systems.

Title: Function improved in essential tremor by incobotulinumtoxinA injection patterns using upper limb biomechanical characterization

Authors: *O. SAMOTUS[1,3], H. V. MORADI[2], J. LEE[2], M. JOG[2];
[2]Clin. Neurolog. Sci., [1]London Hlth. Sci. Ctr., London, ON, Canada; [3]Clin. Neurolog. Sci., Western Univ., London, ON, Canada

Abstract: Background: Essential tremor (ET) is the most prevalent movement disorder and causes a loss of function in the upper extremities (UE). Oral medications are usually ineffective with frequent adverse effects which detriments a patient's quality of life. In the past, focal therapy reduced postural tremor severity but has not provided any functional benefit. Wearable motion sensors can objectively distinguish complex movements of upper limb tremor which can be utilized to accurately target muscles which generate tremor. Objective: To investigate the use of multi-sensor kinematic measures of UE tremor for selection of injection parameters, optimization and monitoring the effect of incobotulinumtoxinA for alleviating functional disability caused by essential tremor. Methods: 24 ET participants attended a total of 13 visits and were injected in UE every 16 weeks, totalling six injection cycles, and attended a follow-up visit six weeks following treatment. Clinical rating scales (item 20, 21 UPDRS, FTM, and QUEST) and kinematic assessments were completed at each visit. Participants in a seated position performed two postural and two weight-bearing functional tasks. Goniometers were placed over each UE joint to quantify tremor severity, as RMS angular amplitude, into directional components: flexion-extension (F/E), pronation-supination, and radial-ulnar in wrist, F/E in elbow, and abduction-adduction and F/E deviations in shoulder. Dosing and muscle selection were determined using kinematic data and clinician's experience. Results: Action tremor score (UPDRS item 21) showed a significant drop of 68.0% after 96 weeks. FTM tremor severity displayed a similar significant reduction of rest, postural, and action tremor by 41.7%, 80.6%, and 57.6%, respectively, at week 96. Wrist postural and action tremor total RMS amplitude significantly decreased by 86.4%. Handwriting and functional performance significantly improved by 38.3% and 41.7%, respectively. Furthermore, quality of life (QUEST) significantly improved by 43.3%. Mild weakness was experienced by less than 10% of participants and did not affect arm function. Conclusion: Kinematic assessment of tremor allows clinicians to characterize multi-joint tremor for optimal selection of injection parameters.

Title: Genetic of prion diseases in Brazil

Authors: *M. C. LANDEMBERGER[1], C. F. MACHADO[2], J. SMID[3], H. R. GOMES[3], L. CHIMELLI[4], N. H. S. CANEDO[4], S. ROSEMBERG[3], R. NITRINI[3], V. R. MARTINS[1]; [1]Mol. and Cell Biol., A.C. Camargo Cancer Ctr., São Paulo, Brazil; [2]IQ, [3]USP, São Paulo, Brazil; [4]UFRJ, Rio de Janeiro, Brazil

Abstract: Global surveillance of vCJD and other forms of CJD was recommended from the WHO for a better understanding of potential causes of iatrogenic CJD, as well as the distribution of various hereditary forms. Prion diseases have been under compulsory notification in Brazil since 2005. From 2005 to 2015, we have received 434 blood samples from notified cases of suspected CJD. Blood samples were analyzed by direct genomic sequencing to identify mutations and polymorphisms in the PRNP gene. Cases with mutation in direct sequencing were cloned to confirm results. The presence of 14.3.3 protein in Cerebrospinal Fluid (CSF) was evaluated using immunoblotting and brain tissue obtained by autopsy or biopsy was analyzed by imunohistochemistry for the presence of spongiosis and proteinase K resistant PrP. The average age of our patients was 60.3 years (range 10-94 years), males representing 52% of the cases. PRNP polymorphisms analysis showed that 51% of the cases were homozygous for methionine at codon 129 (M129M), 30% were heterozygous (M129V) and 19% were homozygous for valine (V129V). The silent polymorphism at codon 117 was detected in 10% of the patients and 5% had deletion at the octarepeat. . Regarding genetic diseases, we found fifteen patients with CJD, in which the mutation E200K (nine cases), D178N (two cases), T183A (one case), V180I (one case) and octarepeat insertion (two cases) were detected. We also diagnosed two patients with GSS syndrome (P102L) and three patients with fatal familial insomnia (129M+178N). Brain tissue of 32 patients was available, 28 (87%) of them had spongiosis and were positive for proteinase K resistant PrP. After clinical evaluation, imaging exams, 14.3.3 protein presence, genetic and immunohistochemical analysis, the notified cases were classified according to the WHO criteria. Among of them, 8.3% were classified as sporadic CJD, 39% as probable CJD, 18% as possible CJD, 4.6% as genetic prion disease, 23.6% as suspected CJD and 6.5% were non-CJD. This study provides the first epidemiologic data about human prion diseases in Brazil. Similar to any other country the availability of brain tissue from these patients is a limiting factor to confirm the diagnosis of prion diseases. This study also represents an important tool for prion-prevention policies and is of great importance for future implementation of clinical trials.

Title: Microglia and the complement pathway in sandhoff and tay-sachs disease

Authors: *B. JUN, F. S. EICHLER;
Neurol., MGH, Boston, MA

Abstract: Sandhoff (SD) and Tay-Sachs Disease (TSD), caused by dysfunctional subunits of the β-hexosaminidase A and B enzymes, are characterized by excessive accumulation of GM2 gangliosides in neurons. In patients and $HexB^{-/-}$ mouse models, GM2 storage leads to synaptic and neuronal loss, leading to a devastating neurological phenotype (Myerowitz et al., 2002). In addition, neuropathology is accompanied by widespread neuroinflammation indicated by microglial activation. However, whether the inflammatory contributions are primary or secondary to the neurodegeneration remains unknown. Recent RNA sequencing data revealed that the *HexB* gene is exclusively expressed in microglia, the immune cells of the CNS, suggesting that the gene defect may be affecting the neuro-immune response (Hickman et al., 2013). Interestingly, the Complement immune pathway, which mediates synaptic regulation during neuronal pruning, has been implicated in neurodegenerative diseases such as AD (Stephan et al., 2012). Here, we report that in $HexB^{-/-}$ mice, but not in WT and $HexB^{+/-}$, there is a marked increase in Complement C1q expression in the cerebellar, cortical, and subcortical brain regions. C1q was localized to neurons and their processes, suggesting opsonization and elimination of these targets. The increase of C1q was confirmed in post-mortem samples of a TSD patient cortex. Further, we found that $HexB^{-/-}$ microglia display elevated expression of Complement receptor 3 (CR3/CD11b), suggesting that they are primed to respond via the classical Complement cascade. Our data support the role of the Complement pathway as a mechanism of neuronal loss induced by activated microglia in GM2 gangliosidoses. **References**

Title: Propofol induces autophagy by causing calcium release from endoplasmic reticulum via activation of IP_3R

Authors: G. REN, *M. F. ECKENHOFF, H. WEI;
Anesthesiol. & Critical Care, Perelman Schl Med. UPENN, Philadelphia, PA

Abstract: Our previous studies have demonstrated that inhalational anesthetic isoflurane abnormally raises cytosolic calcium levels and causes cell death by apoptosis. We hypothesize here that intravenous anesthetic propofol affect the autophagy process by causing calcium release from the endoplasmic reticulum via inositol 1,4,5-trisphosphate ($InsP_3R$) receptors, which is associated its effect on cell survival. For these studies, chicken B lymphocytes with all three $InsP_3R$ isoforms knocked out (DT40-TKO) or with only the type I receptor (DT40-R1), and SH-SY5Y human neuroblastoma cells were treated with propofol at 200 and 250 μM. Cytosolic calcium concentrations ($[Ca^{2+}]_c$) were measured using Fura-2 340/380 ratio and cell viability was determined by LDH and MTT assays. Autophagy activity was monitored by measuring levels of LC3-II using Western blot assays. We found that a short treatment (2.5 hours) with 200 μM propofol induced autophagy in SH-SY5Y cells, which protected these cells from propofol's cytotoxicity. Propofol obviously increased $[Ca^{2+}]_c$. Chelation of cytosolic calcium with BAPTA-AM decreased LC3-II levels induced by propofol and resulted in increased cell death, suggesting an adequate baseline level of $[Ca^{2+}]_c$ is required for adequate autophagy function and maintenance of cell survival. Furthermore, propofol induced autophagy only in the DT40-R1 but not in the DT40-TKO cells, suggesting type 1 $InsP_3R$ is required for propofol to regulate autophagy. Inhibition of calcium release from $InsP_3R$ in SH-SY5Y cells with Xestospongin C also reduced autophagy activity induced by propofol. In summary, a short exposure to propofol induces autophagy which requires adequate calcium release from the endoplasmic reticulum via $InsP_3R$ and provides cytoprotection.

Michigan Protein Folding Disease Initiative - Pilot Drug Screen

Title: High-throughput screen for inhibitors of RAN translation

Authors: *K. M. GREEN[1], M. G. KEARSE[2], P. K. TODD[2,3];
[2]Neurol., [1]Univ. of Michigan, Ann Arbor, MI; [3]Veteran Admin. Med. Ctr., Ann Arbor, MI

Abstract: Repeat associated non-AUG (RAN) translation is a non-canonical translational initiation event that occurs at nucleotide repeat expansions associated with neurodegenerative diseases such as ALS, frontotemporal dementia, and ataxia. Translation through expanded repeats results in production of toxic homopolymeric or dipeptide repeat-containing proteins that accumulate in the brains of patients with repeat expansion disorders and contribute to disease pathogenesis. Consequently, RAN translation constitutes a potentially powerful therapeutic target for multiple neurodegenerative disorders. We therefore developed an assay to screen for small molecule inhibitors of RAN translation associated with CGG repeat expansions at the fragile X locus. Such expansions cause Fragile X-associated Tremor Ataxia Syndrome and trigger RAN translation of a toxic polyglycine protein, FMRpolyG, in patients and animal models. This assay utilizes a RAN translation reporter with 100 CGG repeats placed upstream of a modified luciferase. *In vitro* translation of this reporter RNA in a rabbit reticulocyte lysate yields a robust and quantitative signal that is specific to the RAN initiation product. Using this system, we screened 3254 bioactive compounds. We obtained an average Z score per plate of 0.79 and an average well-to-well variation (CV) of 6.93%. We identified 211 compounds that reduced signal by at least 3 standard deviations relative to controls. Several classes of compounds were highly represented within this group, including known protein synthesis inhibitors, DNA/RNA intercalators, and free radical scavengers. We are now performing counter screens and dose response assays to identify compounds that selectively inhibit RAN translation and these will be advanced to *in vivo* disease models. This approach should be applicable to other repeat expansions and could serve as a template for therapeutic development in neurodegenerative disorders.

Title: Disrupted fractalkine signaling impairs synaptic plasticity and long term memory retention

Authors: B. GRIMMIG[1], L. DESFOSSES[2], L. DALY[2], C. HUDSON[3], X. WANG[4], E. WEEBER[4], *P. C. BICKFORD[2,3];
[1]Neurosurg. and Brain Repair, USF, Tampa, FL; [2]Neurosurg. and Brain Repair, USF Morsani Col. of Med., Tampa, FL; [3]Res. Service, James A Haley Veterans Hopsital, Tampa, FL; [4]USF Byrd Alzeimers Ctr., Tampa, FL

Abstract: CX3CL1 (Fractalkine) is a chemokine that regulates microglial activity and has been shown to protect the brain from the damaging consequences of chronic inflammation. Microglia have also been implicated as critically involved in sculpting neural circuits in the developing CNS as well as refining those in adulthood during periods of learning. Both the expression of CX3CL1 and microglial function are affected by age, possibly compromising the capacity for synaptic remodeling thus negatively impacting neural plasticity. Here, we characterize the cognitive behavioral effects of disrupted microglial activity in fractalkine knock out mice at different ages. CX3CL1-/- mice show impaired recall in a contextual fear conditioning task beginning at 14 days post training at 3 months of age and this deficit remains at 15 months of age. Although these mice do not show abnormal locomotor activity they do show superior motor learning at 3 months of age, however this difference is not maintained as they age. Impaired neurogenesis was also observed, indicated by a reduced number of both Ki67 and doublecortin labeled cells in the subgranular zone of the hippocampus at 3 months of age. However this deficit is not observed at later ages. We also examined synaptic function in CX3CL1-/- knock out mice and found age-dependent alterations in synaptic plasticity for both NMDA receptor-independent and -dependent long-term potentiation.

Title: Chronic HIV exposure and aging render mPFC pyramidal neurons in the reward circuits more vulnerable to excitatory stimuli

Authors: *L. CHEN[1,2], C. E. KHODR[1,2], S. DAVE[1,2], L. AL-HARTHI[3], X.-T. HU[1,2];
[1]Dept. of Pharmacol., [2]Ctr. for Compulsive Behavior & Addiction, [3]Dept. of Immunol. and Microbiology, Rush Univ. Med. Ctr., Chicago, IL

Abstract: The medial prefrontal cortex (mPFC) plays an important role in regulating cognitive function and reward-associated behaviors, and is dysregulated in HIV+ humans. Despite combined antiretroviral therapy (cART), neurological and neuropsychiatric deficits are still prevalent among HIV infected patients. Therefore, it is important to understand the neuropathophysiology in the mPFC associated with HIV neuroinvasion. Our previous studies showed that acute exposure to HIV-1 protein Tat induces hyper-excitation of mPFC pyramidal neurons in adolescent (~5-6 week of age) and young adult (5-6 month of age) rats, indicating that prolonged exposure to HIV-1 Tat cause neuronal injury/death. Our recent studies using HIV-1 transgenic (Tg) rats, which express 7 of the 9 HIV-1 proteins (env, tat, rev, nef, vpr, vif, and vpu), further reveal that mPFC pyramidal neurons in adolescent HIV-1 Tg rats also exhibit hyper-excitability. To determine the influence of aging and effects chronic exposure to low levels of HIV-1 proteins *in vivo*, we evaluated the neuropathophysiological properties of mPFC pyramidal neurons from 12-month-old HIV-1 Tg rats and compared that to those from age-matched non-Tg rats. Whole-cell patch-clamp recordings were performed for such evaluation. We found that mPFC pyramidal neurons from aged HIV-1 Tg rats showed a significant increase in evoked firing as compared to those from age-matched non-Tg rats. Such increased firing in neurons from aged HIV-1 Tg rats was significantly reduced by selective blockade of L-type Ca2+ channels (L-channel) with nifedipine (5 μM, acutely applied in bath), indicating involvement of the L-channels in this neuronal hyper-excitation. Additionally, we also found significant changes in the membrane properties (e.g., more depolarized resting membrane potential and decreased rheobase, a minimal depolarizing current that was required for generation of firing), which confirmed increased excitability of mPFC pyramidal neurons in aged HIV-1 Tg rats. These novel findings reveal that, like in the younger rats, the mPFC neuronal function in aged HIV-1 Tg rats is also altered following chronic exposure to HIV-1 proteins *in vivo*. Combined chronic HIV exposure and aging render mPFC pyramidal neurons in the reward circuits more vulnerable to excitatory stimuli. Whether and to what extent such mPFC neuropathophysiology found in the neurons from aged HIV-1 Tg rats was greater than that seen in the neurons from adolescent rats are currently under investigation.

Title: Increased risk aversion with age on a probability discounting task

Authors: *V. L. TRYON[1], H. O. KING[1], J. M. LONG[2], P. R. RAPP[2], S. J. Y. MIZUMORI[1]; [1]Psychology, Univ. of Washington, Seattle, WA; [2]Lab. of Behavioral Neurosci. at the Natl. Inst. on Aging, NIH, Baltimore, MD

Abstract: Normal cognitive aging results in changes in risk-based decision making. The goals of the current study were to characterize how aging may influence risk-based decision making on a probability discounting task using rats, and then test whether a mitochondria enhancing drug impacts the age-related effect. The task tested rats' preference for a lever that lead to a large reward with varying probability (the risky option) or a lever that lead to a small reward 100% of the time (the certain option). Pressing the certain lever led to the delivery of 1 sugar pellet 100% of the time while pressing the risky lever led to 4 sugar pellets with varying probability across trial blocks. The descending probabilities associated with the risky lever were 100%, 50%, 25%, and 12.5%. A session consisted of 8 blocks of trials, a forced choice block followed by a free choice block. Each forced choice block contained 8 trials in which one lever was presented at a time to inform the rat of the current reward probability. Next were 10 free choice trials in which both levers were made available, and rats were free to choose amongst the 2 options. Then, we tested the impact of a therapeutic intervention using a mitochondria targeted drug, SS-20 on the deficits observed in aged animals' decision making strategies. SS-20 is a cardiolipin-targeted agent that has been shown to enhance mitochondrial energetics. As expected, based on earlier studies with aged animals, the aged rats displayed significantly increased discounting behavior compared to young controls. Interestingly, the degree of probabilistic discounting was correlated with performance on a spatial memory test using the Morris water maze. However, at this time, it does not appear that SS-20 changed the discounting behavior in young or aged animals. It is possible that SS-20 is improving the energetics of neural tissue but that the test was not sensitive enough to pick up these effects. Indeed, open field tests that were also administered before and after drug exposure revealed that the peptide may have a protective effect on age-related physical

deterioration. To investigate how reward processing may change in the aged brain, an additional study is underway in which neural activity from midbrain regions important for the processing of rewards is being recorded in another group of young and aged animals during a different version of the probabilistic discounting task. Our findings should help explain why older animals are more risk averse than their younger counterparts. Together, this work provides further details of altered decision making strategies with age and seeks to elucidate possible neural mechanisms that may underlie their altered behavior.

Title: Examination of sex differences in c-Fos expression in adult and aged Fischer 344 rats reveals that females, but not males, display enhanced neural activation after social interaction

Authors: *A. E. PERKINS[1], R. L. SPENCER[2], E. I. VARLINSKAYA[1], E. A. WOODRUFF[2], L. A. CHUN[2], J. M. INTERRANT[1], T. DEAK[1];
[1]Binghamton Univ., Binghamton, NY; [2]Univ. of Colorado-Boulder, Boulder, CO

Abstract: There is a significant decline in social behavior across the lifespan. This can be detrimental to aging individuals, since positive social interaction produces significant health benefits. Neural activation patterns following social experience in rodents may provide insight into factors that mediate an aging-related decline in social behavior. To answer this question, two experiments were conducted in parallel. In Exp. 1, 3-4 month-old adult male and female F344 rats (n = 6-8/group) were left undisturbed in their home cage as controls (HCC), exposed to the testing context alone for 30 min (CXT), or exposed to the context for 20 min, followed by a 10 min social interaction (SI) test with an age- and sex-matched conspecific. C-Fos induction was assessed by *in situ* hybridization in hippocampus (CA1, CA3, & DG), barrel cortex (BF layers 2/3, 4, & 5/6), cingulate cortex (CING layers 2/3, 4, & 5/6), medial amygdala (MeA), and the paraventricular nucleus of the hypothalamus (PVN). In the second experiment, the same behavioral testing parameters were used in 3- and 18-month-old male F344 rats (n = 6-9/group),with expression of c-Fos, cytokines (IL-6, IL-1, & TNFα), and social peptide receptors (OTR & AVPR1a) assessed in the PVN and amgydala (AMG) using RT-PCR. In the first experiment, analysis of social behavior revealed that females displayed more social investigation

than males. Additionally, in DG, females demonstrated greater c-Fos induction after social interaction (relative to being in the context alone), whereas males displayed identical increases in c-Fos when exposed to context alone or a social partner. When cytokine expression was examined in male 3- and 18-month old rats in Exp. 2, IL-6 was significantly elevated in the AMG following either CXT or SI, regardless of age. Exposure to CXT or SI did not influence expression of OTR or AVP1a in either the AMG or PVN. Notably, however, a similar pattern in c-Fos induction was observed in the AMG of males via both measurement approaches (*in situ* hybridization and RT-PCR). Taken together, these data confirm the use of this behavioral paradigm to explore aging-related changes in the circuitry that underlies the response to social interaction. Overall, marginal increases in c-Fos in the PVN suggest that the social testing procedure is minimally stressful, yet the profound induction in other structures confirms the sensitivity of this model for studying the neural circuitry of social behavior. Given the profound sex differences observed in Exp. 1, future studies will extend this research into aged females while continuing to explore the involvement of immune factors and social peptides in aging-related changes in social behavior.

Title: Changed HRG expression and cell types in micro-environment of old NSC niche

Authors: Y. KIM[1], H. LEE[2], Y. JUNG[2], *Y. K. KWON[1];
[1]Kyung Hee Univ., Seoul,, Korea, Republic of; [2]Life and Nanopharmaceutical science, Kyunghee university, Seoul, Korea, Republic of

Abstract: Heregulin(HRG) is a component of neural stem cell (NSC) niche regulating self-renewal and differentiation in NSC microenvironment. NSCs of old mice brain are slow in self-renewal and their developmental potential is reduced. NSC niche in old mice brain may be different from young mice. Here we compared the expression of HRG and its receptor, ErbB4, and expression of their target genes in NSC niche of young and old mice brain. First, we searched what cell types in brain are changed between young and old mice using transgenic mice expressing pax6-GFP. We found Pax6+GFP expressing NSCs were remarkably reduced in

addition to proliferating type2 cells. ErbB4+type1 cells and DCX+type3 cells were also diminished. When we isolated NSC from SVZ, the size and numbers of neurospheres cultured from older brain were smaller and expression of NeuN, GFAP, vGluT1 and GAD in neurospheres from older brain were diminished in immunoblot assays. Expression of HRG-β mRNA together with DISC-1 and Dlx2 in neurospheres cultured from SVZ of the older brains also decreased but HRG-α increased slightly in RT-PCR assay. In young brains NRG-EGF domains and NRG-ICD are expressed in brain vascular pericytes but not in the older brains. Numbers of brain vascular pericytes and expression of ErbB4 are diminished in older brains. This suggests reduced expression of HRG may be a cause of changed micro-environment of old NSC niche. Title: Aging transition of perimenopause is associated with bioenergetic shift and decline in long-term potentiation in the female brain

Authors: ***F. YIN**[1], J. YAO[1], H. SANCHETI[1], T. FENG[1], T. E. MORGAN[2], C. E. FINCH[2], C. J. PIKE[2], W. J. MACK[3], E. CADENAS[1], R. D. BRINTON[1];
[1]Sch. of Pharm., [2]Davis Sch. of Gerontology, [3]Keck Sch. of Med., USC, Los Angeles, CA

Abstract: Perimenopause is a transition state of female aging that proceeds- and leads to reproductive senescence and is associated with multiple neurological symptoms, including those associated with increased Alzheimer's disease (AD) risk, such as depression, insomnia and subjective memory impairment. The current study determined the biological transformations that occur in the aging female brain during the perimenopausal transition and its implications for AD risk. A preclinical model of human perimenopause was developed that assessed chronological and endocrine aging in female rats. Levels of key neuroactive steroids in serum and brain were determined by LC-MS/MS. Bioenergetic-, redox-, inflammatory-, and AD pathology-related gene expression was determined by customized low density gene array followed by bioinformatic analysis. The perimenopausal transition state was further characterized by the expression of key metabolic enzymes, the activity of signaling pathways, and mitochondrial respiratory capacity. Functional outcomes were assessed in this model using (a) FDG-microPET

for cerebral glucose metabolism, (b) long-term potentiation for synaptic plasticity, and (c) glucose tolerance test for peripheral metabolic status. Gene expression analyses indicated two distinct aging programs: chronological and endocrine. Modest decline in bioenergetic gene expression occurred with chronological aging. Conversely, a critical period emerged during the endocrine transition from regular to irregular cycling characterized by a down-regulation of genes required for glucose metabolism and mitochondrial function, which were confirmed by declines in brain glucose metabolism, mitochondrial capacity and synaptic plasticity. Bioinformatic and biochemical analyses indicated that bioenergetic profiles were likely regulated by the upstream insulin/IGF1 and AMPK/PGC1α signaling pathways. The onset of acyclicity was accompanied by a rise in genes required for mitochondrial function, inflammation, and fatty acid metabolism. Subsequent chronological aging resulted in an overall decline in genes involved in mitochondrial function and β-amyloid degradation. These findings provide novel mechanistic insights into the impact of the aging perimenopausal transition on brain metabolism and synaptic function, which could have implications for identifying phenotypes of AD risk and a critical window for earliest detection in aging females. Title: Continuous 17β-estradiol combined with cyclic progesterone modulates female brain bioenergetic functions in an endocrine status dependent manner

Authors: *Z. MAO[1], F. YIN[1], J. YAO[1], T. E. MORGAN[2], E. CADENAS[1], R. D. BRINTON[1]; [1]Sch. of Pharm., [2]Davis Sch. of Gerontology, USC, Los Angeles, CA

Abstract: The perimenopause is an aging transition unique to the female that is associated with multiple neurological symptoms. Our recent study in a rodent model of human perimenopause revealed the perimenopausal transition from regular- to irregular cycling as a critical period for brain metabolic function, characterized by a significant decline in bioenergetic and synaptic functions. Combinations of estrogens and progestogens in varying regimens are widely used as hormone therapy for menopause-related climacteric symptoms. We previously reported that a

two-month treatment of continuous 17β-estradiol (E2) in combination with cyclic progesterone (P4) (E2+CyP4) on ovariectomized (OVX) young rats (3-month-old) induced a bioenergetic gene-expression profile comparable to the ovary intact females. The present study was aimed to determine the efficacy and optimal intervention window of the E2+CyP4 therapy on female rat brain during the perimenopausal transition. Placebo or E2+CyP4 therapy was initiated on female rats at 9-10 months old with either regular cycling or irregular cycling, and for each cycling status, Sham OVX or OVX surgery was performed before the intervention. Hormone therapy consisted of two 30-day cycles of continuous E2 and cyclic P4 (10 days/cycle) delivered by silastic capsules. Upon completion of the regime, rats were subject to genomic, biochemical and brain metabolic investigations. Our preliminary data indicate that the efficacy of E2+CyP4 therapy on brain bioenergetic functions in terms of glucose metabolism and mitochondrial respiratory capacity was differentially affected by the endocrine status of the rats when the intervention was initiated. Outcomes of this study in the model of natural perimenopause will determine the window of opportunity for preventing the at-AD-risk bioenergetic phenotype by hormone intervention and will provide mechanistic details for developing novel strategies to maintain neurological health and function throughout menopausal aging. This work was supported by NIA 5P01AG026572 to RDB; Project 1 to RDB & EC.

Title: Mechanism of perimenopausal hot flash: involvement of brain hypometabolism and mitochondrial uncoupling

Authors: *R. D. BRINTON, F. YIN, J. YAO, A. MISHRA;
Sch. of Pharm., USC, Los Angeles, CA

Abstract: The goal of the current study is to determine the mechanism of the signature symptom of the menopausal transition, the perimenopausal hot flash. We hypothesized that loss of ovarian hormone regulation of bioenergetics in brain induces a series of adaptive responses in the brain bioenergetic system, that are initiated by decline in glucose metabolism, followed by activation of alternative fuel sources, ketones and free fatty acids, which lead to mitochondrial uncoupling and temperature dysregulation. We used the ovariectomy (OVX) rat model as a reliable and

predictive inducer of temperature dysregulation. Loss of ovarian hormones in the OVX rats led to decreased uterine weight, increased body weight and most importantly, a significant increase in peripheral (tail skin) temperature. Further, our analyses in the OVX rat model indicated that peripheral temperature dysregulation coincided with decreased cerebral glucose metabolism (FDG-PET) in brain and systemic glucose intolerance. OVX-induced changes were completely or partially prevented by 17beta-estradiol treatment, suggesting an obligatory role of estrogen signaling in these events. We further tested our hypothesis that loss of ovarian hormones leads to disruption and uncoupling of the proton motive force-dependent energy conservation systems and the consequent dissipation of energy as heat. Results of these analyses indicated that mitochondrial respiratory control ratio (RCR) was decreaed in OVX rats and was accompanied by mitochondrial uncoupling. In parallel, the uncoupling of brain mitochondria in OVX'd rats was concurrent with the upregulation of mitochondrial uncoupling proteins (UCPs) in multiple brain regions. Finally, to investigate the relationship between mitochondrial uncoupling in the brain and the increase in peripheral temperature, we induced mitochondrial uncoupling in the brain by intracerebroventricular injection of 2,4-dinitrophenol (2-DNP), a mitochondrial uncoupler. Preliminary analyses indicate that injection of 2-DNP into brain induced a rise in tail skin temperature as well as fluctuations in brain temperature. Collectively, we established the physiological and bioenergetic phenotype of a rat model of hot flash, and using this model, our findings provide new mechanistic details of hot flash by connecting loss of ovarian hormones, brain hypometabolism, mitochondrial uncoupling and dysfunction, and peripheral temperature dysregulation. Title: Mechanistic pathways linking mitochondrial hydrogen peroxide production and white matter degeneration in the aging mammalian female brain

Authors: *L. KLOSINSKI[1], J. YAO[1], S. CHEN[1], Z. MAO[1], E. TRUSHINA[2], S. TIWARI-WOODRUFF[3], L. ZHAO[4], R. BRINTON[1];
[1]USC, Los Angeles, CA; [2]Mayo Clin., Rochester, MN; [3]Univ. of California Riverside, Riverside, CA; [4]Univ. of Kansas, Lawrence, KS

Abstract: White matter hyperintensities are an early hallmark of Alzheimer's Disease (AD) which ultimately manifest in later stages of the disease as white matter degeneration. We propose a mechanistic link between white matter hyperintensities / degeneration and mitochondrial H2O2 generation which activates the phospholipase A2 (PLA2) and arachidonic acid (AA) pathway to initiate a cascade of white matter degradation in the aged mouse brain. Female mice were sacrificed at 3, 6, 9, 12, and 15 months of age followed by analyses of gene and protein expression, electron microscopy, lipidomics and immunohistochemical analysis, coupled with enzyme activity. The degenerative cascade begins with a statistically significant increase in PLA2 activation at 12 months of age. Consistent with increased PLA2 enzyme activity, myelin degradation associated genes, AA and alkaline ceramidase, were significantly upregulated at 12 months of age. Upregulation of AA epoxygenase ($p=0.004$) is indicative of an increase in AA availability, while an increase in alkaline ceramidase ($p=0.01$) indicates activation of the sphingomyelinase ceramide pathway. While myelin synthesis genes exhibited a pattern of downregulation between 12 and 15 months of age, myelin degradation genes remained upregulated, indicating that white matter degeneration continues after 12 months of age. Immunohistochemical mapping of myelin basic protein indicated that myelin area increased in major myelin tracts between 9 and 12 months, followed by a precipitous decline between 12 and 15 months. Electron microscopy analysis of myelin organization revealed that the expansion of myelin area was due to loss of myelin compactness and structural integrity. Structural changes in myelin integrity were widely manifested as a phenotype of distorted myelin sheaths. Myelin degeneration was further confirmed by lipidomic analysis that revealed an increase in myelin's constituent components, ceramides and fatty acids, at 12 and 15 months respectively. These findings create a mechanistic foundation and temporal trajectory for progression of white matter degeneration in aged brain. Title: Mitochondrial gene expression during perimenopause and chronological aging

Authors: *Y. WANG[1], F. YIN[2], R. D. BRINTON[2];
[1]Clin. and Exptl. Therapeutics, Sch. of Pharm., [2]Pharmacol. and Pharmaceut. Sciences, Sch. of Pharm., USC, Los Angeles, CA

Abstract: Human mitochondrial genome contains 37 genes, including 13 protein-encoding genes, which are all core subunits belonging to complexes I, III, IV, or V of the electron transport chain (ETC). Alterations in gene expression can lead to changes in cellular respiration and bioenergetics, which are implicated in multiple neurodegenerative diseases including Alzheimer's disease. Compared to males, females over 60 years old are at greater risk for Alzheimer's disease. To investigate the effects of endocrine transition during perimenopause and chronological aging on mitochondrial gene expression in female brain, we used a rat model recapitulating fundamental characteristics of the human perimenopause. Specifically, female Sprague-Dawley between 9-10 months old were classified as either regular cycling, irregular cycling, or acyclic based on their estrus status. 6-month-old regular cycling and 16-month-old acyclic rats were included to distinguish the effect of chronological aging from endocrine aging. We observed that in the hippocampus, MT-ND3 (complex I), MT-CYB (complex III), and MT-ATP6 (complex V) had significantly lower expression in both irregular and acyclic 9-month-old animals comparing to regular cyclic 9 month ones; MT-CO1, MT-CO2, and MT-CO3 had significantly lower expression in acyclic 9-month old animals compared to regular cyclers. Although other protein coding genes did not show significant differences, they did share a similar trend in decreased gene expression. In terms of chronological aging, relative to 6 month old female rats, 9 month old animals exhibited an increase in mitochondrial genes expression in hippocampus, whereas a decline in mitochondrial gene expression occurred by 16 months of age. In contrast, the cerebral cortex exhibited a different pattern of gene expression. During perimenopause, mitochondrial gene expression patterns in irregular cycling and acyclic rats were not significantly different from regular cyclers. Rather than have a surge in expression at 9 month as seen in hippocampus, mitochondrial gene expression in cortex continuously decreased as animals aged, and at 16-month-old, 8 out of 13 protein coding genes spanning ETC complexes I, III, IV, and V were significantly lower level compared to 6-month-old animals. Our data suggest that in the hippocampus, mitochondrial gene expression is sensitive to both endocrine and chronological aging. We have also shown regional differences in mitochondrial gene expression between the chronological and endocrine programs with the hippocampus exhibiting both chronological and endocrine aging whereas the cerebral cortex exhibited only chronological aging.

Title: Expression of alternative splicing factors change in a brain region-specific manner with loss of circulating 17β-estradiol in the aged female rat brain

Authors: *C. L. SHULTS, E. PINCETI, Y. S. RAO, T. R. PAK;
Cell. & Mol. Physiol., Loyola Univ. Chicago, Maywood, IL

Abstract: Aging increases alternative splicing (AS) events in the brain of both healthy and neurodegenerative individuals. Loss of circulating 17β-estradiol (E2) associated with menopause further compounds the effects of aging in women, yet increases in age-related AS have not been studied in females. Age-related changes in the expression of the CNS-specific RNA-binding splicing factor NOVA1 have been implicated in increased AS events in male-only studies. There are many important splicing-related factors, like NOVA1, present in the brain that may be affected not only by aging, but also by loss of circulating E2. We hypothesized that splicing factor expression changes with aging and longer periods of E2 deprivation in a brain region-specific manner. In our model of surgically-induced menopause, 18 month old animals were ovariectomized (OVX) , and then, after varying deprivation periods (1 wk, 4 wks, 8 wks, 12 wks), were treated with either vehicle or 2.5 ug/kg E2 for 3 consecutive days. All animals were euthanized 24 hours after the last treatment for tissue collection of the hypothalamus, dorsal hippocampus, and ventral hippocampus. Expression of three splicing factors, HNRNPH1, DDX17, and CELF5, all significantly changed in brain region-specific manner with longer periods of E2 deprivation and subsequent E2 treatment. Expression of three other splicing factors, NOVA1, CELF4, and RBFOX1, were significantly altered in a region-specific manner, but not in every brain region. For example, NOVA1 expression was significantly altered in the hypothalamus and ventral hippocampus, but not in the dorsal hippocampus. Interestingly, there was a significant interaction between length of E2 deprivation and E2 treatment on the expression of HNRNPH1 in all three brain regions. These data suggest that both age and E2 contribute to changes in splicing-related factors, which could result in increased AS in the aged female brain.

Title: Mitogen Activated Protein kinase pathways are altered by loss of circulating estrogen in the aged female brain and heart in a region specific way

Authors: *E. PINCETI[1], C. L. SHULTS[2], Y. S. RAO[2], T. R. PAK[2];
[1]Cell. and Mol. Physiol., Loyola Univ. Chicago, Maywood, IL; [2]Cell and Mol. Physiol., Loyola UniversityChicago, Maywood, IL

Abstract: Aging and the coincident loss of circulating estrogens at menopause lead to increased risks for neurological and cardiovascular pathologies. Clinical studies show that estrogen therapy (ET) can be beneficial in mitigating these negative effects, in both the brain and heart, when it is initiated shortly after the perimenopausal transition. However, this same therapy is detrimental when initiated >10 years postmenopause. Importantly, the molecular mechanisms underlying this age-related switch in ET efficacy are unknown. Estrogen receptor β (ERβ) mediates both neuroprotective and cardioprotective functions of estrogens. Phosphorylation of steroid receptors of the same family as ERβ affects nearly every aspect of their signaling, including their ability to interact with coregulatory proteins and regulate gene transcription. This raises the possibility that aging and/or estrogens alter cellular signaling pathways resulting in altered ERβ-mediated physiological effects of ET. Indeed the cellular stress associated with aging has been shown to activate the Mitogen Activated Protein Kinases (MAPK) p38 and ERK. Our hypothesis is that age and estrogen deprivation following menopause alters the expression and activation of p38 and ERK kinases in the brain and heart. To test this hypothesis, we designed the following *in vivo* paradigm: surgically induced menopause was established in 18 mo. old rats through bilateral ovariectomy (OVX) and an acute dose of 17β-estradiol (E2; 2.5μg/Kg once/day x 3 days) or vehicle was administered at varying time points post-OVX (1 week, 4 weeks, 8 weeks, or 12 weeks). The mRNA expression and activation of p38 and ERK kinase in the hypothalamus, dorsal and ventral hippocampus and heart was measured using qRT-PCR and western blot analysis. The results showed that age and estrogen differentially regulate kinase activity in both the brain and heart, and the effects were also brain region specific. For example, the mRNA expression of the kinases tended to increase in all brain regions, yet their activity was differentially modulated. Overall, it is well understood that MAPKs signaling plays an integral role in aging, and their aberrant regulation might be involved in age-related disorders. Clinical studies show benefits of ET during early menopause but detrimental effects later, which might be reflective of changes in kinase expression and activation status. Title: Age related changes in GABAergic inhibition in mouse auditory cortex, measured using *in vitro* flavoprotein autofluorescence imaging

Authors: *K. STEBBINGS[1], H. CHOI[1], A. RAVINDRA[1], J. TURNER[3], D. CASPARY[4], D. LLANO[2];
[2]Mol. and Integrative Physiol., [1]Univ. of Illinois At Urbana Champaign, Urbana, IL; [3]Psycology, Illinois Col., Jacksonville, IL; [4]Pharmacol., Southern Illinois Univ. Sch. of Med., Springfield, IL

Abstract: To examine aging-related changes in the earliest stages of auditory cortical processing, population auditory cortical responses to thalamic afferent stimulation were studied in young and aged mice. Cortical responses were measured using flavoprotein autofluorescence imaging, and aging-related changes in inhibition were assessed by measuring the sensitivity of the cortical responses to blockade of GABAA receptors using bath-applied SR95531. The maximum auditory cortical response to afferent stimulation was not different between young and old animals under control conditions, but older animals showed a lower sensitivity to GABA blockade with SR95531. Other parameters, such as EC50 and slope of the input-output curve differed between old and young animals at baseline, but showed equal sensitivities to SR95531. Hearing loss did not independently contribute to these aging-related changes, though cortical thickness was a strong predictor of most imaging variables. To determine if the observed differences between slices from young and aged animals were due to differences in slice health, the redox state of the slices was assessed by measuring the FAD+/NADH ratio using fluorescence imaging. We found that this ratio is highly sensitive to known redox stressors such as H2O2 and NaCN; however, no difference was found between old and young animals. These data extend previous work suggesting that auditory cortical inhibition diminishes with age and that the observed differences in the auditory cortex are not likely to tissue metabolic differences.

Title: Ampakines stimulate dendritic growth in the hippocampus of middle-aged, environmentally enriched rats

Authors: *J. C. LAUTERBORN, L. C. PALMER, Y. JIA, B. HOU, D. T. PHAM, W. WANG, B. H. TRIEU, C. D. COX, S. KANTOROVICH, C. M. GALL, G. LYNCH;
Anat. & Neurobio., Univ. of California at Irvine, Irvine, CA

Abstract: Positive allosteric modulators of AMPA-type glutamate receptors (ampakines) up-regulate brain derived neurotrophic factor, and have been shown to rescue synaptic plasticity and reduce pathology in a neurodegenerative disorder rodent model. In the present study, we assessed 3 month (oral) treatments with the ampakine CX929 in middle-aged (MA) rats, housed in an enriched environment (EE), for effects on morphology and function of hippocampal field CA1 pyramidal cells and on measures of learning. The daily CX929 or vehicle treatments began at 9-10 months of age, and morphological effects were compared to vehicle-treated young rats. Dendritic branching and spine measures were assessed from 3D-reconstructions of Lucifer Yellow-filled cells. Sholl analyses of apical dendritic branching confirmed that aging results in substantial dendritic retraction, despite environmental enrichment. This effect was fully offset by CX929 treatment with values from ampakine (AK)-treated MA rats being comparable to those from young adults (young vs MA-vehicle: $p<0.0001$; young vs. MA-AK: $p>0.50$; MA-vehicle vs. MA-AK: $p<0.008$). Similar results were obtained for the basal dendrites and for measures of total dendritic length. While spine density did not differ between MA-vehicle and young rats, there was a significant increase in spine density in AK-treated rats relative to MA-vehicle and young groups. In a second set of MA rats, we examined the effects of 3 month CX929/EE treatment on synaptic physiology in CA1 stratum radiatum. Baseline synaptic physiology was subtly affected by CX929 treatment, in a manner consistent with greater dendritic branching. As anticipated from the morphological changes, the magnitude of LTP was substantially greater in MA-AK vs. MA-vehicle rats ($p=0.002$). Behaviorally, the ampakine group showed certain forms of long term memory that were lacking in MA-vehicle rats in tests conducted using novel, complex environments. Collectively, these findings provide evidence that long-term treatment with an ampakine can offset age-related losses in dendritic branches and that this is associated with improvements in plasticity and complex learning. Given that adverse side effects were not observed after prolonged treatment, the results are encouraging with regard to reducing age-related deterioration of brain.

Title: Long-term HMB supplementation ameliorates aging effects in the dendritic morphology of mPFC layer 5 pyramidal neurons in aged male and female rats

Authors: *D. G. KOUGIAS[1], S. O. NOLAN[2], T. KIM[2], W. A. KOSS[2], J. M. GULLEY[1,2], J. M. JURASKA[1,2];

Abstract: Beta-hydroxy-beta-methylbutyrate (HMB), a supplement commonly used to maintain muscle in elderly and clinical populations, has been unexplored in the aging brain. In both healthy aging humans and rat models, cognitive deficits and dendritic shrinkage are associated with age-related changes in neurons within the prefrontal cortex (PFC). We have previously reported that aging male and female rats had a decrement in water maze performance, and HMB supplementation prevented that decrement in males alone. Our laboratory has also previously shown that aging male and female rats have smaller dendritic trees and fewer dendritic spines in the medial PFC when compared to young adults (Markham & Juraska, 2001). The current study explores the effects of relatively short- and long-term (7- and 31-week) oral HMB supplementation starting at 12 months of age in male and female rats on the dendritic tree of layer 5 pyramidal neurons in the medial PFC. At 11 months of age, female rats were ovariectomized to model human female aging following menopause, and male rats underwent sham surgeries. HMB was voluntarily ingested in a sucrose solution (450 mg/kg twice daily) while controls received a sucrose solution. Upon sacrifice, brains were obtained for Golgi Cox staining. The dendritic morphology of layer 5 pyramidal neurons was quantified and spines were counted. As expected, there was a retraction of dendritic material in both males and females in the apical and basilar trees as well as fewer spines in old age, compared to the middle-aged, controls. However, this dendritic loss did not occur in the HMB-treated rats of either sex in either dendritic branching or total number of dendritic spines. Thus, HMB ingestion for 31 weeks forestalled the effects of aging on the dendritic tree of this population of neurons.

Title: Differential expression of calcium binding proteins (CBPs) in hippocampal subregions with aging

Authors: *D. SIMKIN, J. MA, A. HOFFMAN, M. OH, J. F. DISTERHOFT;
Physiology, Feinberg Sch. of Med., Northwestern Univ., Chicago, IL

Abstract: Extensive evidence suggests that dysregulation of Ca^{2+} homeostasis contributes to aging- and Alzheimer's-related impaired learning/memory associated with cognitive decline (Thibault et al., '07). For example, in aged CA1 hippocampal neurons, an enhanced activity dependent Ca^{2+} influx overwhelms endogenous Ca^{2+} buffers, resulting in higher free cytosolic Ca^{2+} concentrations and enhanced Ca^{2+}-dependent postburst-afterhyperpolarization as well as impaired synaptic plasticity and reduced intrinsic excitability (Tombaugh et al., '05; Disterhoft and Oh, '06). Despite reports of cell-permeable Ca^{2+}-chelators (which reduce the impact of increased Ca^{2+} influx) ameliorating aging-related spatial learning deficits and increasing cellular excitability in rats (Tonkikh et al., '06), associated systemic side effects prevent their therapeutic use. However, cells possess effective homeostatic mechanisms to regulate Ca^{2+}-signaling and intracellular concentration, such as Ca^{2+}-buffering (through chelation) by Ca^{2+}-binding proteins (CBPs). Recently, our laboratory determined that increased Ca^{2+} influx is partially countered by enhanced endogenous intracellular Ca^{2+}-buffering capacity in aged CA1 hippocampal pyramidal neurons (Oh et al., '13). As not all aged subjects experience impairments in memory, cognitive decline may not represent a "more aged" phenotype, but rather be associated with specific neuroproteomic changes compounding age-related alterations. Thus the increased Ca^{2+} buffer capacity may represent an adaptive cellular mechanism to compensate for the increased Ca^{2+} influx observed in aged animals. Understanding how age-related changes in the hippocampal neuroproteome contribute to altered neuronal excitability with either impairment or the preservation of memory function with age are critical objectives that remain to be achieved. Thus we examined changes of known Ca^{2+}-associated buffering proteins that can impact intrinsic neuronal excitability using MicroWestern array (MWA) technology in young (2-4 mo) and aged (29-31 mo) rats. This innovative technology allows for the expression of hundreds of proteins to be semi-quantitatively profiled at one time, therefore identifying a wide range of target proteins

that could potentially contribute to the preservation of memory function with age. Several classical CBPs were found to be reduced with aging in CA1 hippocampal tissue such as calbindin, hippocalcin and calreticulin. We are investigating the age-related differential expression of those and other CBPs in the hippocampal subregions (CA1, CA3 and dentate gyrus).

Title: Acute insulin on Ca^{2+} homeostasis and glucose utilization in single hippocampal neurons

Authors: *S. MAIMAITI[1], K. L. ANDERSON[1], J. POPOVIC[1], L. BREWER[1], Z. MAJEED[2], H. FRAZIER[1], N. M. PORTER[1], P. W. LANDFIELD[1], O. THIBAULT[1];
[1]Pharmacol. and Nutritional Sci., [2]Biol., Univ. of Kentucky, LEXINGTON, KY

Abstract: Recent work from our lab identified that intranasal insulin improves memory in the aged F344 rats (Maimaiti et al., 2015). It is well documented that neurons in the brain are insulin sensitive. It has also been shown that brain insulin sensitivity may be reduced in Alzheimer's disease (AD) and/ or aging. Further, clinical trials have repeatedly shown that intranasal insulin can significantly improve memory not only in AD patients, but also in younger healthy individuals. However, the mechanism whereby insulin can alter neuronal function is not clear. While prior work has highlighted changes in AMPA and NMDA receptors, very little work has focused on voltage-gated calcium channels/ currents (VGCCs) as a target of insulin action in the brain. Earlier studies from several labs have looked at intracellular Ca2+ as a key neuronal molecular regulator of hippocampal-dependent memory. Elevated intracellular Ca2+ levels in hippocampal neurons have been shown in aged animals with poor spatial memory. Recently, we have shown that insulin can reduce the Ca2+-dependent afterhyperpolarization (AHP) in hippocampal neurons in both young and aged animals (Maimaiti et al., 2015). The goal of the present work was to test the hypothesis that insulin reduces VGCCs thereby reducing the AHP. We used whole cell patch clamping, Ca2+ imaging (Bis-Fura-2) and glucose imaging techniques (2-NBDG) to measured Ca2+ currents, intracellular Ca2+ concentration and glucose utilization in 13-17 DIV mixed hippocampal neurons in culture. Active, boiled (10 nM) glulisine insulin Apidra® (rapid-acting, zinc-free form of insulin) and human recombined insulin were tested for

acute effects on neuronal VGCCs, Ca2+ levels and glucose utilization. Results show that neurons treated with 10 nM Apidra® had significantly reduced Ca2+ currents. This indicates the mechanism of insulin-mediated memory improvement could be due to reduced calcium flow through VGCCs and the ensuing reduction in the AHP (Pancani et al., 2013).

Title: Acute intranasal insulin in young and aged F344 rats: signaling and MRI brain changes

Authors: *K. L. ANDERSON[1], S. MAIMAITI[1], Z. R. MAJEED[2], H. FRAZIER[1], V. BAKSHI[1], L. D. BREWER[1], N. M. PORTER[1], A.-L. LIN[1], O. THIBAULT[1];
[1]Pharmacol. and Nutritional Sci., [2]Biol., Univ. of Kentucky, Lexington, KY

Abstract: In an attempt to combat decreased insulin signaling in the brain of Alzheimer's disease (AD) patients, several groups have used intranasal insulin in clinical and pre-clinical settings. Results show improved memory in young volunteers, patients with mild cognitive impairment, as well as in animal models of aging, diabetes or AD. While some studies have linked insulin signaling in the brain with tau or Abeta clearance mechanisms, with changes in excitatory neurotransmitters or synaptic plasticity, reductions in Ca2+, or improved hypothalamic perfusion, it is not clear how intranasal insulin alters functional communication, improves learning, or facilitates memory retrieval, particularly in animal model of aging. Here we characterized the impact of acute (single dose) intranasal insulin across different brain regions at different times following delivery. We tested the impact of Apidra® on 8 different brain regions in young (3-4 months) and aged (21-24 months) F344 rats (n=12/age group). Animals received a unilateral dose of Apidra® (0.0715 IU/rat) or saline. Olfactory bulbs and brains were removed at 30, 60, or 120 min after delivery. Insulin activity was quantified with a focus on the canonical Akt and pAkt protein expression pathway with Western blots. The pAkt:Akt ratio significantly increased at 30m in the right olfactory bulb, which was exposed to insulin, and went down to normal levels by 120 min. Dorsal and ventral signaling increases were noted at 60 and 120 min post delivery. Acute Apidra® was also tested on memory retrieval on the Morris water maze in young and aged F344 (n=20/age group) following a single dose. Saline

delivery lasted for 8 days with MWM training starting on the fifth day. On the 9th day, half the animals received Apidra. In a subset of these animals, neurotransmitter levels were determined by MR spectroscopy (MRS) and cerebral blood flow was measured by MRI. Our work highlights new details on acute intranasal insulin delivery, and in particular its' impact on memory retrieval compared to acquisition (Maimaiti et al., 2015). Changes in MRS and MRI signaling also helped rule out effects mediated solely by blood flow dynamics. These results also provide insights on improved timing between insulin delivery and behavioral characterization.

Abstract: Insulin signaling is indispensable for key metabolic pathways in the periphery, and recently several studies have demonstrated that insulin signaling is also important for brain function. Early stage clinical trials report on the positive impact of intranasal insulin on memory recall in young subjects and in patients with mild cognitive decline or Alzheimer's disease (AD). However, the underlying molecular mechanisms for the actions of insulin signaling on brain cognitive function are not well understood. Here we sought to investigate the role of insulin in neuronal physiology by overexpressing a constitutively active human insulin receptor (Lebwohl et al., 1991) in rat pheochromocytoma (PC12) and HEK 293 embryonic kidney cells to obtain insights into the trafficking of the protein, as well as its' activity and sensitivity to exogenous insulin. Cells were transfected by electroporation with pCI-ires-dsRed (a mammalian expression plasmid containing a gene encoding a red fluorescence protein) or pCI-IRβ-ires-dsRed (the construct with a truncated human insulin receptor beta subunit (IRβ) transcript). The vector was originally test in HEK293 cells. The expression of human IRβ receptor in PC12 cells was

corroborated by the expression of red fluorescent protein (dsRed) since IRβ and dsREd were co-expressed under the control of the same promotor (CMV). The expression level and effect of IRβ receptor overexpression on insulin signaling is confirmed by performing immunoblots, using antibody against tagged IRβ, and measuring pAkt/Akt ratio, respectively, because Akt is one of the main downstream signaling molecule targets for the insulin receptor signaling pathway. Our data show that overexpression of insulin receptor enhances neurite outgrowth in PC12 cells and increases the pAkt/Akt ratio. Biotinylation experiments also revealed insertion of the protein in the plasma membrane. Further studies were performed to analyze the sensitivity of the truncated insulin receptor activation to acute insulin application. This initial characterization of the protein provides insights into future intervention approaches to combat reduced insulin signaling in AD and/ or aging.

Title: Neuronal adenosine A2A receptor overexpression affects AMPA and NMDA currents in CA1 hippocampal neurons

Authors: *L. V. LOPES[1], M. TEMIDO-FERREIRA[1], J. E. COELHO[1], D. G. FERREIRA[1,2], T. F. OUTEIRO[2], M. BADER[3], H. MARIE[4], P. A. POUSINHA[4];

Abstract: Aging and Alzheimer's disease (AD) are associated with cognitive impairments, accompanied by structural and functional alterations in the hippocampus. There is compelling evidence of hippocampal upsurge of adenosine A2A receptors (A2AR) associated to cognitive deficits. Blockade of A2AR in experimental models mimicking aging or AD prevent, or even revert, hippocampus-related impairments (Batalha et al, 2013; Laurent et al, 2015, Mol. Psychiatry). This suggests that dysregulation of hippocampal A2AR function may drive part of the detrimental processes leading to aging and AD. However, the underlying mechanisms are still unknown. We generated transgenic rats overexpressing the human A2AR under the control of the CAMKII promoter [tg (CAMKII-hA2AR)], inducing a specific neuronal overexpression. In order to characterize the impact on neuronal excitability and synaptic transmission, we performed whole-cell patch-clamp recordings in CA1 hippocampal neurons from transgenic versus wildtype (WT) animals. We measured Paired Pulse Ratios (PPRs), in the range of 50 - 200ms intervals: a PPR facilitation was observed in neurons from WT animals at all intervals, more evident for the shorter intervals (n=10). The magnitude of PPR was reduced in tg(CAMKII-hA2AR) rats when compared to the WT neurons (n=10; $P<0.05$), albeit maintaining the same facilitatory profile. These effects were completely rescued by SCH 58261 (50 nM). We assessed the changes in AMPAR and NMDAR contribution, by quantifying the AMPAR/NMDAR which we found to be decreased in tg(CAMKII-hA2AR) animals (n=19-21; $P<0.05$). Current-voltage (I-V) relationships in pharmacologically isolated NMDAR or AMPAR EPSCs revealed that AMPAR activation was decreased (n=7; $P<0.05$), while the I-V profile of NMDAR was increased (n=7; $P<0.05$). Such pre- and post-synaptic effects are not due to neuronal excitability, since no differences were observed between WT and tg(CAMKII-hA2AR) animals in the excitability parameters. Altogether these data show that neuronal A2AR overexpression, per se, shares some electrophysiological features observed in both AD models and aged animals, strongly suggesting that A2AR overexpression might be one of the key events in the AD- and aging-associated glutamatergic synaptic dysfunction.

Title: Phagocytic macrophages are associated with processes involved in age and cognitive decline

Authors: *E. SHOBIN[1,2], T. L. MOORE[1], D. L. ROSENE[1];
[1]Anat. and Neurobio., [2]Grad. Program for Neurosci., Boston Univ., Boston, MA

Abstract: The rhesus monkey is a good model of normal aging as it is free from Alzheimer's disease yet shows age-related decline in cognitive domains similar to humans (Moss, et al. 2007). Previous studies in the monkey have shown that neurons are not lost but instead, myelin pathology occurs and correlates with cognitive impairments (Bowley, et al. 2010). In exploring possible mechanisms our prior studies have shown that microglia become chronically pro-inflammatory (M1) with age and this activation is associated with cognitive decline (Sloane, et al. 1999). To determine if activated microglia in the monkey become phagocytic in response to myelin degradation we used antibody to Galectin-3 (Gal-3), a lectin selectively up-regulated in phagocytic macrophages and essential for normal phagocytosis as Gal-3 knockout mice have impaired phagocytosis (Sano, et al. 2003). We used brain sections from young (6-10 years, n = 7) and old (20-30 years, n = 14) behaviorally tested rhesus monkeys and quantified Gal-3 immunostaining in frontal white matter regions. There was a significant increase in Gal-3+ cells in old compared to young monkeys ($p < 0.001$). Additional analysis in only the old monkeys showed that Gal-3+ cell density was significantly greater in those cognitively impaired compared to those relatively cognitively spared ($p < 0.05$). To further assess the relationship of phagocytosis to myelin damage, sections are being processed with double label IHC for damaged myelin basic protein (dMBP) and Gal-3. Other sections are being processed with double label IHC to determine the proportion of microglia positive for the LN3 marker for M1 microglia that are also Gal-3+ phagocytic and how this relates to the magnitude of myelin damage.

Title: Prolactin receptor signaling mitigates retinal function deficiency associated with ageing

Authors: *E. ARNOLD, S. THEBAULT, G. MARTÍNEZ DE LA ESCALERA, C. CLAPP; Neurobio. Inst., Natl. Autonomous Univ. of Mexico, Queretaro, Mexico

Abstract: Age retinal degeneration is characterized by the progressive destruction of retinal cells, causing deterioration and eventual loss of vision. We explored whether the hormone prolactin (PRL) provides trophic support to aged retinal cells, thus protecting the retina from age related degeneration. Retinal function, apoptosis, gliosis, and neurotrophin expression were assessed by electroretinogram, TUNEL, GFAP immunohistochemistry, and real-time PCR, respectively, in for PRL receptor null mice. Lack of PRL signaling associates with photo responsive dysfunction and gliosis that correlated with the down-regulation of neurotrophins (bFGF, GNDF, and BDNF) and antioxidant glutathione S-transferase μ-type 2 expression. Most of these effects were exacerbated in aged (9 month-old) compared with young (3 month-old) mice. This study unveils PRL as a trophic factor regulating neuronal-glia cell interactions in the aged retina, and its potential therapeutic value against age related retinal degeneration.

Title: Age-related changes in substance P immunoreactivity and motoneuron morphological alterations in lumbosacral spinal nuclei

Authors: H. W. S. TSANG[1], M. ZHANG[1], G. BLACK[1], M. J. SAFFREY[2], *R. N. RANSON[1]; [1]Applied Sci. (Biomedical Sciences), Northumbria Univ., Newcastle Upon Tyne, United Kingdom; [2]Dept. of Life, Hlth. and Chem. Sci., Open Univ., Milton Keynes, United Kingdom

Abstract: Incontinence and sexual dysfunction increase in the elderly. In humans, voluntary control is partially mediated by Onuf's nucleus located in lumbosacral spinal cord (LS-SC). Its homolog in rodents is divided into two spinal nuclei, the dorsolateral nucleus (DLN) and the spinal nucleus of the bulbocavernosus muscle (SNB). In these nuclei are motoneurons (MNs) that directly innervate the ischiocavernosus and external urethral sphincter (DLN), and those that innervate the levator ani, bulbocavernosus muscle, and external anal sphincter (SNB). Synaptic contacts onto SNB-MNs are reduced in aged (24 months) rats. Furthermore, a reduction in the number of MNs in 22 month-old rats has been reported. Here, we present immunofluorescence data on age-related changes in the amount of substance P (SP) in the LS-SC of C57BL/6 male

mice. In addition, we present data on SP inputs to MNs of the DLN/SNB, and semi-quantitative ultrastructural data on age-related morphology of DLN-MNs. SP immunoreactivity in the DLN, SNB, and dorsal horn where lower urinary tract sensory input is received, decreased in aged (24-25.5 month old) mice. However, SP immunoreactivity increased significantly in all three regions from aged to very aged (30-31 month-old) animals. Somatic SP appositions to DLN-MNs also increased significantly in very aged mice. Immunolocalization of SP terminals to DLN-MNs showed symmetric synaptic contacts. The cross-sectional area of DLN-MNs increased by 22% from 3-4.5 months to 24-25.5 months. A notable alteration to the ultrastructural morphology of DLN-MNs from 4 - 32 month-old animals was a progressive increase in electron dense organelles, which were likely lipofuscin-containing structures. These lipofuscin bodies were rare in 4 month-old material, but were larger, clustered and more frequently seen in 32 month-old. Rough endoplasmic reticulum (RER), polyribosomes and mitochondria were the predominant organelles/structures in the perinuclear region in 4 month-old DLN-MNs. By 32 months, lipofuscin dominated the perinuclear region. In MNs of the very aged, membranes of the Golgi apparatus, cristae and outer membrane of mitochondria were generally slack in appearance. In addition, the nuclear membrane displayed frequent deep invaginations that partially enveloped cytoplasmic contents including RER and polyribosomes. Together, age-related changes seen in this study may contribute to dysfunctional alterations in the ability to maintain continence and facilitate sexual reflexes.

Title: Aging increases the activity of neurons in the bed nucleus of the striata terminalis (BNST)

Authors: *H. E. SMITHERS[1], J. BROWN[1], J. TERRY[1], A. RANDALL[1,2];
[1]Univ. of Exeter, Exeter, United Kingdom; [2]Univ. of Bristol, Bristol, United Kingdom

Abstract: The BNST is a nucleus in the limbic forebrain that plays a role stress, fear and anxiety. The BNST is also sexually dimorphic and has been implicated in determination of sexual identity. As well as acting a major output pathway for the amydala, this nucleus is thought to act as a relay for cortical and limbic control of hypothalamic function. Aging is reported to alter neural activity in various brain regions including the prefrontal cortex and hippocampus,

however, to our knowledge, the effects of healthy aging on electrophysiological properties of BNST neurons has not been examined previously. This study examined the effect of age the intrinsic properties of BNST neurons in cohorts of female mice. *In vitro* patch clamp recordings were made from 300µM coronal brain slices prepared from either adult female mice of 3-5 months (young) or 29 months (Old). The resting membrane potential did not differ between the cohorts (young -69 ± 2 mV, Old -67 ±2 mV) however a far higher proportion of the cells recorded from aged animals (62%, n=50) fired at rest compared to the younger cells (42%, n=56, Chi Squared p = 0.001). In firing cells maintained spontaneous firing rates as high as 10 Hz were observed, although the median value was circa. 4 Hz in both cohorts. At a set membrane pre-stimulus potential of -80 mV no differences in a number of passive membrane properties or action potential properties were observed. These include input resistance (Young 445 ± 38 MΩ, Old 501 ± 49 MΩ), membrane time constant (Young 29 ± 2 ms, Old 29 ± 2 ms) and AP Zenith (17 ± 1 mV, Old 17 ± 2 mV). To examine excitability, incremental depolarizing current stimuli (5-80 pA) lasting 500 ms were applied to BNST neurons at -80 mV. As the amplitude of the stimulus was increased both the probability and the rate of AP production rose. Firing Rates in the aged cohort were significantly higher than in cells from younger animals (2-way ANOVA p = 0.011). A higher proportion of cells from the older animals fired in response to each depolarising step. This was most evident with the +20 pA step (Young 15/55 cells, Old 22/16 firing). In combination with the increased spontaneous firing at rest, these data indicate aging heightens excitability of BNST neurones and likely impacts their functions such as modulation of the HPA axis.

Title: Bexarotene treatment rescues aging-related loss of synaptic proteins in a neuronal LRP1-dependent manner

Authors: *M. TACHIBANA, M. SHINOHARA, Y. YAMAZAKI, C.-C. LIU, J. ROGERS, G. BU, T. KANEKIYO;
Mayo Clin., Jacksonville, FL

Abstract: Apolipoprotein E (apoE) plays a critical role in maintaining synaptic integrity by transporting cholesterol to neurons through its cell surface receptor, the low-density lipoprotein receptor related protein-1 (LRP1). Although controversial, Bexarotene (Bex), a retinoid X receptor (RXR) agonist, has been reported to have potential beneficial effects on cognition by

increasing brain apoE levels and lipidation. However, it remains unclear if Bex treatment can restore synaptic function in aged mice and whether neuronal LRP1 is involved in the pathway. To investigate the potential effects of Bex, forebrain neuron-specific LRP1 knockout (nLRP1-KO) and littermate control mice were administered Bex-containing diet (100mg/kg/day) or control diet at the age of 20-24 months for 8 weeks. We found that upon Bex treatment, levels of brain apoE and ABCA1 were significantly increased both in control and nLRP1-KO mice. While levels of synaptic proteins, synaptophysin and PSD95, were decreased during aging, they were restored in the cortex and hippocampus of Bex-treated mice compared to control mice. Western blotting also showed that PSD95, GluR1 and NMDAR1, which are key postsynaptic proteins that regulate synaptic plasticity, were increased by Bex treatment in the brains of control mice. Interestingly, Bex treatment did not affect the levels of these proteins in nLRP1-KO mice. These results indicate that the beneficial effects of Bex on synaptic integrity depend on the presence of neuronal LRP1. However, Bex treatment resulted in weight loss by 10-15% as well as prominent hepatomegaly in both control and nLRP1-KO mice, which is likely due to hepatic dysfunction. Furthermore, immunohistochemical analysis indicated that GFAP-positive astrocytes and Iba-1 positive microglia were significantly increased in Bex-treated mice compared to control mice, indicating exacerbated neuroinflammation. Taken together, our results demonstrate that apoE targeted treatment by RXR agonist, has a potential effect on synapses through LRP1 during aging; however, the potential therapeutic value of Bex might be limited due to harmful side effects.

Title: An enriched environment modulates factors associated with healthy brain aging in rats

Authors: *M. J. ZIGMOND[1], F. AMBROSIO[2], S. L. CASTRO[1], J. D. JAUMOTTE[1], D. L. KOROL[3], L. A. NEWMAN[3], L. H. SANDERS[1], R. J. SMEYNE[4], A. D. VALLEJO[1]; [1]Neurol., [2]Physical Med. & Rehabil., Univ. of Pittsburgh, Pittsburgh, PA; [3]Biol., Syracuse Univ., Syracuse, NY; [4]Dept. of Developmental Neurobio., St. Jude children's Res. Hosp., Memphis, TN

Abstract: The sedentary and environmentally impoverished lifestyle that characterizes many older individuals within modern society may play a critical role in the motor, cognitive, and emotional decline that often occurs during advanced years. Clinical and animal studies suggest that an enriched environment (EE) can increase socialization, motor learning, and mobility, and promote changes in the brain that appear to facilitate healthier aging, including neurogenesis, reduced cellular stress, synaptogenesis, and increased neurotrophic factor levels. We are currently assessing the behavioral, physiological, and neurobiological impact of EE in older rats using a behavioral test battery and biochemical, molecular biological, and anatomical methods. F344/BN male rats 18 month old at the outset of our studies were housed individually for at least 4 mo in a standard shoebox cage (SE) or in groups of 6 in an EE (1 m x 1 m x 1 m) containing running wheels, tunnels, platforms, and toys. All rats were exposed to a 12:12 light-dark cycle with ad libitum food and water, and videotaped for 14 hours each day, including during the dark cycle. Although physical activity was low relative to that of younger rats housed under similar conditions, we observed a good deal of exploration, climbing, playing, and social interactions. Body weight increased significantly in the EE rats, but not in the SE rats. After 4 months, rats were euthanized, the brain, peripheral tissues, and blood collected, and the brain dissected into several regions. Several biochemical, histological, and body composition assessments are currently being made. For example, post-mortem analysis of muscle showed that citrate synthase activity and fat content in the gastrocnemius were similar in rats from both conditions, supporting the evidence from video records that rats in EE conditions were not aerobically active. In addition, compared to SE rats, EE rats showed a 3.8-fold increase in BDNF in the hippocampus and a 60% increase in the ratio of dopamine (DA) metabolites to DA in the striatum, consistent with an increase in striatal DA turnover. Additional assays are ongoing, including those for neurotrophic factors, muscle composition, mitochondrial damage, inflammation, and gene expression. Thus far our results suggest that housing in an EE produces significant changes consistent with increased neuroplasticity even in the absence of increased aerobic activity, emphasizing the likely importance of other behavioral components of environmental enrichment. We hypothesize that these changes are associated with an increase in brain health and improved behavioral capacity during aging.

Title: Enriched environment improves micturition activity in awake freely moving aged mice

Authors: *F. SOEDA[1], N. GOTO[1], S. SAMESHIMA[1], S. MISUMI[1], K. TAKAHAMA[2,3]; [1]Dept. of Envrn. and Mol. Hlth. Sci., Grad. Sch. of Pharmaceut. Sci., [2]Res. Inst. for Drug Discovery., Sch. of Pharm., Kumamoto Univ., Kumamoto, Japan; [3]Fac. of Hlth. Sci., Kumamoto Hlth. Sci. Univ., Kumamoto, Japan

Abstract: We previously reported that enriched environment (EE) promotes micturition activity of freely moving normal mice. However, it is not known about the effect of EE on disorder of micturition function associated with aging in mice. In this study, we examined whether or not rearing in EE affects micturition activity in senescence-accelerated mouse prone 8 (SAMP8) mice. Male SAMP8 (32 weeks old) mice were reared in standard environment (SE) or EE for 5 weeks. As a control, senescence-accelerated resistant (SAMR1) mice were reared in SE. Micturition activity of freely moving mice was measured by using an apparatus developed by us. Mice were fed ad libitum and were kept under a 12:12-h light-dark cycle. In the light period, SAMP8 reared in the SE showed significant increase in total voided volume, single voided volume, mean flow rate and maximum flow rate of urine when compared with SAMR1. On the other hand, the mice reared in EE showed significant decrease in single voided volume, mean flow rate and maximum flow rate of urine when compared with that reared in SE. In the dark period, there was no significant difference in these parameters among the three groups. Volume of water intake during the measurement of micturition activity did not change among the three groups. Preliminary microarray analysis of the micturition centers of SAMP8 found that the level of some molecules may be changed when reared in EE compared to SE. The results suggest that rearing in EE may improve micturition activity in the resting period of SAMP8 mice. Further studies are needed to identify the molecules associated with amelioration of micturition activity in SAMP8 reared in EE.

Title: Daily exposure to environmental novelty in young mice promotes corticostriatal and behavioral flexibility in old age

Authors: *S. L. HONG[1], S. J. BARTON[2], G. V. REBEC[2];
[1]Biomed. Sci., Ohio Univ., Athens, OH; [2]Psychological and Brain Sci., Indiana Univ., Bloomington, IN

Abstract: We assessed early rearing conditions on aging-related changes on neuronal signaling patterns in motor cortex and dorsal striatum as mice explored a plus-shaped maze. Mice were raised in one of the following four conditions beginning at ~4 weeks of age: 1) Isolated Empty Cage (IHEC); 2) Isolated Running Wheel (IHRW); 3) Enriched Environments - Static (EEST); and 4) Enriched Environment - Dynamic (EEDY). Both enriched groups included toys and other mice. For EEDY, the toys and the location of sources of food and water were changed daily, but remained constant for EEST. All mice remained in their respective environments for 25 weeks followed by single housing in empty cages for the remainder of the experiment. Beginning at ~40 weeks of age, all mice were tested at regular monthly intervals in a plus-shaped maze in which we measured the number and pattern of arm choices and recorded local field potentials (LFPs). Unpredictability in cortical and striatal LFPs was assessed by approximate entropy (ApEn). Corticostriatal synchrony was assessed by obtaining phase locking values (PLV) at four time points relative to the center choice point of the plus maze: A) 2s-1s prior; B) 1s prior-choice point; C) choice point-1s after; and D) 1s-2s after. Our results indicate a unique plasticity in EEDY cortical and striatal ApEn levels, which were elevated relative to IHRW and IHEC. In old age, higher PLV values indicative of greater corticostriatal synchrony were observed in comparison to the IHEC group. Behaviorally, the IHEC and EEST groups demonstrated a reduced ability to adapt to repeated exposures to the plus maze; arm-choice patterns and number of arm entries were unchanged over time. Collectively, our results highlight the benefits of early exposure to daily environmental novelty in the maintenance of healthy brain function and behavioral flexibility in aging; this effect persists even months after environmental changes are withdrawn.

Title: Treadmill exercise attenuates aging-related bradykinesia in aged rats: potential involvement of increased nigral glial cell line-derived neurotrophic factor family receptor-alpha 1 (GFR-α1) expression and dopamine tissue content

Authors: *J. C. ARNOLD[1], M. F. SALVATORE[1,2];
[1]Pharmacology, Toxicology, & Neurosci., Louisiana State Univ. Hlth. Sci. Ctr., Shreveport, LA;
[2]Pharmacol. & Neurosci., Univ. of North Texas Hlth. Sci. Ctr. at Ft. Worth, Ft. Worth, TX

Abstract: Given the burgeoning increase in our elderly population, lifestyle strategies that mitigate aging-related impairments are essential. Bradykinesia, a cardinal symptom of Parkinson's disease (PD), also affects up to 30% of the elderly population. Exercise may improve locomotor deficits in PD models and patients, but the neuroanatomical and molecular basis for these effects have not been pinpointed to striatal dopamine (DA) recovery. In PD, striatal DA loss exceeds 80% at onset of bradykinesia, but in aging, striatal DA loss has not ever been reported to exceed 50%. However, in aging and PD alike, the onset of bradykinesia may be associated with 50% DA loss in the substantia nigra (SN). Here, we hypothesized that an established treadmill exercise regimen could attenuate aging-related bradykinesia (ARB) in conjunction with increased DA and the glial cell line-derived neurotrophic factor (GDNF) receptor, GDNF family receptor-alpha 1 (GFR-α1) in the SN. The rationale for this hypothesis is based on observations that striatal infusion of GDNF in aging models increases locomotor activity and DA in the SN, but not striatum. Exercise may also increase GDNF expression, and exogenous GDNF may increase GFR-α1 expression in the SN. We have also reported that GFR-α1 decreases only in the SN in aging, and replenishing the quantity of GFR-α1 lost due to aging increases locomotor activity in combination with increased DA and tyrosine hydroxylase (TH) expression in SN, but not striatum, in aged rats. Using our treadmill exercise regimen, we assessed the impact of short- and long-term exercise on ARB and GDNF signaling in aged rats. Our results demonstrate that two rounds of our exercise regimen increased GFR-α1 expression and DA tissue content in SN of aged rats: a result that reflects the previously reported effect of exogenous GDNF. Notably, a repeated regimen of long-term exercise followed by an equal amount of rest eventually attenuated ARB when compared to non-exercise rats. These studies may be applicable in PD models, in that reduction of age-related loss of DA in the SN may be an important mechanism of reducing bradykinesia. Finally, our work may suggest that a therapeutic strategy that reduces ARB and increases DA synthesis in the SN may be a sufficient means to target bradykinesia, particularly in those who may be physically unable or unwilling to exercise.

Title: On the spectrum: sensory perception influences socio-communication in ASD

Authors: *R. A. STEVENSON[1], M. SEGERS[3], M. D. BARENSE[2], S. FERBER[2];
[2]Dept. of Psychology, [1]Univ. of Toronto, Toronto, ON, Canada; [3]Dept. of Psychology, York Univ., Toronto, ON, Canada

Abstract: Autism Spectrum Disorder (ASD) has become increasingly common, now at one in 68 births. One of the primary factors in ASD is difficulty in social communication. While socio-communication issues have long been included in the diagnostic criteria, emerging theories posit that these difficulties may arise from divergent developmental cascades that stem from atypical sensory perception during development. In short, most higher-order cognitive functioning, including social communication, are dependent upon sensory perception. Differences in sensory perception, particularly throughout development, may thus lead to differences in social communication. We explored this hypothesis through a series of experiments in individuals with and without ASD focusing on the ability to integrate individual pieces of sensory information into coherent, unified representations - a process known as perceptual binding. Using four well characterized perceptual paradigms, we measured individuals' abilities to perceptually bind social and non-social sensory information within the visual system (using the composite-face effect and the composite-letter effect, respectively), as well as across the visual and auditory system (using the McGurk effect and the sound-induced flash illusion). We also used a standard speech-in-noise paradigm to assess individuals' speech perception abilities. Finally, real world measures of socio-communicative abilities were measured using the ADOS-2 and the Social Responsiveness Scale. Behaviourally, perceptual binding at all levels were related to communicative abilities, and differently so for individuals with ASD relative to their typically developed peers. Individuals with ASD showed strong, positive relationships between their abilities to perceptually bind across sensory modalities and to perceive spoken language. At the more local level, visual binding was inversely related to speech perception abilities, suggesting a trade-off in ASD between more global, between-sensory perception and more local, within-sensory perception. These data converge with fMRI data suggesting that individuals with ASD are less able to make use of the sensory cues to perceptually bind across sensory modalities, which leads to decreases in neural processing efficiency with socio-linguistic, audiovisual stimuli. Furthermore, this evidence that higher-order cognitive function in ASD, in this case speech perception, is strongly related to lower-level perceptual differences, suggest that early sensory processing may be a valuable target for future remediation strategies in ASD.

Title: Characterization of levels of corporeal awareness in Autism Spectrum Disorders and neurotypical controls

Authors: *V. KALAMPRATSIDOU[1], E. B. TORRES[2];
[2]Psychology Dept., [1]Rutgers Univ., Piscataway, NJ

Abstract: This work tests the extent to which it is possible to detect and improve corporeal self-awareness by combining a variety of external sensory inputs with kinesthetic re-afference from the person's real-time movements. In previous work we developed a paradigm that permits probing the person's ability of distinguishing self from others. That paradigm presented the person with a movie of an avatar endowed with veridical motions of the person and with noisy variants of it. A decision making task determining 'ME' vs. 'NotME' was used to assess the person's ability to recognize self-motions. Here, upon initial testing to assess the ability to recognize self-motions, we have the participant physically interact with the avatar as we steer the kinesthetic re-afferent noise in various ways and then retest the person using the same above-mentioned paradigm. To this end we have developed a co-adaptive interface that projects on a large screen an avatar endowed with the real-time captured motions of the participant using the Phase Space (480 Hz). We first parameterize the stochastic signatures of the motor output variability inherently present in the person's motions during the performance of dancing routines. We use the continuous Gamma family of probability distributions to empirically estimate the stochastic trajectories of 22 joints of the body as they rotate and translate. We then utilize the Gamma shape and scale parameters to generate various sources of noise in the joint angular rotations and their temporal dynamics. We use self-noise and others-noise to selectively alter the original stochastic signatures of the person's motions in segments of the routine performed largely beneath the subjects' awareness vs. deliberate segments. We discuss our results in the context of profiling corporeal awareness in participants in the spectrum of autism vs. neurotypical controls in order to develop proper volitional control, enhance intentionality in the person's actions and probe the extent to which the person learns to distinguish self from others.

Title: SHANK3 single nucleotide variant associated with social behavior in rhesus macaques

Authors: *S. MADLON-KAY[1], A. BEY[1], R. PASSMAN[1], L. BRENT[2], K. WATSON[3], P. SKENE[1], J. HORVATH[4], M. PLATT[1], Y.-H. JIANG[1];

Abstract: Autism spectrum disorders (ASD) are characterized by impairments in communication and social interaction that arise from the interaction of genes and experience during development. Mutations in the SHANK3 gene have been identified as one of several monogenic causes of ASD. The functional role of SHANK3 in neural development and function has been illuminated by studies in transgenic mice and flies. However, the role of SHANK3 in the social phenotype of ASD has proven more difficult to decipher, in part due to the relative simplicity of mouse and fly social behavior and the relatively impoverished nature of laboratory social environments. An alternative approach is to study naturally occurring genetic variation in free-ranging populations of animals with complex, human-like social behaviors and environments. Rhesus macaques provide a candidate model species due to their extensive use in both laboratory and field research, homologous neural circuitry, complex social behaviour, hierarchical social structure, and the strong contribution of social competence to biological success. Moreover, prior studies have demonstrated a strong genetic component to social function in these animals. Here, we identify SHANK3 sequence variants in a large free-ranging population of rhesus macaques on Cayo Santiago island and the social phenotypes they predict. We sequenced the SHANK3 region in an initial sample of 285 rhesus macaques. We identified one C>T single nucleotide variant (SNV) in a conserved proline rich region that contains Homer, Dynamin, and Cortactin binding sites. This SNV is non-synonymous, with the major allele coding for Proline (CCT) and the minor allele coding for Leucine (CTT). Forty animals were heterozygous at this allele. We investigated the impact of this SNV on social phenotypes using social network analysis, which quantifies position of each animal in the social network and describes their relationship to the rest of the population. These analyses were based on 2 years of observational data regarding the types and frequencies of interactions occurring between animals in this population. We found that animals heterozygous at this locus had stronger affiliative "betweenness", which is a social metric quantifying an animal's tendency to affiliate with groups of animals that do not affiliate with each other and thus connect otherwise separate social

clusters. We speculate that this SHANK3 SNV may increase social 'adventurousness', thereby increasing willingness to interact with partners outside of one's preexisting social circles. Further functional study may provide additional insight for functional significance of this SNV.

Title: Altered brain connectivity patterns in face processing in autism spectrum disorder

Authors: *I. M.REZAZADEH[1], S. K. LOO[1], S. J. WEBB[2], M. C. GRABB[3], B. H. KING[2], J. T. MCCRACKEN[1];

Abstract: Background. Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by impairments in social cognition, with one manifestation being deficient face processing. Recent studies have found widespread cortical under-connectivity, local over-connectivity, and mixed results suggesting disrupted brain connectivity as a potential neural signature of autism. In the present study, we investigated whole brain connectivity during different stages of face processing using high-density electroencephalography (EEG) in young adults with ASD and compared them with typically developing (TD) controls. Methods. Data: 63 participants (35 with ASD, 28 TD controls), aged 18 to 35 years, participated in this study. They performed the FACES task (Webb, 2012) in which upright and inverted pictures of human faces and objects (houses) were randomly presented while 128-channel EEG was recorded. Behavioral Measures: The Social Responsiveness Scale (SRS) and Autism Diagnostic Observation Schedule (ADOS) scores were collected as measures of social cognition in TD and ASD groups. EEG Pre-Processing: Data were exported to EEGLAB in Matlab for pre-processing. EEG connectivity analyses: A neural connectivity matrix for all possible pairs of electrodes was calculated by measuring coherence values in each 100ms window. Network connectivity patterns (especially in face-sensitive brain regions) were then extracted to measure small-world properties such as network efficiency, clustering coefficient, and path length. Results. Preliminary results suggest significant group differences in cortical activation and brain connectivity patterns in the early and mid-stages of face processing between ASD and controls. Specifically, the ASD group exhibited attenuated cortical activation (i.e., less theta/alpha/gamma power synchronization and

beta-band desynchronization, all p's<0.05) relative to controls. In addition, the ASD group demonstrated higher coherence values suggesting stronger local connectivity (all p's < 0.01). Conclusion. Group differences in neural connectivity patterns between ASD and controls may reflect 1) compensatory mechanisms to overcome deficits such as attenuated cortical activation of individual brain regions; and/or 2) potential neural differences underlying social cognition and behaviors. Title: Objective characterization of sensory-motor physiology underlying dyadic interactions during the Autism Diagnostic Observation Schedule-2: implications for research and clinical diagnosis

Authors: *C. WHYATT[1], A. MARS[1], E. M. DICICCO-BLOOM[2], E. B. TORRES[1]; [1]Rutgers Univ., Piscataway, NJ; [2]Robert Wood Johnson Med. Group, New Brunswick, NJ

Abstract: Traditionally viewed as a social-cognitive disorder, Autism Spectrum Disorder (ASD), is conceptualized through the use of a 'triad of impairments': socialization, communication and imagination (1). Current diagnostic tools reflect this overarching bias, focusing on levels of socialization and higher-order thinking posed from one single perspective: that of the examiner. Yet by definition, social interactions require more than one participant. Here we investigate the impact of the closed-loop dyadic interaction on the scores that determine the cut-off of an autism diagnosis. To this end we characterize the statistical signatures of sensory-motor physiological parameters underlying the social exchange between both individuals -the examiner and the examinee- partaking in the behaviors evoked by the social presses of the Autism Diagnostic Observation Schedule-2 (ADOS-2, 2). This standard subjective tool is amenable to systematically assess the dyad under various conditions: (a) same examiner and same child using different modules; (b) different examiners and same child using the same modules as in (a). We report the results of this systematic examination from 20 children with

ASD and 10 age- and sex-matched controls. Preliminary analyses in 10 children reveals that the prompting style of the examiner highly impacts the child's responses and that in turn, the child's response can reshape the style of the same examiner. This work highlights the role of both participants on the ensuing outcome. Results therefore underscore the need to reconsider the design of such diagnostic tools in order to effectively capture the social abilities of the child. More importantly, such tools may reveal the potential capabilities and the types of accommodations and supports that the child may need to better function and adapt within society. We report that from the perspective of a neutral observer, i.e. the objective biometrics used to quantify the outcome of the interaction, these types of current diagnostic tools may be confounded, and statistically falsifiable. Additionally, results illustrate potential implications for research that relies upon such tools in their current form. Title: Quantitative and qualitative improvement of cognitive and social skills in autistic children after virtual stimulation

Authors: *C. CRESPO-CORTES[1], P. CARRILLO[2], G. A. CORIA-AVILA[3], L. I. GARCIA[3], R. TOLEDO[3], M. E. HERNANDEZ[3], J. MANZO[3];

Abstract: Previous studies showed benefits of virtual stimulation with the Nintendo Wii console and the "Wii Sports" videogame on motor skills of autistic children. Now we continued to a socialization phase of the same 10 autistic children from 5 to 13 years old, patients from the Child Rehabilitation Center of Veracruz. Again, we used the Nintendo Wii and the "Wii Sports" videogame. Socialization last 15 weeks, playing twice a week, 20 minutes per session. On the

first test children played against the facilitator. On the second, children were exposed to another children from the experimental group. Results from the first test showed that children were capable to identify sports, were interested on facilitator´s game, and evoked communicative intention. 70% or more were capable to recognize their turn, respect the turn and respond the question who´s next? For the second test, results showed 85% of the children displayed similar behaviors, socialize with the partner, and pay attention to the entire game. Thus, we hypothesized that virtual stimulation can improve not only motor skills but also cognitive processes such as memory, attention and learning, and facilitate social behavior. Finally after 16 months of continuous playing, we also hypothesized that they could modify their behavior in other situations, such as home or school. Hence, a group of data was collected from each parent with a survey form, answering daily situations of 3 common areas: school, house and free time. Results showed that 100% of parents have a positive perception about the impact of virtual stimulation on their children. All parents conclude that in addition to other therapies, following the videogame trials children improved faster; parents are sure that this kind of stimulation help to focus the attention of their children at home and at school; 8 of 10 parents perceived improvement in longer periods of waiting time at home (wait for meals, wait when parents are at phone/bathroom/kitchen), on daily situations (stay in line on supermarket) and social situations (tolerate sounds or touch from relatives or friends). They also perceived virtual stimulations trough videogames as a key factor of improvement skills at school, such as coloring, better use of pencils, stay sit and motor skills at gymnastics. Thus, we suggest that long-term virtual stimulation could be used as a good tool for the behavioral and cognitive improvement of autistic children.

Title: Sex differences in real-world executive functioning in children with Autism Spectrum Disorder

Authors: *E. I. WHITE[1], G. L. WALLACE[2], A. B. RATTO[3], A. C. ARMOUR[3], H. S. POPAL[1], A. MARTIN[1], L. KENWORTHY[3];
[1]NIH, Bethesda, MD; [2]George Washington Univ., Washington, DC; [3]Children's Natl. Hlth. Syst., Washington, DC

Abstract: Females with Autism Spectrum Disorder (ASD) are diagnosed less frequently and later, on average, than males. Questions surround whether these differences could be due to a distinctive profile of behavioral deficits for females with ASD as compared to males. The present study is the largest to date examining executive function and adaptive ability in females with ASD. It utilizes parent ratings of real-world executive functioning and adaptive behavior on the Behavior Rating Inventory of Executive Function (BRIEF) and Vineland Adaptive Behavior Scales-II (VABS-II), respectively, within a well-characterized age and IQ matched sample of 51 males (mean age = 9.94, *SD* = 1.79; mean IQ = 107.22, *SD* = 21.52) and 51 females (mean age = 9.79, *SD* = 1.73; mean IQ = 105.92, *SD* = 21.11) with ASD. A mixed-model ANOVA with Sex (male, female) as the between subjects factor and BRIEF domain (8 scales) as the within subjects factor revealed a main effect of sex (F=11.39; p=.001) which was qualified by an interaction between Sex and BRIEF domain. Post-hoc *t*-tests revealed significantly greater impairments (i.e., higher T scores) for females with ASD on 5/8 BRIEF scales: Inhibit, Initiate, Working Memory, Plan/Organize, and Monitor. These differences appear despite no significant sex differences on the VABS-II and similar correlations between the BRIEF and VABS-II for both males and females. The correlational analyses show that for both males and females with ASD, greater overall executive function impairments (utilizing the Global Executive Composite [GEC] scale of the BRIEF), are related to decreases in Daily Living Skills (males: r=-.35, p<.05; females: r=-.33, p<.05). These results indicate relative executive function weaknesses in females with ASD that occur despite similar adaptive abilities and intelligence and suggest a potentially altered behavioral profile for females, as compared to males, with ASD.

Title: A new vasopressin V1a antagonist restores normal cognitive and social behavior while revealing a specific brain network in the rat valproate model of autism

Authors: *C. GRUNDSCHOBER, T. MUEGGLER, F. KNOFLACH, C. RISTERUCCI, P. SCHNIDER, B. BIEMANS;
Roche Innovation Ctr., Basel, Switzerland

Abstract: The neuropeptide vasopressin plays an important role in regulating social behavior. In humans, prenatal exposure to the anticonvulsant drug valproate (VPA) has been associated with an increased risk of autism in the newborn. In rats, a single injection of valproate to pregnant dams at day 12.5 of gestation, the time of the neural tube closure, induces a range of behavioral abnormalities in the offspring, such as deficits in social behavior as well as in working and spatial memory. Based on synaptic and phenotypic similarities, the rat VPA model can be considered a valid model of human autism. In this work we investigated the role of central vasopressin 1a (V1a) receptor signaling on the phenotype of the rat valproate model of autism. Rats prenatally exposed to VPA were treated daily during 1 week with a new brain penetrant V1a receptor-specific small molecule antagonist starting at postnatal day 23 or 53. Rat behavior was assessed in the Morris water-maze and in the 3-chamber social interaction test. Long term potentiation was measured in hippocampal slices. Finally, VPA rats and wild-type controls were scanned by functional magnetic resonance imaging at postnatal day 60 and after chronic V1a antagonist treatment, to reveal changes in brain perfusion due to prenatal exposure to VPA and potential normalization by V1a antagonism. At postnatal day 60, chronic treatment with our V1a receptor-specific small molecule antagonist completely reversed the impairments in social behavior, spatial memory and learning typically seen in VPA rats. At postnatal day 30 the deficit in juvenile play behavior was also rescued by antagonist treatment. In line with the behavioral finding, the hippocampal LTP deficit seen in VPA rats was normalized by the compound. In functional magnetic resonance imaging VPA rats were found to be characterized by decreased brain perfusion in piriform cortex, ventral hippocampus and PAG and increased brain perfusion in VTA, dorsal striatum, cingulate and dorsal hippocampus compared to control rats. Chronic V1a antagonism specifically normalized brain perfusion in dorsal striatum, VTA and piriform cortex. Our data show that chronic inhibition of vasopressin V1a receptors restores normal behavior in VPA rats by normalizing perfusion in a brain network important for olfactory processing, repetitive behavior and reward. These results suggest that V1a antagonists have the potential to improve social interaction in autism, a core symptom for which there is currently no drug treatment.

Title: Characterization of sensory-motor physiological signatures underlying decision making about corporeal self-awareness

Authors: *S. MISTRY[1], P. YANOVICH[2], E. TORRES[3];
[1]Mathematics, Rutgers Univ., Piscataway, NJ; [2]Computer Sci., [3]Psychology, Rutgers, Piscataway, NJ

Abstract: Corporeal self-awareness is fundamental for the development of proper frame of references to be used as anchors and help interpret relative motions within the social scene. Various disorders of the nervous system are currently characterized based on social impairments, but no connection exists between bodily rhythms, their underlying physiology and social interactions. Studies of human motion perception could help us understand this connection but they are often conceived as a top down process. Namely, while we view others in three dimensions, we never see our full bodies in three dimensions. Current approaches cannot explain how humans are able to integrate visual information with the physical body-action component. Here we present a new paradigm for studying biological motions from a bottom up approach with millisecond time precision. We examine the contributions of the peripheral nervous system to the development of volitional control of our decisions through our actions. We ask if there is a congruent map between kinesthetic reafferent signals from our own physiological motions and cognitive social decisions. First we recorded the motions of 16 subjects throughout the body at 15 joint locations performing gait patterns and various exercise routines. Using noise pattern extraction procedures in the temporal and spatial domain, we generated an avatar endowed with the subject's movements. In a perceptual task, we asked subjects to decide "ME" or "NOT ME" and found that despite the noise, subjects could systematically discriminate between the two. Additionally, we uncovered power laws linking velocity dependent parameters in their decisions, body motions, and decision times. Hand speeds were found to be the most predictive and reliable measures while the response times were the most variable. We then endowed stick figures, skeletons, and humanoid avatars with the veridical motions of the subject's decision making to assess the extent to which subjects could recognize themselves making the decision. We registered motion, temperature, heart rate, and galvanic skin conductance to further characterize the physiological signatures of decision-making involving different virtual humans. We report our results in 10 additional subjects.

Title: Increased social behaviors and GluA2 phosphorylation in mice-lacking glutamate receptor interacting proteins

Authors: *M. HAN[1], R. MEJIAS-ESTEVEZ[1], R. ROSE[1], S.-L. CHIU[2], A. ADAMCZYK[1], R. HUGANIR[2], T. WANG[1];
[1]Sch. of Medicine, Inst. of Genet. Med., [2]Sch. of Medicine, Dept. of Neurosci., The Johns Hopkins Univ., Baltimore, MD

Abstract: Glutamate receptor interacting protein 1 and 2 (GRIP1/2) are highly homologous neural-enriched scaffolding proteins that bind to the C-termini of glutamate receptors 2/3 (GluA2/3) via their PDZ domains 4-6 (PDZ4-6). GRIP1/2 play an important role in the regulation of GluA2/3 trafficking and neural plasticity. Loss of GRIP1/2 results in decelerated recycling of GluA2 in primary neurons and lack of LTD expression at cerebellar Purkinje cells. Autism-associated gain-of-function mutations of GRIP1 correlate with an accelerated recycling of GluA2 and increased deficits in the reciprocal social interactions in patients. To understand the role of GRIP1/2 in social function, we investigated social behaviors and glutamate-signaling proteins in several brain regions of neuron-specific Grip1/2 double knockout (DKO) mice. DKO mice were generated by crossing Grip2 conventional KO mice with Grip1 conditional (neuron-specific deletion via nestin-cre expression) KO mice and were matched for age, sex, and strain background with wild type (wt) control mice for behavioral testing. Compared to wt mice, DKO mice show a significant increase in sociability, preference for social novelty, and dyadic male-male social interactions. Immunoblot analyses of AMPA type glutamate receptors, metabotropic glutamate receptor mGluR, mTOR, and GABA signaling proteins in DKO mice identified a significant increase in the phosphorylated GluA2 at serine 880 in brain cortex and cerebellum but not striatum. GluA2 phosphorylation is known to affect its interactions with several scaffolding proteins including GRIP1 and PICK1 and alters receptor recycling and AMPA synaptic strength. These data suggest that AMPAR mediated-glutamate signaling in specific brain regions play an important role in the modulation of social behaviors in mice.

Title: A direct GABAergic output form the striatum to the amygdala

Authors: *Y. ZHANG[1], X. LI[2];
[1]Dept. of Neurobio., Zhejiang Univ. Sch. of Med., Zhejiang Province, China; [2]Zhejiang Univ., Hangzhou Zhejiang, China

Abstract: The ability to transform stimuli predicting negative outcomes is critical for survival, and perturbations of emotional processing underlie many psychiatric disease states. Classical work focused on the amygdala as a central structure for fear memory. Recent advances, however, have identified the striatum mediating fear learning and the expression of fear behaviors. So, whether these two brain regions have any connections to modulate this fundamental behavior? Here we show that MSNs in the striatum can project to the amygdala. Using the technic of retro tracing, we find that, rather than interneurons expressing parvalbumin (PV), somatostatin (SOM) interneurons receive most innervations from the straitum. More work is still needed to clarify the function of this connection.

Title: Hearing one's name in autism spectrum disorder: an fMRI investigation

Authors: *S. HUEMER[1], F. KRUGGEL[2], V. MANN[3], J.-G. GEHRICKE[4];
[1]Psychology, Loyola Marymount Univ., Los Angeles, CA; [2]Biomed. Engin., [3]Cognitive Sci., [4]Pediatrics, Univ. of California, Irvine, Irvine, CA

Abstract: The goal of this preliminary passive listening study was to compare brain activation between a group of 10 adolescents with autism spectrum disorder (ASD) and 10 neurotypical controls as they passively listened to their own first names. T1 and T2 weighted MR images were acquired on a Philips Achieva 3T scanner, equipped with an 8-channel phased array coil. During each of the three functional imaging sequences, 110 volumes were taken. Besides the images, four contrasts were acquired (SFN=subject's first name, OFN=other familiar (people's) names, OBJ=object of high interest, NUM=number between 1 and 5). General activation patterns were more pronounced when the scores from a test of verbal receptive ability (PPVT) were used (high scoring group = HS, low scoring group = LS) in place of group designation, which supports our theory of distinct activation differences between high functioning and low functioning individuals with ASD that align with verbal ability. When hearing their own name, controls and the HS group continued the pattern of activation in areas of self-referential processing and areas associated with hearing one's name (including BA 7, BA 9, BA 13, BA 17, BA 22, BA 31, BA 19), which we had predicted. Interestingly, we found an involvement of the right hippocampus (BA 54) in the HS group. When hearing their own name, the ASD group showed overall less distributed activation and they relied more heavily on prefrontal structures (especially the frontal pole, BA 10), as we had predicted and as also show activated when the 4-year-old girl with ASD heard her own name in a previous case study (Carmody et al., 2007). Interestingly, we also found increased activation in the left thalamus in the LS group. In summary, subjects who scored higher on the test of verbal ability, the self-referent stimuli activated key brain regions in controls that are linked to self-reference and embedded in long-term memory in a generally more posterior neural network. In comparison, subjects who scored lower on verbal ability activated more anterior brain regions associated with short-term episodic memory. Our study may imply that reduced self-reference is not implicitly "known" but rather acquired and "remembered" like factual information, especially in 'lower functioning' ASD subjects characterized by lower verbal ability but more data is needed to draw any further conclusions.

Title: Modeling increased autism risk following maternal SSRI use

Authors: *S. E. MALONEY, S. AKULA, K. CHANDLER, J. D. DOUGHERTY;
Genet., Washington Univ. Med. Sch., Saint Louis, MO

Abstract: The steady increase in prevalence of autism spectrum disorder (ASD) in recent years implies environmental factors in the risk of developing ASD. Four recent studies have reported an increased risk of ASD diagnosis and autistic symptoms in the offspring of mothers taking selective serotonin reuptake inhibitors (SSRIs) during pregnancy, independent of the mothers' depressive symptoms. In addition, transcriptomic analyses of autistic human brains revealed abnormalities in cortical cell-type patterning, implicating transcriptional dysregulation as an underlying mechanism of dysfunction in ASD. The objective of this study was to model the recent human patient population findings to directly examine the risk of presenting ASD-relevant behaviors following developmental SSRI exposure and to understand its consequences on long-term transcription in the brain. Female mice were treated with the SSRI fluoxetine (Prozac; FLX), at the equivalent of the maximum recommended human dose, from just prior to pregnancy through lactation, thus exposing mouse pups to maternal SSRI through neurodevelopment. Behaviors relevant to ASD were assessed in FLX- and vehicle-exposed male and female offspring beginning postnatal and continuing through adulthood. FLX-exposed pups produced fewer ultrasonic vocalizations as compared to vehicle-exposed littermates, indicating the disruption of a behavioral marker of development that is implicated in communication. As adults, the behavior of the mice was also evaluated in behavioral paradigms of sociability, olfactory communication, sensorimotor and locomotor abilities, and repetitive patterns of behavior. To identify transcriptomic consequences of maternal SSRI exposure during neurodevelopment, translating ribosome affinity purification (TRAP) was used to selectively profile actively translated mRNA in a cell-specific manner. RT-qPCR was used to evaluate FLX-induced transcript expression differences in 5HT receptors, trophic factors, excitatory and inhibitory neuron markers and glial markers. This study tests the hypothesis that brain cells may be permanently altered as a result of developmental SSRI exposure, and has the potential to identify persistent molecular changes that may represent targets for treatment. Further, the impact of maternal SSRI use on the risk of developing ASD-related behavioral deficits will be defined. An understanding of the risks of SSRI exposure on the developing brain of a model organism will provide critical information that may have implications for the safety of antidepressant use in pregnant women.

Title: Optogenetic and electrophysiological dissection of oxytocin in brain circuits underlying social and fear behavior: differentiating roles for the central and medial amygdala

Authors: C. HEGOUBURU[1], S. GHOSH[1], S. CHENAUX[1], R. TRIANA DEL RIO[1], G. GIOBELLINA[1], I. SALGADO[1], C. GRUNDSCHOBER[2], *R. STOOP[1];

Abstract: The neuropeptide oxytocin (OT) appears to play an important role in social behavior but can also reduce fear responses. OT receptors (OTR) are both found in the medial (MeA) and central amygdala (CeA) where an extensive network of OT fibers that originates from different nuclei in the hypothalamus can be found. Previous works have shown that OT can reduce fear through effects in the CeA, whereas social recognition memory seems to be mediated by the MeA. In the present study we examined to what extent both systems can operate in separate or concerted manner. To compare sensitivity of both nuclei to OT we measured increases in spiking activity in *in vitro* recordings following repeated applications of different OT agonists and blocking effects OTR antagonist. We found responses in 29% of neurons in the CeA and in 18% of neurons in the MeA. Neurons in the MeA exhibited significantly less desensitization upon consecutive OT applications which could be selectively blocked by specific OTR antagonists. To compare contributions of OT signaling in the MeA and CeA in behaving rats, we injected the OTR agonist TGOT and antagonist atosiban targeted through cannulae to either nuclei. OT in the MeA increased sniffing of the companion rat, in both CeA and MeA increased 50 kHz social calls and atosiban in the CeA increased 22 kHz alarm calls. In a custom designed two chamber interaction test, OT in the MeA increased time in proximity to the companion whereas atosiban in both CeA and MeA decreased this interaction time. In a third experiment we assessed interactions between OT signaling in MeA and CeA by measuring effects of social interaction in the two chamber on fear behavior. We found a decrease in fear expression in the presence of the companion rat that was blocked by OT antagonist in the CeA. This could be mimicked by optogenetic stimulation (OpS) of ChR2-OxT neurons in the paraventricular nucleus of the hypothalamus (PVN). Concomitant electrophysiological recordings during exposure to fear revealed rapid increases in neuronal activity of OTergic neurons in the PVN and decreases or

increases in activity in the CeA depending on sensitivity to OT as assessed by OpS. These findings open up the possibility to modulate OT signaling selectively in different brain regions by targeted pharmacological intervention. In addition, they show an interaction between social behavior and fear responses that appears to be mediated by OT in the amygdala. We are currently examining the precise interaction between MeA and CeA in these effects. Our findings may have important implications for the understanding and possible treatment of changes in social behavior among which for example autism spectrum disorders.

Title: Potential contributions of GABA-A and alpha7 nicotinic receptors to behavior in the BTBR mouse model of autism

Authors: *R. F. YOSHIMURA, M. B. TRAN, D. J. HOGENKAMP, A. J. DUNNIGAN, T. K. GEE, K. W. GEE;
Pharmacol., Univ. of California, Irvine, Irvine, CA

Abstract: Autism spectrum disorder (ASD) is characterized by core behavioral symptoms including deficits in social interaction and stereotyped behavior. ASD is often comorbid with epilepsy, cognitive impairment and anxiety. Studies on ASD patients have demonstrated a down-regulation in the enzymatic synthesis of γ-aminobutyric acid-A ($GABA_A$) and a selective reduction in $GABA_A$ receptor ($GABA_AR$) expression. Restoring normal levels of inhibitory neurotransmission could be a promising avenue to treat ASD. There are multiple pathways to approach this deficit in $GABA_AR$ mediated neurotransmission. One is to enhance the function of the $GABA_AR$'s in response to the endogenous release of GABA. Another is to enhance the release of GABA in response to endogenous stimuli. This can potentially be achieved with positive allosteric modulators (PAM's) of α7 nicotinic acetylcholine receptors (nAChR's) on GABAergic interneurons which, in turn, could enhance the release of GABA. In theory, simultaneously modulating the function of $GABA_AR$'s and α7 nAChR's could enhance the cholinergic activation of α7 nAChRs on the interneuron to promote GABA release while augmenting the postsynaptic responses to GABA at the interneuron-pyramidal neuron synapse.

We have tested the $GABA_AR$ PAM, 2-261, and the α7 nAChR PAM, AVL-3288, in both the social approach and self-grooming behavioral paradigms. By testing these distinct mechanisms individually and in combination, we can potentially elucidate their contributions to the behaviors associated with this mouse model of autism. The data from these studies can help guide us towards novel treatments for ASD.

Title: Prenatal zinc prevents communication and tyrosine hydroxilase impairments in a rat model of autism induced by prenatal lipopolysaccharide

Authors: *T. B. KIRSTEN[1,2], G. P. CHAVES-KIRSTEN[3], C. SCAVONE[3], M. M. BERNARDI[1], L. F. FELÍCIO[2];
[1]Envrn. and Exptl. Pathology, Paulista Univ., Sao Paulo, Brazil; [2]Dept. of Pathology, Sch. of Vet. Medicine, Univ. of Sao Paulo, Sao Paulo, Brazil; [3]Dept. of Pharmacol., Inst. of Biomed. Science, Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract: Previous investigations by our group have shown that prenatal exposure to lipopolysaccharide (LPS), an endotoxin that mimics infection with Gram-negative bacteria, induces autistic-like behavior. No effective treatment yet exists for autism. Therefore, we used our rat model to test a possible treatment for autism. We selected zinc as the prenatal treatment to prevent or ease the impairments induced by LPS because LPS induces hypozincaemia. Communication, which is impaired in autism, was tested in pups by ultrasonic vocalizations. Because we previously had demonstrated that our rat model of autism presented impairments in the dopaminergic system, i.e., decreases striatal dopamine, its metabolites, and tyrosine hydroxylase (TH) levels, we also evaluated TH protein expression in the striatum and substantia nigra of rats prenatally exposed to LPS and zinc via westernblotting. TH is considered a biomarker of dopamine synthesis because is the first enzyme in the dopamine biosynthetic

pathway. Pups that were prenatally exposed to LPS spent longer periods without calling their mothers, and posttreatment with zinc prevented this impairment induced by LPS to the same levels as controls. Prenatal LPS exposure also decreased 30% the TH levels in the striatum compared to the control group, and zinc posttreatment after LPS resulted in values statistically similar to those of control and LPS groups. Substantia nigra analysis revealed no changes between the three groups. These results showed that prenatal LPS exposure impaired communication, and striatal dopaminergic system of juvenile rats. Because the zinc posttreatment revealed similar TH levels as those of the control group, we concluded that zinc treatment may have prevented the striatal dopaminergic impairment. Thus, prenatal zinc prevented communication, and striatal dopaminergic impairments. The present study revealed a potential beneficial effect of prenatal zinc administration for the prevention of autism, with a possible correlation with striatal dopaminergic mechanism.

Title: Advanced paternal age as a risk factor for autism: Behavioral and morphological alterations in rats and humans

Authors: *R. K. SCHWARTING[1], D. SEFFER[2], A. KRUG[3], J. C. EGGEBRECHT[2], H. RIPPBERGER[2], B. DIETSCHE[3], H. BACKES[3], T. KIRCHER[3], M. WÖHR[2];

Abstract: It is widely recognized that advanced maternal age is a risk factor for bearing a child with mental retardation, such as Down syndrome. In contrast, however, few people are aware of the fact that advanced paternal age (APA) constitutes a risk factor for mental illness in offspring as well. Children born to older fathers have an increased risk of developing severe neurodevelopmental disorders, such as autism (ASD) and schizophrenia, as shown in a number of well-conducted epidemiological studies, with some of them even reporting accumulating risk across generations. This is particular relevant as ASD diagnoses have climbed steadily since the 1970s - along with a marked increase in the number of fathers older than 40 years in the past couple of decades. It is estimated that approximately 10% of the increase in ASD diagnoses is

due to APA. To study APA effects on brain and behavior, a large cohort of 670 healthy subjects was investigated with the schizotypal personality questionnaire (SPQ-B) and the NEO-FFI. It was found that APA had linear effects on SPQ-B sum scores and all of its subscales as well as neuroticism after controlling for maternal age, subjects' age, sex and level of education. In addition, APA was linearly correlated with increased grey matter volume in the right parahippocampal cortex and the right inferior frontal cortex in a subsample of 342 subjects, which is in line with reports of increased grey matter volumes in these brain areas in ASD. However, despite the fact that epidemiological studies demonstrated an association between APA and neuropsychiatric disorders, the underlying causality is not yet understood since experimental evidence in humans is not feasible. Therefore, we recently developed a rat model, comparing offspring from young (2 months) and old (12 months) fathers, while maternal age was the same in both conditions (2 months). By means of this comparison, we found that rats from old fathers display behavioral alterations with relevance to all ASD core symptoms, including social communication deficits and impaired reversal learning. This finding indicates that at least part of the APA effects obtained in humans are not due to differences in personality traits or socio-economic status that have been repeatedly reported when comparing young and old fathers. As recently suggested effects might be linked to reduced quality of spermatocytes due to epigenetic modifications or accumulating genetic deficits, i.e. mutations, as a consequence of "copy errors" during cell division. Since there is evidence for altered hippocampal size in ASD diagnosed patients, rats' brain morphology was investigated at different developmental stages.

Title: Common symptoms, distinct brain function: an fMRI study of social cognition in the autism and schizophrenia spectrums

Authors: *A. STANFIELD[1], R. PHILIP[2], H. WHALLEY[1], L. ROMANIUK[1], J. HALL[3], E. JOHNSTONE[1], S. LAWRIE[1];

Abstract: Introduction: Although there are overlaps between autism and schizophrenia, especially in social domains, in their most severe forms they are usually readily distinguished clinically by their age of onset, degree of communication impairment and the presence or absence of positive psychotic symptoms. However, it is now recognized that there exist 'spectrum' forms of both disorders without such marked and distinguishing impairments. Autism spectrum disorders (ASD) and schizophrenia spectrum disorders, such as schizotypal personality disorder (SPD), have many overlapping and few distinguishing features, particularly in social domains. However, it is not known whether these social deficits result from shared or distinct brain mechanisms. To establish this, we compared social cognition in ASD and SPD using functional magnetic resonance imaging (fMRI). Methods 21 individuals with SPD, 28 with ASD, 10 comorbid for both conditions (CM) and 33 controls were compared with respect to clinical symptoms (Positive and Negative Syndrome Scale); neuropsychological measures of social cognition (social judgement and Ekman60 faces tasks); and an fMRI task where they made social or non-social judgements from face stimuli. Results The ASD and SPD groups showed few differences in negative symptoms or social cognition outwith the scanner. However, fMRI showed that, compared to those with ASD, the SPD group showed greater activation increases when making social compared to non-social judgements in three clusters covering posterior cerebellum, fusiform and inferior temporal gyri bilaterally, the left superior temporal sulcus and temporoparietal region, and right occipital regions; further hyper-activation was identified in the SPD group in left amygdala using a small volume correction (all $p<0.05$ family-wise error corrected). Control activations lay between the ASD and SPD groups. CM individuals showed frontal activation differences compared to the ASD group alone. Conclusions Although the social cognitive deficits in ASD and SPD appear superficially similar they are the result of different brain mechanisms. These differences have implications for therapeutic interventions targeted at social dysfunction in these conditions and validate their classification as separate disorders.

Title: Audiovisual processing of social robot stimuli: understanding therapeutic outcomes in adolescents with autism spectrum disorder

Authors: *L. F. PRZYBYLOWSKI, III[1], F. SARTORATO[1], A. PHILLIPS[1], M. PROUGH[2], J. J. DIEHL[2], D. K. SARKO[1];
[1]Anat., Edward Via Col. of Osteo. Med., Spartanburg, SC; [2]Psychology, Univ. of Notre Dame, Notre Dame, IN

Abstract: For children with autism spectrum disorder (ASD), social robots are being increasingly utilized as therapeutic tools in order to enhance social skills and communication. Social robots strike an ideal balance between inanimate toys, which do not elicit social behaviors, and human beings, whose body language and social interactions can frustrate and distress individuals with ASD. These robots have been shown to increase engagement and attention in adolescents with ASD, particularly in the age range of 12 to 17. The perceptual mechanism underlying these behavioral benefits remains poorly understood, but may be related to enhanced processing of audiovisual cues during social interactions with robots. To test this, we examined the effect of naturalistic versus robotic audiovisual stimuli on the size of the temporal binding window (a timeframe in which two stimuli from different sensory modalities are likely to be perceptually bound as a unified, synchronous event) in adolescent children. One representative "unit of social interaction" was chosen for the initial stimulus set: videos of naturalistic human speech paired with biological motion (a human saying "no" while shaking her head) versus comparable robotic speech paired with biological motion (a social robot, used clinically, saying "no" while shaking its head). Subject perceptual responses were tested at various stimulus onset asynchronies (SOAs). We predicted that a narrower temporal binding window (indicating enhanced audiovisual integration) would be seen for naturalistic stimuli in healthy subjects, but that robotic speech stimuli might result in enhanced audiovisual processing for subjects with ASD. Although multisensory processing (including audiovisual integration) is known to be impaired in individuals with ASD, we hypothesize that social robots may confer effective therapeutic outcomes through enhanced processing of audiovisual cues, particularly during communication and social interactions. Ultimately, clinical outcomes might be elucidated through assessment of factors such as alleviation of social anxiety or amelioration of hyper/hyposensitivity to various sensory stimuli. Such experiments have the potential to strengthen the evidence supporting the clinical use of robots for individuals with ASD through psychophysical assessment of perceptual outcomes.

Title: Developmental hyperserotonemia affects partner play preference and reduces oxytocin expressing cells in the adult PVN of male, but not female, rats

Authors: *K. WAGNER, A. M. K. MADDEN, S. L. ZUP;
Psychology, Univ. of Massachusetts Boston, Boston, MA

Abstract: There are marked sex differences in human behavior and disease, including a pronounced disproportion in the incidence of neurodevelopmental disorders such as Autism Spectrum Disorder (ASD), with males being diagnosed more often than females. Elevated blood serotonin (hyperserotonemia) in perinatal development (DHS) has been implicated in ASD pathogenesis. Thus, pre-and postnatal administration of a general serotonin agonist, 5-methoxytptamine (5-MT), has been used as a model of DHS to investigate the social behavior and relevant brain morphology implicated in ASD. Our previous study examining the effects of DHS found that male juvenile rats actually played less than females, findings that oppose the accepted dogma that males consistently exhibit more play behavior. We hypothesized that the reduced male play was due to play partner preference changes, such that vehicle males weren't playing less per se, but were avoiding play with 5-MT treated males. To test this possibility, we used a three-chamber sociability partner preference paradigm. On postnatal day 25 (P25) control males preferred to play with vehicle females over vehicle males; however, when forced to choose between vehicle females and 5-MT treated males, this female preference is abolished. These findings suggest that vehicle males can distinguish between other vehicle males and 5-MT treated males. Furthermore, 5-MT treated males do not show the same female preference, demonstrating a marked change from control males and thus possibly an abnormal social behavior profile. In order to determine potential neurochemical correlates to these behavioral changes, we next examined the number of oxytocinergic (OXT+) cells -in the paraventricular nucleus (PVN) in adult vehicle and 5-MT treated male and female rats. Our previous findings have shown that DHS treatment reduces the number of OXT+ cells in the medial PVN of juvenile females, but not males. Interestingly, by adulthood, DHS males have a decreased number of OXT+ compared to control males; however, a possible sex difference in OXT+ in adult animals has never been examined. Current preliminary data demonstrate that adult males treated with 5-MT perinatally have fewer OXT+ cells in the PVN than any other group, including adult females perinatally treated with 5-MT, suggesting that the reduced number of OXT+ cells seen in juvenile females may serve ultimately as a protective mechanism, especially if normal OXT+ cells are restored by adulthood.

Title: A neural correlate of disembodied intention?

Authors: *N. TADIMETI[1], J. COLE[3], E. TORRES[2];
[2]Psychology, [1]Rutgers Univ., Piscataway, NJ; [3]Neurol., Poole Hosp. NHS Fndn., Poole, United Kingdom

Abstract: There are proprioceptive pathways to the posterior parietal cortex (Prevosto et al 2011) that may participate in the formation of intentional plans for action. In the non-human primate model (rhesus macaques), this part of the cortex has been implicated in forward planning (Mulliken and Andersen, 2008) and anticipatory trajectory planning (Torres et al 2013). The question of whether kinesthetic reafference from ongoing movements is necessary to update the forward model and maintain intentional plans is still open. Addressing this question would also shed light on the distinction between embodied cognitive (volitional) control and disembodied intent. For example, work involving stimulation of the parietal and pre-motor regions in human subjects has proposed that in the absence of electromyographic activity from movements, the subjective feeling of motor execution seems to emerge from conscious intention and its predicted consequences, rather than from kinesthetic afference (Desmurget et al., 2009). Yet, these participants had intact sensory afferent fibers. It remains unknown how the brain's networks would be engaged in the absence of sensory kinesthetic afferent input from the body. The present work involving subject IW without afferent input from the neck down (Cole and Sedgwick, 1992), enables us to investigate the question relating kinesthetic reafference and intentionality. Electroencephalographic activity (EEG) using the Active Two multi-channel BioSemi system (Amsterdam, the Netherlands) was registered (scalp signals at 256 Hz sampling rate from 64 channels using the international 10-20 system) as participants attempted to control the left and right directions of an external cursor (Torres and Choi, 2013). Twenty subjects (29years old +/-7) participated including IW, a 61 year old left-handed man who had suffered a peripheral deafferentation at the age of 19 years old. We show the dynamically unfolding network patterns using a combination of stochastic analyses (Torres et al 2013) and the brain connectivity toolbox (Rubinov and Sporns, 2010). We identified self-emerging modules and hubs and characterized the stochastic signatures of the flow between brain regions. We report the extremely different dynamics of IW in relation to controls.

Abstract: Babies with incipient autism spectrum disorders (ASDs) and pups of genetic mouse models of ASDs exhibit atypical vocalizations. However, the precise sequence structure of and functional impacts of such atypicalities on social communication between babies and mothers have not been isolated and determined. We used vocal call data from a genetic mouse model of ASDs to test the hypothesis that call type sequences have functional impacts on maternal approach. Calls were recorded from Tbx1 heterozygous and wild-type littermates at P8 or P12 during 5-min maternal separation. Tbx1 heterozygous pups emitted significantly fewer complicated call types, compared to wild-type pups at P8; vocal calls considerably declined thereafter for wild-type pups so that the two groups were indistinguishable for any call type by P12. Wild-type pups emitted longer complicated call types than heterozygous pups at P8. Wild-type pups exhibited decreased lengths of these calls by P12 so that the two genotypes no longer differed at that time. Wild-type and heterozygous pups did not differ in the pitch or peak amplitude of vocal calls. Shannon entropy analysis showed that pups non-randomly chose call types to emit two, three and four successive calls. A sequence structure of calls exists in normal mouse pups and Tbx1 heterozygous pups have a higher degree of non-random sequence. Markov modeling determined the predominant sequences of calls of wild-type and heterozygous pups. Wild-type pups more frequently connected complicated call types than heterozygous pups. In contrast, heterozygous pups more frequently formed connections among simple call types than wild-type pups. A Sparse Partial Least Square Discriminant Analysis (sPLS-DA) showed that

wild-type pup call sequences were more individually variable along the two identified components, compared to call sequences of heterozygous pups. Finally, we tested the effects of wild-type and heterozygous call sequences on maternal approach. We used C57BL/6J mothers 7-8 days postpartum to assess their response to the representative call sequences of Tbx1 wild-type and heterozygous pups. C57BL/6J mothers stayed longer in the tube from which wild-type calls were presented compared to that from which no call was presented; heterozygous calls did not induce such a preference. When a randomized wild-type sequence was presented, mothers did not show a preference for the sound tube compared to the no-sound tube. Our data suggest that an ASD risk gene has a negative impact on social communication with mothers due to atypical sequence structures of vocalizations during the neonatal period.

Title: Potential N170 in mexican children with autism spectrum disorder

Authors: *C. VELA[1,2], P. TORRES[3], D. E. GRANADOS[4];
[1]Psychobiology laboratory, Univ. Veracruzana, Xalapa-Enriquez, Mexico; [2]Doctorado en Ciencias Biomédicas, [3]Doctorado en Investigaciones Cerebrales, [4]Lab. de Psicobiología, Univ. Veracruzana, Xalapa-Enríquez, Veracruz, Mexico

Abstract: Background: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder, characterized by impairments in social and comunicative behavior, there are stereotyped behaviors and restricted interests, which may or not be associated with intellectual deficit (APA, 2013). The use of the electroencephalogram (EEG) is a noninvasive method to examine the activation time in which the brain processes sensory and cognitive information, allowing study brain function during normal development and diseases. The event-related potentials (ERP) refer to the average electrical signal recorded in relation to a specific time event (Ahmadlou & Adeli, 2014). Face processing task are usually used for investigation of emotional and social abnormalities of ASD patient. A commonly investigated visual ERP component in face perception is the N170. The N170 has been associated with the perceptual processing of faces. A negative peak occurring approximately about 160-170 ms in response to pictures of faces (Bentin

et al.1996). ASD children have shown prolonged N170 latencies compared with normal children (Hileman et al. 2011). Aim: To describe the response of N170 in perception of face and balloons in children with ASD. Methods: Eight children with ASD (age: 6-13) and eight developmental typical children participed in this study. In children with ASD were observed different severity levels. We recorded full-scalp EEG while the children looked at pictures. The stimuli of neutral unfamiliar faces and balloons were presented in gray-scale images. EEG was recorded using Neuroscan system, with a 64 electrodes. The data were average across three electrodes (O1, Oz, O2) and the time window extending from -100 ms to 500 ms. Results: No significant differences were observed in N170, the response of children with ASD was to 218 ms (-3 μv) for faces and 219 ms (-3.3 μv) for balloons, while the response of children with developmental typical was to 201 ms (-4 μv) for faces and 194 ms for balloons (-4.6 μv). Conclusions: The responses of N170 in faces were later in children with ASD. It is necessary to increase the sample size to confirm the data.

Title: Unifying statistical framework to study brain-body physiological interactions in typical and pathological nervous systems

Authors: *E. B. TORRES;
Psychology Dept, Rutgers Univ., Piscataway, NJ

Abstract: The focus of mental illnesses and neurological disorders has been primarily on the central nervous system (CNS), specifically the brain and the spinal cord. The peripheral nervous systems (PNS) however, are bound to play a fundamental role in providing internal kinesthetic sensory feedback to enable corporeal and facial awareness. These are necessary ingredients to build a frame of reference on the self so as to compute relative relations in the external world, including those occurring in the social scene. Failure to form or to maintain such anchors results in disorders of the nervous system that give rise to social and cognitive impairments. Such impairments manifest in different forms clinically termed autism, schizophrenia, bipolar disorder, executive dysfunction, among others. At present it is unknown what the role of sensory-motor information may be in these disorders, particularly the potential roles of re-

afferent kinesthetic information from mechanoreceptors, nociceptors and thermo-receptors in scaffolding and maintaining social and cognitive abilities. We here present a new statistical framework that enables the combination of various signals from motions and autonomic functions (heart rate, temperature, blood flow volume, etc.) to enable the characterization of various behavioral states in a number of disorders of the nervous system where social interactions are impeded. We provide a statistical parameterization of individuals in the spectrum of autism and schizophrenia in relation to de-afferentation, stroke and Parkinsonism. The same statistical framework used here to study bodily interactions is then used to analyze time-series of EEG signals from Brain Computer Interfaces (BCI) interactions, thus providing a way to connect the rate of change of bodily statistical signals with that of EEG activity. We combine this new statistical platform[1] with tools from the brain connectivity toolbox[2] to analyze brain activity dynamically. We then adapt such tools to dynamically track the peripheral network's activities across the body. We discuss our results across different pathologies and underscore the need to distinguish (and connect) in each case mental intent and physical body volition. **References** 1 Torres EB, Cole J, Poizner H (2014) Frontiers in Human Neuroscience 8:823-19. 2 Rubinov M, Sporns O (2010) NeuroImage 52:1059-69.

Title: Anodal and cathodal tDCS as a therapy for fine motor skill impairment in Autism Spectrum Disorder

Authors: *S. M. OWEN[1], N. HOSEINI[1], G. C. FREY[1], H. J. BLOCK[1,2];
[1]Kinesiology, [2]Program in Neurosci., Indiana Univ., Bloomington, IN

Abstract: Restricted, repetitive behaviors (RRBs) are one of the core diagnostic criteria of autism spectrum disorder (ASD) yet there is little information on the causes and treatment of these debilitating symptoms. These behaviors range from simple repetitive motor behaviors to more complex cognitive behaviors such as compulsions and restricted interests. Two distinct types of RRBs have been conceptualized. "Lower order" repetitive sensory and motor behaviors and "higher order" rigid cognitive behaviors. Perry et al. (2007) demonstrated that sensorimotor gaiting and lower order RRBs reflect inhibitory abnormalities. According to the motor control theory, the RRBs common to those with ASD occur as the result of a deficient motor system and

its attempts to maintain homeostasis and engage in goal-oriented motor skills (Radonovich et al., 2013). Impairments in motor control are the most commonly reported research findings associated with ASD. The purpose of this study is to determine whether or not manual dexterity can be improved by manipulating inhibition and excitation of the motor cortex with tDCS. To date, 4 subjects, ages 18-25 years, right handed, and with the clinical diagnosis of ASD, have each completed 3 conditions. Conditions consisted of anodal (excitatory), cathodal (inhibitory), and sham tDCS, experienced in different visits at least 4 days apart. Condition order was randomized across subjects. Each subject was timed as they performed a block of eight baseline trials on a Purdue Pegboard Test with 1 minute rest between trials. The goal was to have subjects plateau so that we could control for any learning effect. Next, each subject received 15 minutes of anodal, cathodal, or sham tDCS. Subjects were given 5 minutes rest when the tDCS was initiated and then continued with their second block of eight pegboard trials for the remaining 10 minutes. The results of the timed trials were then averaged to determine whether stimulus type had any effect on performance and whether performance became faster or slower. Preliminary results for these subjects show that on average, speed increased 2.2% in the sham condition, 4.0% in the anodal condition, and speed decreased 0.4% in the cathodal condition. However, there was considerable inter-subject variability; two subjects showed improved performance with anodal stimulation while the other two did not. These results suggest that application of anodal tDCS may help to improve fine motor skill in this population.

Title: Characterization of sensory-motor physiological signatures of typical and atypical gait patterns in autism of known and unknown etiology

Authors: ***D. WU**[1], J. NGUYEN[2], S. MISTRY[3], E. TORRES[4], J. V. JOSÉ[1,5];
[1]Physics, Indiana Univ., Bloomington, IN; [2]Cell Biol. and Neurosci., [3]Biomath., [4]Psychology, Rutgers Univ., Newark, NJ; [5]Integrative and Cell. Physiol., Indiana Univ. Med. Sch., Indianapolis, IN

Abstract: Autism Spectrum Disorders (ASD) encompasses a very heterogeneous group of individuals with neurodevelopmental delays and atypical behavioral patterns, often including odd gait. Across the broad spectrum of ASD some subgroups are of idiopathic origins, while in

others the disorders can be traced back to a genetic mutation/deletion. In such cases it is amenable to characterize the sensory-motor physiology underlying various features of the behavioral phenotype, which is currently described by observational methods. One group of interest in ASD is 22q13 Deletion Syndrome (Phelan-McDermid Syndrome, PMS) caused by SHANK3 gene deficiency. The SHANK3 codes for a master scaffolding protein that forms a key framework in the postsynaptic density of glutamatergic synapses. Efficient synaptic transmission at the central and peripheral levels of the nervous system is critical for motor control, so its disruption can interfere with all aspects of behavioral development required for proper social and cognitive interactions. Because PMS gives rise to both sensory-motor issues and an autistic phenotype, it offers a model to help us understand social deficiencies in relation to sensory-motor deficiencies. This study characterizes the sensory-motor physiology underlying gait patterns in children with PMS who also received a diagnosis of ASD. We compare their signatures to those of individuals with idiopathic ASD and with neurotypical controls. In this ongoing study we have characterized thus far the signatures of 15 PMS children of both sexes (ages 6-16 years old) and 10 neurotypical age- and sex-matched controls. Further we have begun the characterization of individuals with idiopathic ASD. We have found a pattern of gait controls that is absent from all PMS participants and present only in 50% of the participants with idiopathic ASD. We discuss our findings in light of new biometrics to characterize both overlapping and disjointed features of PMS-ASD and idiopathic-ASD.

Title: Characterization of sensory-motor behavior under different mindsets

Authors: ***J. RYU**, E. TORRES;
Rutgers Univ., Piscataway, NJ

Abstract: Evidence has shown that our motions exhibit different signatures of variability depending on the level of intent (Torres, 2011). The stochastic signatures of speed variability from goal-directed movements differ from those of supplemental movements. This suggests that different principles may govern these different types of movements. However, we do not know

whether such signatures may be affected by an individual's type of mindset. Here we explore how and whether different mindsets lead an individual to exhibit different characterizations of sensory-motor behavior. In the experiment, participants were instructed to touch the screen when prompted. Subsequently, participants heard a high tone that rang 100ms, 400ms, or 700ms after the touch. Participants were then provided with a sliding scale between 0 to 1 second, and were to indicate how long they perceived the time elapsed between the touch and the high tone. They performed this task on 60 trials in three conditions. All participants started with the control condition, where they performed this task right after they became familiarized with the procedure. In the mindfulness condition, participants performed a meditation practice, and then performed the task. In the cognitive load condition, participants were given a dual task to count backwards from 400 by 3 while they performed the task. In order to collect data, motion sensors were attached to the upper body including the index finger to measure the change in position, velocity, and acceleration at each moment. The positional trajectory of the pointing and retracting movements were examined along with the temporal speed profiles of those movements, allowing us to extract and plot a frequency distribution of the kinematic parameters (e.g., peak speed, time to peak speed). We used maximum likelihood estimation to empirically estimate the shape and scale parameters of the continuous Gamma family of probability distributions. We charted each subject on the Gamma parameter plane and tracked the levels of predictability and reliability of their speed levels. Our preliminary data suggests that cognitive overload increases the noise-to-signal ratio and decreases the predictability of the subjects' speed maxima, than under mindful or control condition.

Title: Sensory-Motor physiological signatures underlying natural behaviors: A characterization across the human spectrum ranging from typical to pathological states

Authors: *U. V. MAJMUDAR, J. NGUYEN, E. TORRES;
Rutgers Univ., Piscataway, NJ

Abstract: The recent revolution in wearable sensors facilitates the continuous registration of a broad spectrum of motion signals during the performance of natural activities of daily living,

including sleep and exercise. Various aspects of sensory-motor physiology underlying behavioral states can now be objectively characterized with unprecedented precision, beyond verbal reports and subjective inferences. Integrating various outputs from such sensors can give us long time series of kinematics and autonomic-system signals throughout the day and across months of continuous recordings. This on the other hand poses new problems to develop analytics that handle large volumes of rapidly accumulating data. We here present new analytical techniques to handle big data and process various physiological signals such as motion, skin surface temperature, heart rate, blood volume, among other outputs from wearable sensing technology. Subjects performed tasks including dancing, walking, sleeping, decision-making, and tasks in response to perceptual stimuli, while wearing sensors on various parts of the body for up to 15 hours. Inertial measurement units (APDM 128Hz, Oregon) recorded acceleration and gyration. A graphical user interface (GUI) was designed and implemented in MATLAB to automatically process large volumes of data and provide longitudinal tracking of the evolution of the stochastic signatures of the subjects' physiological signals. In addition to the use of the GUI in typical populations, we demonstrate the use of this GUI in a variety of clinical populations with neurological disorders and mental illnesses. The latter include schizophrenia, bipolar disorder, and general executive dysfunction. The former included autism, sensory processing disorder, and a genetic deletion giving rise to an autistic phenotype. We propose the use of the GUI interface and the statistical platform to characterize bodily responses and provide real-time, objective read-outs of the subject's volitional control as a function of statistically predictive outcomes. Furthermore, during therapeutic interventions we use the wearables and biometrics to characterize and track levels of anxiety, stress, dysregulation as well as compliance, self-regulation and positive outcomes. These objective outcome measures provide indexes to assess the effectiveness, risk and generalization of a plethora of interventions that are now subjectively assessed and for which no insurance coverage currently exists.

Abstract: Prenatal valproic acid (VPA) exposure has been proposed as an animal model reproducing both behavioral and anatomical impairments of autism spectrum disorders (ASD). Some of the behavioral features of the model are hyper-responsiveness to novel environment and decreased number of social behaviors. Learning and memory in this model have not been analyzed in detail. Our group has previously reported rearrangement neuronal dendritic in several limbic regions on rats exposed to VPA in gestational stage. There are some studies in which the neurotrophic peptide mixture Cerebrolysin (Cbl) has been used to ameliorate abnormalities in models of aging and neurodevelopmental disorder such as Alzheimer, schizophrenia and brain injury. Three studies of Cbl administration in autistic patients have yielded promising results. In this study we aimed at evaluating the effect of Cbl administration (5 to 21PD) on pups (age 21PD) and adult rats (age 70PD) prenatally exposed to VPA. We determined the effects of Cbl on behavioral response (social interaction, responsive to novel environment), learning and memory (novel object recognition), and neuronal morphology (using Golgi-Cox stain) in prefrontal cortex, amygdala, hippocampus and nucleus accumbens. We found that Cbl administration has a different effect on hyper-responsiveness to novel environment, social interaction and memory; as far as morphology is concerned, we have found interesting changes in dendritic morphology and density spines in all the limbic regions studies after Cbl administration; in all those issues, the results were different depending on the age.

Title: An association between lower- and higher-level visual perception in autism spectrum disorder

Authors: *J. GUY[1,2], L. MOTTRON[3], C. BERTHIAUME[3], A. BERTONE[1,2,3];
[1]Integrated Program in Neurosci. (PNLab), McGill Univ., Montreal, QC, Canada; [2]Perceptual Neurosci. Lab. for Autism and Develop., Montreal, QC, Canada; [3]Ctr. d'excellence en Troubles Envahissants du Développement de l'Université de Montréal (CETEDUM), Hôpital Rivière-des-Prairies, Montreal, QC, Canada

Abstract: Individuals with Autism Spectrum Disorder (ASD) present a perceptual profile that is defined by atypical performance on tasks mediated by lower- (primary visual areas) and higher-level (large-scale neural mechanisms) visual analysis. These differences characterize the distinct visuo-perceptual profile in ASD, broadly described as strengths in detailed, local processing (mediated by lower-level analysis) with or without concurrent difficulty in global processing (mediated by higher-level analysis). This profile has been based largely on isolated levels of processing, providing little information with respect to how performance within the same individual varies with increasing task complexity. It is therefore important to elucidate the relationship between perceptual abilities mediated by different levels of analysis to understand how alterations in the building blocks of perception affect higher-order cognitive and social functions in ASD. We investigated whether enhanced local processing in lower-levels of visual analysis influenced higher-level perception in the same group of children and adolescents with and without ASD by asking the following questions: Does enhanced local processing in low-level perception predict enhanced local performance in high-level perception, specifically for non-social information? Does enhanced local processing in low-level perception influence performance in high-level perception, specifically for social information? A total of 27 and 48 respective children and adolescents with and without ASD performed three tasks, each soliciting a progressively complex visual analysis: (i) low-level perception was assessed by measuring contrast sensitivity to sine-wave, luminance- defined gratings of different spatial frequencies; (ii) high-level perception for non-social information was assessed by measuring local and global reaction times for consistent and inconsistent stimuli in a hierarchical figures task; and (iii) high-level perception for social information was assessed by measuring thresholds in a face-identity discrimination task. Our results revealed that increased sensitivity for high-spatial frequencies in the low-level task predicted faster reaction times in the local condition of the high-level, non-social task. No significant relationship was found between enhanced local performance in the low-level and high-level, social task. The significant association between low- and high-level, non-social tasks suggests that alterations in the "building blocks" of early perception are linked to differences in higher-order visual processes in ASD.

Title: Regulation of mitochondrial form and function by mitochondrial fission factor (mff) splice variants and phosphorylation

Authors: *R. A. MERRILL[1], T. WILSON[1], N. SRAYOSHI[1], J. WANG[1], Y. KONG[1], J. CRIBBS[1], M. GHONEIM[2], H. N. HIGGS[3], M. SPIES[2], S. STRACK[1,3];
[1]Dept. of Pharmacol., [2]Dept. of Biochem., Univ. of Iowa, Iowa City, IA; [3]Dept. of Biochem., Dartmouth Med. Sch., Hanover, NH

Abstract: Mitochondria are dynamic organelles that undergo tightly regulated fission and fusion processes. Dynamin-related protein 1 (Drp1), a large GTPase, mediates fission by oligomerizing into spirals around the mitochondrion, which contract and physically divide the organelle through GTP hydrolysis. Mitochondrial fission factor (Mff) promotes mitochondrial fission by targeting Drp1 to the outer mitochondrial membrane. Mff has 4 alternatively spliced exons that make up 16 different splice variants having differential tissue expression (0000 lacks all alternative exons, 1111 contains all). The shortest variant, 0000, is the most commonly expressed across different tissues and the most effective at driving fission. Addition of alternative exons leads to less Drp1 recruitment and a decrease in fission. In neurons, the most abundant splice variant is 0011, which promotes less fission than Mff 0000. *In vitro* and in cell data indicate Mff 0000 forms tetramers that diffuse rapidly, while Mff 0011 forms slowly diffusing oligomers of tetramers. Mff is highly phosphorylated at multiple sites and phosphorylation opens the tetramer to enhance Drp1 recruitment and fission. Additionally, phosphorylation of Mff 0011 prevents tetramers from oligomerizing and inhibiting fission. Finally, increased fragmentation resulting from Mff activation leads to an increase to neuronal sensitivity in a culture model of stroke. These results point to Mff as a new target for therapeutic intervention into stroke and neurodegenerative diseases associated with excessive mitochondrial fission.

Title: Postischemic oral resveratrol attenuates neuronal damage in mice with photothrombotic cerebral ischemia

Authors: *W. LEE, Y. FANG, C. KIM;
Pusan Natl. Univ. Sch. of Med., Yangsan, Gyeongsangnam-Do, Korea, Republic of

Abstract: Resveratrol is a naturally occurring stilbene found in the red grape skin and certain medicinal plants, and is known to provide protection against various infections and stresses. In addition, it has been reported that resveratrol has multiple beneficial health effects such as anticancer, antiviral, anti-inflammatory, anti-ageing and neuroprotective effects. Indeed, most of the protective biological actions associated with resveratrol have been related to its intrinsic radical scavenging properties. In this study, we investigated whether postischemic oral administration of resveratrol reduces photothrombosis-induced cerebral ischemic injury. Male C57BL/6 mice were anesthetized and systemically administered Rose Bengal. Permanent focal ischemia was induced in the medial frontal and somatosensory cortices by irradiating the skull with cold white light. Animals were treated with resveratrol (100 mg/kg, twice) immediately and 20 h after photothrombosis and were sacrificed 24 h after ischemic insult. Resveratrol caused a significant reduction in infarct size and cell apoptosis, and further reduced the expression of IDO, TNF-α and p-STAT2 in the ischemic region. In contrast, resveratrol significantly increased the expression of TrpRS, p-JAK1, p-JAK2 and p-STAT1. These observations suggest that postischemic oral resveratrol can reduce the neuronal damage following photothrombotic cerebral ischemia via modulating the phosphorylation of JAK/STAT families and reducing the inflammatory responses.

Title: BDNF "highjacks" the SUMO pathway to induce synaptic GABAergic plasticity after ischemia

Authors: *Z. S. THIROUIN[1,2], R. GILL[3], R. A. MCKINNEY[3], S. K. TYAGARAJAN[1,2]; [1]Inst. of Pharmacol. and Toxicology, Zürich, Switzerland; [2]Neurosci. Ctr. Zurich, Zurich, Switzerland; [3]Dept. of Pharmacol. and Therapeutics, McGill Univ., Montreal, QC, Canada

Abstract: GABAA receptors (GABAARs) mediate most of the fast inhibitory neurotransmission in the CNS, and diverse cellular signaling pathways tightly regulate their availability at the synapse. The recruitment and the clustering of these receptors at the synapse are facilitated by the scaffolding protein gephyrin. Accumulating evidence suggests that gephyrin is subject to diverse post-translational modifications, affecting its scaffolding properties and resulting in changes in GABAergic transmission. We recently identified that gephyrin inter- and intra-molecular interactions that facilitate its synapse scaffolding function are regulated via SUMOylation at specific residues. In the current study, we report that the neurotrophin BDNF facilitates gephyrin SUMOylation under both physiological and pathological conditions to down regulate GABAARs and gephyrin scaffolding at GABAergic synapses. BDNF signaling specifically influences the sub-cellular localization of a subset of SUMO pathway proteins, which in turn modify gephyrin to influence its scaffolding at GABAergic synapses. Furthermore, using an oxygen-glucose deprivation (OGD) paradigm with organotypic hippocampal slice cultures to mimic brain ischemia, we measured functional changes in GABAergic mIPSC amplitude and frequency in CA1 pyramidal neurons. We observed a significant reduction of GABAergic mIPSC frequency but not amplitude 24h post-OGD which returns to baseline after one week. This effect could be effectively prevented using a blocker for BDNF signaling, TrKB-Fc. Interestingly, we could also successfully block BDNF-induced changes at GABAergic synapses by over-expressing a SUMOylation-defective point-mutant of gephyrin. Our data reveal that BDNF signaling modulates the SUMO pathway to induce GABAergic synaptic plasticity in conditions of brain pathology such as ischemia.

Title: Wnt5a regulates differentiation of stroke-responsive neural progenitors

Authors: *A. J. BRUMM, M. MACHNICKI, A. RANDHAWA, J. TOOR, G. COPPOLA, S. T. CARMICHAEL;
Neurol., UCLA, Los Angeles, CA

Abstract: Ischemic stroke induces proliferation of neural progenitor cells (NPC) in the subventricular zone (SVZ) and migration of doublecortin+ neuroblasts to peri-infarct tissue. In a mouse model of distal middle cerebral artery occlusion (dMCAO), stroke-responsive neuroblasts preferentially migrate to angiogenic vasculature within peri-infarct tissue and form a neurovascular niche adjacent to the stroke core. Angiogenesis causally regulates neurogenesis within this niche, but specific angiogenic blood vessel-derived (angiocrine) factors that mediate neuroblast recruitment, survival, and differentiation have not been well described.The secreted protein Wnt5a and multiple putative receptors (Fz2, Ryk) were identified from whole genome expression profiling at 7d after stroke as a novel ligand-receptor(s) system differentially regulated in peri-infarct angiogenic blood vessels and stroke-responsive neuroblasts, respectively. To assess *in vitro* roles for Wnt5a in NPC proliferation and differentiation, neurosphere-expanded NPCs from the adult mouse SVZ were treated with recombinant Wnt5a protein. Wnt5a (10-100 ng/ml for 48 hr) increased proliferation by 27.6% compared to media control, assessed by EdU incorporation from 24-48 hr. When differentiated for 5d, Wnt5a (10 ng/ml) increased MAP2+ neuronal differentiation by 48.2% compared to media control. Wnt5a (10-100 ng/ml) had no significant effect on *in vitro* proliferation or tube formation of mouse brain endothelial cells. To assess an endogenous *in vivo* role for Wnt5a in peri-infarct tissue signaling, lentivirus expressing a Wnt5a-specific miRNA under a ubiquitous EF1α promoter was injected into peri-infarct tissue at the time of stroke. Compared to control virus, Wnt5a knockdown did not affect the number of stroke-responsive neuroblasts in peri-infarct tissue at 14d after MCAO. However, Wnt5a knockdown significantly reduced neuronal differentiation at 60d after stroke, resulting in a 72% decrease in the number of BrdU+NeuN+ mature neurons in peri-infarct tissue (BrdU i.p. d3-10 after MCAO). These results demonstrate that Wnt5a modulates proliferation and differentiation of SVZ-derived NPCs and regulates peri-infarct

neurogenesis after stroke. Ongoing experiments aim to assess the effects of *in vivo* Wnt5a gain of function on NPC proliferation and differentiation and the receptor(s) and downstream signaling involved in SVZ-derived NPC proliferation and differentiation *in vitro*. These studies provide insight into an endogenous signaling system that regulates post-stroke neurogenesis, a process with demonstrated impact on functional recovery from stroke in rodent models.

Title: Aging is associated with suppressed activation of stress response pathways in post-ischemic brains: implications for impaired functional recovery from ischemic stress

Authors: *W. YANG, S. LIU, Z. YU, H. SHENG, W. PASCHEN;
Anesthesiol, Duke Univ. Med. Ctr., Durham, NC

Abstract: Introduction: Aging is associated with increased risk for stroke and impaired functional recovery from transient ischemia. This suggests that the brain's ability to respond to an ischemic challenge declines with age. We, therefore, hypothesized that stress response pathways, enabling cells to withstand stress conditions, become dysfunctional with advanced age. To test our hypothesis and comprehensively analyze the effects of age on the response of brains to a transient interruption of blood supply, we subjected young and aged mice to transient forebrain ischemia, and analyzed a variety of stress response pathways. These included the heat shock response (HSR), the unfolded protein response (UPR), and ubiquitin, SUMO and O-linked β-N-acetylglucosamine (O-GlcNAc) modifications of proteins. Methods: Transient forebrain ischemia was performed on male 2- and 22 -month-old mice. Mice were anesthetized with isoflurane, temperature-controlled, and subjected to 10 minutes common carotid artery occlusion. Changes in mRNA and protein levels were analyzed by qPCR and Western blot, respectively. Statistical analysis was performed by ANOVA followed by Tukey's post-hoc test. Results: Hsp70 expression, Xbp1 splicing, and eIF2α phosphorylation were activated in young and aged mice to the similar extent after ischemia, indicating activation of HSR and UPR. Interestingly, we found that levels of ubiquitin-, SUMO1-, and SUMO2/3-conjugated proteins were markedly increased in brains of young mice, but these responses were significantly suppressed in the cortex and hippocampus of aged mice. Transient ischemia triggered a global

increase in levels of O-GlcNAc modified proteins in young mice, but this stress response was completely absent in brains of aged animals, both in the cortex and hippocampus. Conclusions: We have reported earlier that SUMO2/3 conjugation is dramatically activated after ischemia, and provided evidence that this is a neuroprotective stress response. SUMO proteomics analysis identified SUMOylation-dependent ubiquitin conjugation as a putative neuroprotective pathway that plays a key role in DNA damage repair. Our results suggest that the DNA damage repair pathway may be impaired in old mice. O-GlcNAc modification of proteins has not yet been studied before in models of brain ischemia, but ample evidence supports the notion that activation of O-GlcNAc modification protects heart from ischemic damage. We, therefore, conclude that the inability of aged mice to activate O-GlcNAc modification of proteins in response to transient ischemia could be a critical factor that limits functional recovery from a period of non-sufficient blood supply.

Title: Protective effects of estrogen against progressive lesion of vascular dementia in rats

Authors: ***Y. ZHU**[1], W. ZHANG[1], N. LI[1], Y. DAI[1,2], Q. ZHANG[2], R. WANG[2];

Abstract: It is well known that bilateral common carotid artery occlusion (BCCAO) on rat causes chronic hypoperfusion to the brain that is paralleled with a progressive worsening in memory and cognitive function, which ultimately leads to vascular dementia (VD). In current study, we aim to outline the characteristics of middle- and late-stage of vascular dementia and the protective role of long-term treatment with physiological dose of 17β-estrogen (E2). BCCAO was performed on Sprague Dawley (SD) rats at 7 days time interval and E2 was subcutaneously administrated using a mini-pump beginning at unilateral ligation of carotid artery and continued until the end of each experiment. The Morris water maze results showed that the rats underwent BCCAO 3m had a significant impairment in spatial memory ability rather than learning function compared to sham control or E2-treatment animals. The difference could be explained as synaptic- and neuronal ultrastructural-dependent cognitive impairment but not hippocampal

neuron number dependent event, as evidence that 1) BCCAO 3m animals had no statistic difference of the number of NeuN-positive staining both in CA1 and CA3 region compared to sham control or E2-treatment group; 2) the neuron number of Annexin V positive staining, indicating early apoptosis enhanced in BCCAO 3m group compared to sham animals both in CA1 and CA3 region; 3) the ultrastructure damage of neuron including mitochondrial crest broke, demyelination, and decrease of post-synaptic density protein 95 (PSD95) presented in hippocampal CA1 region of BCCAO 3m animals, but not in sham animals; 4) the protein expression of myelin basic protein 2 (MBP2) and PSD 95 significantly attenuated in hippocampal CA1 region of BCCAO 3m group compared to sham control. E2 treatment profoundly reversed the damage induced by BCCAO. However, in 6 m rats after BCCAO, survival neuron significantly decreased and spatial learning and memory deficit compared to sham control animals. And the levels of p-APP, p-tau and Aβ1-42 in BCCAO 6m significantly increased compared to sham animals in both CA1 region and cortex. Continuously administration of E2 markedly prevented the dementia induced by BCCAO. Taken together, the results highlight the characteristics inducing progressive lesions in memory and cognitive function, which BCCAO could cause ultrastrutural-dependent spatial memory storage deficit but not learning ability in early-, or middle-stage of VD, but in 6m after BCCAO, hippocampal CA1 neuronal loss, the accumulation of Aβ1-42 due to vascular dementia. Further study need to be carried out to clarify the molecular mechanisms in the future.

Title: Ischemic stroke and Neuregulin-1: understanding mechanisms using the Neuroscience Information Framework and biological approaches

Authors: *M. C. SURLES-ZEIGLER[1], A. BANDROWSKI[2], M. MARTONE[2], J. GRETHE[2], Y. LI[1], B. FORD[1];
[1]Neurosci. Inst., Morehouse Sch. of Med., Atlanta, GA; [2]Ctr. for Res. in Biol. Systems, Univ. of California,San Diego, La Jolla, CA

Abstract: Exogenous administration of neuregulin-1 (NRG-1) has been shown to reduce neuronal injury in rat following a middle cerebral artery model of stroke, but the mechanism is not fully understood. Herein we describe our approach to identify biological pathways regulated by NRG-1 in a rodent permanent middle cerebral artery (pMCAO) model of ischemic stroke. We used two approaches to understand these mechanisms: 1) an informatics-based approach where we reanalyzed currently available data about "Neuregulin-1" in about 200 curated biological databases; and 2), an experimental approach using microarray data to test a specific hypothesis. For the informatics approach, we used the Neuroscience Information Framework (NIF), a search engine for neuroscience data, to identify existing data sets and information about NRG-1. NIF is a unique resource that searches hundreds databases allowing users to broadcast a query about a specific topic quickly. A search for the term "NRG1", returned over 63,055 results distributed broadly across over 27 NIF categories. The NIF category, "Pathways" allowed for the identification of 4 pathway databases, BioGRID + interactions, WikiPathways + ChemPathways, CTD + DiseasePathway and KEGG + PathwayGeneOrthologs, returning 458 genes related to NRG1. An enrichment analysis was performed using the Gene Ontology (GO) and the GOrilla database to identify 3 candidate pathways: Fc receptor signaling pathway (43 genes), innate immune pathway (47 genes) and immune response-regulating signaling pathway (45 genes). For the biological approach, rats were allocated to 3 groups (1) NRG-1+ pMCAO (2) Vehicle + pMCAO (3) Sham. Animals were sacrificed 3 hours following surgery, brain tissue of the ipsilateral cortical regions were dissected, RNA isolated and microarray completed with the Affymetrix Rat Genome 2.0st array. Statistical analysis was completed using the R/Bioconductor platform and Cytoscape software (http://www.cytoscape.org/). Our previously published studies also demonstrated that inflammatory pathways were also the most relevant to the effects of NRG-1 24 hours following stroke. However, genes significantly upregulated 3 hours following ischemia and NRG-1 treatment in preliminary studies included Dusp6 (a negative regulator of the MAPK pathway) and protocadherin 6 (involved in the establishment and maintenance of specific neuronal connections in the brain) and associated with the MAPK cascade. We are currently exploring the temporal regulation of gene expression by NRG-1 and its relationship to neuroprotection. Our results demonstrate the potential utility of in silico biology in combination with experimental methods.

Title: Caspase-9 activation in cerebral ischemia does not require MMP-9

Authors: E. CANEPA[1], T. KICHUK[1], A. GEEVARGHESE[1], B. R. CHRISTOPHE[2], E. S. CONNOLLY[2], *C. M. TROY[3];

Abstract: Activation of specific caspases - a family of cell death proteases - in cerebral ischemia causes neuronal death. In previous work, we showed that the inhibition of initiator caspase-9 prior to and during stroke reduces neuronal death, infarct volume, and edema, and promotes functional recovery. Ischemic edema is a major cause of mortality during the first 72 hours following stroke, but its mechanisms are poorly understood. Resolving these pathways could unveil therapeutic interventions. To evaluate the role of caspase-9 in the development of edema, we assessed whether the inhibition of caspase-9 in cerebral ischemia reduced edema by measuring blood brain barrier permeability using Evan's blue extravasation and found that inhibition of caspase-9 blocked vasogenic edema. It has been shown by others that matrix metalloproteinase-9 (MMP-9) null animals develop less edema and show less extravasation of Evan's blue during ischemia. It had been proposed that MMPs regulate edema and that activation of MMP-9 occur upstream of caspase activation. Our preliminary studies showed that specific inhibition of caspase-9 abrogated the elevated caspase-9 in the cerebral vasculature and increased MMP-9 expression. To determine the hierarchical relation of caspase-9 and MMP-9 during ischemia we examined the induction of caspase-9 in wild-type and MMP-9 null mice. We find that caspase-9 induction occurs in wild-type and MMP-9 null mice after transient middle cerebral artery occlusion (tMCAo). These data support that caspase-9 acts upstream of MMP-9 in the vasogenic pathway, rather than the converse previously proposed. Ongoing studies are determining how caspase-9 regulates MMP-9 activation in cerebral ischemia. These data suggest a novel mechanism for the induction of vasogenic edema during cerebral ischemia. Thus, targeting caspase-9 in stroke might improve vascular health and provide neuroprotection, which could aid functional recovery.

Title: The point mutation uch-l1 c152a protects primary neurons against cyclopentenone prostaglandin-induced cytotoxicity: implications for post-ischemic neuronal injury

Authors: *H. LIU[1,3], M. E. ROSE[3,1], R. W. HICKEY[4], G. UECHI[2], M. BALASUBRAMANI[2], S. H. GRAHAM[3,1];

Abstract: Cyclopentenone prostaglandins (CyPGs), such as 15-deoxy-Δ12,14 -prostaglandin J2 (15dPGJ2), are reactive prostaglandin metabolites that exert a variety of biological effects. CyPGs are produced in ischemic brain and disrupt the UPP. Ubiquitin-C-terminal hydrolase L1 (UCH-L1) is a brain-specific deubiquitinating enzyme that has been linked to neurodegenerative diseases. Using MS/MS analysis, we found that the C152 of UCH-L1 is adducted by CyPGs. Mutation of C152 to alanine (C152A) inhibited CyPG modification and conserved recombinant UCH-L1 protein hydrolase activity. Next, a knock-in mouse expressing the UCH-L1 C152A mutation (KI) was constructed with the bacterial artificial chromosome technique. Brain expression and distribution of UCH-L1 in the KI mouse is similar to that of the wild-type mouse. Primary cortical neurons derived from KI mice were resistant to 15dPGJ2 cytotoxicity compared to neurons from wild-type mice as detected by the WST-1 cell viability assay and Caspase-3/ PARP cleavage. This protective effect was accompanied with significantly less ubiquitinated protein accumulation and aggregation in KI primary neurons after 15dPGJ2 treatment. Additionally, 15dPGJ2 -induced axonal injury is also significantly attenuated in KI neurons as compared to wild-type. Furthermore, increased cell viability was observed in post-hypoxia primary neurons from KI mice as compared to wild-type controls with both *in vitro* anoxia and oxygen glucose deprivation models. Taken together, these studies indicate that UCH-L1 function is important in hypoxic neuronal death and the C152 site of UCH-L1 plays a significant role in neuronal survival after hypoxic/ischemic injury.

Ca' Granda Ospedale Maggiore Policlinico, Milan, Italy, Italy

Abstract: Cervical artery dissection (CeAD) represent a major cause of ischemic stroke in young adults. Some rare inherited connective tissue disorders are known to be associated with arterial dissection and may be involved in the pathogenesis of CeAD. We report the case of a 41 years old male who presented sudden onset of vertigo with nausea and vomiting. Neurological evaluation was normal except for rotatory nystagmus. Cerebral CT scan was normal. CT angiography disclosed an acute dissection of the left vertebral artery (V1, V3-V4 segments) and a post-dissection aneurysm of right carotid artery. 24 hours CT evidenced an acute left cerebellar infarction. Anticoagulation was started with full recovery within a few days. Given the presence of multiple spontaneous dissections he underwent molecular analysis in order to disclose a possible underlying collagen pathology. After ruling out COL3A1 and COL4A1 mutations by Sanger sequencing, we extended the molecular analysis taking advantage of a True Seq Custom Panel, developed to improve the diagnostic yield of connective tissue disorders. This custom panel targets the coding regions of 23 genes encoding for collagen isoforms and other extracellular proteins. The enrichment was performed at the Regional Center of Ehlers Danlos Syndrome (Ospedale Maggiore Policlinico, Milan) and sequence runs were generated on a MiSeq (Illumina) platform. We detected a COL6A1 variant c.2669C>T (p.S890L) with uncertain pathogenicity significance and a novel variant c.8008T>C in FBN1 gene, likely resulting in the change of the evolutionary conserved Tyrosine with a Cysteine at codon 2670 (Y2670C). In silico evaluation of the Y2670C mutation, supported its pathogenic value. FBN1 variants in the absence of criteria of Marfan Syndrome have been reported in association with thoracic aortic aneurysm/dissection and bicuspid aortic valve. Our findings enlarge the clinical spectrum of FBN1 mutations and support the importance of genetic screening in selected patients with isolated supra-aortic dissections even in the absence of positive familial history. Connective tissue disorders show genetic and clinical overlap: our study confirms the efficacy of panel sequencing approach to achieve a firm diagnosis even in patients with atypical presentations.

Title: Role of brain-derived estrogen in regulation of pro-survival and pro-apoptotic factors in the hippocampal ca1 region following global cerebral ischemia

Authors: *R. WANG[1], Q. ZHANG[1], R. VADLAMUDI[2], D. BRANN[1];
[1]GEORGIA REGENTS UNIVERSITY, Augusta, GA; [2]Dept. of Obstetrics and Gynecology, Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: 17β-Estradiol (E2) is a steroid hormone that has been implicated to exert many beneficial effects in the brain, including neuroprotection, anti-inflammatory effects, and enhancement of synaptic plasticity and cognition. The ovary is well known to be the primary source of E2 generation in the body; however, recent work by our lab and others has shown that aromatase, the enzyme responsible for synthesis of E2 from androgens, is also expressed in the forebrain of the rat, particularly in the hippocampus. To further enhance understanding of local E2 function and roles in the forebrain, we examined aromatase expression in the hippocampus of the ovariectomized rat following 4-vessel global cerebral ischemia (GCI), and determined the effect of knockdown or inhibition of aromatase on neuroprotection, pro-survival and pro-apoptotic factors, and synaptic proteins in the hippocampus. Our results revealed that following GCI, protein expression of aromatase in the hippocampal CA1 region initially decreased at 3h after reperfusion, rebounded at 1day, which was followed by a significant elevation at 3 days and 7 days post-reperfusion, as compared to sham group. Continuous central administration of aromatase antisense oligonucleotide (AS) or aromatase inhibitor letrozole led to enhanced neuronal damage following GCI, as evidenced by an increase in TUNEL-positive cells and a decrease of NeuN-positive cells in the hippocampal CA1 region, as compared to reperfusion 7d and missense control. Furthermore, aromatase-AS treatment abolished the increased phosphorylation level of ERK1/2 and CREB observed at 3h and 1d following GCI. Interestingly, protein levels of the pro-survival factor BDNF were significant attenuated by aromatase-AS treatment, while levels of the pro-apoptotic factors, p-JNK and p-P38, were markedly enhanced by aromatase-AS treatment. Finally, aromatase-AS treatment also significantly reduced expression of the synaptic proteins PSD95 and synaptophysin, indicating a role for local E2 in regulation of synaptic function after GCI. As a whole, the results suggest that local E2 exerts an important pro-survival effect in the hippocampus after cerebral ischemia by regulating the balance of pro-survival and pro-apoptotic factors, as well as modulating expression of key synaptic proteins. (Supported by NIH/NINDS research grant R01NS088058)

Title: Activation of Serpin-1B-mediated apoptotic pathway in focal brain ischemia

Authors: *V. V. DIDENKO;
Neurosurg., Baylor Col. of Med., Houston, TX

Abstract: Serpin 1B-mediated apoptosis is one of the most recently identified apoptotic pathways. Its activation was previously demonstrated in neural tissue development. Here we demonstrate that this apoptotic pathway is also activated in focal brain ischemia. In this presentation we show the co-existence of caspase-dependent and serpin-mediated mechanisms of apoptosis in ischemic brain. The relative contributions of these two different pathways in progression of ischemic injury are discussed. The identification and visualization of serpin1B-mediated apoptosis in tissue sections of experimental stroke in rat model became possible by using the newly-developed *in situ* approach.

Title: Mitochondria/endoplasmic reticulum dysfunction exacerbates oxidative damage in aging white matter ischemia

Authors: *C. BASTIAN, K. STAHON, S. GRIFFITH, G. KIDD, S. BRUNET, S. BALTAN;
Dept. of Neurosci., Cleveland Clin. Fndn., Cleveland, OH

Abstract: White matter (WM) is frequently affected by stroke. Aging WM shows reduced functional recovery following stroke compared to younger WM. Free radicals accumulate with aging due to overproduction or insufficient clearance, resulting in increased oxidative stress. Mitochondria/endoplasmic reticulum (ER) interactions are crucial for protection from oxidative stress. We hypothesized that aging WM is more susceptible to oxidative stress damage mediated by mitochondrial/ER dysfunction, leading to decreased ATP synthesis and impaired Ca^{2+} homeostasis. Mouse optic nerves (MON) obtained from C57BL/6J and Thy-1 CFP(+) mice at 1 month (young) or 12 months (aging) of age were used. Axon function was quantified by recording evoked compound action potentials. Mitochondrial/ER structure and interactions were determined by 3D-electron microscopy, Western blotting, ATP assays, and CFP (+) fluorescent mitochondrial imaging. Oxidative stress was assessed by nitric oxide synthase (NOS) and glutathione assays and by Western blotting for oxidative stress markers (3-NT and 4-HNE). Oxygen-glucose deprivation (OGD) for 60 min resulted in decreased functional recovery of aging WM compared to young WM. Aging WM displayed elevated NOS activity and increased levels of by-products of lipid peroxidation (4-HNE) and protein nitration (3-NT), indicating aggravated reactive oxygen and nitrogen species mediated damage. Structurally, compared to young axons, aging axons were larger, with thicker myelin, and were characterized by longer and thicker mitochondria due to altered levels of mitochondrial shaping proteins. This was further confirmed by 3D-EM and CFP (+) imaging and may compensate for the decreased ATP levels detected in aging WM. Moreover, mitochondrial-ER interactions were compromised due to decreased association between the organelles and due to decrease in levels of mitochondrial trafficking protein miro-2, which suggests defective Ca^{2+} homeostasis in aging axons. WM exposed to OGD showed ultrastructural changes such as axonal and mitochondrial swelling, loss of cristae, and a decrease in ATP levels. Calnexin, an ER stress response chaperone protein, was decreased under baseline conditions in aging axons, but did not show upregulation following OGD when compared to young axons, suggesting a defect in unfolded protein responses. We conclude that aging WM is increasingly vulnerable to stroke because of inherent structural changes in axons and mitochondria/ER interactions, leading to depletion of ATP and defective Ca^{2+} dynamics, resulting in increased oxidative stress.

Title: Transgenic mice overexpressing human angiotensin i receptor gene are susceptible to stroke injury

Authors: *J. TULSULKAR[1], S. JAIN[2], A. RANA[2], A. KUMAR[2], Z. SHAH[1];
[1]Medicinal biochemistry, [2]Physiol. and phamacology, Univ. of Toledo, Toledo, OH

Abstract: Hypertension is one of the co-morbid conditions for stroke and profoundly increases its incidence. Angiotensin II (AngII) is shown to be at the center stage in driving the renin angiotensin system via activation of angiotensin 1 receptor (AT1R). This makes the AT1R gene one of the candidates whose differential regulation leads to the predisposition to disorders associated with hypertension. A haplotype block of four SNPs is represented primarily by haplotype-I, or Hap-I (TTAA), and haplotype-II, or Hap-II (AGCG), in the promoter of human AT1R (hAT1R) gene. To better understand the physiological role of these haplotypes, transgenic (TG) mice containing Hap-I and Hap-II of the hAT1R gene in a 166-kb bacterial artificial chromosome (BAC) were generated. Mice received injection of endothelin-1 (1 mg/ml) directly in to the striatum and were evaluated for neurologic deficit scores and sacrificed for analysis of infarct volume and mRNA levels of various proteins. Mice containing Hap-I suffered from significantly higher neurological deficits and larger brain infarcts than Hap II. Similarly, the molecular analysis of oxidant and inflammatory markers in brains of mice showed a significant increase ($p < 0.05$) in NOX-1 (2.3-fold), CRP (4.3-fold), and IL6 (1.9-fold) and a corresponding reduced expression of antioxidants SOD (60 %) and HO1 (55 %) in Hap-I mice as compared to Hap-II mice. These results suggest that increased expression of hAT1R rendered Hap-I TG mice susceptible to stroke-related pathology, possibly due to increased level of brain inflammatory and oxidative stress markers and a suppressed antioxidant defense system.

Title: Ischemia/reperfusion injury leads to upregulation of contractile proteins of pericytes

Authors: *S. YILMAZ OZCAN[1], L. ALARCON-MARTINEZ[1], B. DONMEZ-DEMIR[1], T. DALKARA[1,2], M. YEMISCI[1,2];
[1]Inst. of Neurolog. Sci. and Psychiatry, Hacettepe, Ankara, Turkey; [2]Fac. of Medicine, Dept. of Neurology, Hacettepe Univ., Ankara, Turkey

Abstract: Pericytes are located on the walls of the pre-capillary arterioles, post-arteriole capillaries and post-capillary venules, wrapping them with their processes. They have many functions in health and disease such as maintenance of the blood-brain barrier, regulation of microcirculation, phagocytosis, and angiogenesis. True capillary (<4μm) pericytes are shown to have a major role in regulation of microcirculatory blood flow in the brain and retina. The contractile abilities are currently disputed. With a novel histological and immunohistochemical method, we showed that alpha-smooth muscle actin (alpha-SMA) which plays a central role in the contractile response of large arteries and arterioles, can be detected in pericytes even in the smallest capillaries of retina and brain of adult mice. We also found that in retinal ischemia done by central retinal artery occlusion or transient Middle Cerebral Artery occlusion (MCAo) made by intraluminal filament method, alpha-SMA mediated capillary constrictions emerge. We also demonstrated by quantitative RT-PCR that alpha-SMA mRNA increased dramatically in ischemic territory after 2 hours ischemia and 6 hours reperfusion of MCAo mice compared to sham operated and naive animals. In addition to alpha-SMA expression, when we analyzed the expression of other contractile genes such as desmin and vimentin, we observed a significant up-regulation in the ischemic MCA territory. The increases in mRNA expressions of these three genes were not statistically significant after 2 hours of ischemia and 3 hours of reperfusion condition. In conclusion, we detected alpha-SMA expression in pericytes, which is induced after ischemia consistent with up-regulation of various contractile genes related to contraction. The question of whether this early increase in pericyte contraction markers is an indication of early angiogenesis or other pathophysiological role played by pericytes in the setting of cerebral ischemia is the subject of our further investigations.

Title: Mass spectrometry analysis of post-ischemic insoluble proteins reveals preferential accumulation of proteins involved in RNA/protein synthesis and cell signaling

Authors: *K. HOCHRAINER[1], A. KAHL[1], K. JACKMAN[1], J. BASKAR[1], S. ZHANG[2], J. ANRATHER[1], C. IADECOLA[1];
[1]Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY; [2]Inst. of Biotech. and Life Sci. Biotechnologies, Cornell Univ., Ithaca, NY

Abstract: Brain injury is frequently associated with accumulation of insoluble protein inclusions (Ross and Poirier, 2004). Although the protein composition of the inclusions is unique for each injury modality, ubiquitin is frequently present (Dantuma and Bott, 2014). We showed that focal cerebral ischemia results in the formation of ubiquitin-positive protein inclusions (Hochrainer et al, 2012). Unlike neurodegeneration, in which irreversible ubiquitin-containing inclusions are formed over a long time and may portend cell death, after ischemia ubiquitination is rapid, transient and does not predict brain damage (Hochrainer et al, 2012). To gain insight into the biological significance of protein inclusions after ischemia we sought to identify the contained proteins. Mice underwent middle cerebral artery occlusion or sham-surgery (n=8/ group). After reperfusion for 1 hour, when ubiquitin is maximally detected in inclusions, mice were sacrificed and insoluble proteins, as determined by their resistance to 2% Triton X-100 solubilization, were obtained from ischemic neocortices. Isolated proteins were digested with trypsin and identified by nanoLC-MS/MS (n=4, each 2 pooled sham and ischemia animals). Relative amounts of proteins detected in sham and ischemia groups were quantified for each run using label-free quantification (MaxQuant). Ischemia versus sham fold change was determined and mean values were calculated across all 4 runs. Proteins with fold change values within the internal standard range (trypsin: 1.04±0.16) were considered unchanged (131, fold change 1.20 - 0.88); 197 proteins were increased (fold change 1.21 - 6.24x10e7) and 213 were decreased (fold change 0.87 - 8.46x10e-8) in the insoluble fraction after ischemia/reperfusion. As anticipated, ubiquitin was among the most increased proteins (5.83x10e7±2.91x10e7). To place the groups of proteins into a biological context we analyzed gene ontology term enrichment using the DAVID (http://david.abcc.ncifcrf.gov) database. Proteins that were unchanged or reduced by the ischemic challenge were mainly clustered around membrane, structural molecule, organelle and macromolecular complex terms ($P<0.001$). However, proteins that were increased associated with DNA/RNA binding, RNA processing and signal transduction ($P<0.001$). Such distinct enrichment of proteins involved in RNA/protein synthesis and cell signaling in post-ischemic ubiquitin-rich inclusions is consistent with a protective mechanism by which proteins sub-serving vital cellular functions are sequestered in inclusions to shield them from the detrimental cellular environment associated with cerebral ischemia.

Abstract: Here we report the effect of post-ischemic salubrinal treatment on the tumor necrosis factor receptor 1 (TNFR-1) pathways using a model of global cerebral ischemia. A two vessel occlusion for 15 minutes, at 45-50 mmHg blood pressure maintained by exanguination, followed by 24 h reperfusion was performed. One hour after the insult, a single dose (1 mg/kg) was injected intraperitoneally. The effects of salubrinal on the different possible pathways (apoptosis, necroptosis or cell survival) ignited by TNFR1 activation were analyzed by qPCR, Western blot or immunostaining in hippocampal CA1 and CA3 as well as the cerebral cortex. TNFR1, caspase 8, cIAP1, IκB, A20, MLKL, RIP1, RIP3, cFLIP, CYLD, NFκB were measured as parameters of these pathways and the most striking effect of the salubrinal treatment was a decrease in the expression of TNFR-1 transcripts 24 h after insult. Our data suggest that salubrinal treatment enhances cell survival and decreases the cell death pathways elicited by TNFR1. This study was supported by MINECO (reference BIO2013-49006-C2-2-R) who also supports Berta Anuncibay-Soto and María Santos-Galdiano. Universidad de Leon fellowship for Enrique Font.

Title: The role of interplay between AKAP1 complex with CaN and PKA in mitochondrial morphology and neuronal survival

Authors: *Y. LIU[1], R. A. MERRILL[2], A. SLUPE[2], K. FLIPPO[2], A. CHAUHAN[3], S. MCKNIGHT[4], S. STRACK[2];
[1]Univ. of Iowa Carver Col. of Med. Depa, Iowa City, IA; [2]Dept. of Pharmacol., [3]Oncology, and Blood & Marrow Transplantation, Univ. of Iowa Carver Col. of Med., Iowa City, IA; [4]Dept. of Pharmacol., Univ. of Washington Sch. of Med., Seattle, WA

Abstract: Mitochondria play important roles in both early (minutes) and late (days) stages of ischemic brain injury and offer attractive targets for development of stroke therapy. Mitochondrial architecture, a product of opposing fission and fusion reactions, shows signs of extreme fragmentation during stroke. Mitochondrial fission catalyzed by the mechanoenzyme dynamin-related protein 1 (Drp1) is tightly regulated through phosphorylation of a highly conserved Drp1 phosphorylation site (S637). When this site is phosphorylated by protein kinase A (PKA), mitochondria fusion is unopposed. PKA is antagonized by the Ca2+-dependent protein phosphatase calcineurin (CaN or PP2B), which dephosphorylates Drp1 at S637 to promote mitochondrial fragmentation and dephosphorylated Drp1 sensitizes PC12 cells to apoptosis.Mitochondria-localized A kinase anchoring protein 1 (AKAP1, aka D-AKAP1, AKAP121, AKAP149) displays potent neuroprotective properties. AKAP1 assembles a mitochondrial “signalosome” by binding both PKA and CaN that integrates death and survival signals through reversible phosphorylation of Drp1 at S637 to restructure the organelle. Using AKAP1 pulldowns, we determined CaN binds to the N-terminus of AKAP1 and this interaction was stabilized via the CaN interaction with a PKA regulator subunit bound to AKAP1. Furthermore, phosphorylation of AKAP1 by PKA may increase the CaN: AKAP1 interaction. By expressing AKAP1 mutants in primary hippocampal neurons, we demonstrate that CaN binding-deficient AKAP1 mutant result in mitochondria elongation while PKA binding-deficient AKAP1 mutant resulted in mitochondrial fragmentation. These findings also correspond to the neuron susceptibility to excitotoxic insult. Finally, mice lacking AKAP1 had smaller mitochondria, age-dependent neurodegeneration and a pronounced increase in infarct volumes following middle cerebral artery occlusion. These data suggest that AKAP1 play a critical role in regulating mitochondrial morphology and neurons are more susceptible to excitotoxic insults without proper AKAP1 activities.

Abstract: Background: Galectin-3 (Gal-3), a member of β-galactosides-binding lectins, has recently emerged as a molecule with immunoregulatory functions. Gal-3 is a pleiotropic protein involved in cell adhesion, activation, proliferation, apoptosis and cell migration. When liberated by macrophages including activated microglia, it exerts strong chemotactic properties on monocytes and macrophages and contributes to phagocytosis in neutrophils and macrophages. Of note, recent investigations have revealed that Gal-3 is required for resident microglia activation and proliferation in response to ischemic insult. So far research addressing a regulatory role for

Gal-3 in microglia morphology is lacking. In this study, We investigated the effects of Gal-3 on microglia function. Given the preferential expression of Gal-3 in glia and its prominent role in inflammatory/remodeling events, Gal-3 might serve as a potential target in neuroinflammatory and neurodegenerative settings. **Methods:** Primary microglia cell cultures, challenged with Gal-3, were exploited for the assessment of morphology and secretory profile using real-time PCR and immunofluorescence while migration was studied using scratch-wound assay. **Results:** *In vitro* measurements revealed that 24 hour-exposure of primary microglia with Gal-3 increased the number and length of Filopodia via. Moreover, at transcriptional level, Gal-3 down-regulated pro-inflammatory cytokines (TNF-a and IL-1b) and upregulated anti-inflammatory cytokine (IL-4) and IGF-1. Interestingly, Gal-3 augmented resting microglia migration 1 day after treatment. **Conclusions:** Our results, *in vitro* and *in vivo*, demonstrate that Gal-3 induces microglial ramification. Gal-3 also modulates the cytokine profile of microglia toward an anti-inflammatory state. Together, these findings suggest the role of Gal-3 as a fine-tuner of microglia cytoskeleton and secretory profile. Our onging investigations in our lab interrogate signaling pathways involved.

Title: Deletion of TRPC6 attenuates nmda receptor-mediated Ca^{2+} entry and Ca^{2+}-induced neurotoxicity in models of cerebral ischemia

Authors: J. CHEN, Z. LI, S. CHAN, *Z. CHENG;
Burnett Sch. of Biomed. Sci., Univ. of Central Florida, Orlando, FL

Abstract: Ischemic stroke is a major cause of death and disability in adults. TRPC6 is a non-selective cation channel which is permeable to Na+ and Ca2+. Recent data indicated that the TRPC6 expression was increased in stroke and that the amount of ischemia/reperfusion (I/R) induced brain damage measured 3 days after I/R was significantly less in TRPC6-/- mice than in WT mice. This seemed to indicate that TRPC6 gene disruption rendered the brain less susceptible to ischemic insults. However, the molecular mechanism by which TRPC6 deletion protected against ischemic brain injury was unknown. According to the literature, the AMPA-NMDA pathway is considered as a major subset of the multiple routes of ionic imbalance that

are induced in brain injury and neurodegeneration. Thus, we hypothesized that TRPC6 deletion prevents Ca2+ overload by altering NMDAR channel activity, which may protect against oxygen-glucose-deprivation (OGD)-induced cell death in primary cultured cortical neurons. In this study, we have demonstrated that deletion of TRPC6 reduces oxygen-glucose deprivation (OGD) and glutamate/NMDA excitoxicity-induced cortical neuron death. In addition, we have shown that OGD increased, but deletion of TRPC6 decreased NMDAR-dependent Ca2+ influx, which is regulated by Na+ entry via both voltage sensitive and non-voltage sensitive Na+ channels. Along with the previous work, we may conclude that cerebral ischemia-induced brain damage is, in part, due to upregulation of TRPC6 ion channels in cortical neurons. Overexpression of TRPC 6 during ischemia and OGD may induce cortical neuronal death through possible TRPC6 dependent Na+ entry which activates NMDA receptors, thus leading to overload of Ca2+. OGD- and glutamate/NMDA excitotoxicity-induced cell death *in vitro* are likely mediated through both TRPC6-NMDA and AMPA-NMDA pathways, and deletion of TRPC6 protects cerebral ischemia-induced brain damage *in vivo*. These findings may provide a potential target for future interventions in stroke-induced brain damage.

Abstract: Immune response and inflammatory signaling are intertwined events after stroke, the second most frequent cause of death and debilitating illness. Microglia, the resident immune cell in brain can be polarized into M1 (pro-inflammatory) and M2 (anti-inflammatory) phenotypes

after brain injury. Initial M1 inflammatory signaling subsides by turning on M2 reparative actions but nonresolving inflammation causes further tissue damage. Members of the IRF family of transcription factors play a major role for innate and adaptive immune responses regulating genes encoding IFNα, IFNβ and IFNγ, including IFNs-inducible genes. Supporting evidence showed IRF2 activates M1 polarization, while IRF2 gene expression and transactivational activities was known to be inhibited by IRF2 binding protein 2 (IRF2BP2). In this study, we hypothesize that IRF2BP2 serves as modulator/suppressor of IRF2 action on microglia/macrophages polarization. Using an animal model lacking IRF2BP2 in myeloid cell-lineage that includes peripheral macrophages and CNS microglia, we are testing whether IRF2BP2 action is neuroprotective or –destructive after CNS focal ischemia. In adult mice, the infarct volume of IRF2BP2$^{-/-}$ mice 4 days after permanent focal ischemia by cerebrocortical photothrombosis was significantly larger compared to IRF2BP2$^{+/+}$ mice. This was supported by behavioral analysis using cylinder and adhesive removal tests, showing IRF2BP2$^{-/-}$ mice have significant deficit of the contralateral forelimb usage compared to IRF2BP2$^{+/+}$ mice. At the same time, the number of cells labeled by anti-Iba1, a marker protein of microglia and macrophages was found to be significantly lower in IRF2BP2$^{-/-}$ compared to IRF2BP2$^{+/+}$, indicating a compromised immune cell build-up after brain ischemia. *In vitro*, cell culture of bone marrow derived macrophages (BMDM) from IRF2BP2$^{-/-}$ mice showed attenuated gene expression of cytokines that marked M1 and M2 polarization compared to IRF2BP2$^{+/+}$ mice. Furthermore, fluorescence activated cell sorting (FACS) analysis after 4d stroke showed lower M1 phenotype in IRF2BP2$^{-/-}$ mice. While the microglia phenotypes can be used as an indicator of the signaling involved during an immune response, our data apparently shows that the loss of IRF2BP2 can result into increased brain cell death and affects microglia population at the site of damage. In conclusion, our study provides novel evidence of a critical role for IRF2BP2 for recovery from the detrimental aftermath of stroke. Further study of IRF2BP2 mechanisms of action in stroke may provide beneficial therapeutic ways of dealing with recovery period.

Title: Molecular mechanisms of axonal sprouting in a cortical circuit induced by limb overuse after stroke

Authors: *E. H. NIE[1], G. COPPOLA[2], S. T. CARMICHAEL[3];
[1]Neurol., UCLA, Los Angeles, CA; [2]Psychiatry and Biobehavioral Sci., [3]Neurol., UCLA David Geffen Sch. of Med., Los Angeles, CA

Abstract: Stroke survivors worldwide are left with permanent sensorimotor and cognitive disabilities for which there are no medical treatments. However, a behavioral paradigm of limb overuse after stroke, known as constraint-induced movement therapy (CIMT), has been shown in clinical trials to result in significant motor improvements. The goal of the current project is to understand how limb overuse shapes cortical circuit reorganization after ischemic stroke, and how specific gene systems drive this important neural repair process. These studies utilize a mouse model of stroke and forelimb overuse that approximates human CIMT. In this model, fluorescent neuronal tracers were used to quantitatively map cortical neurons that connect to premotor cortex upon post-stroke limb overuse. We find that recovery involves the activity-dependent formation of connections between premotor cortex (PMC) and retrosplenial cortex (RSC), a parietal area involved in spatial learning. The finding was significant and replicated across two independent cohorts ($p<0.05$, Hotelling's T test). Moreover, retrograde corticospinal tract tracing confirms that the activity-induced connections are anatomically distinct from layer V corticospinal motor areas. Next, tracer-labeled cells in RSC and matched control neurons were FACS purified for RNA-Seq. Pathway analyses indicate that limb overuse induces canonical signaling in calcium signaling, cell cycle, and Ephrin A pathways. A top network hit was identified in cell growth, proliferation and tissue development. The RSC-PMC circuit is characterized by circuit-specific expression of activity-induced and growth-related genes. From the relatively small group of 162 genes that are regulated by limb overuse, top candidates have been statistically prioritized (FDR<0.1, $p<0.005$) for in-vitro neuronal outgrowth screening using primary cortical neurons. Current knockout experiments in-vitro have shown that gRNAs directed against these genes can facilitate CRISPR/cas9 gene-editing of these candidates. Cel-I mutation detection has confirmed gene knockout for axonal outgrowth studies. Ongoing design of an AAV-mediated cas9 for in-vivo delivery aims to target the prioritized candidates that increase neuronal outgrowth from the in-vitro screening dataset. Quantitative cortical mapping will examine how the genetic modifications affect the RSC-PMC circuit mapped in the first phase of this study. Through single and multiplexed genetic gain and loss-of-function studies, we now hope to understand how injury and activity-dependent molecular pathways converge in the RSC-PMC circuit during limb overuse and brain repair after stroke.

Title: Aging upregulates Ca^{2+}-permeable AMPA receptors and renders them the predominant mediators of injury during white matter stroke

Authors: *S. BALTAN, S. GRIFFITH, C. BASTIAN, B. SCOTT, S. BRUNET;
Dept. of Neurosciences, Cleveland Clin., Cleveland, OH

Abstract: Stroke risk increases with age. The human brain is comprised of equal portions of gray matter and white matter (WM) and both are injured during stroke. AMPA/kainate glutamate receptors mediate excitotoxic injury and it was shown that blockade of AMPA and kainate receptors with a broad spectrum glutamate receptor blocker, NBQX (30 μM), preserves axon function and promotes recovery following ischemia in young and aging WM. Using selective glutamate receptor blockers, we investigated whether excitotoxic injury is mediated via age-specific glutamate receptor subtypes. Mouse optic nerves (MONs) obtained from male C57BL/6J mice at 1 month or 12 months of age were used to determine the cellular expression and labeling intensity of the Ca^{2+}-permeable AMPA receptor subunit GluR4. GluR4 subunit immunoreactivity was observed on GFAP (+) astrocytes and APC (+) oligodendrocytes increased with aging, suggesting that Ca^{2+}-permeable AMPA receptors may become predominant in mediating ischemic injury in aging WM. Axon function was quantified while exposing MONs to oxygen-glucose deprivation (OGD) for 60 minutes. Young MONs typically recovered better after OGD than aging MONs. Blocking Ca^{2+}-permeable AMPA receptors (NASPM, 10μM) or kainate receptors (UBP 302, 1 μM) individually provided no protection in young WM (OGD: 20.0 ± 2.1%, n=14; AMPA: 23 ± 2.0%, n = 5; kainate: 22 ± 4.4%, n = 9). In contrast, blockade of Ca^{2+}-permeable AMPA receptors resulted in significant recovery in aging WM, while blockade of kainate receptors showed more modest recovery (OGD: 10.9 ± 1.1%, n=9; AMPA: 38.8 ± 6.4%, n= 3, $p<0.001$; kainate: 24 ± 4.3%, n=5, $p<0.01$). On the other hand, blocking both the Ca^{2+}-permeable and Ca^{2+}-impermeable AMPA receptors with GYKI (30μM) preserved axon function in young as well as aging WM (Young: GYKI, 34.5 ± 3.3, n=5, $p<0.01$; Aging: 37.7 ± 3.8, n=7, $p<0.001$). Combined blockade of Ca^{2+}-permeable AMPA and kainate receptors preserved both young and aging WM (Young: 50 ± 7.8%, n=4, $p<0.05$; Aging: 40.5 ± 9.4%, n=6, $p<0.001$). Finally, broad spectrum glutamate receptor blockade with NBQX showed axon recovery similar to blocking with both NASPM and UBP302 in young and aging WM (Young: 51± 3.5, n=8, $p<0.001$; Aging: 40.8 ± 1.6, n=10, $p<0.001$). Our results suggest that in young WM, activation of either AMPA or kainate receptors mediate ischemic injury, while in aging WM, activation of Ca^{2+}-permeable AMPA receptors are primarily responsible for ischemic WM injury.

Title: Differential activity of aminopeptidase N (EC 3.4.11.2) contributes to selective vulnerability of Cornu Ammonis 1 to oxygen-glucose deprivation in the rat hippocampus

Authors: ***Y. OU**, S. WEBER;
Chem., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The selective vulnerability of the hippocampus proper to oxygen-glucose deprivation (OGD) has been known for over a century, with the Cornu Ammonis 1 (CA1) region being more susceptible to neuronal cell death than the CA3 (Stanika et al., 2010). Ectopeptidases are membrane-bound enzymes whose catalytic domains face the extracellular space (ECS). They are conventionally viewed as having a clearance role, but recently they have been shown to modulate peptide levels in response to either pathological (e.g. stress) or trophic triggers (e.g. preconditioning) (reviewed in Ou et al., 2014). We developed a novel sampling tool called electroosmotic push-pull perfusion (EOPPP) that introduces exogenous neuropeptide substrates into the ECS and collects hydrolysis products with good spatial resolution (Rupert et al., 2013). This method was used to measure ectopeptidase activity in the CA1 and CA3 of rat organotypic hippocampal slice cultures (OHSCs). We demonstrated that higher activity of bestatin-sensitive Leu-enkephalin-hydrolyzing aminopeptidase N contributes to CA1 vulnerability to OGD. Inhibition of this enzyme significantly reduced CA1 damage relative to that in CA3 as a result of OGD. *References:* Ou Y, Wu J, Sandberg M, Weber S (2014) Electroosmotic perfusion of tissue: sampling the extracellular space and quantitative assessment of membrane-bound enzyme activity in organotypic hippocampal slice cultures. Title: Neuroprotection against ischemic cell death - a novel role of polycomb group protein EZH2

Authors: P. SHARMA, T. LENG, Z.-G. XIONG, Z. YANG, R. SIMON, *A. ZHOU; Morehouse Sch. of Med., Atlanta, GA

Abstract: Polycomb group (PcG) proteins are transcriptional repressors, regulating a broad spectrum of genes through epigenetic mechanisms. PcG proteins are assembled into multi-protein Polycomb Repressive Complexes (PRC) and exert their function by concerted modifications of histone proteins. Previous studies have shown critical roles of several PcG proteins of the PRC1 complex in neuroprotection against ischemic injury both *in vivo* and *in vitro*. The roles of other PcG proteins in the neuronal response to ischemia are not known. The objective of this study was to investigate the possible involvement of PcG proteins of the PRC2 complex in neuroprotection, with a focus on the Enhancer of Zest Homolog-2 (EZH2), a methyltransferase that trimethylates histone H3 at lysine 27. We also examined whether or not enhanced neuroprotection can be achieved by simultaneous regulation of both PRC1 and PRC2 group proteins. All experiments were performed on differentiated neuroblastoma NS20Y cells. Over-expression of recombinant EZH2 protein was achieved by transfection. Inhibition of EZH2 activity was achieved by incubating cells with EPZ6438, an EZH2-specific inhibitor. Simulated ischemia was modeled by oxygen-glucose deprivation (OGD). OGD-induced cell injury was determined by LDH assay. Potassium currents were recorded by whole-cell patch clamp. Levels of mRNA or protein of interest were determined by qPCR, Western blotting and immunocytochemistry, respectively. Interaction of EZH2 protein with the promoter region of its potential target gene was examined by chromatin immunoprecipitation (ChIP) followed by PCR analyses. Results to date have shown that over-expression of EZH2 reduced OGD-induced injury, whereas inhibition of EZH2 activity exacerbated the injury. Whole cell potassium currents were significantly decreased with EZH2 over-expression and increased with EZH2 inhibition. An interaction between EZH2 and the promoter region of potassium channel gene Kcna1, either directly or indirectly, was evidenced by the results of ChIP assay. Further, a compounding repressive effect on whole cell potassium currents was observed when histone

modification activities of both EZH2 and BMI1 - a PRC1 protein, were inhibited, when compared with that of inhibition of EZH2 or BMI1 alone. In conclusion, our results support a role of EZH2 in neuroprotection against ischemic injury in cultured neuronal cells. The underlying mechanisms may involve PcG protein-mediated suppression of potassium channel proteins. Further studies will aim at the involvement of additional PcG proteins and a possible, broader involvement of potassium channel proteins.

Title: Pyruvate and cilostazol protect cultured rat cortical pericytes against tissue plasminogen activator (tPA)-induced cell death

Authors: *H. KIM[1], T.-Y. KIM[1], Y. YOON[2], J.-Y. KOH[3];
[1]Asan Inst. For Life Sci., Seoul, Korea, Republic of; [2]Dept. of Ophthalmology, Asan Med. Ctr., Seoul, Korea, Republic of; [3]Dept. of Neurology, Asan Med. Ctr., Seoul, Korea, Republic of

Abstract: Since even a brief ischemia can cause permanent brain damage, rapid restoration of blood flow is critical to limiting damage. Although intravenous tPA during the acute stage is the treatment of choice for achieving reperfusion, this treatment is sometimes associated with brain hemorrhage. Agents that reduce tPA-related bleeding risk may help expand its therapeutic window. This study assessed whether zinc dyshomeostasis underlies the toxic effect of tPA on brain vascular pericytes; whether pyruvate, an inhibitor of zinc toxicity, protects pericytes against tPA-induced cell death; and whether cilostazol, which protects pericytes against tPA-induced cell death, affects zinc dyshomeostasis associated with tPA toxicity. Cultured pericytes from newborn rat brains were treated with 10-200 μg/ml tPA for 24 h, inducing cell death in a concentration-dependent manner. tPA-induced cell death was preceded by increases in intracellular free zinc levels, and was substantially attenuated by TPEN. Pyruvate completely blocked direct zinc toxicity and tPA-induced pericyte cell death. Both cAMP and cilostazol, a PDE3 inhibitor that attenuates tPA-induced pericyte cell death *in vitro* and tPA-induced brain

hemorrhage *in vivo*, reduced zinc- and tPA-induced pericyte cell death, suggesting that zinc dyshomeostasis may be targeted by cilostazol in tPA toxicity. These findings show that tPA-induced pericyte cell death may involve zinc dyshomeostasis, and that pyruvate and cilostazol attenuate tPA-induced cell death by reducing the toxic cascade triggered by zinc dyshomeostasis. Since pyruvate is an endogenous metabolite and cilostazol is an FDA-approved drug, *in vivo* testing of both as protectors against tPA-induced brain hemorrhage may be warranted.

Title: Mechanisms of neuroprotection elicited by polycomb group protein scmh1

Authors: *A. KEY, P. SHARMA, Z. YANG, A. MCDOWELL, A. ZHOU;
Neurosci. Inst., Morehouse Sch. of Med., Atlanta, GA

Abstract: Background Polycomb group (PcG) proteins are repressive, transcriptional regulatory proteins controlling the expression of a broad spectrum of genes by means of histone protein modifications. They function in multi-protein complexes. SCMH1 is a PcG protein associated with polycomb repressive complex (PRC) I. It, together with several other PcG proteins of PRC-I such as BMI1 and RING1B, have been shown to exhibit neuroprotective roles against ischemic injury, both in ischemic mouse brains *in vivo* and in cultured neuronal cells *in vitro* (Stapels et al., 2010, Sci Sig xxx). Little is known for the molecular mechanisms that underlie SCMH1-mediated neuroprotection. Unlike RING1B or BMI1 proteins of PRC-I, SCMH1 does not possess any histone modification activity. Hence, we speculate that SCMH1 may exert its role primarily by mediating protein-protein/protein-DNA interaction and/or sustaining the integrity of PRC-I. The objective of this study was to characterize changes in neuronal cells that can be induced by changes in the level of SCMH1 protein and to identify proteins that may interact with SCMH1, as our first step in dissecting SCMH1-mediated neuroprotective mechanisms. Methods Over- or under-expression of SCMH1 protein was achieved by transfection of recombinant SCMH1 cDNA or siRNA against SCMH1, respectively, into neuronal NS20Y cells. For comparison, over-expression of several other PcG proteins was also included. Cellular levels and subcellular distribution of SCMH1 protein was determined by Western blot and immunocytochemistry analyses, respectively. Protein interaction with SCMH1 under normal or

ischemic conditions was determined by immunoprecipitation using an anti-SCMH1 antibody followed by Western blotting of the known PRC-I protein and mass spectrometry analysis of the entire interactive complex. Results A profound change in the morphology of NS20Y cells was observed in cells with SCMH1 over-expression. When examined under light microscrope, SCMH1-over-expressing cells presented more processes when compared with that in wildtype cells. Such a change was not seen in NS20Y cells over-expressing other PcG proteins of PRC-I: BMI1 and RING1B and PRC-I protein EZH2. Western blot analysis of cellular proteins that were immunoprecipitated with an anti-SCMH1 antibody resulted in a positive identification of PRC-1 protein RING1B. This supports the association of SCMH1 with PRC-I in neuronal cells. On-going mass spectrometry analysis focus on other immunoprecipitated proteins extracted from cells subjected to different ischemic conditions, and is expected to reveal protein networks that may be regulated by SCMH1.

Title: A transcriptional program underlying neuronal survival

Authors: *B. MAINO[1], S. PAPARONE[2], C. SEVERINI[3], V. D'AGATA[4], M. CIOTTI[2], P. CALISSANO[3], S. CAVALLARO[2];

Abstract: A shift of the delicate balance between apoptosis and survival-inducing signals determines the fate of neurons during the development of the central nervous system and in its homeostasis throughout adulthood. Both apoptosis- and survival-signaling pathways converge into the nucleus and regulate gene expression. Although the transcriptional program of neuronal apoptosis has been elucidated, the transcriptional program underlying neuronal survival is still unknown. We conducted whole-genome expression profiling to decipher the transcriptional regulatory elements controlling the apoptotic/survival switch in cerebellar granule neurons following the induction of apoptosis by serum and potassium deprivation and the rescue by different neurotrophic factors. Although acting through different upstream signaling pathways, the survival effects of neurotrophic factors converged to common transcriptional cascades. In addition to revealing the existence of a previously unknown transcriptional program underlying

neuronal survival, our analysis identified common transcriptional changes intersecting neuronal apoptosis and survival, forming the basis for further functional analyses and pharmacological investigation.

Title: Profiling plasma miRNA in intracerebral hemorrhage of small and large volume size

Authors: R. C. MARTINEZ[1], A. VARMA[2], I. O. IWUCHUKWU[3], *D. NGUYEN[4]; [1]Neurol., Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA; [2]Kasturba Med. Sch., Manipal, India; [3]Ochsner Med. Ctr., New Orleans, LA 70121, LA; [4]Neurosurg., Ochsner Hlth. Syst., New Orleans, LA

Abstract: Introduction: The potential role of miRNA as biomarkers in the pathophysiology of cerebral injury has been increasingly recognized. Studies have suggested that the expression patterns of miRNA change in relation to cerebrovascular diseases such as ischemic and hemorrhagic stroke. However, knowledge on the association of plasma miRNA with hemorrhagic stroke is still lacking. It is known that in intracerebral hemorrhage (ICH) hematoma volume >30 ml is associated with worse clinical outcome. We aim to determine the difference in circulating miRNA expression in plasma of patients with acute spontaneous ICH stratified by volumes (< 30ml and > 30ml). Methods: Ten patients with acute spontaneous ICH were recruited and categorized into small volume (<30ml) and large volume (>30ml) hematoma. Blood samples were collected within 48 hours of admission. Total RNA containing miRNA were extracted from 200ul of plasma samples using RNeasy Plasma miRNA Mini Kit. The cDNA and real-time PCR were carried out using the miRCURY LNA Universal RT and ExiLENT Sybr Green kits and run on an ABI 7500 real-time PCR. Ten candidate miRNAs were selected from our screen of 752 miRNAs using the Exiqon platform: miR-23a-3p, miR-24-3p, miR-30c-5p, miR-103a, miR-125b-5p, miR-183, miR-190-5p, miR-338-3p, miR-374b, and hsa-let7a. Results: We report here for the first time the presence of miRNA in brain pathogenesis associated with ICH as well as differentiation between small and large hematoma volume. MiR-103a was detected in high abundance in all ten ICH patients. On the other hand, miR-338 and miR-190 were found at low levels. The miR-125b was found at moderate but consistent levels across all samples.

Comparison between the large and small hematoma volume revealed that all patients with <30cc hematoma volume had detectable levels of miR-23a-3p, but also in some large volume patients. Notably, miR-183 was only detected in the ICH with the greatest volume (80ml). Conclusion: These results do not demonstrate distinct differences in expression of miRNA in plasma between <30ml and >30ml hematoma. Expressions of miR-338 and miR-125b were consistent across all samples which suggest that they may be potential biomarkers of spontaneous ICH, regardless of hematoma size. Additionally, we may imply that miR-183 is sensitive for very large volume hematoma.

Title: Test-retest reliability of transcranial magnetic stimulation measures in stroke

Authors: *J. M. CASSIDY[1], H. CHU[2], J. R. CAREY[3];
[1]Neurol., Univ. of California, Irvine, Irvine, CA; [2]Div. of Biostatistics, Sch. of Publ. Hlth., [3]Program in Physical Therapy, Dept. of Physical Med. and Rehabil., Univ. of Minnesota, Minneapolis, MN

Abstract: Objective: Determining the efficacy of non-invasive brain stimulation (NIBS) requires reliable transcranial magnetic stimulation (TMS) measures for probing corticomotor excitability. Despite the introduction of TMS nearly 30 years ago, there remains a lack of investigation concerning the reliability of TMS measures in stroke. The primary objective of this study was to examine the test-retest reliability of several intracortical and interhemispheric TMS measures in individuals with chronic stroke. **Methods:** Participants completed two sessions of TMS testing separated by approximately 24 hours. Test-retest reliability of ipsilesional resting motor threshold (RMT), cortical silent period (CSP) duration, short-interval intracortical inhibition (SICI), intracortical facilitation (ICF), and interhemispheric inhibition (IHI) was assessed using two-way, mixed intraclass correlation coefficients ($ICC_{(3,k)}$). Secondary analyses

included the computation of standard error of measurement and minimal detectable change values for each TMS measure. We also examined the influence of motor-evoked potential (MEP) analysis methodology (i.e. MEP amplitude vs. MEP area) on TMS paired-pulse measurement reliability by visually inspecting corresponding 95% confidence intervals for ICCs. **Results:** Eleven individuals (3 females; average age = 66 ± 9.4 years) with chronic stroke completed the study. Participants tolerated all procedures. CSP and log-transformed ICF and RMT measures demonstrated good to excellent reliability (ICCs ≥ 0.75). SICI and IHI measures derived from both MEP amplitude and MEP area measures demonstrated poor reliability (ICC < 0.50). The overlap of confidence intervals across all paired-pulse TMS measures suggested nonsignificant differences in measurement reliability between TMS measures calculated from MEP amplitude vs. area. **Conclusions:** Considerable differences in reliability exist amongst TMS measures regardless of the MEP method of analysis. Results from this study will strengthen future NIBS studies with regard to corticomotor excitability measurement selection and will ultimately help address present-day concerns of intra- and inter-individual variability in NIBS response.

Title: Feasibility of robotic assessment in cynomolgus macaques following middle cerebral artery occlusion (MCAO)

Authors: *S. V. OLESOVSKY[1], J. Y. NASHED[1], J. Z. WANG[1], T. ST. AMAND[1], D. J. COOK[1,2];

Abstract: Recent studies have highlighted the efficacy of non-human primate(NHPs) stroke models for preclinical, translational prior to initiating human trials. However, the relevance of NHP neurobehaviour in modeling human clinical grading has not been reliably demonstrated. Robotic assessment tools represent a quantitative, reliable and reproducible means to assess neurobehaviour following stroke in both humans and NHPs. Here we investigate the feasibility of robotics to explore neurobehavioural deficits in NHPs following MCAO. To investigate the feasibility of robotic assessments in NHPs following MCAO we employed the KINARM exoskeleton, which permits elbow and shoulder movements in the horizontal plane. Two Cynomolgus macaques underwent transient MCAO for 90min and recovered for 30days. Following the 30 day recovery period NHPs were trained to perform unassisted reaching

movements with both their affected and non-affected limbs in the KINARM exoskeleton. NHPs made reaching movements from a centrally positioned start target to 1 of 8 peripheral targets uniformly distributed around the start target. Each target required differing amount of elbow and shoulder movement. Following MCA stroke, the NHPs became proficient as the centre-out reaching task. In both animals we observed inter-limb differences. Reaching movements with the non-affected arms were straight with bell-shaped velocity profiles. In contrast, the reaching movements with the affected arm of both animals were highly variable, compared to the non-affected arm, and reaching movements often contained multiple velocity peaks. Finally, initial direction errors were far more prevalent in the affected arm (>83%) compared to the non-affected arm (<18%). These initial results qualitatively match the performance of human stroke subjects, suggesting that robotic neurobehavioural assessment in NHPs with stroke is feasible and have translational relevance to subsequent human studies.

Title: Altered hippocampal resting-state functional connectivity in patients with heart failure

Authors: *B. PARK[1], M. A. WOO[2], P. M. MACEY[2], G. C. FONAROW[3], R. M. HARPER[4], R. KUMAR[1,5,6];
[1]Anesthesiol., [2]Sch. of Nursing, [3]Div. of Cardiol., [4]Neurobio., [5]Radiological Sci., [6]Bioengineering, Univ. of California At Los Angeles, Los Angeles, CA

Abstract: Heart failure (HF) is accompanied by damage to brain areas responsible for mood, cognition, and autonomic regulation, which are independent predictors for morbidity and mortality in the condition. Injury to affective and cognitive regulatory regions, including the hippocampus, may lead to symptoms of depression and deficient memory through altered spontaneous functional connections to other brain areas. However, how the hippocampus in HF is connected abnormally with other brain regions during resting conditions, and what functional deficits accompany these impaired connections are unclear. Our aim was to assess hippocampal functional connectivity (FC) with other brain regions in HF subjects, compared to healthy controls. We acquired resting-state functional MRI data from 17 hemodynamically-optimized

HF (age, 54.4±8.1 years; body-mass-index (BMI), 29.4±5.7 kg/m2; 12 male; left ventricular ejection fraction, 28.0±7.0%) and 45 control subjects (age, 50.9±7.6 years; BMI, 25.1±3.8 kg/m2; 30 male) using a 3.0-Tesla MRI scanner. Data were processed using SPM8 with standard procedures, canonical nuisance signals were removed by regression, and data were band-pass filtered. Using left and right hippocampal seed regions, we calculated individual correlation maps between each seed area and all other brain voxels, and converted those values into z-scored maps. We compared z-scored maps voxel-by-voxel between HF and control subjects using analysis of covariance (covariates; age and gender; $P<0.05$; cluster-corrected). The left hippocampus showed decreased FC in HF with the right superior frontal gyrus and left inferior parietal lobule, while increased FC in HF appeared with the left middle cingulate cortex, left superior temporal gyrus, left calcarine cortex, and right cerebellum. The right hippocampus in HF showed decreased FC with the bilateral thalamus, right middle frontal gyrus, and left inferior occipital gyrus, compared to controls. However, increased FC from the right hippocampus in HF appeared within the left supplementary motor area, vermis, and left middle frontal gyrus. Resting state functional connections in HF are altered between the hippocampus and other autonomic, affective, and cognitive regulatory areas, and the changes are lateralized predominantly to left rostral brain areas. The reorganization of function, especially with cerebellar, cingulate, and frontal regions, may reflect compensatory means to restore capabilities of damaged areas, and likely result from structural brain injury reported-earlier in HF.

Title: Circulating miRNA profile in cerebrospinal fluid and plasma of patients with spontaneous intracerebral hemorrhage

Authors: A. VARMA[1], *R. C. MARTINEZ[3], I. IWUCHUKWU[2], D. NGUYEN[2]; [2]Neuro-Critical Care, [1]Ochsner Med. Ctr., New Orleans, LA; [3]Neurol., Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA

Abstract: Background and Objectives: Intracerebral hemorrhage (ICH) in patients with stroke carries a significant morbidity and mortality. miRNA, which are non-coding RNA, have been identified in tissues and recently in plasma (circulating miRNA). Access to brain tissue is often

challenging, hence cerebrospinal fluid (CSF) serves as a surrogate for brain tissue. It is hypothesized that differences in circulating miRNA compared to miRNA in CSF may reflect the local events of injured brain tissue. In this study, we described the expression pattern of CSF and circulating miRNA in patients with spontaneous ICH. Methods: Total RNA containing miRNAs were isolated from 200 ul of CSF (n=5) and plasma (n=3) using serum/plasma kit (Exiqon). All RNA samples were within acceptable limits as analyzed using miRNA QC panel. For miRNA profiling, the Exiqon Human miRNome panel I and II containing 752 well-characterized miRNAs were used and run using a CFX384 thermal cycler. Cycle threshold data were obtained using the regression method. Quality control assessment, global mean normalization, and differential miRNA expression were analyzed using the unpaired T-test and GenEx software (Exiqon). Similarity of miRNA expression patterns between CSF and plasma samples were analyzed by hierarchal clustering and heat maps using default settings. Results: Quality control assessment using RNA and cDNA spike-in controls were within acceptable values. Hemolysis analysis for possible cellular derived miRNA contamination was negative. Statistical analysis for differentially expressed miRNAs found 166 miRNAs that were significantly expressed ($p<0.01$), of these 110 miRNAs expressed at greater than 3- fold higher in CSF, and 42 miRNAs that were expressed at greater than 3-fold higher in plasma. Hierarchal clustering and heat maps showed miRNA expression patterns in CSF tightly cluster and are distinct from miRNA expression in plasma. Conclusion: We demonstrated that miRNAs are present in CSF and plasma of patients with ICH. miRNAs are potentially useful noninvasive biomarkers for diagnosis of disease, its complications and outcome. Our current focus is to confirm and correlate miRNAs expression to clinical outcome based on ICH blood volume classifier.

Title: Hemodynamic lag: prevalence after stroke and effects on functional connectivity

Authors: *J. S. SIEGEL, L. E. RAMSEY, A. Z. SNYDER, G. L. SHULMAN, M. CORBETTA;
Neurol., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Stroke can cause a disruption to the brain's vascular supply, not only within but also outside of areas of infarction. In addition to reduced blood flow, altered hemodynamics have been reported. We investigated temporal delays (lag) in resting state functional magnetic resonance imaging signals in 130 stroke patients who were scanned 2 weeks, 3 months and 12 months post stroke onset. 30 controls were scanned twice at an interval of 3 months. Hemodynamic lag was determined using cross-correlation with the global gray matter signal. Behavioral performance in multiple domains was assessed in all patients. Regional cerebral blood flow and carotid patency were assessed in subsets of the cohort using arterial spin labeling and carotid Doppler ultrasonography. Severe hemodynamic lag was observed in 30% of stroke patients sub-acutely. Approximately 10% of patients showed lag at 1-year post-stroke. Hemodynamic lag corresponded to gross aberrancy in functional connectivity measures. Hemodynamic lag also correlated with performance deficits in multiple domains and with local and global perfusion deficit. Correcting for lag partially normalized abnormalities in measured functional connectivity. However, post-stroke FC-behavior relationships in the motor and attention systems persisted even after hemodynamic delays were corrected. Resting state fMRI can reliably identify areas of hemodynamic delay following stroke. Our data reveal that hemodynamic delay is common sub-acutely and of clinical importance. Such changes grossly alter measures of functional connectivity and should be accounted for in any future resting state fMRI analyses in patients with vascular pathology.

Title: Impaired resting-state insular brain functional connectivity in heart failure

Authors: *R. VIG[1], B. PARK[1], M. A. WOO[2], G. C. FONAROW[3], R. M. HARPER[4], R. KUMAR[1,5,6];

[1]Anesthesiol., [2]Sch. of Nursing, [3]Div. of Cardiol., [4]Neurobio., [5]Radiological Sci., [6]Bioengineering, UCLA, Los Angeles, CA

Abstract: Brain structural and metabolic deficits appear in multiple areas in heart failure (HF) subjects, including the insular cortices that may contribute to deficient autonomic regulation by altering spontaneous functional connections with other brain areas. Our aim was to assess insular functional connectivity (FC) with other brain regions in HF subjects at rest, compared to healthy controls. We acquired resting-state functional MRI data from 17 hemodynamically-optimized HF (age, 54.4±8.1 years; body-mass-index (BMI), 29.4±5.7 kg/m2; 12 male; left ventricular ejection fraction, 28.0±7.0%) and 45 control subjects (age, 50.9±7.6 years; BMI, 25.1±3.8 kg/m2; 30 male), using a 3.0-Tesla MRI scanner. Data were processed using SPM8 software with standard procedures, effects of gray matter, white matter, cerebrospinal fluid, and 6 rigid motions and their derivatives were removed by regression, and data were low band-pass filtered. Using the left and right insular seed regions, we calculated individual correlation maps between each seed area and all other brain voxels, and converted those values into z-scored maps. We compared z-scored maps voxel-by-voxel between HF and control subjects using analysis of covariance (covariates; age and gender; $P<0.05$; cluster-corrected). No significant differences in age or gender appeared, but BMI values were significantly higher in HF over controls. The left insula showed decreased FC in HF with the left supplementary motor area and left cerebellum, while increased FC in HF appeared with the left inferior frontal gyrus over control subjects. The right insula in HF showed decreased FC with the right superior parietal gyrus and right postcentral gyrus, and increased FC appeared in the left inferior frontal gyrus, left temporal pole, and left cerebellum over control subjects. Sensory integrative roles of the right insula would be affected with the reduced parietal cortex FC, and expected, considering the specific insular injury in HF. The enhanced FC with the left side may compensate for the loss in right-side autonomic influences. The insula FC changes demonstrate the disparate roles for the left and right structures, and show the complex reorganization that occurs with projections to other brain areas from this somatosensory/autonomic integrative region in HF.

Abstract: Post-ischemia inflammation has been a target of stroke therapy for some time but no treatments have successfully made it beyond clinical trials. These therapies have largely been targeted at reducing the overall inflammatory response rather than trying to modify how inflammatory cells respond to stroke. Furthermore, neurogenic mechanisms fail to repair damaged brain tissue following stroke despite an acute proliferative burst of neural stem cells (NSC). To start to address these issues, we first examined the effect of hypoxia on the phenotype of microglia and neural progenitor cells. While grown under oxygen-glucose deprivation (OGD) conditions, NSCs exhibit an increase in proliferation after 24 hours. However, this proliferative capacity rapidly declines back to normal levels beyond 24 hours. Additionally, mRNA expression of BDNF, NT3, NGF, GDNF, and IGF-1 are all significantly increased in NSCs following 24 hours of OGD which could account for the initial proliferative burst. Next, because of their ability to interconvert microglia from an inflammatory to a regenerative phenotype, we utilized mesenchymal stem cells (MSC) to investigate whether the pro-inflammatory phenotype of microglia following hypoxia can be changed. For this purpose, microglia were grown in conditioned media from both naïve MSCs (nMSC) as well as interferon-γ (IFN-γ)-activated MSCs (aMSC). Interestingly, microglia treated by aMSC conditioned media exhibited a reduction in expression of the pro-inflammatory cytokines IL-1β, IL-6, and TNF-α up to 48 hours in culture and had increased expression of the pro-regenerative cytokines IL-10 and IL-4 up to 7 days in culture. Taken together, these results suggest that neural progenitor cells may be beneficial for neuronal survival and repair following an ischemic event, and that MSCs may have the capacity to promote a pro-regenerative microglial phenotype that can enhance brain repair following ischemia.

Title: Effects of the constraint-induced movement therapy (cimt) and neural precursor cell (npc) transplantation in the corpus callosum of the hemiplegic mouse model

Authors: *P. RUMAJOGEE[1], S. ALTAMENTOVA[1], D. VAN DER KOOY[2], M. G. FEHLINGS[1];
[1]Genet. and Develop., Univ. Hlth. Network, Toronto, ON, Canada; [2]Dept. of Mol. Genet., Inst. of Med. Science, Univ. of Toronto, Toronto, ON, Canada

Abstract: BACKGROUND: Cerebral palsy (CP) is the most common paediatric neurodevelopmental physical disability, with a prevalence of 2.3/1000 births, causing severe motor and developmental disturbances. It has been suggested that Constraint-Induced Movement Therapy (CIMT) could provide functional benefit by stimulating neural cell generation from endogenous neural precursor cell (NPC). However, the underlying mechanisms of CIMT and optimal timing/mode of application remain poorly understood. METHODS: We use the Hypoxic-Ischemic model (HI) model which involve the Right Common Carotid Artery Occlusion (RCAO) of P7 C57Bl/6 mice pups, followed by Hypoxia (8% oxygen for 45 minutes). The project on has 3 major aspects: 1) Regeneration, which will focus on the effects of NPC transplantation in the corpus callosum (CC), known to be impacted early in the course of demyelinating conditions. 2) Rehabilitation, which will focus on the effects CIMT (via Botox injections). 3) A third aspect will also investigate the potential of CIMT and transplanted NPCs. RESULTS: Our preliminary results support the use of the HI model as an interesting model for Hemiplegic CP. We have shown: A) Differences between Injured and Control animals, as well as within injured groups. B) A good development and integration of NPCs in CC, as well as some co-localisation with Olig4 and NeuN positive cells. C) A potential role of NPCs in functional recovery. D) An improved the Botox injection protocol, which will allow a more efficient CIMT. CONCLUSION: This work suggests that the variability of injury observed after the exact same experimental procedure can recapitulate various aspects of clinical CP phenotype, which might be useful when creating translational treatment strategies. Further investigation is needed in order to decipher the mechanisms of CIMT and a potential role of NPCs to improve this therapy.

Title: Intravenously transplanted human bone marrow mesenchymal stem cells preferentially migrate to spleen and abrogate splenic inflammatory response in a chronic ischemic stroke model

Authors: *S. A. ACOSTA, N. TAJIRI, J. HOOVER, Y. KANEKO, C. V. BORLONGAN; Universty of South Florida, Tampa, FL

Abstract: Adult stem cell therapy is an experimental stroke treatment. Here, we assessed homing and anti-inflammatory effects of bone marrow stromal cells (hBMSCs) in chronic stroke. At 60 days post-stroke, animals received intravenous hBMSCs (4X106 labeled or non-labeled cells) or vehicle (saline). A sham surgery group served as additional control. *In vivo* imaging was conducted between 1 hour and 11 days post-transplantation, followed by histological examination. Labeled hBMSCs migrated to spleen which emitted significantly higher fluorescent signal across all time points, especially during the first hour, but were only modestly detected in the head region at the 12 hours and 11 days, compared to non-labeled hBMSCs and vehicle-infused stroke animals, or sham (p's < 0.05). At 11 days post-transplantation, *ex vivo* imaging confirmed preferential hBMSC migration to the spleen over the brain. H&E staining revealed significant 15% and 30% reductions in striatal infarct and peri-infarct area, respectively, and a trend of rescue against neuronal loss in the hippocampus. Unbiased stereology showed significant 75% and 60% decrements in MHCII-activated inflammatory cells in gray and white matter, and a 43% diminution in TNF-α cell density in the spleen of hBMSC- transplanted stroke animals compared to vehicle-infused stroke animals (p's < 0.05). Human antigen immunostaining revealed 0.03% hBMSCs survived in spleen and only 0.0007% in brain. hBMSC migration to spleen, but not brain, inversely correlated with reduced cerebral infarct, peri-infarct, and inflammation. hBMSC transplantation exerts therapeutic effects on chronic stroke possibly by abrogating the inflammation-plagued secondary cell death.

Title: hESC-Oligodendrocyte Precursor Cell transplantation after white matter stroke enhances recovery

Authors: *I. L. LLORENTE[1], N. C. MANLEY[2], C. C. CASE[2], E. WIRTH, III[2], S. T. CARMICHAEL[1];
[1]Neurol., Univ. of California , Los Angeles, Los Angeles, CA; [2]Asterias Biotherapeutics, Inc., Menlo Park, CA

Abstract: Subcortical white matter stroke (WMS) constitutes up to 25% of all stroke subtypes and is the second leading cause of dementia. We have developed a new subcortical WMS model in NSG mice with a large infarct area that mimics the larger white matter lesions seen in moderate to advanced human white matter ischemia or vascular dementia. While there is no therapy for white matter stroke, cell transplantation is emerging as a viable therapy to restore neurological function. WMS has a very different pattern of cellular injury than occurs in traditional stroke models. The neural elements damaged in WMS are: oligodendrocytes, oligodendrocyte progenitor cells (OPCs), astrocytes, and axons. Human embryonic stem cell-derived oligodendrocyte progenitor cells (hESC-OPCs) provide an attractive candidate for a WMS therapy. These cells are in a lineage that matches the most damaged cellular element in white matter ischemia: cells in the oligodendrocyte lineage. We determined the tissue outcomes in myelination patterns, reactive astrocytosis, microglial/macrophage responses, MRI appearance of WMS, and the optimum injection site for hESC-OPC transplantation. Transplant of hESC-OPCs at subacute time points (7 days after stroke) outside of the ischemic stroke produced widespread migration of these cells throughout subcortical white matter. This resulted in increased myelination within the damaged white matter, reduced measures of reactive astrocytosis and inflammation. Transplantation of cells into the stroke site resulted in larger infarct area, the same level of astrocytosis and inflammatory responses within the damaged white matter and less measure of myelination compared to hESC-OPCs transplanted outside of the infarct area. MRI imaging of white matter stroke after hESC-OPC transplantation outside of the lesion showed reduction in the hyperintensities that characterize this damage in both the mouse model and in humans. Behavioral evaluation of recovery is ongoing. These studies suggest that hESC-OPC transplantation in moderate to advanced white matter stroke, as seen in vascular dementia, may provide a therapy to promote white matter repair and recovery. Title: miR-711 up-regulation induces neuronal cell death after traumatic brain injury

Authors: *B. SABIRZHANOV[1], B. A. STOICA[2], Z. ZHAO[2], D. J. LOANE[2], J. WU[2], S. DORSEY[2], A. I. FADEN[2];

Abstract: Traumatic brain injury (TBI) is a leading cause of mortality and disability. MicroRNAs (miRs) are small noncoding RNAs that negatively regulate gene expression at post-transcriptional level and may be key modulators of neuronal apoptosis, yet their role in secondary injury after TBI remains largely unexplored. Changes in miRs after controlled cortical impact (CCI) in mice were examined during the first 72h using miR arrays and qPCR. One selected miR (711) was examined with regard its regulation and relation to cell death; effects of miR-711 modulation were evaluated after CCI and using *in vitro* cell death models of primary cortical neurons. Levels of miR-711 were increased in the cortex early after TBI and *in vitro* models through rapid up-regulation of miR-711 transcription (pri-miR-711) rather than catabolism. Increases coincided with down-regulation of the pro-survival protein Akt, a predicted target of miR-711, with sequential activation of FoxO3a/GSK3α/β, pro-apoptotic BH3-only molecules PUMA and Bim, and mitochondrial release of cytochrome c and AIF. miR-711 and Akt (mRNA) co-immunoprecipitated with the RNA-induced silencing complex (RISC). A miR-711 hairpin inhibitor attenuated the apoptotic mechanisms and decreased neuronal death in an Akt-dependent manner. Conversely, a miR-711 mimic enhanced neuronal apoptosis. Central administration of the miR-711 hairpin inhibitor after TBI increased Akt expression and attenuated apoptotic pathways. Treatment reduced cortical lesion volume, neuronal cell loss in cortex and hippocampus, and long-term neurological dysfunction. miR-711 changes contribute to neuronal cell death after TBI, in part by inhibiting Akt, and may serve as a novel therapeutic target.

Title: Adenosine A2A receptor blockade alleviates memory dysfunction caused by traumatic brain injury via ROCK2 inhibition

Authors: Y.-L. NING, Z.-A. ZHAO, N. YANG, Y. PENG, R.-P. XIONG, X. CHEN, Y. ZHAO, P. LI, *Y. ZHOU;
Res. Inst. Surg and Daping Hosp. ,TMMU, Chongqing, China

Abstract: Memory dysfunction is one of the most serious neuropsychiatric disorders of traumatic brain injury (TBI) because its long-lasting effects prevent survivors resuming normal civilian life. However, the mechanisms are poorly understood and there is no treatment available. Adenosine A2A (A2AR) is one of the key modulators of cognitive function and brain injury in the central nervous system (CNS). In this study, the effects of adenosine A2AR on TBI-induced memory dysfunction and the underlying mechanisms were investigated. Moderate controlled cortical impact (CCI) was used to perform a TBI model in adult male c57BL/6 mice. At 1 week post-CCI, mice exhibited impaired spatial reference memory and working memory in a Morris Water Maze paradigm, accompanied by hippocampal neuronal degeneration including neuronal loss and neurite dystrophy. Activation of A2AR with selective A2AR agonist CGS21680 significantly exacerbated CCI-induced memory dysfunction and the hippocampal neuropathological damages, which was rescued by selective A2AR antagonist ZM241385 and Rho-associated coil kinase (ROCK) inhibitor fasudil. Further investigation of primary mice hippocampal neurons demonstrated that A2AR activation decreased length and brunches of dendrites, suppressed synapsin1 expression and increased Tau protein S262 phosphorylation during Okadaic acid (OA)-induced toxicity *in vitro*. Moreover, fasudil rescued all of the above deteriorated neurite damages. Western blot analysis demonstrated that CGS21680 increased, while ZM241385 decreased the expression of ROCK2. Together, A2AR blockade alleviated memory dysfunction following TBI via ROCK2 inhibition, suggesting A2AR and ROCK pathway as potential therapeutic targets for the treatment of TBI-induced cognitive impairment.

Title: Activated neutrophils are modifiers of barrier disruption after pediatric traumatic brain injury

Authors: *A. TRIVEDI, K. TERCOVICH, L. J. NOBLE-HAEUSSLEIN;
Univ. of California, San Francisco, San Francisco, CA

Abstract: Blood brain barrier (BBB) compromise is a key pathophysiological component of secondary damage after traumatic brain injury (TBI). We have previously shown by immunohistological outcomes that controlled cortical impact to the developing murine brain at postnatal day 21 (p 21), an age that approximates the toddler aged child, results in a unique inflammatory signature, characterized by the prolonged recruitment of neutrophils (up to 14 days post injury) to cortical and subcortical brain regions. Moreover, barrier disruption, as determined by measures of vasogenic edema, is attenuated in neutrophil elastase knockout mice, suggesting that the activational state of neutrophils is a determinant of barrier disruption. Here, we confirm the prolonged time course of neutrophil recruitment in the injured developing brain by flow cytometry and provide the first evidence that recruitment involves distinct subsets of neutrophils. Neutrophils are activated via the downstream signaling pathway dependent on spleen tyrosine kinase (Syk). Conditional knockouts of Syk (sykf/f MRP8-cre+) along with cogenic littermates (sykf/f) were used to study the dependency of barrier disruption on activated neutrophils by two complementary assays, Evan's blue albumin (EBA) extravasation as measured by colorimetry and by histological measures of fluorescence intensity resulting from extravasation of different molecular weight dextrans. Barrier disruption to EBA was attenuated in sykf/f MRP8-cre+ compared to brain-injured sykf/f. Fluorescently tagged dextrans corresponding to the molecular weights of albumin (MW 70kD) and fibrinogen (MW 500kD) revealed profound leakage in the ipsilateral hemisphere. While the 70kD dextran was distributed more broadly throughout the injured hemisphere, the 500kD dextran was prominent surrounding vascular structures. Importantly, barrier disruption to these tracers was significantly reduced in the sykf/f MRP8-cre+ mice. Together, these findings support the extended recruitment of subsets of neutrophils to the injured developing brain. While the long-term consequences of this extended recruitment remain unclear, we find that the activational state of neutrophils is a key determinant of barrier disruption and as such may influence subsequent recovery processes.

Title: The role of mTOR/Akt pathway in recovery of neural electrophysiology in an *in vitro* model of traumatic brain injury

Authors: *P. SWIATKOWSKI[1,2], B. L. FIRESTEIN[2];
[2]Cell Biol. & Neurosci., [1]Rutgers Univ., Piscataway, NJ

Abstract: Traumatic brain injury (TBI) affects approximately 1.7 billion people each year and is the leading cause of death in people under 45 years of age in the United States. TBI is primarily caused by deformations of the brain tissue due to mechanical trauma, followed by rapid release of glutamate and subsequent excitotoxicity (secondary damage). Additionally, the early phase of secondary injury has been found to cause loss of dendritic spines and formation of varicosities along dendrites and axons. Several groups have associated spine loss with behavioral deficits following brain injury, and further evidence shows that aiding neurons in spine reemergence drastically improves functional recovery. The mTOR/Akt pathway has been implicated in the modulation and regulation of synaptic strength, synaptic activity, maturation, and axon regeneration, all of which might contribute to functional recovery of neurons subjected to TBI. To mimic mechanical and secondary injury as a result of TBI in rat cortical neurons, we grew these cells *in vitro* on either silastic membranes or glass coverslips and subjected them to stretch or NMDA -induced injury, respectively. In this study, we addressed electrophysiological properties, such as field potentials and spontaneous EPSCs, of neurons subjected to two types of injury and potential recovery following mTOR/Akt pathway manipulation. To manipulate these pathways, we used several compounds, such as the PTEN inhibitor bpV, the Akt inhibitor MK2206 and the mTORC1 inhibitor RAD001 (a rapamycin analog), and assessed their effects on neural electrophysiology following injury. We predict that further investigation of the role of mTOR/Akt pathway in TBI will contribute to improved functional recovery of neurons and subsequently improve lives of affected individuals. This work is supported by NJCBIR grant CBIR14IRG019 and NJCBIR multi-investigator grant CBIR12MIG011 and National Institutes of Health under Ruth L. Title: N-acetyl-seryl-aspartyl-lysyl-proline improves functional recovery in rats after traumatic brain injury

Authors: ***Y. ZHANG**[1], M. CHOPP[2,3], Y. MENG[1], L. ZHANG[2], Z. ZHANG[2], A. MAHMOOD[1], Y. XIONG[1];
[1]Neurosurg., [2]Neurol., Henry Ford Hosp., Detroit, MI; [3]Physics, Oakland Univ., Rochester, MI

Abstract: N-acetyl-seryl-aspartyl-lysyl-proline (AcSDKP) is a naturally occurring multifunctional tetrapeptide. The pharmacokinetics and metabolism of AcSDKP have been well established, and there is no apparent toxicity in rodents. AcSDKP can readily cross the blood brain barrier which poses significant challenges to the permeation of neuroprotective agents. This study was designed to test the hypothesis that AcSDKP treatment initiated 1 hour post injury provides neuroprotection and improves functional recovery in rats after traumatic brain injury (TBI). TBI was induced by controlled cortical impact over the left parietal cortex. Young adult male Wistar rats with TBI were randomly divided into the following groups: (1) Vehicle group (0.01N acetic acid); (2) AcSDKP (0.8 mg/kg/day). AcSDKP or vehicle was administered subcutaneously starting at 1 hour post injury and continuously for 3 days through an osmotic minipump. Sensorimotor function and spatial learning were assessed using a modified neurological severity score and Morris water maze tests, respectively. Animals were sacrificed 35 days after injury and brain sections processed to assess lesion volume, hippocampal cell loss, angiogenesis, neurogenesis and dendritic spine remodeling after AcSDKP treatment. Compared to the vehicle treatment, AcSDKP treatment initiated 1 hour post injury significantly improved sensorimotor functional recovery (Days 14-35, $p<0.05$) and spatial learning (Days 32-35, $p<0.05$), reduced cortical lesion volume by 30% ($p<0.05$) and hippocampal cell loss, enhanced neurogenesis and the number of dendritic spine in the injured hippocampus ($p<0.05$). AcSDKP treatment initiated 1 hour post injury provides neuroprotection and neurorestoration after TBI, indicating that this small tetrapeptide has promising therapeutic potential for treatment of TBI. These data warrant further investigation of the optimal dose and therapeutic window of AcSDKP treatment for TBI and the associated underlying mechanisms.

Title: Asparagus racemosus exhibits anti-post traumatic stress disorder (PTSD)-like effect through 5HT1A mediated mechanism in experimental rats

Authors: *R. VIG, D. GARABADU, P. ADITYA, S. KRISHNAMURTHY;
Indian Inst. of Technol. (BHU), Varanasi, India

Abstract: Post-traumatic stress disorder (PTSD) is considered as one of the most prevalent anxiety disorder in worldwide. Though several synthetic drugs are prescribed for PTSD, their use is limited because of their adverse effects. Asparagus racemosus (AR) is considered as adaptogen according to Ayurvedic medicine. It exhibits anxiolytic and anti-stress activities in both preclinical and clinical studies. Therefore, the present study investigated the therapeutic effect of standardized methanolic root extract of AR (MAR) in an experimental animal model of PTSD. On day-2 (D-2) of the experimental schedule, male rats were subjected to induce PTSD-like behaviors using modified stress re-stress (SRS) protocol of 2 hr restraint and 20 min forced-swim test (FST) followed by halothane anesthesia. The rats were exposed to re-stress (FST) on D-8 and at six day intervals on D-14, D-20, D-26 and D-32. The rats were treated with MAR (50, 100 and 200 mg/kg; p.o.) and standard drug, sertraline (STL; 10.0 mg/kg; p.o.) from D-8 to D-32. MAR (200 mg/kg) attenuated SRS-induced depressive-like behavior in terms of decrease in immobility period in rats during FST. The highest dose of MAR also reduced anxiety in elevated plus maze (EPM) test in PTSD-like animals in terms of increase in the percentage entries and time spent in open arms. Further, MAR (200 mg/kg) improved SRS-induced cognitive deficit such as loss in spatial recognition memory in Y-maze test in terms of increase in the percentage in entries into novel arm compared to known arm. The SRS-induced decrease in the plasma corticosterone level in rodents were reversed with the repeated treatment of MAR (200 mg/kg), suggesting the fact that MAR may modulates SRS-induced alteration in hypothalamic-pituitary-adrenal cortex-axis function in rats. Furthermore, MAR (200 mg/kg) reversed the SRS-induced alteration in serotonergic activity in amygdala. Subsequently, the effect of MAR (200 mg/kg) on 5-HT1A-mediated mechanism in PTSD pathophysiological condition was evaluated. The 5-HT1A receptor antagonist (WAY-100635; 1.0 mg/kg, i.p.) attenuated the MAR (200 mg/kg)-induced improvement in depression, anxiety and cognitive impairment in PTSD-like rats in FST, EPM and Y-maze paradigms respectively. These observations emphasize the fact that MAR (200 mg/kg) may exert anti-PTSD-like effect in animals through 5-HT1A-mediated mechanism. Hence, AR could be a potential therapeutic option in the management of PTSD.

Abstract: Mild traumatic brain injury (mTBI) is a majority of TBI survivor and may lead to various physical, cognitive, emotional and psychological-related disorders following mTBI. Until now, there is no efficient intervention to manage the development of mTBI. Earlier studies showed that glucagon-like peptide-1 (GLP-1) has potential neuroprotective effects. Here, we identified its sister incretin, glucose-dependent insulinotropic polypeptide (GIP), as the novel approach mTBI. GIP was delivered by i.p. implanted with ALZET micro-osmotic pumps. Beam walking and adhesive removal test were assessed for sensorimotor functions in rats with mTBI. Glial fibrillary acidic protein (GFAP), bone marrow tyrosine kinase gene in chromosome X (BMX)/epithelial, endothelial tyrosine kinase (Etk) and beta-amyloid precursor protein (APP) were applied as the molecular markers by immunohistochemistry (IHC) staining or western blotting (WB). The results show that the sensorimotor deficits were reduced after two weeks treatment of GIP. Based on the results of IHC and WB, the sensorimotor recovery could involve with the astrocytic activation, inflammative response and axonal injury. These findings suggest that the GIP may have beneficial effects in the management of secondary events following mTBI in rodent models. Future preclinical studies will be needed to further identify the mechanism of action, leading to more effective drug therapies in human.

Title: A combined regimen of environmental enrichment and citalopram improves attentional set-shifting after brain trauma

Authors: *C. O. BONDI, M. J. LAPORTE, H. M. TENNANT, J. P. CHENG, A. E. KLINE; Safar Ctr. for Resuscitation Res., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Introduction Traumatic brain injury (TBI) models in the laboratory have been associated through the literature with declines in long-term learning and memory, although the types of behavioral tests typically do not focus on complex attention impairments related to the frontal lobe, which are common in most brain injuries. Specifically, executive function and cognitive flexibility represent sophisticated brain capabilities to use environmental feedback to "unlearn" a previously valid set of rules, filter out distractions and switch gears to new contingencies. Previously, we demonstrated that a controlled cortical impact (CCI) injury produced significant impairments in executive function and cognitive flexibility in the attentional set-shifting test (AST), a complex cognitive paradigm analogous to the Wisconsin Card Sorting Test, which is used to measure strategy-switching deficits in patients with frontal lobe damage, TBI, and psychiatric disorders. Hypothesis Exposure to clinically relevant therapies post injury, such as environmental enrichment (EE) and the antidepressant drug, citalopram, will attenuate cognitive performance deficits on AST when provided alone, but especially when given in combination. Methods Isoflurane-anesthetized male rats were subjected to CCI injury (2.8 mm cortical deformation depth at 4 m/s) or sham injury. Groups of rats from both surgical conditions were exposed EE housing, an endorsed animal model of rehabilitation, while daily injections of citalopram, a treatment known to alleviate depressive-like symptoms and improve cognition in humans, were also provided alone or in combination with EE. Rats were tested on the AST at four weeks post-surgery. The AST involves a series of increasingly difficult discriminative tasks to obtain food reward, including simple and compound discriminations, stimulus reversals, and intra- and extradimensional (ED) shifts. Results EE exposure provided significant cognitive recovery after injury, although performance may further benefit from the combined therapy with citalopram, as findings indicate. Conclusions Exposure to EE housing and daily citalopram administration provided the most cognitive recovery on AST after injury, which supported the hypothesis. Significance The combined treatment in this study aims to reflect simultaneous rehabilitation and pharmacological treatments given to patients in a clinical setting. Future

studies will continue to investigate in more detail the ideal cognitive recovery timeline and specific brain pathways and mechanisms involved in restoring higher function after TBI.

Title: Delayed and abbreviated environmental enrichment after experimental traumatic brain injury increases hippocampal neurogenesis

Authors: N. LAJUD[1], J. P. CHENG[2], C. O. BONDI[2], *A. E. KLINE[2];
[1]Ctr. de Investigación Biomédica de Michoacán, Inst. Mexicano del Seguro Social, San José la Huerta, Mexico; [2]Phys Med. & Rehab, Psych, Safar Ctr. Resuscitation Res., Univ. Pittsburgh, Pittsburgh, PA

Abstract: Continuous environmental enrichment (EE) exposure improves neurobehavioral outcome after experimental traumatic brain injury (TBI). One likely mechanism for the benefit is increased neurogenesis. Delayed and abbreviated EE, which is more akin to clinical rehabilitation in terms of timing, also enhances neurobehavioral recovery comparably to early and continuous exposure after TBI; however, its effect on hippocampal neurogenesis is unknown. *The aim of this study was to test the hypothesis that delayed and abbreviated EE is sufficiently robust to induce hippocampal neuroplasticity after TBI*. Anesthetized adult male rats received a controlled cortical impact (2.8 mm depth at 4 m/sec) and were randomly assigned to either standard housing (TBI+STD), continuous EE(TBI+EE), or delayed and abbreviated EE (TBI+EE, 3 day delay, 6 hr day). BrdU (500 mg/kg) was provided twice per day for 3 days and then sacrificed 10 days later. The brains were cut on a freezing microtome at 40 μm and immunostained for BrdU or triple immunofluorescence for BrdU, DCX and NeuN. Continuous EE lead to a 91% ($p \leq 0.05$) increase in BrdU labeled nuclei density in the subgranular zone of the dentate gyrus when compared to STD. Abbreviated EE resulted in a 156% increase ($p \leq 0.01$) relative to STD. Triple immunofluorescence showed no differences in the percentage of BrdU/DCX or BrdU/NeuN double labeled cells among the groups; however in the continuous EE group, DCX positive cells displayed larger ramifications when compared to abbreviated EE. In conclusion, abbreviated EE with a 3 day delay effectively induced hippocampal neurogenesis

after TBI, which supports the hypothesis. These findings elucidate a possible mechanism for the benefits observed with both continuous and delayed-and-abbreviated EE.

Title: Time-dependent mechanisms of striatal stimulation for enhanced neural recovery following traumatic brain injury

Authors: A. HUGUENARD, *H. KATNANI, E. ESKANDAR;
Dept. of Neurosurg., Massachusetts Gen. Hosp., Boston, MA

Abstract: In a previous publication (Katnani et al.; Society for Neuroscience Abstracts 2014) we found that unilateral deep brain stimulation (DBS) in the nucleus accumbens (NAc) in the sub-acute phase of traumatic brain injury can enhance functional recovery and induce widespread cellular adaptation. Specifically, histology following behavioral testing revealed an increase in neuronal precursor cells in prefrontal cortex and restoration of corticostriatal synaptic density for animals that received stimulation. To expand on this finding, we next investigated the time-dependent processes of gross cellular adaptation induced by stimulation during recovery. Mice underwent a unilateral controlled cortical impact injury and were implanted with sham or stimulating electrodes targeted to the NAc. At 2, 5, 7, or 14 days after stimulation, brains were extracted for immunohistochemical analysis. Four categories of markers were studied: cellular proliferation (BrdU, NeuN, DoubleCortin, and GFAP), cell migration and plasticity (Synaptophysin and GAP43), cell injury, scarring, or death (Caspase 3, Iba-1, and FluoroJade-B), and finally cellular activation (c-Fos). Analysis was focused in the hippocampus, anterior rostral migrating stream, striatum, subventricular zone, and perilesional area, revealing an increase in markers of neuroproliferation, neuroplasticity, and neuroprotection for animals treated with DBS. These findings begin to elucidate the underlying dynamics of gross cellular mechanisms induced by striatal DBS following brain injury.

Title: A hemostatic, tissue adhesive with immunomodulatory properties

Authors: *J. L. SKOUSEN, M. POLEI, P. A. TRESCO;
Dept. of Bioengineering, Univ. of Utah, Salt Lake City, UT

Abstract: The search for the ideal hemostat, sealant and adhesive for use in neurosurgical applications continues. Despite recent advances, the only agents approved for use across this spectrum are fibrin-based products, which result in neuroinflammation, fibrous tissue deposition and scar formation where they are applied. This is especially problematic as neuroinflammation and scar formation can result in aberrant electrical conduction at the application site and can isolate implants from functioning in concert with adjacent tissue. What is needed is a new tissue adhesive that rapidly clots blood, can fill large wound cavities, and provides immunomodulatory signals to promote constructive wound healing with reduced scarring. To accomplish this we have developed an adhesive composed of extracellular matrix (ECM) and aldehyde-modified chondroitin sulfate (CS-aldehyde). ECM was chosen as the adhesive's foundation due to its innate ability to initiate and promote the clotting cascade. In addition to ECM's hemostatic properties, a number of studies have shown that ECM collected from decellularized tissues is also immunomodulatory and reduces inflammatory sequela by directing reactive macrophages toward a pro-healing rather than a classically activated, pro-inflammatory phenotype. Multiple formulations of the adhesive were prepared by varying the ratio of either cell-type-specific or commercial ECM to the CS-aldehyde crosslinker. To examine the adhesive and wound filling abilities of the resulting formulations, we applied them to surgical incisions made on freshly isolated rat brains. We found that the adhesives were capable of adhering together surgically separated tissues as well as filling large wound cavities. Current work is focused on further characterizing the mechanical, hemostatic and immunomodulatory properties of the various adhesive formulations before testing in a controlled cortical brain impact injury model in rodents.

Title: Administration of lithium improves neurotransmission and increases vesicular docking proteins in the striatum after traumatic brain injury

Authors: *S. W. CARLSON[1], A. DESANA[2], E. MADHA[2], H. Q. YAN[1], C. E. DIXON[1]; [1]Neurosurg. and VA Pittsburgh Healthcare Syst., [2]Neurosurg., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Traumatic brain injury (TBI) impairs neuronal function and can culminate in lasting cognitive impairment. While impaired striatal dopamine release is reported after experimental TBI, little is known about the mechanisms underlying this consequence. Our previous work suggests that reductions in proteins comprising the soluble N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) complex, the machinery facilitating vesicular fusion, may contribute to altered synaptic vesicle properties and impaired neurotransmission. Cysteine-string protein α (CSPα) is an important chaperone protein that facilitates SNARE complex formation and is increased in response to lithium treatment. The objective of this study was to evaluate the effect of lithium administration on CSPα abundance and neurotransmission in the striatum after controlled cortical impact (CCI). Methods: Sprague-Dawley rats received CCI (2.7mm) or sham injury. Animals were treated with vehicle or 1.0mmol/kg/ml lithium chloride daily (i.p. injection) for 1wk, beginning 5 minutes post-injury. The brains were dissected at 1wk post-injury and processed for immunoblotting of CSPα (n=3-4/group). At 1wk post-injury, CCI-injured and sham-injured rats were subjected to microdialysis and evoked dopamine release was measured by high-performance liquid chromatography (n=4-5/group). Results: CCI results in a 40% reduction in CSPα abundance in the striatum following injury. Treatment with lithium after CCI increased CSPα in the striatum by 15%, compared to vehicle treatment. CCI was associated with a significant reduction in peak dopamine release following high-potassium stimulated release ($p < 0.05$). The peak dopamine levels with post-traumatic treatment of lithium were not different from sham injury ($p=0.75$). Conclusions: These findings provide the first evidence of altered SNARE protein abundance in the striatum after CCI. We demonstrate for the first time that lithium improves neurotransmission following TBI. These findings suggest that treatment with lithium after TBI may increase the abundance of important proteins that facilitate neurotransmitter release into the synaptic cleft.

Title: Effects of early glucocorticoid antagonism or late progesterone agonism on the psychological symptoms of mild traumatic brain injury in male and female rats

Authors: *L. C. FOX, D. R. DAVIES, G. M. PALMER, J. L. SCHOLL, M. J. WATT, G. L. FORSTER;
Univ. of South Dakota, Vermillion, SD

Abstract: Mild traumatic brain injuries (mild TBIs) comprise three-quarters of total TBIs in the United States each year, and often occur in settings of stress (warfare, sports, etc.). Their psychological symptoms can have major impacts on wellbeing. These symptoms most often include generalized anxiety and posttraumatic stress-like behaviors. Stress at the time of injury is known to influence severity of post-mild TBI symptoms, and neuroactive steroids may play a role in preventing these effects. Prior to injury, blockade of glucocorticoids may lessen the impact of stress on damaged neurons. Progesterone delivery after injury has shown promise in restoring cognitive function in moderate-to-severe TBI, but its effect on psychological symptoms of mild TBI has not been evaluated. Using our validated model of social defeat immediately prior to weight-drop induced mild TBI, adult male and female Sprague-Dawley rats (9wks old) received either injury or sham surgery. Rats were treated either with mifepristone (20 mg/kg) 40min before impact, or progesterone (4 mg/kg) 3 hours after impact and once per day for 5 days. Female rats were intact and naturally cycling. Female social defeat was achieved with a 3-week isolation paradigm for non-lactating residents, who then showed similar levels of aggression toward intruding females as did male resident rats toward intruding experimental males. Animals were evaluated for anxiety 8 days after injury in the elevated plus maze (EPM). Contextual fear conditioning was assessed in the same animals 11 days after injury, using a foot-shock paradigm with an initial conditioning day and 3 days of extinction testing. Sex differences were assessed, as well as differences across estrus phases. We show that glucocorticoid antagonism prior to injury prevents anxiety symptoms from arising, restoring mild TBI animals to control levels of time spent in the open arms of the EPM. Female rats were less anxious than males overall, and displayed less freezing behavior as a whole than did males during fear conditioning trials. While early targeting of glucocorticoid receptors holds promise in preventing affective symptoms seen after mild TBI, later targeting of progesterone receptors after injury has already occurred may achieve similar benefit.

Title: Water-soluble gelatinase inhibitor O-phosphate prodrug and its metabolite p-hydroxy SB-3CT ameliorate motor functions against brain damage after severe traumatic injury in mice

Authors: *M. R. JUAREZ[1,4], Z. CHEN[2,4], M. LEE[5], B. TOMLINSON[2,4,3], M. GOOYIT[5], R. NIZAM[2,4], D. HESEK[5], B. BOGGESS[5], V. A. SCHROEDER[5], W. R. WOLTER[6], M. A. SUCKOW[6], J. CUI[2,7,4], S. MOBASHERY[5], M. CHANG[5], Z. GU[2,7,4];

Sci., Freimann Life Sci. Ctr. , Univ. of Notre Dame,, Notre Dame, IN; [7]Univ. of Missouri Grad. Sch., Ctr. for Botanical Interaction Studies, Columbia, MO

Abstract: Traumatic brain injury (TBI) affects 1.7 million individuals in the United States, resulting in 52,000 annual deaths and accounting for 30% of all injury deaths. While the primary causes of TBI are immensely broad, studies point to matrix metalloproteinases (MMPs), particularly MMP-9 as a key factor in the pathogenesis of TBI secondary injury. It includes generation of reactive oxygen species and pro-inflammatory cytokines, resulting in neuroinflammation, edema, blood-brain barrier (BBB) breakdown, oxidative stress, mitochondrial dysfunction, and apoptosis. SB-3CT (1) is a potent and selective gelatinase (MMP-2 and MMP-9) inhibitor, which effectively reduces brain damage after severe TBI in mice. However, SB-3CT is poorly water-soluble and is metabolized primarily to p-hydroxy SB-3CT (2), a more potent inhibitor than SB-3CT. In the present study, we examined the effects of the O-phosphate prodrug (3) of p-hydroxy SB-3CT on motor functions and histological changes in C57Bl/6J mice with TBI. Prodrug 3, an inactive MMP inhibitor, has enhanced water solubility by more than 2000-fold and is readily hydrolyzed to the active metabolite 2 in human blood.

Pharmacokinetics and brain distribution studies in mice showed that metabolite 2 crossed the blood-brain barrier (BBB) and achieved therapeutic concentrations in the brain. Mice were divided into three groups: sham, vehicle, and prodrug 3/metabolite 2. Prodrug 3 was administered intravenously at 7.8 mg/kg at 30 minutes after TBI, followed by subcutaneous injections of p-hydroxy SB-3CT at 25 mg/kg 1 hour after TBI and daily for the next 3 or 6 days. Simple Neuroassessment of Asymmetric Impairment (SNAP) and beam-walking tests were performed to assess neurological impairment; cresyl violet staining using the stereological technique was used to assess brain lesion. SNAP results for the sham were the lowest, as expected, followed in increasing order by 7-day treatment, 3-day treatment and vehicle. While foot faults for sham and 3-day treatment stayed relatively constant over time, the average number of foot faults in 7-day treatment mice decreased, indicating greater motor control. Our results suggest prodrug 3/metabolite 2 treatment over seven days improves motor functions and decreases neuronal damage. These findings indicate that selective inhibition of MMP-9 by a water-soluble thiirane inhibitor is a promising therapy for treatment of severe TBI.

Title: Dietary omega-3 polyunsaturated fatty acids ameliorate PTSD-like behaviors while improving hippocampal morphology following mild traumatic brain injury in rats

Authors: *J. D. FIGUEROA[1], T. HEERS[1], P. KALYAN-MASIH[1], J. VEGA-TORRES[1], E. KINNEY-LANG[2], M. DE LEON[1], A. OBENAUS[2];

Abstract: Despite accumulating evidence showing an elevated risk for post-traumatic stress disorder (PTSD) following mild traumatic brain injury (mTBI), there has been little progress in developing effective secondary preventive interventions. We have shown that long-chain omega-3 polyunsaturated fatty acids (n-3 PUFAs) exhibit therapeutic potential for the treatment and prevention of the neurological deficits associated with neurotrauma. However, studies showing the effects of n-3 PUFAs to ameliorate the PTSD-like brain and behaviors are lacking. The present study: (1) examines the efficacy of n-3 PUFAs to ameliorate PTSD-like behaviors following mild controlled cortical impact (CCI) TBI in adult rats and (2) evaluates the impact of dietary n-3 PUFAs on hippocampal volumes following chronic mTBI. Rats were fed with either control chow or chow enriched with n-3 PUFAs (750 mg/kg/day) for 4 weeks before being subjected to a single mTBI. We used a controlled cortical impact (CCI; 4 mm diameter tip, 0.5 mm depth, 6.0 m/s speed, 200 ms dwell) to induce mTBI. Animals were allowed to survive for 4 weeks after trauma and the brains collected for high-resolution magnetic resonance imaging (MRI). We found that consumption of n-3 PUFA significantly reduced functional deficits in locomotion (CatWalk gait analyses), sensorimotor gating (pre-pulse inhibition; PPI) and anxiety-like behaviors following mTBI. Magnetic resonance imaging (MRI) demonstrated that dietary n-3 PUFAs preserved hippocampal volume when compared to animals fed with the control chow ($p < 0.05$). Immunofluorescence revealed an increased number of neurons in the hippocampus of animals fed n-3 PUFA diets when compared to controls. Collectively, our study demonstrates that the neurobehavioral responses associated with PTSD-like behaviors are ameliorated by dietary n-3 PUFAs following mTBI.

Title: Selective PDE4B inhibition reverses chronic memory impairments following traumatic brain injury

Authors: *D. J. TITUS[1], C. FURONES[1], W. D. DIETRICH[1], M. E. GURENY[2], C. M. ATKINS[1];
[1]Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami Miller Sch. of Med., Miami, FL; [2]Tetra Discovery Partners, Grand Rapids, MI

Abstract: Development of learning and memory impairments after traumatic brain injury (TBI) is a common consequence for TBI survivors. However, there are no effective treatments to improve TBI-induced cognitive impairments. A pan-phosphodiesterase 4 (PDE4) inhibitor was shown to reduce cognitive deficits after TBI, but clinical development is hampered by unwanted side effects. Our previous study found that TBI induces expression of the subfamily isoform PDE4B2. Developing more subtype-selective inhibitors would greatly improve clinical translation to TBI survivors. In the present study, we hypothesized that treating animals with a subtype-specific PDE4B inhibitor could reverse the cognitive deficits induced by TBI. To test this hypothesis, adult male Sprague Dawley rats received sham surgery or moderate parasagittal fluid-percussion brain injury (2 atm). After 3 mos of recovery, animals were treated with a selective PDE4B inhibitor 2-(4-{[2-(5-chlorothiophen-2-yl)-5-ethyl-6-methylpyrimidin-4-yl] amino} phenyl) acetic acid (A33) (0.3mg/kg, i.p) or vehicle. At 30 min after treatment, animals received cue and contextual fear conditioning, water maze training, and spatial working memory assessment. A33 treatment significantly reversed the TBI-induced deficits in the cue and contextual fear conditioning and water maze retention. To further understand the underlying cellular mechanisms of these memory impairments, we examined long-term potentiation (LTP) in area CA1 of the hippocampus at 3 mos after TBI or sham surgery. There was a significant reduction in basal synaptic transmission and impaired LTP in hippocampal slices from TBI animals as compared to sham surgery animals. A33 treatment (0.3 μM) significantly reduce the deficits in basal synaptic transmission and rescued expression of LTP. These results suggest that a subtype-selective PDE4B inhibitor may be a potential therapeutic to reverse chronic cognitive dysfunction and deficits in hippocampal synaptic plasticity following TBI.

Title: Effect of repetitive transcranial magnetic stimulation (rTMS) in traumatic brain injury (TBI) of rats

Authors: L. VERDUGO[1], A. HERNANDEZ-CHAVEZ[1], E. HERNANDEZ -LOPEZ[1], A. GARCIA-ESPONOZA[1], F. ESTRADA-ROJO[1], M. MARTINEZ-VARGAS[1], *L. NAVARRO[2], A. PEREZ-ARREDONDO[1];
[1]Physiol., [2]UNAM Fac Med., Mexico DF 04510, Mexico

Abstract: TBI is one of the leading causes of death and disability worldwide. In addition to the damage caused at the moment of injury, it causes secondary injury, but also induces neuroprotective mechanisms; which may even be promoted through external strategies. We analyzed the effect of rTMS in the behavioral recovery and brain histological analysis of rats with TBI. We used 70 male Wistar rats, maintained in vivarium conditions for 7 days, some of them habituated in movement restriction boxes for 15 min daily. Afterward, they were divided into 6 group; G1: control without movement restriction; G2: control with movement restriction and sham rTMS; G3: control with movement restriction and rTMS, G4 to G6 were anesthetized and subjected to TBI using a standardized device; G4: TBI without movement restriction; G5, TBI and movement restriction plus sham rTMS; G6: TBI and movement restriction plus rTMS. rTMS (2Hz) or restriction was applied for 15 min daily for 7 days. Body weight, water and food intake, and motor skill behavior using a neurobehavioral scale were measured every day. Subsequently the animals were anesthetized and perfused. Brains were cryopreserved and 20 µm cuts were obtained and cresyl violet staining. Cell number and dispersion were analyzed on hippocampal regions CA1 and CA3. Data for body weight, water and food intake were analyzed using a 2-way ANOVA and Duncan as post-hoc test, while neurobehavioral scale and histological data were analyzed using Kruskal-Wallis and Kolmogorov-Smirnov test as post-hoc. Statistical analysis showed significant differences by groups and days in body weight, water and food intake. In the neurobehavioral scale, G4, G5 and G6 were different between them and with the rest. In G4, impairment was observed in day 1 post-TBI and continued until day 7 post-TBI; in G5, the impairment lasted from day 1 to 5 post-TBI; while in group 6, the impairment only persists until day 3 post-TBI. In relation to histological data we didn't find differences in cell number, but we found statistical differences in percentage of dispersed cells in CA3; G4 showed more dispersion than G1, G2 and G3. All these data indicate a beneficial effect of rTMS on the rodent model of TBI used. Repetitive TMS could have possible therapeutic effect in head injury

Title: water soluble analog of progesterone for the treatment of traumatic brain injury

Authors: *B. WALI[1], I. SAYEED[1], D. GUTHRIE[2], N. TURAN[3], D. LIOTTA[2], M. NATCHUS[2], D. G. STEIN[1];
[1]Emergency Med., [2]Chem., [3]Neurosurg., Emory Univ., Atlanta, GA

Abstract: BACKGROUND: Despite substantial body of experimental preclinical work documenting progesterone (PROG) as a neuroprotective agent, two recently completed phase III clinical trials show efficacy in the treatment of moderate to severe TBI. Although a number of problems with trial designs have been published, the use of PROG as a therapeutic agent also has practical limitations, including its poor solubility, stickiness in the intravenous bag and the instability of its formulation. The purpose of this study was to develop and optimize a PROG analog that is more potent, stable and easily administered by direct injection in field conditions. Here we present data on EPRX-1723 which has been tested in a well-established rat model of traumatic brain injury followed by functional/behavioral outcome measures to determine its efficacy. **Methods:** CCI was induced with a magnetic contusion device and rats were randomly assigned to different treatment groups. At 24 h, animals were killed and brains were removed for edema assay. For behavioral outcome dose of 10 mg/kg EPRX-1723 and PROG were given one hour post-injury and at 6, 24, hours and 2, 3, 4, 5, 6, and 7 days post-injury. The animals were tested pre-injury to establish a baseline of performance on grip strength and sensory neglect, then were retested at 4, 9 and 21 days post-TBI. MWM testing started on Day 11. A probe trial was given at 19d post injury. At 22d post injury, rats were perfused and brains extracted and processed for lesion size. **Results:** EPRX-1723 (10 mg/kg) when administered intramuscularly immediately after TBI, significantly reduced cerebral edema level, and improved recovery from motor, sensory and spatial learning deficits as well as or better than native PROG. Pharmacokinetic investigation of EPRX-1723 after a single intramuscular injection in rats revealed that the prodrug was rapidly converted to the active metabolite EPRX-036, which can be seen in plasma in a dose dependent manner thus demonstrating first order elimination kinetics. Similar measurements in brain tissue show that levels of EPRX-036 were present in concentrations that were slightly lower than those in plasma confirming that it readily crosses the blood brain barrier. **Conclusion:** Recent Phase III trials with PROG did not reveal benefit on a quality of life outcome measure_but the treatment delays ranged between at least 4-9h post-injury. Our results suggest that the water soluble EPRX-1723 represents a substantial advantage over those formulations used in the trials. EPRX-1723 may eventually provide a substantial advantage over PROG in that it can be given in the field by first responders and thereby reduce the time between injury and treatment.

Abstract: Widespread traumatic damage to axons, termed diffuse axonal injury (DAI), may be a central contributor to functional/behavioral deficits following traumatic brain injury (TBI). Studies suggest axonal injury is not limited to time of injury and that progressive axonal injury continues many days post injury. Protein quality control and degradation play important roles in CNS homeostasis, particularly during injury or disease. The fidelity of the autophagic process is particularly relevant to CNS cells, and in particular, post-mitotic neurons that utilize autophagy to selectively target misfolded or aggregated proteins and defective organelles for removal. The role of autophagy in TBI is clouded by conflicting reports of autophagy being both detrimental and beneficial. Although there is substantial evidence that markers of autophagy are increased in both human and animal brains following TBI, it is not clear whether those changes result in functional autophagy. We have recently demonstrated that the axonal scaffolding protein, CRMP2, is involved in autophagy as engineered knockdown of CRMP2 reduces autophagy flux. Further, Lanthionine ketimine ethyl ester (LKE), binds to CRMP2 and stimulates autophagy in mammalian CNS cells. In this study, we utilized the mouse central fluid percussion model, a model of diffuse axonal injury. The progressive nature of DAI suggests that there is a period of time in which a pharmacological treatment might be effective to stabilize neuronal architecture, stimulate productive autophagy and allow repair mechanisms to function. In the present study we show that LKE, a bioavailable derivative of a natural brain sulfur amino acid metabolite, lanthionine ketimine, which we have previously shown to alleviate pathology and slow cognitive decline in the 3xTgAD mouse model, can spare cognition and pathology following DAI through mechanisms involving CRMP2 and autophagy modulation. To this effect, 30 minutes following a moderate TBI, and throughout the survival period, LKE was administered and mice subsequently evaluated for learning/memory impairments and biochemical and histological changes over a 5 week period.

Title: Stabilizing intracellular calcium channels prevents acute and sustained tau pathology in traumatic brain injury and AD models

Authors: N. KAPECKI[1], S. FISHER[1], B. DESAI[1], *C. A. BRIGGS[2], N. JAMNIA[3], D. PETERSON[1], D. KOZLOWSKI[3], G. STUTZMANN[1];
[1]Neurosci., Rosalind Franklin Univ. / The Chicago Med. Sch., North Chicago, IL; [2]Neurosci., Rosalind Franklin Univ., North Chicago, IL; [3]Biol. Sci., DePaul Univ., Chicago, IL

Abstract: The cellular mechanisms contributing to the proximal and long-term debilitating effects of a traumatic brain injury (TBI) are receiving increasing scrutiny. The tauopathies and amyloid deposits following a TBI are reminiscent of Alzheimer's disease (AD); indeed, TBI is a leading risk factor for sporadic AD. A common pathogenic feature between TBI and AD is calcium dysregulation through the ryanodine receptor (RyR). Acute dysregulated calcium signaling contributes to tau and amyloid aggregation within hours-to-days post-injury, while sustained calcium dysregulation likely contributes to the structural, synaptic, and behavioral deficits. In this study, we identify common features between TBI and AD to determine if similar upstream pathogenic mechanisms are recruited. If so, we hypothesize that our novel allosteric RyR modulators which ameliorate a multitude of AD features will be effective in reducing TBI-generated histopathology in the short-term (days), and prevent the progression to an AD phenotype in the long-term (weeks to months). We used a controlled-cortical impact TBI model in control and AD mice. Using immunohistochemistry against AD-associated tau and amyloid species in fixed brains sections, and *in vivo* 2-photon imaging in anesthetized animals, we show a rapid emergence of phospho-tau in the cortex and hippocampus of AD brains with a subsequent proliferation to the contralateral hippocampus within 7 days. Control mice showed a rapid phospho-tau response in the ipsilateral cortex and hippocampus, but this did not spread contralaterally during the 7-day time period. Amyloid plaques followed a similar pattern, with more aggressive aggregation and proliferation in the AD models. Upon treatment with a RyR-

targeted allosteric modulator within one hour of induced injury, and maintained for either 3 or 30 days post-injury, tau and plaque pathology were markedly reduced, as measured in fixed brain tissue and *in vivo*. Our data indicate that stabilizing RyR-evoked calcium signaling after a TBI impedes injury progression and reduces AD-related histopathology. We propose that by stabilizing aberrant intracellular calcium signaling soon after a TBI, we can generate both immediate and long-term therapeutic benefits and reduce the conversion to AD.

Title: Effect of creatine supplementation on cognition during hypoxia in mild traumatic brain injury

Authors: *C. E. TURNER, W. BYBLOW, S. BARKER-COLLO, R. KYDD, N. GANT; The Univ. of Auckland, Auckland, New Zealand

Abstract: The brain relies on an uninterrupted supply of oxygen in order to function optimally. Dysfunctional oxidative metabolism occurs with many neurological conditions, including mild traumatic brain injury (mTBI). Creatine is a compound that replenishes cellular energy without oxygen and can be administered as a dietary supplement. Creatine is capable of improving cognitive functions during oxygen deprivation [1] and may have similar effects for those recovering from mTBI. The aim of this study was to assess the effects of dietary creatine monohydrate supplementation on brain creatine and cognitive functions after mTBI. Spectroscopy was used to measure neural creatine availability. Neuropsychological assessments were conducted during a hypoxia protocol that induces cognitive impairments similar to those experienced after mTBI [2]. Neuropsychological function was measured at baseline and following 7 days of dietary creatine supplementation during the hypoxia intervention. Participants adhered to the 7 day supplementation regime, confirmed by an 8% increase in creatine within sensorimotor cortex. Creatine improved hypoxia-induced impairments in a range of cognitive domains scores that are commonly impaired following mild TBI. Verbal, visual and composite memory domains, psychomotor speed, and an overall neurocognitive index appear to be protected from oxygen deprivation by creatine supplementation. An enhanced energy-buffering capacity associated with augmented neural creatine stores likely increases energy provision in metabolically-vulnerable brain tissue. These preclinical findings suggest that creatine has utility to improve brain function in patients recovering from mTBI. References

Title: The efficacy of progesterone depends on the traumatic brain injury model

Authors: *A. M. CHOO[1], R. KOMLO[1], M. MANZANO[1], A. BARBOZA[1], Q. CHANG[1], T. HANANIA[2];
[1]PsychoGenics, Montvale, NJ; [2]PsychoGenics, Tarrytown, NY

Abstract: Progesterone was previously reported to improve outcomes in pre-clinical studies of traumatic brain injury. Recent phase 3 clinical trials, however, reported no clinical benefit of progesterone treatment for moderate-to-severe as well as severe traumatic brain injuries. Given the heterogeneity in human traumatic brain injuries, we aimed to reassess the effectiveness of progesterone treatment in two pre-clinical traumatic brain injury models. We compared progesterone treatment (16 mg/kg for 5 days) in mechanically identical controlled cortical impacts to the medial frontal cortex and the parasagittal cortex in rats. During the first week following injury, progesterone improved motor performance on the beam balance in both injury models. In the Morris water maze test, progesterone improved learning and memory only in animals that had received impacts to the medial frontal cortex and not in the parasagittal injury model. In the elevated plus maze, lesions to the medial frontal cortex increased the time the rats spent in the open arms which may indicate decreased anxiety and greater risk-taking behavior. This behavior was not attenuated by progesterone. The increase in the open arm time was modest in parasagittal injuries. Nonetheless, progesterone attenuated this modest increase back to levels similar to that of sham surgical controls. These data illustrate that the efficacy of post-traumatic progesterone treatment may depend on the brain region injured. Hence, the clinical translation of progesterone could benefit from additional stratification of patients accounting for the position of the brain lesions.

Title: Hippocampal degeneration after traumatic brain injury: the roles of the PGE_2 EP1 receptor

Authors: A. V. GLUSHAKOV[1], J. M. GALVIS[1], S. L. SOLASKI[1], *S. DORÉ[2];
[1]Anesthesiol., [2]Dept. of Anesthesiology, Neurology, Psychiatry, Neurosci., Univ. of Florida, Gainesville, FL

Abstract: Over the past decade, PGE_2 EP1 receptor blockers have been studied as a promising strategy for the treatment of neurological disorders and as a potential safer alternative to the cyclooxygenase-2 inhibitors. Preclinical data have demonstrated their efficacy in the treatment of ischemic and excitotoxic conditions by improving behavioral and anatomical outcomes and by promoting cell survival. However, according to recent reports, EP1 receptor roles are complex and the neuroprotective effects of its inhibition might be compensated or overpowered by adverse effects or toxicity in models of brain trauma and intracerebral hemorrhage. Consequently, the goal of this study was to investigate the effect of a selective EP1 receptor antagonist, SC-51089, on delayed neurodegeneration induced by traumatic brain injury (TBI) using a controlled cortical impact (CCI) model with two different injury magnitudes in mice. The data demonstrate that neurological deficit scores at 24 and 48 h after CCI rose with increasing injury magnitude. Repeated post-treatment with 20 ug/kg of SC-51089 has no significant effects on neurological deficit scores compared to vehicle groups with either magnitude. Of interest, 10 days after the severe CCI in the SC-51089 treatment group, the delayed hippocampal tissue loss was greater compared to controls. In mild-to-moderate TBI, the significant change in viable cell density was observed in the DG region of the contralateral hippocampi, whereas in its ipsilateral counterparts and other hippocampal regions, no statistically significant differences were observed. No significant changes in areas covering the pyramidal or granule cell layers in CA1-3 and DG regions, respectively, between corresponding control and SC-51089 treatment groups, were observed, suggesting that the changes in density are not due to hippocampal edema. The data, in combination with published reports, suggest that the EP1 inhibition worsened delayed degenerative processes in the hippocampus at sub-acute time points after TBI, and that this effect is more profound with increased trauma severity, likely due to the increased contribution of hemorrhagic injury.

Title: A specific multi-nutrient intervention, designed to enhance synapse formation and function, improves functional outcome following traumatic brain injury

Authors: *O. THAU ZUCHMAN[1], P. N. PALLIER[1], M. DAVIES[1], M. GROENENDIJK[2], M. C. DE WILDE[2], J. L. TREMOLEDA[1], A. T. MICHAEL-TITUS[1];

Abstract: Traumatic brain injury (TBI) leads to major neurological impairment and at present there is no satisfactory treatment for this condition. Recent clinical trials in Alzheimer's disease have demonstrated the efficacy of Fortasyn® Connect (FC), a specific multinutrient combination that was designed to compensate for the loss of neuronal membranes and synapses in dementia patients. This specific multi-nutrient combination contains essential nutritional precursors and cofactors such as docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA), choline, uridine monophosphate, phospholipids, folate, vitamins B6, B12, C, E and selenium, which synergize to support neuronal membrane formation and function. Recent clinical trials have shown improvement in cognitive function and increased cortical connectivity in Alzheimer's disease patients following daily intake of this multi-nutrient combination. TBI can lead to major tissue disruption, neuroinflammation and axonal damage. In the long-term TBI increases the risk of developing neurodegenerative conditions. Because of the relevance of neuronal membranes and synapses also in TBI, we hypothesised that a diet supplemented with this specific multi-nutrient combination could have protective and pro-regenerative effects after TBI. We investigated in a mouse model of TBI whether this supplemented diet can counter the tissue injury occurring after TBI and lead to an improved neurological outcome. Adult male C57/BL6 mice received an injury by controlled cortical impact (CCI) and were then assessed on a multitude of behavioural tasks, carried out at various time intervals, for 70 days post-injury (dpi). Following TBI, animals were fed daily with a control diet or the FC until the end of the study. FC significantly attenuated over the whole duration of the study the global deficit post-TBI assessed using a modified neurological severity score (mNSS). FC also decreased the injury-induced impairment in the Rotarod test (used to explore motor coordination, balance and strength), which was carried out in the injured animals in the first 3 dpi. Following CCI, mice

developed a marked impairment in spatial memory, which was assessed in the Morris Water Maze (MWM) between day 13 and day 18 post-TBI. The dramatic injury-induced deficit revealed in the probe trial in the MWM, was corrected by FC diet. These results suggest that a diet supplemented with FC multi-nutrient combination, which has already been shown to be very well-tolerated in patients with dementia, has marked therapeutic potential in TBI.

Title: Neurons are lost in brain regions controlling movement and fear after mild TBI and rescued by a CB2 receptor inverse agonist

Authors: W. BU[1], H. REN[1], Y. DENG[1], N. DEL MAR[1], N. M. GULEY[1], Y. GAO[1], M. G. HONIG[1], S. A. HELDT[1], B. M. MOORE, II[2], *A. J. REINER[1];
[1]Anat. & Neurobio., [2]Pharmaceut. Sci., The Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: In our closed-head model of mild TBI (mTBI), a high-pressure air blast is targeted to the left side of the mouse cranium, producing axonal injury, microglial activation, and motor and emotional deficits, but no overt contusive injury (Heldt et al. Frontiers Neurol. 2014). Here we report neuronal loss in several specific brain regions by 2-3 months after blast. Using stereology, we found 20% fewer NeuN-immunolabeled neurons in cortex on both sides, and 30% fewer NeuN-immunolabeled neurons in striatum on both sides in mice that had received 50-60 psi blasts as compared to their sham blasted littermates. For substantia nigra, 33% of tyrosine hydroxylase-immunostained dopamine neurons were lost on the left side and 13% on the right. Since our previous work showed that treatment with the novel cannabinoid type-2 receptor

(CB2) inverse agonist SMM-189 alleviates the motor deficits caused by mTBI in our model, by converting brain microglia from a pro-inflammatory M1 phenotype to a pro-healing M2 phenotype (Reiner et al., Int J Mol Sci. 2014), we examined the effects of SMM-189 on neuronal loss. We found that daily SMM-189 intraperitoneal injection, for two weeks beginning just after blast, yielded about 66% bilateral rescue of the cortical neuron loss, about 50% bilateral rescue of the striatal neuron loss, and near complete rescue of the dopaminergic nigral neuron loss. This, together with the rescue of corticospinal tract axons (Reiner et al., Int J Mol Sci. 2014), may contribute to the post-mTBI motor improvement seen with SMM-189 treatment. Mice subjected to blast mTBI also exhibit increased fearfulness that is alleviated by SMM-189. Given the role of basolateral amygdala (BLA) in fear control, we examined specific neuronal populations within it. Blast produced a 33% loss of thy1+ pyramidal neurons, no significant loss of thy1-negative BLA neurons, and a 47% loss of parvalbuminergic (PARV+) inhibitory BLA interneurons. The preferential loss of thy1+ neurons (which suppress fear) compared to thy1-negative neurons (which predominantly are pyramidal neurons that promote fear) may explain how mTBI produces increased fearfulness. Furthermore, the substantial loss of PARV+ interneurons associated with increased fear after mTBI suggests that the PARV+ interneurons may preferentially inhibit the thy1-negative fear-promoting pyramidal neurons. SMM-189 treatment rescued about 33% of the thy1+ neuron loss and about half of the PARV+ neuron loss. Thus, fear deficits after mTBI may result from loss of fear-suppressing neuron types in BLA, and SMM-189 may produce its benefit by their rescue.

Title: Hippocampal neurophysiology in awake behaving swine after diffuse brain injury

Authors: *P. KOCH[1], A. TEKRIWAL[1], M. GROVOLA[2], A. V. ULYANOVA[1], D. K. CULLEN[2,1], J. A. WOLF[2,1];
[1]Dept. of Neurosurgery, Ctr. for Brain Injury and Repair, Univ. of Pennsylvania, Philadelphia, PA; [2]Neurosurg., Philadelphia VA Med. Ctr., Philadelphia, PA

Abstract: We have previously established an acute recording methodology to interrogate hippocampal circuitry after diffuse brain injury (DBI) in a swine model of rotational injury. Injuries were administered over a range of coronal rotational accelerations (180-260 rad/sec) that induced little or no loss of consciousness (< 15 min), yet exhibited axonal pathology. Limitations of electrophysiological recording under anesthesia have led us to develop a chronic hippocampal electrode implantation model in the awake, freely moving swine, allowing examination of hippocampal networks engaged in relevant behavior after injury. Repeated concurrent electrophysiological and behavioral measures enable examination of how network level interactions may be disrupted after DBI. We have developed a stereotaxic surgical technique for precise implantation of a custom 32-channel silicone electrode into the swine hippocampus that allows for recordings of both single units in layer CA1 and dentate, as well as simultaneous laminar field potentials while the animal is awake and freely moving during behavioral tasks. We have also developed a novel object recognition task for swine, a behavior known to be hippocampal dependent. Pigs were trained on this task prior to electrode implantation. Preliminary behavioral results indicate that sham injured swine reliably interact longer with novel objects versus familiar objects. Moreover, we demonstrate robust extracellular field potentials out to 6 months post-implantation, as well as stable unit recordings pre- and post-implantation. Using spectral density analysis we report a prominent peak in hippocampal theta rhythm power in the freely behaving pig with positive shifts in peak frequency and peak power during periods of locomotion. This dominant hippocampal rhythm has previously been shown to be disrupted in rodent traumatic brain injury models. Here we demonstrate the feasibility of combining chronic hippocampal electrophysiological recordings with concurrent behavior in freely moving large animals. Combining this methodology with our established DBI model in pigs may reveal mechanisms of trauma-induced network dysfunction which may lead to innovative neuromodulatory therapies.

Title: Precision and reliability of diffusion-weighted magnetic resonance imaging in healthy muscles of the lower extremity

Authors: *J. G. MCPHERSON[1,2], M. WASIELEWSKI[2], J. M. ELLIOTT[2];
[1]Biomed. Engin., Florida Intl. Univ., Miami, FL; [2]Physical Therapy and Human Movement Sci., Northwestern Univ., Chicago, IL

Abstract: Diffusion-weighted magnetic resonance imaging (DW-MRI) is commonly used to identify regions of injury within the central nervous system (CNS). However, in cases when CNS injury is suspected but not visible - for example a mild, diffuse contusion of the spinal cord - DW-MRI of skeletal muscle may provide an alternative approach to assessing the likelihood of neural damage. Indeed, animal models have demonstrated an increased apparent diffusion coefficient in denervated skeletal muscle compared to typically innervated muscles. Further, these changes appear to precede findings from electrophysiological testing. Particularly in cases of suspected spinal cord injury arising from a motor vehicle collision, rapid and early changes in muscle properties distal to the site of trauma may be strong predictors of the rate and extent of recovery. Thus, the adaptation of DW-MRI to skeletal muscle holds considerable promise from both diagnostic and prognostic standpoints. Despite this, the precision and reliability of DW-MRI in skeletal muscle has yet to be established in individuals without neurological injury, significantly limiting its utility in cases of suspected CNS damage. Therefore, the objective of this pilot study was to investigate the precision, intra-rater, inter-rater, and short and long-term reliability of DW-MRI in muscles of the lower leg. Six neurologically uninjured individuals (3 male, 3 female) provided informed consistent and underwent a DW-MRI scan of the bilateral plantar and dorsiflexor muscles. Three individuals returned approximately 6 months later for a duplicate scan of the same muscle groups. DW-MRI scans were performed on a Siemens Trio 3T MRI scanner. Diffusion gradients were applied in 3 orthogonal directions at b-values of 0, 100, 300, and 500 s/mm2. Two region of interest (ROI) definitions were used: the first encompassing the entire area of the muscles at a given level and the second defined as the largest circular region that could be fully contained within the border of the muscles. Novice raters created and determined all ROI. Precision statistics included root-mean-square coefficient of variation (RMS-CV) and least significant change (LSC). Intra- and inter-rater reliabilities were assessed using intra-class correlation coefficients. RMS-CV values averaged 2.95 across raters and muscles, with LSC values averaging 8.18%. Intra- and inter-rater agreement averaged 98% for all comparisons and ROI definitions, with excellent short and long-term reliability. These results serve as essential validation of DW-MRI in skeletal muscle and will enable successful interpretation of DW-MRI results in future investigations.

Title: Assessment of thoracic and cervical spinal cord injuries using intercostal motor evoked potentials in humans

Authors: *F. D. BENAVIDES[1], A. J. SANTAMARIA[1], A. Y. FLORES[2], J. D. GUEST[1];
[1]The Miami Project to Cure Paralysis, Univ. of Miami, Miller Sch. of Med., Miami, FL;
[2]Pediatrics - Critical Care 2, Univ. of Miami, Miami, FL

Abstract: Background. Trans-cranial motor evoked potentials (tcMEPs) are a quantitative tool to assess conductivity of motor pathways, typically to limb muscles. However, tc stimulation can also be used to assess conduction in individual segments of the thoracic spinal cord by recording MEPs from intercostal muscles (ICs). The possibility to establish a functional motor level in the disrupted thoracic spinal cord could allow tracking of changes in adjacent segments and serve as a tool to evaluate natural recovery and/or the impact of therapeutics. In 1965, Guttman and Silver published observations that intercostal muscles were triggered reflexively in complete quadriplegics by breathing. However, we noted during the tcMEP study of a T2 thoracic AIS A subject that IC were prominent well below the sensory level and subsequently sought to understand this unexpected finding. Objectives. To characterize and analyze intercostal MEPs in normal and injured subjects after thoracic spinal cord injury. Methods. MEPs were recorded in 4 paraplegic patients (T2-T6, ASIA-A) utilizing surface electrodes located in the IC spaces, placed to avoid overlying surface muscles; recordings from subjects were compared to recordings collected in 4 control volunteers. The SCI subjects were enrolled in an FDA and IRB approved clinical trial at the University of Miami. Results. MEP amplitudes were decreased in segments below the injury site in SCI subjects, latencies were found slightly delayed or unchanged. In all subjects amplitudes and latencies were consistent within samples collected during the same session; latencies were more consistent than amplitudes between follow-up sessions and subjects. tcMEP evoked shorter and higher amplitude MEPs when the coil was placed over the vertex (compared to lateral cortical position). Conclusion. MEPs can be recorded with surface or needle electrodes from the intercostal spaces. Amplitudes change is the most reliable marker of injury level. Evoked signal is found in segments below complete injuries, suggesting a multi segmental innervation in IC muscles. ICs-MEPs may be used to help in establishing a functional level in thoracic injuries as well as to assess the safety and progression of cell transplantation strategies.

Title: Use of swimming test for evaluating spasticity after contusive spinal cord injury

Authors: ***Y. RYU**[1,2], N. FUJITA[1], T. OGATA[2];
[1]Grd. Sch. of Agr. and Life Sci., Univ. of Tokyo, Tokyo, Japan; [2]Dept. of Rehabil. for Motor Dysfunction, Natl. Rehabil. Ctr., Saitama, Japan

Abstract: Spasticity is a common disabling complication after spinal cord injury (SCI) which includes multiple symptoms such as muscle spasm, clonus and hyperreflexia. However, these symptoms of spasticity have not been fully recapitulated in animal SCI models. Also, methods for monitoring the symptoms of spasticity repeatedly after SCI have not been established yet. By these limited conditions of spasticity models, not only the mechanism but also the assessment of experimental intervention against spasticity remains unclear. Here, we attempted to quantitatively analyze spasticity including muscle spasm and clonus after SCI by swimming test and confirm the feasibility of the test by cage observation with simultaneous electromyography (EMG) recording from hind limb of rats. Rats were given 250kd contusive injury with Infinite Horizon impactor at Th8 level. Three weeks after SCI, EMG wires were inserted into tibialis anterior muscle and gastrocnemius muscle. The SCI rats weekly perform swimming test starting at 3 weeks after SCI. In each session, rats swam for 100 cm distance for ten times. The spastic behaviors during swimming were confirmed by simultaneously recorded EMG pattern. On the other hand, cage observation during 20 hour was done at 4 weeks after SCI. The spastic EMG activities were identified and confirmed by video monitoring. The number of spastic episode during 20 hour was recorded. Also, Hoffman(H) reflex test was taken at 6 weeks after SCI. According to the frequency of the spastic symptoms during swimming test, SCI rats were categorized into spasticity positive group or spasticity negative group. There were no statistical differences in the histological lesion size at epicenter between two groups. About 70% of rats with SCI showed spastic behavior classified by swimming test. The prevalence of spastic behavior of spasticity positive group during ten times swimming (one session) constant from 4 to 6 weeks after injury. Spasticity positive groups showed more spasm and clonus during cage observation and more hyperexcitablility tested by rate-dependent depression of the H reflex test than spasticitiy negative group. The EMG patterns during swimming test confirm that the episodic behaviors are related to spasticity. In addition, the consistency between swimming test and cage observation indicates the feasibility of swimming test to represent the spasticity of the rat. Based on our finding, we assume that swimming test can be used for evaluating spasticity with good reproducibility. For future work, we are now examined what factors related to present spasticity at tissue and molecular level.

Abstract: We recently developed a novel urodynamic model allowing repetitive measurements of both bladder and external urethral sphincter function at different time points in the same rat under fully awake conditions (Schneider MP et al., BJU International 2015). We now applied this model to assess the development of lower urinary tract dysfunction as a consequence of spinal cord injury (SCI) in adult rats over 6 weeks. A urodynamic catheter into the bladder and external urethral sphincter electromyography (EMG) electrodes were implanted into female Lewis rats. Two weeks after implantation, baseline urodynamic investigation showed a normal fast, large volume voiding response to bladder filling. The external urethral sphincter EMG showed peak activity at the high filling state immediately before as well as after voiding and a lower, slow wave bursting activity during voiding and tonic activity in the non-voiding phase. We used 3 different types of spinal cord lesions at T8 level: complete microsurgical transection, or severe compression by a vascular clip leading to complete (180 sec. clip time) or large but incomplete (60 sec. clip time) lesions. Urodynamic measurements were performed weekly in awake animals upon 6 weeks after SCI. Histological investigation of the spinal cord was performed to assess lesion completeness after perfusion. In the control animals (n=10) without SCI, urodynamic and EMG findings were similar throughout the whole study duration and no pathological effects were observed. In contrast, almost all rats with SCI (n=15) developed detrusor sphincter dyssynergia (DSD) characterized by high tonic sphincter activity during the voiding phase, resulting in dripping and interrupted release and very prolonged voiding phases. Typically, like in human spinal cord injured patients, DSD developed slowly over time, about three weeks after injury in the rats. All these pathophysiological changes were highly reproducible and resemble closely the DSD state typically found in humans with SCI.

Title: Biological effects of vibration simulating helicopter and MRAP transport on spinal cord injured pigs

Authors: *N. MANOUCHEHRI[1], F. STREIJGER[1], J. H. T. LEE[1], A. D. MELNYK[1,2], J. D. CHAK[1,2], S. TIGCHELAAR[1], K. SO[1], E. B. OKON[1], S. JIANG[1], R. KINSLER[3], K. BARANZANJI[3], P. A. CRIPTON[1,2], B. K. KWON[1,4];

Abstract: Incidents that cause spinal cord injury (SCI) typically require vehicular transport via ambulance or helicopter to evacuate the patient to an emergency medical center. During ground or air transportation, the spinal cord injured patient is inevitably subjected to various degrees of vibration. Others have shown that exposure to a wide range of vibrations may contribute to the development of pathological changes in the spinal cord and can lead to acute and sub-acute alterations in the cellular environment. Within the setting of a compromised spinal cord, the effects of vibration from different modes of transportation on further injury have not been directly studied. This has particular relevance in military conflicts where helicopters and Mine-Resistant Ambush Protected (MRAP) vehicles are often used to transport soldiers who have suffered a SCI. The purpose of this study was to determine if the application of vibration relevant to these forms of transportation influence the injured spinal cord and subsequent recovery from it. We employed our porcine model of thoracic SCI in which the spinal cord was injured at T10 with a combination of weight-drop contusion and sustained compression. Shortly after injury, animals were either exposed to i) no vibration, ii) 3 hours of vibration simulating a military helicopter, or iii) 3 hours of vibration simulating MRAP ground ambulance transportation. The experimental setting allowed us to apply vibratory stimuli with controlled frequency, amplitude, and duration - these parameters were provided by the US military. CSF samples, taken at various intervals during and after vibration, were biochemically analyzed for the presence of inflammatory mediators and structural biomarkers. Hind-limb recovery was assessed by a locomotor rating scale, i.e. Porcine Thoracic Injury Behavior Scale (PTIBS) for 12 weeks after SCI. The spinal cord was evaluated histologically to quantify the extent of white and grey matter sparing through the injury site. We observed that the concentrations of various biomarkers such as GFAP, MCP-1, IL-6, and IL-8 were elevated in all groups between 6-12 hours post injury but

were very similar between the vibrated and non-vibrated groups. Hind-limb function was also very comparable between the three groups of animals throughout the 12 week recovery. As predicted from the biochemical and behaviour data, there were no histological differences in the amounts of spared white or grey tissue matter. Thus, in summary, this study suggests that exposure to whole-body vibration simulating helicopter or MRAP transportation does not result in significant behavioural or histological worsening after traumatic SCI.

Title: Generating graded spinal cord contusion injury using Louisville injury system apparatus (LISA) in adult mice

Authors: ***X. WU**[1,2,3], W. QU[1,2,3], C. M. E. FRY[1,2,3], H. DAI[1,2,3], Y. ZHANG[4], C. SHIELDS[4], X.-M. XU[1,2,3];

Abstract: The Louisville Injury System Apparatus (LISA) impactor has been shown to be consistent, reliable, and reproducible in producing rat contusive spinal cord injury (SCI) due to its precise determination of the “0” point of spinal dorsal surface with a laser sensor and precise

generation of cord displacement (Zhang et al., J. Neurotrauma 25:1227-1240, 2008). However, the LISA device has yet to be tested in mice. In the present study, we examined whether the LISA impactor could be extended to creating graded contusive SCIs in mice. Three groups of C57Bl/6 mice received a T10 laminectomy followed by the creation of 0.2, 0.5 and 0.8mm spinal cord displacement injuries from the dorsal surface of the spinal cord using LISA. The sham group received laminectomy alone. Locomotor assessments using Basso Mouse Scale (BMS), grid walking, and TreadScan analysis were performed for up to 6 weeks post-injury. All mice were sacrificed at 7 weeks and the spinal cords containing the lesion epicenter were collected, sectioned, and examined. Our results showed that LISA produced accurate cord displacements in all 3 injury groups: 0.201 ± 0.0026 (mean ± standard deviation), 0.500 ± 0.0014, and 0.801 ± 0.0024, representing mild, moderate and severe injuries to the cord. The BMS and grid walking assessments showed statistically significant differences among the 3 injury groups. The TreadScan analysis allowed assessments of mice with a BMS score >5. For this criteria, the 0.2 and 0.5mm injury groups were assessed and significant differences in TreadScan measures were found between the 2 groups. Significant differences in TreadScan measures were also found between the 0.2mm and sham groups. Histological analysis showed statistically significant difference in lesion area, lesion length, and spared white matter at the injury epicenter among the 3 injured groups. We conclude that the LISA device can produce precise graded contusive SCIs in mice that result in severity-dependent behavioral and histopathological deficits.

Title: Spinal Cord pressure, blood flow and oxygenation and the effect of Duraplasty after SCI

Authors: ***K. SHORTT**[1], F. STREIJGER[1], N. MANOUCHEHRI[1], K. SO[1], E. OKON[1], B. K. KWON[1,2];

Abstract: Severe swelling of the human spinal cord is typically observed after traumatic spinal cord injury (SCI). Intrinsic cord swelling within the pia mater may result in increased

intraparenchymal pressure and reduced perfusion. The swollen cord can fill the subarachnoid space and be pushed up against the dura mater, causing a further increase in intraparenchymal pressure. In keeping with this, clinical studies of severe TBI have revealed that dural opening is required to relieve cerebral and improve blood flow and oxygen supply. Expansion duraplasty in human SCI is not routinely performed, but recently has been reported to reduce intraspinal pressure as measured by a subdural pressure probe (Phang et al, J. Neurotrauma, 2015). In this study, we directly measured intraparenchymal pressure, blood flow, oxygenation, and metabolic responses in our porcine model of SCI to evaluate these changes over the first week post-injury and to determine the intraparenchymal effects of expansion duraplasty. Our porcine model utilizes 20-25 kg Yucatan minipigs that are more similar to humans in their spinal cord anatomy and size than rodents, and importantly, have a notable CSF space around the spinal cord. This allows us to model the swelling and filling of the intrathecal space that is observed after human SCI. Following contusion plus compression SCI, animals were randomized to either having an intact dura or having a duraplasty to expand the subarachnoid space. Adjacent to the injury site we inserted monitoring probes directly into the parenchyma to measure spinal cord blood flow, oxygenation, metabolic responses (with microdialysis), and hydrostatic pressure. Monitoring was continued for 7 days. Our preliminary data reveals that adjacent to the injury site, the pressure within the spinal cord spiked at the time of impact and remained increased during the compression period. When the spinal cord was decompressed, a sharp pressure drop occurred, after which the pressure climbed gradually. The magnitude of pressure change away from the injury site was far less pronounced. Currently we are also compiling the data from the intraparenchymal blood flow, oxygenation, and microdialysis probes. In summary, we observed an increase in cord pressure and swelling following SCI, which is also routinely observed in individuals with acute SCI. Such cord swelling is poorly understood, and is quite likely to have an impact on neurologic recovery. Our data will provide fundamental insights into this phenomenon that could guide best practices and optimize neurologic outcome. Ref: Phang et al, J Neurotrauma. 2015 May 4. Title: Hemodynamic management of acute spinal cord injury: Use and effects of common vasopressors on spinal cord blood flow, oxygenation and downstream metabolic responses after SCI in a porcine model

Authors: *K. SO[1], F. STREIJGER[1], N. MANOUCHEHRI[1], E. B. OKON[1], K. SHORTT[1], J. H. T. LEE[1], B. K. KWON[1,2];

Abstract: Early intervention strategies after a traumatic spinal cord injury (SCI) remain limited, with vasopressor support of mean arterial pressure and spinal cord perfusion being one of the few treatment options available. After an acute SCI, a drop in the Mean Arterial Pressure (MAP) is commonly observed, leading to a decrease in spinal cord blood flow (SCBF). Reduced cord perfusion and ischemia are major contributors to secondary damage. Thus, clinicians aim to restore adequate SCBF by augmenting the MAP with vasopressor drugs. However, such drugs have differing pharmacological properties and as such, each has its own distinct effect on restoring SCBF and minimizing ischemia. Therefore, a clinically relevant question is, which vasopressor agent is best suited to augmenting spinal cord perfusion and minimizing ischemia within the injured spinal cord? To answer this question, we compared three commonly used vasopressors, norepinephrine (NE), phenylephrine (PE), and dopamine (DA), to determine their intraparenchymal effects on SCBF, oxygenation and downstream metabolic responses after SCI. Using our pig model of a contusion/compression SCI, we compared the effects of NE, PE, and DA, during sustained compression and also after decompression. To mimic the clinical resuscitation goals of hemodynamic management for acute SCI patients, the MAP of experimental animals was increased by 20 mmHg. Throughout the experiment, the intraparenchymal oxygenation/blood flow response as well as metabolite levels of glucose, lactate, pyruvate, L/P ratio, glutamate and glycerol were assessed, both proximal and distal to the injury site. Preliminary data suggest that NE and PE both increase the blood flow and oxygenation proximal to the injury site. While PE does not increase blood flow as readily as NE close to the injury site, the oxygenation increases are similar. Increases in blood flow and oxygenation with DA treatment was only achieved at extremely high administration levels, far beyond what would be clinically relevant. Evaluation of metabolic responses using intraparenchymal microdialysis shows some increase in tissue glucose levels with Norepinephrine. Further study will clarify the differences in intraparenchymal responses to these vasopressor agents.

Title: Changes in spinal cord metabolism, oxygenation and blood flow after acute SCI using a porcine model

Authors: *E. B. OKON[1], F. STREIJGER[1], N. MANOUCHEHRI[1], K. SHORTT[1], K. SO[1], B. K. KWON[1,2];

Abstract: Hypoxia and ischemia have been long recognized as common and potentially harmful events after spinal cord injury (SCI). This has led to the development of treatment strategies aimed at optimizing intraparachymal spinal cord blood flow (SCBF), which has been extensively studied after acute SCI. However, the relationship between SCBF, oxygenation, and downstream tissue ischemia has not been well established. In this study we evaluated the intraparenchymal blood flow, oxygenation and metabolic responses within the spinal cord during the (sub)-acute phases of SCI. Here, we used a porcine model of SCI involving a combination of contusion and compression components. Using intraparenchymal microdialysis, extracellular fluid from the spinal cord at 1.2 and 3.2 cm caudal to the center of the impact was interrogated for up to 7-days. These samples were analyzed for various markers of cellular damage, ischemia and energy status, including lactate, pyruvate, L/P ratio and glucose. Furthermore, additional sensors were implanted into the cord at the same position to measure responses of oxygenation and blood flow. Proximal to the injury site (1.2-cm), SCBF and oxygenation decreased dramatically following SCI and while the cord remained compressed. Following decompression, they recovered slightly but remained below baseline. At around 2 days post-injury, SCBF levels steadily increased such that at the end of the experiment, levels reached far above baseline. Oxygenation levels tended to increase after day 1. Glucose values decreased significantly upon SCI, and subsequently returned to baseline by day 1. Lactate to pyruvate (L/P) ratio, a marker for tissue ischemia, increased significantly within minutes after SCI and cord compression and subsequently decreased after decompression. However, the L/P ratio increased again to levels 5-fold above baseline by day 7. Distal from the injury site (3.2-cm), the response to SCI, compression and decompression was minimal, however, over the course of 7-days, gradual changes were observed. Glucose levels began to fall below baseline around 5 days post-injury. In addition, oxygenation and SCBF decreased slowly but continuously over time, while the L/P ratio steadily increased up to 4-fold above baseline. Taken together, our preliminary data sheds light on the dynamic changes that occur with oxygenation, SCBF, and metabolic responses in the penumbra of the traumatic spinal cord injury site.

Title: Effect of injury severity on serum and cerebrospinal fluid miRNA expression profile after traumatic spinal cord injury in pigs

Authors: *S. S. TIGCHELAAR[1], F. STREIJGER[2], S. SINHA[3], N. MANOUCHEHRI[2], K. SO[2], I. MALENCIA[4], A. COURTRIGHT[4], T. BEECROFT[4], K. VAN KEUREN-JENSEN[4], C. NISLOW[3], B. KWON[2,5];

Abstract: With limited treatment options currently available to clinicians, there is an urgent need for non-invasive biomarkers to aid in the scientific development and clinical validation of novel therapies for acute spinal cord injury (SCI). Micro RNAs (miRNAs) are small regulatory noncoding RNA molecules approximately 22 nucleotides in length that mediate post-transcriptional silencing of gene expression via the interaction with specific sequences in target messenger RNA. The current body of literature suggests that miRNAs influence a wide range of biological processes such as proliferation, differentiation, adult neurogenesis, synaptic plasticity and apoptosis. Many miRNAs are highly expressed in the adult nervous system in a temporally and spatially controlled manner in normal physiology, and are also directly implicated in the pathogenesis of various neurodegenerative diseases including traumatic SCI. Besides their specific spatial, temporal and cellular-level expression, our interest in microRNAs furthermore stems from their stability within blood, making it possible for blood samples to be utilized in order to measure markers specific to the injured central nervous system. In this study, we compared the miRNA expression profiles of serum and cerebral spinal fluid (CSF) between various injury severities in a porcine model of SCI. Female Yucatan minipigs underwent a T10 SCI using a weight drop impactor followed by compression for 5 minutes. Animals were grouped into three levels of injury severity, which were induced by altering the height of the weight drop (10, 20, and 40 cm). Next-generation sequencing technology was used to compare effects of injury severity on miRNA levels obtained daily over a period of 7 days post-injury. Extracellular miRNAs were then isolated and sequenced using the Illumina HiSeq system and the generated data was aligned using miRDeep2 and tested for differential expression with

DESeq software. Using a porcine model of SCI, we demonstrate miRNA profiles in CSF and serum samples during acute and sub-acute stages after SCI. Our results reveal pronounced trends in miRNA expression and their potential target interactions provide valuable insight into the molecular mechanisms of SCI. We are currently also examining serum and CSF samples from human SCI patients collected at identical post-injury time points for a direct comparison of miRNA responses to SCI between the two species. This characterization is important to establish whether biomarkers of SCI found in pigs can be transferred to humans and visa-versa.

Title: Characterization of circulating monocytes in individuals with acute spinal cord injury

Authors: ***O. BLOOM**[1], R. MONAHAN[2], K. GIBBS[1], A. PAPATHEODOROU[2], A. STEIN[3], M. BANK[4];
[1]Feinstein Institute, Hofstra North Shore LIJ Sch. of Med., Manhasset, NY; [2]Feinstein Inst., Manhasset, NY; [3]Hofstra North Shore LIJ Sch. of Med., Manhasset, NY; [4]North Shore Univ. Hosp., Manhasset, NY

Abstract: Introduction: Acutely after traumatic spinal cord injury (SCI), inflammation exacerbates neuronal loss and promotes secondary tissue damage. We and others recently discovered a subset of elevated circulating inflammatory mediators in individuals with acute or chronic SCI (Bank et al 2015, Stein et al 2013). Conversely, immune depression has also been noted in individuals with acute SCI and neurological recovery is inversely correlated with infections after SCI (Riegger et al 2009, Failli et al 2012, Kopp et al 2013). In the present study, our objective was to profile the distribution and activation status of circulating monocyte and dendritic cell subsets in individuals with acute SCI. Uninjured individuals of the same age range and gender distribution served as controls. Methods: This prospective, IRB-approved, observational pilot study of adult SCI participants was performed in an academic medical center. "Acute" SCI was defined as <1 week from initial injury. PBMCs were isolated from blood by Ficoll density gradient. Multicolor flow cytometric analysis of PBMCs was performed to examine the number, percentage and phenotype of circulating monocyte and dendritic cell

subsets, using gating schemes recommended by the Human Immunology Project (Maecker et al 2012). Activation status was measured by cell surface expression of MHCII/HLA-DR, as indicated by the median fluorescence intensity (MFI) of a fluorescent anti-HLA-DR antibody conjugate. Results: Uninjured (N=7) and SCI (N=3) participants included 2 females in each group. Uninjured and SCI participants were of similar ages (mean±sem, range): (52±4, 45-57 and 53±5, 48-58 years) ($P<0.7$). Mechanisms of injury for SCI participants were: Fall (n=1), MVA (n=2). All SCI individuals had a cervical level injury (C4-C6) and two had neurologically incomplete injuries. In this initial small number of participants, we did not observe differences in the relative distribution of CD3- CD56- circulating monocyte and dendritic cell subsets in SCI as compared to uninjured individuals. However, in acute SCI, we did observe statistically significant decreases in activation status of several cell subsets, as indicated by decreased HLA-DR cell surface expression: CD11c+ CD16- dendritic cells ($P<0.004$), CD14++ CD16- classical monocytes ($P<0.004$), and CD14+ CD16+ non-classical monocytes ($P<0.02$). This data confirms and extends previous studies of circulating immune cell populations in acute SCI (Riegger et al 2009, Kopp et al 2013). Studies are ongoing to confirm and extend these findings in additional participants.

Title: Circulating microRNAs reflect neural dysfunction in patients with cervical spondylotic myelopathy (CSM): Implications for a novel biomarker of disease pathobiology

Authors: *A. M. LALIBERTE[1], S. K. KARADIMAS[1], S. KALSI-RYAN[2], A. NOURI[2], E. MASSICOTTE[2], M. G. FEHLINGS[2,3];
[1]Genet. and Develop., Univ. of Toronto, Toronto, ON, Canada; [2]Spine Program, [3]Develop. and Genet., Univ. Hlth. Network, Toronto, ON, Canada

Abstract: Introduction: While increasing evidence points to a beneficial role for surgical decompression in CSM, approximately 5% of patients with CSM sustain neurological decline following decompression with risk factors remaining unclear. Additionally, patients with

significant cord compression on MRI but minimal clinical symptoms represent a significant management challenge. We hypothesize, based on recent work from preclinical animal models, that circulating microRNAs (miRs) could reflect the pathobiology of CSM and thus could serve as biomarkers of disease progression. **Methods**: Thirty CSM and ten healthy subjects were recruited for the initial screening study with another 40 subjects recruited for validation. Blood plasma was collected from all subjects, and 179 miRs were screened using the Exiqon miRCURY Plasma PCR platform. The Normfinder algorithm was used to determine optimal normalization for the dataset. Subjects were divided into healthy, mild CSM, moderate/severe CSM groups (based on mJOA scale) and ANOVA was used to determine significant differences. Logistic regression models were created to distinguish healthy versus CSM subjects, as well as mild versus moderate/severe CSM cases. Model validation was performed using an 80 replicate bootstrap re-sampling procedure. **Results**: The mean age and mJOA scores were 53.3±10.8/15.9±0.8, 60.1±9.4/12.4±1.4, and 51.7±10.9 in mild CSM, moderate/severe CSM and healthy subjects, respectively. The gender ratio was 1:1 in healthy and CSM groups. Eight miRs had significant ($p<0.05$) expression differences between groups. Four of those miRs (let-7f-5p, miR-34a, let-7c, miR-154-5p) contributed to the logistic regression models. These models discriminated well between healthy and CSM subjects (let-7f-5p [OR= 0.106], miR-34a [OR=0.232], let-7c [OR=27.4], AUC = 0.837) and between mild CSM and moderate-severe CSM patients (let-7f-5p [OR=0.040] and miR-154-5p [OR=5.5], AUC = 0.930). Model performance with the bootstrap replicates decreased marginally in discrimination of healthy versus CSM subjects (AUC=0.713), but remained high for CSM severity discrimination (AUC=0.889) **Conclusions**: The results reported herein demonstrate that plasma miR expression can predict the presence and severity of CSM. Based on previous work in the preclinical model, it is plausible that these miRs are related to the underlying ischemic and inflammatory mechanisms driving myelopathy. Future work will focus on assessing potential of miRs in identifying patients at risk for neurological decline following decompression and those with cord compression and minimal clinical symptoms that are at risk for disease progression.

Abstract: In recent years, the field of spinal cord injury (SCI) research has identified multiple replication failures which could result in an inability to translate findings into standards of patient care. Several theories have emerged about the cause of the inability to replicate, both from the preclinical and clinical perspectives. One emerging theory implicates methods that data are collected, analyzed and selected for publication. Our group has developed a novel approach to address these concerns, known as syndromics, applying large scale bioinformatics and multivariate statistics to identifying complex interactions in pathophysiology using the full set of multidimensional data gathered for each individual test subject. We have compiled such data into the VISION-SCI database, with raw data from over 3000 mice, rats and monkeys donated by members of the SCI research community. Application of data-driven analytics to preclinical health records identified significant syndromic impact of perioperative hypertension (MAP) as a major predictor of poor neurological recovery. Here, we apply data from the VISION-SCI database to test the reproducibility of the relationship between MAP and neurological recovery in adult male and female rats receiving a range of thoracic bilateral SCI contusions (T9; weight-drop impactor; 12.5, 25, 50mm). We applied topological data analysis (TDA), which deploys ensemble machine learning in multidimensional space to heterogeneous, complex big-data on measures of perioperative vitals (body temperature, heart rate, blood pressure), blood gases, weight monitoring, bladder care, locomotor functional recovery (BBB, 1-6 weeks) and terminal tissue sparing (6 weeks) (N=334). TDA revealed a data-driven, syndromic relationship between perioperative care and locomotor recovery on a subset of the animals (N=72). Cross-validation of TDA-identified patterns was performed on the remaining animals (N=262) using an analytical workflow of TDA, post-hoc repeated-measures general linear model (GLM) and bivariate correlations. TDA identified syndromic dysfunction in BBB recovery, significantly predicted by hypertensive episodes (MAP>140mmHg) during SCI operation. Cross-validation in the independent dataset revealed a similar significant difference in BBB recovery inversely predicted by MAP. GLM on BBB recovery revealed MAP significantly predicted locomotion in both datasets, and correlational analyses confirmed an inverse relationship. Together the data indicate

that our big-data analytical model identified and replicated the finding that upper extremes of perioperative MAP predict poor recovery following SCI.

Title: Dietary strategies following spinal cord injury: Ketogenic Diet and Modified Adkins Diet with oral administration of ketone supplementation

Authors: *F. STREIJGER[1], K. WU[1], O. JANG[1], W. T. PLUNET[1], J. LIU[1], W. TETZLAFF[1,2]; [1]ICORD, UBC, Vancouver, BC, Canada; [2]Dept. of Zoology, UBC, Vancouver, BC, Canada

Abstract: Contrary to our current clinical practice, we reported that feeding a low carbohydrate, high fat ketogenic diet (KD) after spinal cord injury (SCI) improved reaching ability that involves fine manipulation of the distal muscles of the digits and supination in rats. Despite these intriguing results, potential clinical application of KD has been significantly hampered by poor tolerability, its strictness, lack of palatability, and potential side effects after long-term consumption. A safer and more tolerable diet therapy would be highly desirable, as it would extend the availability to more patients with SCI. The Modified Atkins Diet (MAD) was designed to mimic the effects on ketosis and seizures of KD, but with less restrictiveness. Unlike the standard Atkins Diet, MAD does not restrict calories, allowing unlimited protein and fat intake, and is more lenient with the use of estimations of portion sizes. Evidence suggesting that the MAD may exhibit similar beneficial properties as the traditional KD is accumulating in other fields. Therefore, the objectives of this study are 1) to determine whether a more palatable MAD would be similarly effective as KD in the SCI setting and 2) to investigate whether the beneficial effects of KD or MAD can be further enhanced by intermittent bolus gavage feeding with oral ketone esters. Here, we used a cervical hemi-contusion model. Following SCI surgery, animals were placed on a carbohydrate-based standard diet, KD, or MAD with or without ketone ester supplementation during the first 3-days of treatment. Forelimb function was assessed using a

battery of tests to assess manual dexterity and distal muscle activation in the forelimb. Our data suggest that ketone supplementation results in a more effective induction of effective ketone levels in the blood compared to KD or MAD alone. Oral administration of ketones effectively induced a rapid and sustained ketosis within 24 hours in both the KD and MAD group. Supplementation of KD with oral ketones increased blood ketones to levels around 3.2 mmol/L, which is almost 2 times higher than we observe after KD consumption in rats without supplementation. Behavioural analyses are currently performed and will be presented. In conclusion, the data generated by this research will further our understanding of the unique nutrition requirements of patients with SCI in order to improve neurological outcome. The possible improvement from this simple dietary intervention would improve quality of life of the affected individuals and safe significant health care costs.

Title: Effective gene silencing in brain and spinal cord *in vivo* models mediated by lipid nanoparticle technology

Authors: O. SEIRA[1], J. LIU[1], A. ANSARI[2], D. ZWAENEPOEL[2], C. L. WALSH[2], A. THOMAS[2], T. LEAVER[2], A. WILD[2], J. R. TAYLOR[2], E. RAMSAY[2], P. CULLIS[3], *W. TETZLAFF[4];

Abstract: Lipid nanoparticles (LNP) are the leading systems for *in vivo* delivery of short interfering RNA (siRNA) for therapeutic applications. The lack of an appropriate protocol to administer LNP into the brain and spinal cord has limited the investigation of their potency to silence neuronal genes *in vivo*. Here, we attempt to bridge this gap in neuroscience research by describing the use of siRNA-LNP to efficiently knockdown gene expression in brain and, for the first time, in spinal cord *in vivo* models. The effectiveness of the siRNA-LNP system was assessed in the brain by direct injection into the cortex. LNPs were seen to be present in cortical neurons, where delivery of the siRNA against PTEN exerted the desired changes in gene expression. Subsequently, LNPs were injected at the site of cervical spinal cord injury and a decrease in expression of the target PTEN was observed in the vicinity of the injury/injection site

10 days later. Moreover, the presence of LNPs in the neurons of the red nucleus located in the brainstem, suggests that the lipid nanoparticles are taken up by axons and retrogradely transported. With no previous reports on this phenomenon, this study reflects the potential of siRNA-LNPs in advancing our understanding of the central nervous system. Furthermore, the ability of this relatively novel siRNA-delivering LNP technology to successfully affect gene silencing in brain and spinal cord *in vivo*, presents a promising prospect for the development of new gene therapies to treat neurological disorders.

Title: AAV-mediated conditional deletion of PTEN in the adult sensorimotor cortex causes robust hypertrophy of cortical motoneurons

Authors: *E. A. GUTILLA[1], O. STEWARD[2];
[1]UC IRVINE SCHOOL OF MEDICINE, Irvine, CA; [2]ANATOMY & NEUROBIOLOGY, UC IRVINE, IRVINE, CA

Abstract: Previous studies have reported neuronal hypertrophy and cortical enlargement following deletion of the phosphatase and tensin homolog on chromosome 10 gene (PTEN) in developing mice and in newborn neurons in adult mice. Here, we show that deletion of PTEN in adult sensorimotor triggers remarkable enlargement of individual cortical motoneurons which give rise to the corticospinal tract (CST) as well as alterations in cortical lamination. Using the same approach we have previously used to promote axon regeneration and functional recovery following spinal cord injury, AAV-Cre was injected locally into the sensorimotor cortex of adult (8 week old) mice with a lox-P flanked exon 5 of the PTEN gene. Control animals received intracortical injections of AAV-GFP. Mice were allowed to survive for up to one year following AAV injections. One group of mice with focal PTEN deletion received bilateral fluorogold injections at cervical level 5 of the spinal cord one week prior to perfusion to retrogradely label

the cells of origin of the CST. Brain sections were immunostained for PTEN to identify the region of PTEN deletion and for phosphorylated ribosomal protein S6 (pS6), which is a marker for mTOR activation. In sections immunostained for PTEN, the area of deletion was marked by a complete absence of immunostaining in a region about 1mm in diameter. Immunostaining for pS6 revealed intensely stained neuronal cell bodies and processes within the region of PTEN deletion; pS6-positive pyramidal neurons in layer V were obviously larger than PTEN-positive neurons in other areas of the cortex. Neurons in layer V that were retrogradely labeled following fluorogold injections into the spinal cord were substantially larger in the area of PTEN deletion than in neighboring layer V neurons with intact PTEN expression. Our results indicate that deleting PTEN re-initiates the ability for robust neuronal growth that is normally restricted to the developmental state. These finings suggest the potential usefulness of PTEN interference in adults to protect and repair vulnerable neurons from the effects of aging traumatic injury, or neurodegenerative disease.

Title: Evoked potential analysis of hmsc and anastomosis mediated functional recovery for chronic thoracolumbar sci

Authors: *X. ZENG[1,2], D. YU[1,2], J. E. ANDERSON[1,2], Z. ALJUBOORI[1,2], R. D. ZAFONTE[3], Y. D. TENG[1,2,3];
[1]Dept. of Neurosurg., Brigham & Women's Hospital/Harvard Med. Sch., Boston, MA; [2]Div. of SCI Res., VA Boston Healthcare Syst., Boston, MA; [3]Physical Med. and Rehabil., Spaulding Rehabil. Hospital/Harvard Med. Sch., Boston, MA

Abstract: We previously reported that anastomosis/neurotization could significantly improve locomotion in rats with thoracolumbar contusion spinal cord injury (SCI). The benefits included enhancing coordinated hindlimb functions of open field locomotion and incline plane performance, and sensorimotor recoveries evaluated by spinal reflex tests. Post-neurotization recovery neurobiology mechanisms comprised enrichment of intraspinal cord synapses and strengthened propriospinal projection connectivity across the contusion site. To further assess specific neural circuit(s) involved in locomotion recovery, we performed a pilot study on evoked

potentials in chronic SCI rats that demonstrated persistent locomotion improvement (i.e., ≥ 12 months) following neurotization treatment. Briefly, female SD rats (220-235g) received T13-L1 moderate contusion (10gx25mm) and T12-L3 neurotization at either 1 week (subacute) or 13 weeks (chronic) after SCI (n=4/each study). For rats with chronic SCI, neurotization was done 7-10 days following human mesenchymal stromal stem cell (hMSC) injection (50K cells/µl; 1µl injection at 1 mm rostral and caudal to the epicenter, respectively and 2µl into the injury site; total: 200K cells/rat; n=4/group). Behavior tests were performed weekly for 10 months in order to confirm sustainability of locomotion recovery. Based on our previous finding, we hypothesized that the regained locomotion capability might be partially facilitated by serotonergic modulation. We therefore administered 5-HT1A and 2A/2C agonists and/or antagonists intraperitoneally or intrathecally to examine their effects on hindlimb function. The results replicated data we reported before, showing that the locomotion recovery could be additionally boosted by treatment with 5-HT1A and 2A/2C agonists acting specifically via corresponding receptors. We next measured cortical motor evoked or peripheral nerve (C7) evoked potentials (EPs) recorded at loci either rostral (T6-T7) or caudal (L3-L4) to the injury epicenter to determine which neural circuit(s) contributed to reactivation of the central pattern generation (CPG). The EP outcomes, together with neural tracing data, suggest that T12-L3 neurotization following hMSC implantation provides a multimodal approach to functional recovery for chronic thoracolumbar contusion SCI. Title: Safety and feasibility of the use of tms on the cervical spinal cord injury site: a radio-telemetric study of cardiovascular and brain activity

Authors: *P. K. BOSE[1,2,3], J. HOU[1,2], R. NELSON[1], M. H. MODARRES[1], F. J. THOMPSON[1,2,4];

[1]North Florida/South Georgia VAMC, Gainesville, FL; [2]Dept. of Physiological Sci., [3]Dept. of Neurol., [4]Dept. of Neurosci., Univ. of Florida, Gainesville, FL

Abstract: Cervical spinal cord injury (cSCI) is frequently a devastating injury that can result in a broad range of life-long disabilities. Development of safe and effective therapies for these long-term disabilities is urgently needed. Our recent work using a combination of treadmill locomotor exercise (Tm) with Transcranial magnetic stimulation (TMS) therapy yielded significant locomotor improvement that was greater than either treatment tested alone (Hou et al, 2014). The present studies were conducted to provide neurological and cardiovascular measures to serve as quantitative safety assessments of the influence of TMS on brain and cardiovascular activity. We utilized implanted telemetry devices to measure blood pressure (BP), heart rate (HR), and brain activity (EEG). The data were acquired for 7 consecutive days before injury, 7 consecutive days after SCI, and after each therapeutic intervention. Beginning at post-cSCI wk-3, animals received Tm and TMSsc as an individual or combined therapy using single pulse TMSsc (sTMSsc) (Hou et al., 2014) or rTMS (15 Hz, 30-70% TMS power). Data were acquired just before intervention and within 2 minutes after interventions, and continued for an hour to test the immediate effects of treatments on BP, HR, and EEG. The BP and HR data and EEG were acquired and analyzed by a digital signal acquisition and analysis system (DSI Ponemah Physiology Platform, Version 5.00) and NeuroScore, 2.1 respectively. Power spectral decomposition of EEG records computed the absolute power for all frequencies from 0.5 to 45 cycles/second (Hz) (Welch's averaged periodogram) on windowed (Hanning) 2-second consecutive segments of EEG records (overlapped by 1 second), which produced EEG power vs. frequency levels at a resolution of 0.5 Hz. We computed quantities that represented the power levels over various frequency bands as follows: δ (0.5 - 3 Hz), θ (3.5 - 7 Hz), α (7.5 - 11.5 Hz), β (13 - 28 Hz), and γ (39 - 45 Hz). We also computed the power for 2 sub-segments of β band: β1 (13 - 17.5 Hz), and β2 (18 - 22 Hz). There were no significant changes in BP and HR in pre- and post-cSCI conditions as well as pre- and post-intervention with sTMS. However, rTMS (with or without Tm exercise) produced significantly elevated BP and HR. cSCI animals showed significantly elevated α band in averaged EEG absolute and relative powers when compared to that of pre-injured data. Interestingly, sTMSsc or rTMS normalized this difference. However, power of the γ band was significantly increased after rTMS with or without Tm. These preliminary studies indicated that sTMSsc does not produce detectable alterations in the electrophysiological patterns of cardiovascular and/or brain activity.

Title: Lipidomic analysis of spinal cord injury: cardiolipin loss and peroxidation mediated by cPLA2 activation

Authors: ***N.-K. LIU**[1], L.-X. DENG[1], M. WANG[2], Q.-B. LU[1], X.-B. WU[1], C. WANG[2], X. HAN[2], X.-M. XU[1];
[1]Indiana Univ., Indianapolis, IN; [2]Sanford-Burnham Med. Res. Inst., Orlando, FL

Abstract: Traumatic spinal cord injury (SCI) is prevalent in the United States, with more than 12,000 cases every year. Mitochondrial dysfunction and neuronal apoptosis have been shown to play a key role in SCI. Alteration (loss and peroxidation) of cardiolipin (CL) is emerging as an important factor in mitochondrial dysfunction and in the initial phase of the apoptotic process. However, whether CL alteration occurs following SCI and, if so, its role in mediating SCI remains unclear. In the present study, we examined alteration of CL following SCI using mass-spectrometry-based lipidomics. Pharmacological, genetic, molecular, biochemical, and immunohistological approaches were used to explore the role and mechanism of CL alteration after SCI. The results showed that the content of CL was significantly reduced at 3 and 24 h after SCI while lyso-cardiolipin (lyso-CL) was increased only at 24 h after the injury. Over 50 distinct CL molecular species were readily identified. Of them, 50% were significantly reduced after SCI. Additionally, mitochondrial 4-HNE also increased at 3 and 24 h after SCI. *In vitro* experiments showed that activation of cPLA2 resulted in CL loss, leading to mitochondrial dysfunction and neuronal death, which were substantially reversed by AACOCF3, a cPLA2 inhibitor. *In vivo* experiments showed that cPLA2 activation was increased in the mitochondria after SCI. Remarkably, blocking cPLA2 pharmacologically with AACOCF3 reduced CL loss, leading to decrease in mitochondrial dysfunction, cytochrome c release, and neural apoptosis after SCI. Genetic deletion of cPLA2 also inhibited CL loss, resulting in neuroprotection after SCI. These findings collectively suggest that CL alteration is an early response following SCI and such SCI-induced CL alteration was mediated by cPLA2 activation, at least in part. Thus, CL alteration may play an important role in the pathogenesis of SCI, and as such could be an attractive therapeutic target for ameliorating secondary SCI.

Title: Persistent inflammatory response to spinal cord injury leads to decrease of mRNA editing through down-regulation of Adar2

Authors: ***S. DRACHEVA**[1,2], A. F. DI NARZO[2], A. KOZLENKOV[2], Y. GE[2], B. ZHANG[2], C. CARDOZO[1], E. KOONIN[3], L. SANELLI[4], Z. MAY[4], Y. LI[4], K. FOUAD[4], D. BENNETT[4]; [1]Dept. Inst. of Health,, Bethesda, MD; [4]Univ. of Alberta, Edmonton, AB, Canada

Abstract: Spasticity is a common sequella of spinal cord injury (SCI) and is a major complaint of injured individuals. It involves simultaneous contractions of many muscles, which are triggered by brief sensory stimuli (e.g., cutaneous inputs). Spastic paralysis has been observed in ~ 80% of individuals with traumatic SCI. Treatment of spasticity with conventional antispastic drugs (e.g., baclofen,) is often not adequate, or is not tolerated because of adverse side effects such as drowsiness and weakness. We have recently showed that SCI leads to a decrease in mRNA editing of serotonin receptor 2C (5-HT2CR) contributing to post-SCI spasticity. Editing of 5-HT2CR is catalyzed by RNA-specific adenosine deaminases (Adar1-2). The extent of editing correlates with 5-HT2CR functional activity: more highly edited isoforms exhibit the least function. Editing substantially increases the functional plasticity of this key neurotransmitter receptor and is thought to contribute to homeostatic mechanisms in neurons. In this work we studied post-SCI mRNA editing and genome-wide RNA expression in a chronic spinal rat model of spasticity using massively parallel sequencing. We detected that the decrease in 5-HT2CR editing is caused by down-regulation of Adar2 and that editing of at least one other Adar2 target, potassium channel Kv1.1, is decreased after SCI. Bayesian network analysis of genome-wide transcriptome data indicates that down-regulation of Adar2 (1) is triggered by persistent inflammatory response to SCI that is associated with activation of microglia and (2) results in changes in neuronal gene expression that are likely to contribute both to post-SCI restoration of neuronal excitability and muscle spasms. The results of this work start to elucidate the specific molecular mechanisms that are associated with alterations of RNA editing in SCI and ultimately could lead to effective anti-spasticity treatments.

Title: HuR modulates the inflammatory response in astrocytes following spinal cord injury

Authors: ***T. KWAN**[1], C. L. FLOYD[2], P. H. KING[3];
[1]Univ. of Alabama At Birmingham, Birmingham, AL; [2]Physical Med. and Rehabil., [3]Neurol., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Background/hypothesis: A rapid induction of inflammatory cytokines in glial cells is generated within minutes following traumatic spinal cord injury (SCI). This initiates a cascade of events that contributes to secondary injury to the spinal cord over time. The RNA binding protein human antigen R (HuR) is reported to bind and stabilize the mRNAs of multiple inflammatory cytokines and chemokines. We hypothesize that reducing HuR expression or activity will dampen the inflammatory response elicited by astrocytes. An increase in HuR expression/activity will result in the opposite. The ability of HuR to modulate the expression of multiple inflammatory cytokines could have implications on damage resulting from secondary injury from SCI and thus, functional recovery. Methods: Primary cortical astrocytes were subjected to a mechanical stretch injury to emulate the viscoelastic forces that occur during trauma to CNS tissue. HuR expression in astrocytes was either knocked down using siHuR or inhibited using MS-444, a small molecule HuR inhibitor. mRNA and protein for the cytokines/chemokines TNFα, IL-1β, IL-6, CXCL-1, LIF and CCL2 were measured 24 hours after stretch injury. *In vivo*, neurons were counted in female FlagHuR-astrocyte transgenic mice and compared against WT mice 24 h after a midthoracic contusion injury. FACS was used to measure neutrophil and microglia/macrophage populations in transgenic and WT mouse spinal cords 24h post-injury. Results: In our *in vitro* model, HuR knockdown and MS-444 treatment reduced the expression of a number of cytokines/chemokines at both the mRNA and protein level. *In vivo*, spinal cords in the transgenic mice overexpressing HuR in astrocytes had fewer neurons at the epicenter of injury 24 hours after SCI and a trend toward increased neutrophil invasion. Conclusion: 1. Knockdown/inhibition of HuR attenuated inflammatory cytokine induction in mechanically stretched astrocytes. 2. Transgenic HuR expression in astrocytes enhanced neuronal loss. 3. The

data suggests that HuR may be a viable target in controlling inflammation and secondary damage in the context of spinal cord injury.

Title: Activated astrocytes modulate survival and fate specifications of adult spinal cord neural precursor cells

Authors: ***C. HART**, S. M. DYCK, S. KARIMI-ABDOLREZAEE;
Physiol. and Pathophysiology, Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: Neural stem/progenitor cells (NPCs) that reside in the adult spinal cord become activated following spinal cord injury (SCI) and contribute to generation of new glial cells. Despite their intrinsic ability to generate both oligodendrocyte and astrocytes, adult NPCs predominantly differentiate into astrocytes in the post-SCI milieu, with only a limited number giving rise to oligodendrocytes. This evidence implicates a role for the injury microenvironment in influencing the regenerative response of spinal cord NPCs. Astrocytes are a key modulator of their microenvironment both in the normal and injury conditions. Following SCI, resident astrocytes undergo drastic changes that result in their transition into an activated inhibitory phenotype. Here, we investigated how reactive astrocytes influence the cellular properties of spinal cord derived NPCs in their post-injury environment using an *in vitro* model of reactive astrogliosis. Rat primary astrocyte cultures were activated by lipopolysaccharide (LPS) and transforming growth factor beta (TGF-β). Astrocyte reactivity was confirmed by increased expression of chondroitin sulfate proteoglycans (CSPGs) and proinflammatory cytokines in the conditioned media of astrocytes treated by TGF-β and LPS, respectively. Primary NPCs were harvested from the spinal cord of adult mice and propagated through passaging. Dissociated NPCs were subject to astrocyte conditioned media (ACM) of normal, LPS and TGF-β treated astrocytes. Using various cellular and molecular *in vitro* assays, we found that exposure to LPS-treated ACM markedly decreased NPCs survival and reduced their capacity for oligodendrocyte differentiation compared to the control normal ACM or serum free media. Importantly, LPS-treated ACM favored astrocyte differentiation of NPCs. We found the same but smaller effect in spinal cord NPCs subject to TGF-β-treated ACM. Interestingly, our analysis showed that increased levels of CSPGs in LPS and TGF-β treated astrocytes was in part responsible for these

inhibitory effects since removal of CSPGs with chondroitinase ABC was able to reverse some of these effects. Our data suggests the impact of reactive astrocytes in regulating the properties of NPCs in their post-injury niche. Identification of astrocyte-derived factors involved in NPCs modulation can potentially improve the regenerative response of NPCs in injury condition. Title: Dendritic plasticity of layer V pyramidal neurons in the primary motor cortex after lesions to the pyramid and thoracic spinal cord

Authors: X. LIN[1], T. ZHAO[2], X. GAO[1], W. XIONG[1], S. ZHAO[1], W. WU[1], X. PING[1], S. LIN[3], X. JIN[1], J. CHEN[1], W. GAN[4], *X. M. XU[5];
[1]Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Gen. Hosp. of Jinan Military Region, Jinan, China; [3]Beijing Inst. of Basic Med. Sci., Beijing, China; [4]New York Univ. Sch. of Med., New York, NY; [5]Neurolog. Surgery, Indiana Univ., Indianapolis, IN

Abstract: Axons originating from layer V pyramidal neurons of the primary motor cortex (M1) form the corticospinal tract (CST) that descends mainly to the ipsilateral medulla pyramid and contralateral spinal cord. Following injury, these neurons may undergo structural remodeling that affects spontaneous recovery. Here we investigated structural changes in the fore- (M1F) and hind-limb (M1H) regions of M1 as well as functional outcomes following 4 types of injuries that all induced CST axotomy: ipsilateral pyramidotomy (PX), contralateral dorsal funiculotomy (FX), contralateral spinal hemisection (HX), and complete spinal cord transection (TX) in adult rats and mice. The PX was performed at the medullary pyramid and all other injuries were performed at the 9th thoracic spinal level (T9). Combined neurobehavior (Treadscan, Basso-Beattie-Bresnahan [BBB] locomotor scale, grid walking, Morris water maze),

electrophysiological (motor-evoked potentials [MEPs]), histological (Golgi-Cox impregnation), and imaging (2-photon confocal imaging) assessments were performed to determine the relationships among motor function, pathway conductivity, and cortical plasticity. Compared to the sham-operated controls, animals receiving different injuries exhibited injury site- and severity-specific deficits and MEP alterations in fore- and hind-limb functions. Among all injury types, TX was associated with the worst spontaneous functional recovery. Two-photon imaging showed that, as early as 1 week post-PX, turnover of apical dendritic spines occurred and the rates of spine formation and elimination were significantly higher in M1F, compared to normal controls. However, PX had no significant effect on spine dynamics in M1H. Both FX and HX increased spine formation of apical dendrites whereas TX had no significant effect on spine dynamics in M1F. In the M1H region, spine elimination of apical dendrites was significantly increased following all injuries at T9. Significantly increased spine formation was found in the FX and HX but not the TX group as compared to the control. Golgi-Cox staining showed that, in the HX group, the dendritic surface area (SA) of both basal and apical dendrites was significantly increased and that, in the TX group, the total length and SA were significantly decreased. These results underscore the profound influences of synaptic structural plasticity on spontaneous recovery that occur overtime after axotomy of the layer V cortical neurons.

Title: The role of L-selectin in leukocyte recruitment and secondary pathogenesis following spinal cord injury

Authors: *D. A. MCCREEDY[1,2], C. J. SONTAG[2], S. M. LEE[2], A. F. MARTINEZ[2], T. M. FANDEL[2], S. D. ROSEN[3], L. J. NOBLE-HAEUSSLEIN[2];

Abstract: L-selectin, a receptor expressed on all leukocyte classes, is implicated in adhesive and signaling roles in the recruitment of myeloid cells to sites of inflammation. Spinal cord injury (SCI) produces prolonged inflammation leading to secondary neural damage and expansion of

the spinal cord lesion area. Given its fundamental role in inflammation, L-selectin may be integral to secondary pathogenesis in the injured spinal cord. Using L-selectin knock-out (KO) mice, we observed improved neurological recovery and greater white matter sparing compared to wild-type (WT) controls that corresponded to reduced oxidative stress and degradation of myelin basic protein in the acutely injured cord. WT mice treated with diclofenamic acid (DFA), an FDA approved non-steroidal anti-inflammatory drug with high L-selectin sheddase activity, immediately post-injury showed improved recovery on the Basso Mouse Scale (BMS) and enhanced white matter preservation compared to vehicle controls. L-selectin KO mice, treated with DFA, showed similar robust levels of behavioral improvement and white matter sparing to that of vehicle treated KO mice, suggesting that the effect of DFA is specific to its L-selectin sheddase activity. To determine if shedding of L-selectin affected early leukocyte recruitment, we performed flow cytometry at 24 hours post-injury on spinal cords from WT mice treated with DFA. CD45+/Gr1+ and CD45+/CD11b+ populations were found to be significantly reduced compared to the vehicle controls. While DFA, given 3 hours post-injury, improved BMS scores and white matter sparing to levels similar to that seen in mice treated immediately post-injury, no long-term benefit was seen when DFA was initiated at 8 hours post-injury. These collective data highlight L-selectin as a novel early and temporally specific initiator of pathogenesis, presumably through mechanisms underlying early recruitment of specific subsets of leukocytes, and support the repurposing of DFA for the treatment of SCI.

Abstract: Spinal cord injury (SCI) leads to major neurological impairment, associated with significant tissue loss. Endogenous repair processes occur following SCI, but they are limited. Recent clinical trials in Alzheimer's disease have demonstrated the efficacy of Fortasyn® Connect (FC), a specific multinutrient combination that was designed to compensate for the loss of neuronal membranes and synapses in dementia patients, and that contains docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA), choline, uridine monophosphate, phospholipids, folate, vitamins B6, B12, C, E and selenium. We tested if this multinutrient combination countered the tissue destruction occurring after SCI and supported regenerative processes, improving the neurological outcome. Adult rats received an injury induced by cord compression at thoracic level, and immediately after SCI they were fed daily with a control diet or a diet supplemented with different doses of the specific FC multinutrient combination (low dose FC, medium dose FC, or high dose FC) for 4 or 9 weeks. At 4 weeks, only 50% of rats that were fed the control diet were able to plantar place their paws, and only 2 rats had recovered gait coordination. In contrast, 6 out of 7 rats fed the diet with the high dose of FC had recovered a coordinated gait. Five of them showed a normal position of the paws and full recovery of toe clearance, and 2 of them showed a gait that was undistinguishable from that of uninjured rats. The BBB score was 17.1 ± 1.6 in this group, in comparison with the BBB score of 8.8 ± 1.3 in rats fed the control diet. This was accompanied by significant protection of oligodendrocytes and myelin in the injured tissue, a decreased microglial neuroinflammatory response, and an increase in pre- and postsynaptic markers. The medium dose of FC that did not show efficacy after 4 weeks of treatment led to improved motor score, increased neuronal and oligodendrocyte survival, decreased microglial activation, and better axonal preservation after 9 weeks of supplementation. These results suggest that a diet supplemented with this specific multinutrient combination has marked therapeutic potential in SCI.

Title: Effect of PPAR-γ agonist on inflammatory mediators in rats following spinal contusion

Authors: J. OH[1], G. PARK[1], Y. KIM[1], J. KIM[2], *Y. W. YOON[1];
[1]Korea Univ. Col. Med., Seoul, Korea, Republic of; [2]Korea Univ. Col. Hlth. Sci., Seoul, Korea, Republic of

Abstract: Lipid metabolism is important to the nervous system owing to the myelin sheath. After spinal cord injury, inflammatory mediators such as eicosanoids are released and they act as peroxisome proliferators that activate peroxisome proliferator activated receptors (PPARs), which play a key role in lipid metabolism and cellular differentiation. PPARs are classified into three isoforms (α, β/δ, γ) in the spinal cord. Above all, PPAR-γ is the most studied and its agonist, pioglitazone, is clinically used for the diabetes treatment. Previously, PPAR-γ shows as an anti-inflammation action. Thus, we investigated how the PPAR-γ agonist affects inflammatory mediators and motor function recovery in spinal contusive rats. Male Sprague-Dawley rats were anesthetized with ketamine/rompun mixture (1:4). Ten gram weight dropped from 12.5 mm height onto the spinal cord of the 10th thoracic vertebral level in rats after laminectomy using NYU device. We examined protein expression of PPAR-γ in the rostral, caudal, injured epicenter and L4-5 of the spinal cord at various times after injury (6, 12, 24h, 3d, 1, 3 and 5 weeks). Pioglitazone or vehicle (100% DMSO) was administered by intrathecal or intraperitoneal injection in the early phase and late phase after SCI. After drug administration, motor function was assessed using a BBB locomotor scale, and mRNA expression of inflammatory mediators was analyzed by real-time PCR. Protein expression changes of PPAR-γ was excessively increased from 6 hours and the increment was maintained for a long time after injury. That was the greatest in the epicenter and affected to the remote L4-5 spinal segments. In the early phase, intraperitoneally injected pioglitazone did not affect motor function compared with vehicle. Recovery of the joint movement was improved by Intrathecal injection of pioglitazone, however, no difference after that. In the late phase when PPAR-γ expression returned to basal level, intrathecal administration of pioglitazone restrained locomotion. After intrathecal administration of pioglitazone, protein expression of PPAR-γ and α was increased but not changed beta/delta in spinal contusive rats. On the contrary to previous reports, mRNA expression of iNOS, COX-2, IL-1B, IL-6 and chemoattractants was increased after that. Therefore, our results demonstrated that the PPAR-γ agonist may be positively help to induce the essential inflammatory mediators in the early phase, but may exacerbate motor recovery in the late phase after spinal cord injury.

Title: Acute neuroprotection after spinal cord injury - going solo or in need of a friend

Authors: ***N. SILVA**, N. VASCONCELOS, E. GOMES, E. OLIVEIRA, C. SILVA, R. SILVA, R. LIMA, N. SOUSA, A. SALGADO;
Life and Hlth. Sci. Res. Inst. (ICVS), Sch. of Hlth. Sci., Braga, Portugal

Abstract: Damage to the spinal cord can result in irreversible impairments or complete loss of motor, autonomic and sensory functions. Systemically administered riluzole and magnesium chloride have been widely investigated as neuroprotective agents in animal models of spinal cord injury (SCI) and were found to promote both locomotor improvements and tissue sparing after SCI. Therefore, we aimed to investigate the neuroprotective efficacy of individual and combined administration of these drugs. An *in vivo* experiment was set using nineteen female Wistar-Han rats that underwent a thoracic spinal cord contusion (T8) using a weight drop method to induce severe injury. An hour after injury, animals were randomly distributed to receive: 1) riluzole (2.5 mg/kg,) 2) magnesium chloride (24.18 mg/kg) in a PEG formulation, 3) a combined treatment (riluzole and magnesium), or 4) saline. Subsequent treatments were given in 4 intraperitoneal injections (spaced 12 hours apart). The Basso, Beattie, and Bresnahan (BBB) locomotor rating scale, an activity box test, and a swimming test were used to evaluate behavioral recovery. Histological analysis of the spinal cords was performed to measure the extent and volume of the lesion, neuronal survival, inflammation, axonal preservation, seratonergic and glutamatergic fiber sparing, and myelin degeneration. Our results show that only the riluzole treatment significantly improved behavioral recovery, promoted tissue sparing, diminished lesion volume, increased seratonergic fiber sparing and axonal preservation in the caudal portion of the spinal cord. The combined treatment, although simultaneously targeting several excitotoxic-related mechanisms, did not further improve behavioral and histological outcome when compared with riluzole given alone.

Title: Functional recovery conferred by a prophylactic Omega-3 and Vitamin E-enriched diet and its potential link to the scavenger receptor/lipid transporter CD36 in spinal cord injury

Authors: *K. CORDERO, J. D. FIGUEROA, M. DE LEÓN;
Loma Linda Univ. Sch. of Med., Loma Linda, CA

Abstract: Spinal cord injury (SCI) is a major cause of disability in the US, devastating the lives of more than 12,000 young adults annually. Although SCI may prove difficult to prevent in most instances, there is a need to further investigate factors affecting susceptibility to damage in the event of injury. In ongoing studies, we have shown that the metabolism of fatty acids is markedly deregulated acutely after SCI, determining the extent of functional recovery after such insult. Emerging observations from our lab show that omega-3 polyunsaturated fatty acids (O3PUFAs) and vitamin E are major modulators of repair mechanisms following SCI in rodents. However, the molecular mediators coupling these beneficial fatty acids to functional recovery after SCI remain understudied. The fatty acid translocase membrane cluster of differentiation 36 (FAT/CD36) is a B class scavenger receptor highly expressed in models of neurological injury and implicated in the uptake and signaling of fatty acids and vitamin E. FAT/CD36 have been shown to be both beneficial and detrimental after injury. Our preliminary evidence suggests that the lipid microenvironment may determine the role of FAT/CD36 after injury. Our objectives are to 1) characterize the spatiotemporal expression and functional roles of CD36 after SCI and 2) determine how if FAT/CD36 contributes to Vitamin E-mediated protection. Our central hypothesis states that FAT/CD36 is acutely upregulated following SCI and its blockade impairs the protective effects of vitamin E and possibly other hydrophobic molecules. This hypothesis is based on: 1) FAT/CD36 ability of transporting hydrophobic molecules such as O3PUFAs and Vitamin E 2) our studies showing that O3PUFAs are neuroprotective after SCI. Our rationale is that, knowledge of how O3PUFAs and vitamin E modulate protection after SCI will provide the foundation for the development of interventions aimed at restoring function. This is expected to help to reduce the disease burden by identifying novel therapeutic targets. We analyzed locomotion recovery, H-reflex depression, bladder recovery, and the temporo-spatial expression of CD36 after contusive injury to the rat spinal cord using behavioral and electrophysiogical studies, Credé's maneuver, immunoblotting and double-labeling immunofluorescent experiments. Our data demonstrates that Vitamin E and O3PUFAs accelerate locomotor and bladder recovery, improves H-reflex depression, and that acute SCI results in a marked upregulation of CD36. Our next step is to determine a possible mechanism through which Vitamin E is improving functional recovery and find if there is a link between Vitamin E protection and CD36 after SCI.

Title: Ephb3 receptors function as dependence receptors to mediate oligodendrocyte cell death following contusive spinal cord injury

Authors: *Y. E. TSENKINA[1], J. RICARD[2], E. RUNKO[1], M. M. QUIALA-ACOSTA[1], J. MIER[1], D. J. LIEBL[1];
[1]Neurosurg., Univ. of Miami Miller Sch. of Med., Miami, FL; [2]Dept. of Biol., Drexel Univ., Philadelphia, PA

Abstract: Spinal cord injury (SCI) leads to functional impairment resulting from regional cell death. SCI-induced apoptosis persists for days to weeks after the initial trauma, where the myelin-producing oligodendrocytes (OLs) are highly susceptible. OL loss underlies progressive demyelination and axonal degeneration contributing to motor disability. Therefore, it is important to examine the mechanisms leading to OL death in the injured spinal cord. Previously, we identified new pro-apoptotic receptors, belonging to the dependence receptors family, that activate terminal caspases in the absence of their cognate ligand(s). Dependence receptors fulfill dual functions depending on their ligand availability. During normal development and tissue homeostasis, they interact with their ligand(s) to promote cell survival, migration and differentiation. However, when deprived from their ligand(s), they can trigger and/or amplify caspase-mediated apoptosis. Ephrins and Eph receptors are membrane-bound proteins that require cell-cell interactions and are known regulators of axon path finding, cell proliferation, migration and synaptic plasticity. In the adult central nervous system (CNS), EphB3 receptors regulate neural progenitors and neuronal survival following traumatic brain injury, supporting a dependence receptor role for EphB3. These studies also revealed that EphB3 could have a pro-apoptotic role enhancing the survival of multiple cell types in the injured CNS. In the present study, we demonstrate that EphB3 receptors mediate OL cell death in the injured spinal cord through dependence receptor mechanism. OLs in the adult spinal cord express EphB3 as well as other members of the Eph receptor family. SCI is associated with tissue damage, cellular loss and disturbances in EphB3-ephrinB3 protein balance acutely after the insult creating an environment for a dependence receptor-mediated cell death to occur. Ablation of EphB3 promotes OL survival associated with increased expression of myelin basic protein and improved locomotor function in mice after SCI. Furthermore, chronic infusion of ephrinB3 to the spinal cord after injury also promotes OL survival. Our *in vivo* findings are supported by *in vitro* studies showing that ephrinB3 administration promotes the survival of both oligodendroglial progenitor cells as well as mature OLs cultured under pro-apoptotic conditions. Our study demonstrates a novel dependence receptor role of EphB3 in OL cell death after SCI, and supports further development of ephrinB3-based therapies to promote recovery.

Title: De-novo myelination of grafted neural progenitor cells in the adult cns

Authors: *M. A. HUNT[1], P. LU[2,3], M. H. TUSZYNSKI[2,3];
[1]Biomed. Sci., [2]Neurosci., Univ. of California San Diego, LA Jolla, CA; [3]Veterans Affairs Med. Ctr., San Diego, CA

Abstract: We previously reported that neural progenitor cells (NPCs) grafted into sites of spinal cord injury (SCI) exhibit extensive axonal outgrowth and formation of new synaptic connections with host neurons, forming novel functional neural relays across lesion sites. In the present study we performed a detailed characterization of axons emerging from NPC grafts. Rat embryonic spinal cord-derived NPCsderived NPCs, constitutively expressing EGFP, were grafted into adult C5 spinal cord hemisections. Three months after grafting, we examined graft-derived axonal diameter and myelination using transmission electron microscopy. In total, 104 graft-derived axons were characterized. Axon diameter ranged from 0.15 to 1.70 μm, and 23% of graft-derived axons were myelinated. The average diameter of myelinated axons (0.72 ± 0.3μm) was significantly larger than that of non-myelinated axons (0.61 ± 0.2μm, $p<0.05$). Notably, the G-ratio of myelinated graft-derived axons was comparable to that of developmentally myelinated axons (0.77 ± 0.05 μm). 67 % of graft-derived axons were in direct contact with host myelin, suggesting that myelin does not repel axons extending from implants of early stage neurons. Title: Attentional effects on the auditory steady-state response in schizophrenia-related disorders

Authors: *L. MORAVEC[1], J. M. HOWELL[2], D. R. WESTFALL[3], D. EWBANK[2], W. P. HETRICK[2], A. R. BOLBECKER[2], A. BREIER[4], B. O'DONNELL[2];
[1]Psychological and Brain Sci., Bloomington, IN; [2]Psychological and Brain Sci., Indiana Univ., Bloomington, IN; [3]Univ. of Illinois at Urbana-Champaign, Urbana, IL; [4]Dept. of Psychiatry, Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Auditory steady state response (ASSR) measures of power and phase synchronization have been reported to be reduced in schizophrenia, most consistently to 40 Hz stimulation. It is possible that a task requiring selective attention to a 40 Hz stimulus might reverse this deficit. In order to test this hypothesis, click trains were used to generate ASSRs at different frequencies of stimulation in an auditory discrimination task. Sixty four patients with a psychotic disorder (schizophrenia, schizo-affective, schizophreniform, or psychotic NOS) and 126 healthy control subjects were tested. The auditory discrimination paradigm used three different stimuli: a 20 Hz click train, a 40 Hz click train, and a distractor tone. Each stimulus was 1000 ms in duration presented at 90 dB SPL with 500 ms inter-stimulus interval. Two conditions were used, each with 400 stimuli. In one condition, the 40 Hz click train was the target; in the second condition, the 20 Hz click train was the target. The subject pressed a button to respond to target stimuli. Within a condition, stimulus probabilities were: target click train (p=.15), non-target click train (p=.70) and distractor tone (p=.15). A 32 channel electroencephalogram (EEG) was recorded from each subject with a sampling rate of 1000 Hz (bandpass:0.1 to 100 Hz). The EEG data was sampled at 1000Hz/channel and filtered from 0.1 to 100 Hz. ASSRs were obtained after averaging EEG across trials for the 20 and 40 Hz click train responses in each condition and applying a fast-Fourier transform to measure power at the stimulus frequency during the stimulus period. Independent sample t-tests showed that 40 Hz power was reduced for both the target and non-target 40 Hz click trains; while 20 Hz power did not differ between groups in either condition. Thus, the 40 Hz deficit observed in schizophrenia-related psychotic disorders appears regardless of the task relevance of a stimulus. Conversely, 20 Hz stimuli are not associated with an disturbed ASSR, even at high levels of attentional demand. These data provide further support for a selective gamma frequency range deficit in the auditory modality in schizophrenia.

Title: Prior cannabis abuse exacerbates impairments in action monitoring in first episode psychosis

Authors: *C. P. WALKER[1], S. BANGALORE[2], E. BELCHER[3], M. CARL[4], R. ZENISEK[5], R. Y. CHO[6];
[1]Psychiatry, Univ. of Texas Hlth. Sci. Ctr. At Houst, Houston, TX; [2]Univ. of Pittsburgh, Pittsburgh, PA; [3]Translational Biomed. Sci., Univ. of Rochester, Rochester, NY; [4]Dept. of Psychology, Univ. of Tennessee, Knoxville, TN; [5]Dept. of Psychology, Univ. of Nevada, Las Vegas, Las Vegas, NV; [6]Psychiatry, Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX

Abstract: Mounting evidence suggests a close relationship between the pathophysiologic mechanisms underlying psychosis and cannabis abuse. This association may be unsurprising, given the dense expression of the cannabinoid CB1 receptors in regions associated with executive functions and action monitoring which are known to be impaired in psychotic illness. One of the critical impairments in psychosis involves the anterior cingulate cortex (ACC) which supports action monitoring processes. However, the impacts of prior cannabis usage on cognitive control and ACC function in psychosis are as yet unexplored. To that end, we recruited 76 participants (24F, M_{age}=22) for an EEG study of the Stroop task. Participants were 34 psychiatrically normal controls, half of whom reported current cannabis abuse and 42 first-episode, med-naive psychosis patients, half of whom were comorbid for cannabis abuse. High-density EEG data were collected, and correct and error response-locked event-related potentials (ERPs) were submitted to a three-stage analysis pipeline using a combination of principal component analysis, independent component (IC) analysis, and permutation testing to reduce noise and data dimensionality. We identified three ICs corresponding to the expected spatial and temporal patterns of traditional ERP analyses of the error-related negativity (ERN; 0-100 ms, frontal distribution) and error-positivity (Pe; 200-400 ms, posterior distribution) which colocalize to generators in the ACC. Behaviorally, cannabis abusers (p=0.009) and psychosis patients (p=0.045) responded slower than healthy non-users. These effects were found to be additive, with no effects found for accuracy. ERP analyses revealed an anterior ERN IC demonstrating reduced amplitudes for cannabis abusers only (p=0.025) irrespective of psychosis diagnosis status, while a posterior Pe IC revealed a cannabis by psychosis interaction (p=0.041) where cannabis abusing patients were found to have a smaller Pe compared to all other groups. This pattern suggests error detection processes are relatively conserved in first-episode psychosis except in the context of comorbid cannabis abuse which then resembles impairments more typical of chronic patients. To our knowledge, this is the first investigation of the effects of cannabis abuse on psychosis and action monitoring, highlighting the link between cannabis abuse and early exacerbation of cognitive deficits in psychotic illnesses.

Title: Converging evidence of aberrant neural synchrony in schizophrenia and relatives

Authors: *E. H. ANDERSEN[1], A. M. CAMPBELL[2], S. E. SCHIPUL[2], S. E. SCHIPUL[2], A. BELGER[2];
[1]Psychiatry, Univ. of North Carolina, Chapel Hill, NC; [2]Univ. of North Carolina - Chapel Hill, Chapel Hill, NC

Abstract: Schizophrenia (SCZ) is characterized by disruptions in both affective and cognitive processes. The integration of these processing domains relies on effective neural communication, which can be indexed by EEG neural synchrony measures of evoked power (EP) and phase-locking factor (PLF) in the time-frequency domain in response to events. In the current study, we examine neural synchrony in two paradigms that recruit the interplay of cognitive and affective systems, and how neural synchrony measures relate across tasks. Participants were recent onset SCZ patients (n=15), familial high-risk (HR, n=14) participants, and matched healthy controls (CON, n=17). The Emotional Oddball (EO) task was a visual oddball with emotional distractors. The Emotional Working Memory (WM) task was a 1-back task with positive, neutral, or negative emotional stimuli. Results EO: We found reduced EP and PLF in the delta band (1-4Hz) to targets in SCZ ($p<.05$) and HR ($p<.05$) relative to CON, reflecting impaired directed attention. Reduced EP ($p<.05$) and PLF ($p<.05$) in the theta band (4-8Hz) to aversive distractors was found in SCZ relative to CON, indicating aberrant task-irrelevant emotional processing. HR participants showed a unique enhancement of EP in beta (16-30Hz) to aversive distractors ($p<.05$), suggesting heightened sustained emotional processing. Emotional WM: A significant Group (CON, HR, SCZ) X Condition (positive, neutral, negative) interaction ($F(4, 74)=3.77$, $p<.01$) revealed elevated EP in theta in response to aversive stimuli for HR compared to CON ($p<.05$) and SCZ ($p=.01$), reflecting increased WM processing. Relating synchrony across tasks,

we found that sustained affective processing (beta EP) in the EO task related to inhibition (delta EP) necessary to maintain task goals ($r=.48$, $p<.05$) and to task-relevant aversive target theta EP ($r=.54$, $p<.001$) in the Emotional WM across groups. HR alone showed a correlation between affective processing to aversive stimuli (beta EP) and WM load-related theta EP for aversive targets (CON: $r=-.26$, $p=.39$; HR: $r=.61$, $p<.05$; z-diff=2.42, $p<.01$). This work suggests that crucial neural connectivity underlies the integration of affective and cognitive processing across both task-irrelevant and task-relevant emotional information. These connections show disruptions (reflected in neural synchrony) in both SCZ and HR, which may affect the integration or inhibition of emotional information within cognitive tasks. Future directions: fMRI data was also collected and analyzed for these paradigms and will provide further understanding of the neural circuitry supporting the dynamics between cognitive and affective systems.

Title: Spindle deficits, cognitive impairment and real-life functioning in schizophrenia

Authors: R. A. FOWLER[1,2], *D. CORRELL[1,2], B. BARAN[1,2], C. DEMANUELE[1,2], T. VUPER[1,2], B. SEICOL[3], C. CALLAHAN[3], E. PARR[3], R. STICKGOLD[3], D. MANOACH[1,2]; [1]Psychiatry, Massachusetts Gen. Hosp. (MGH), Charlestown, MA; [2]Athinoula A. Martinos Ctr. for Biomed. Imaging, Charlestown, MA; [3]Dept. of Psychiatry, Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: Sleep spindles correlate with human intelligence and are thought to mediate sleep-dependent memory consolidation. Schizophrenia (SZ) patients have markedly reduced sleep-dependent consolidation of motor procedural memory that correlates with reduced sleep spindle density. We investigated whether decreased sleep spindle density also correlates with worse performance on cross-sectional cognitive measures and real-life functioning in SZ. In a baseline visit, 23 SZ patients and 27 demographically-matched healthy controls were administered the MATRICS Consensus Cognitive Battery (MCCB) and the Wechsler Abbreviated Scale of Intelligence (WASI). Only patients also completed the UCSD Performance-based Skills Assessment (UPSA) to assess real-life function. A week later, participants were monitored with inpatient polysomnography for two nights. They learned a motor sequence task (MST) on the

second night and were tested the following morning. Sleep spindles during stage 2 sleep (N2) were identified using a wavelet spindle detector. Spindle density was calculated as the number of spindles per minute of artifact-free N2 sleep and averaged across the two nights. SZ participants had significantly lower IQ estimates on the WASI and worse performance on the MCCB (composite score). Sleep data were available for a subset of participants (12 patients, 12 controls). Patients showed a non-significant reduction in spindle density compared to controls (2.12±.44 vs. 2.34±.48: t(22)=1.13, p=.27). Spindle density inversely correlated with UPSA scores (r=-.60, p=.04) and verbal IQ in patients only (trend, r=-.54, p=.07). These correlations are not significant with correction for multiple comparisons. There was no significant correlation between spindle density and MCCB scores in either group. In line with our previous results, we observed a positive trend level correlation of spindle density with overnight improvement on the MST (r=.49, p=.13). Contrary to our hypotheses, real life functioning and higher verbal IQ correlated with decreased spindle density. However, we replicated previous findings that spindle deficits in SZ correlate with motor procedural memory consolidation on the MST. These findings may reflect that sleep-dependent memory consolidation is more proximally related to spindle density than cross-sectional cognitive measures or functional outcome. We are presently increasing the sample and analyzing the remaining sleep data to better understand the relations between sleep spindles, cognitive measures and functional outcome.

Title: Hallucinations and immunoreactivity: IL-6 is elevated in subjects who experience 'Voices Conversing'

Authors: C. ROSEN[1], K. A. CHASE[1,2], B. FEINER[1], J. MELBOURNE[1], H. GIN[1], *R. P. SHARMA[1,3];
[1]Dept Psychiatry, Univ. of Illinois at Chicago, Chicago, IL; [2]Dept. of Human Genet., Univ. of Chicago, Chicago, IL; [3]Jesse Brown Veterans Affairs Med. Ctr., Chicago, IL

Abstract: Background: Within a spectrum model of psychosis, utilizing a finely grained map of hallucinatory experiences allows for the integration of an underlying symptom dimension to

possible biological or pharmacological measures. Thus, the details of a hallucinatory experience such as ‘voices conversing’ may be better understood by an association with a biological variable such as an immunoreactive molecule. This type of analysis is relatively unexplored. Methods: Seventy-four participants with present-state psychosis with AVHs were recruited from the University of Illinois at Chicago. Inclusion criteria for the study included persons between the ages of 21 - 60 who were currently experience auditory verbal hallucinations. The results of this study constitute the findings of an investigation that explores quantitative and qualitative methodologies of the Schneiderian classification of auditory hallucinations, specifically of voices conversing. Participants were categorized as experiencing ‘voices conversing’ or ‘voices not conversing,’ and symptom differences were compared on the PANSS subscales. Levels of IL-6 mRNA were examined in peripheral blood mononuclear cells (PBMC) from these subjects through real-time RT-PCR. IL-6 mRNA values were normalized to GAPDH and β-Actin, and computed using a geometric mean. Results: When comparing these two groups, we found that participants who experienced voices conversing also demonstrated increased positive symptoms, cognitive disorganization, depressive symptoms and thought disturbances than those who did not experience voices conversing. Additionally, IL-6 mRNA levels were significantly elevated in those participants who did experience voices conversing when compared to those who did not experience voices conversing. Discussion: AVHs are among the most experientially complex transdiagnostic symptoms; thus research that explores potential clinical and biological associations can have significant translational and nosological implications. In this exploratory analysis, we demonstrate that immunoreactivity, a widely supported abnormality in psychotic disorders, is also enhanced in Schneiderian based symptomology of voices conversing, which may indicate a symptom specificity that extends beyond diagnostic characterization.

Title: Magnocelullar deficits in high-risk psychosis syndrome: an ERP study

Authors: *S. A. CORRAL[1], B. ABURTO[1], R. CASTILLO[1], R. MAYOL[1], A. MATURANA[1], V. DE ANGEL[1], D. GONZALEZ[1], H. SILVA[1], A. MARTINEZ[2], P. A. GASPAR[1];
[1]Univ. of Chile, Santiago, Chile; [2]Columbia Univ., New York, NY

Abstract: Background: Cognitive deficits found in schizophrenia (SZ) have been widely studied and may be mainly explained by changes in multimodal cortical areas. However, recent evidence suggests that the deficit could be begin at a sensory processing level. This can be measured by visual event-related potentials (ERP) such as the P1/N1 complex, mainly in the magnocellular pathway. The aim of this study is to determine whether there is a deficit in visual attentional processing in UHR subjects and evaluate potential alterations in the magno and parvocellular pathways. Methods: In this study (N = 6) healthy controls (HC) were evaluated and (N = 6) patients with UHR syndrome as diagnosed by the Structured Interview for Prodromal Symptoms (SIPS). Both groups were presented with visual attention stimuli on a screen where high and low spatial frequency (SF) gabors were observed. These were designed to evaluate the performance of the parvocellular and magnocellular pathways respectively. During the execution of this task, electrical activity was recorded using a Biosemi 64-channel electroencephalogram (EEG). The average evoked activity by an analysis of event related potentials (ERP) was then obtained. Results: In the low SF condition, the amplitude of the P1/N1 complex was altered in the UHR group compared to HC. Additionally, the UHR group had a significantly lower number of correct responses in low SF stimuli in the task. Conclusions: Amplitude changes in the P1/N1 complex in the magnocellular pathway in patients with SZ have been consistently found in previous literature. However there is little evidence of this in an UHR population. The abnormality in the amplitude of the P1/N1 complex observed in people with UHR may be important to understand visual sensation alterations in this at risk population.

Title: Gamma band auditory steady-state responses in first episode psychosis and chronic schizophrenia

Authors: *N. ORIBE[1,2], H. KUGA[2], I. NAKAMURA[1], Y. HIRANO[1], T. ONITSUKA[1], T. UENO[2];
[1]Kyushu Univ., Fukuoka, Japan; [2]Natl. Hosp. Organization Hizen Psychiatric Ctr., Yoshinogari, Japan

Abstract: Background Gamma band auditory steady state response (ASSR) have been reported to be abnormal and considered to be a robust biomarker in chronic schizophrenia patients. However, whether ASSR is compromised in the early course of the illness or not is yet to be determined since there have been only a few reports regarding with the ASSR in first episode schizophrenia. In addition, none of the previous studies employed higher frequency stimuli than 40Hz. Methods We measured ASSR responses in chronic schizophrenia patients (SZ, N=26), first episode psychosis patients (FEP, N=6) as well as healthy control subjects (HC, N=35) while presenting click trains varying in rate of stimulation (20, 30, 40 and 80 Hz). EEG-evoked power and phase locking were obtained in response to each stimulation frequency. Results SZ showed significant reduction in phase locking to the 40Hz stimuli compared with HC while FEP showed intact responses both in phase locking and evoked power to the 40Hz stimuli. There were no significant group differences in responses to other frequency bands. Conclusions These results suggest that neural circuits abnormalities indexed by the ASSR are differentially altered in the course of the illness.

Title: Chondroitin Sulfate Proteoglycan expression in the human olfactory system: implications for the pathophysiology of schizophrenia

Authors: *F. J. HAMATI[1], A. BOYER-BOITEAU[1], H. PANTAZOPOULOS[1], S. BERRETTA[1,2];
[1]Translational Neurosci. Lab., McLean Hosp., Belmont, MA; [2]Dept. of Psychiatry, Harvard Med. Sch., Boston, MA

Abstract: Background: Chondroitin sulfate proteoglycans (CSPGs), one of the main components of the brain extracellular matrix, were found to be altered in the medial temporal lobe, prefrontal cortex and olfactory epithelium (OE) of people with schizophrenia (SZ). These molecules are

robustly expressed in the olfactory system, where they regulate neuronal differentiation and axon guidance. Interestingly, odor identification deficits have been observed in patients with SZ and first-degree relatives. Together, these observations suggest that a disruption of CSPG expression in the olfactory system may contribute to the olfactory deficits observed in SZ. As a first step toward testing this hypothesis, we are investigating the pattern of CSPG expression in the olfactory mucosa (OM) and bulb (OB) of healthy individuals. More precisely, we are testing the hypothesis that distinct CSPGs surround olfactory axon bundles, forming channels that guide them through the OM to their odor-specific glomeruli within the OB. Methods: Dual and triple antigen immunofluorescence was used on OM and OB sections from healthy human subjects to label the axons of olfactory receptor neurons (ORN), and investigate their relationship with CSPGs, as labeled with the lectin, wisteria floribunda agglutinin (WFA), or Aggrecan and 6-sulfated (CS56) CSPG-immunodetection. Results: In the OM, CSPGs form complex, channel-like structures that tightly surround ORN axon bundles. Distinct channel-like structures were labeled by different CSPGs with no detectable overlap, suggesting CSPG-specific segregation of ORN axon bundles. In the OB, CSPG-labeling surrounds incoming axonal bundles along the superficial olfactory nerve layer in addition to their corresponding glomeruli. However, consistent with the pattern in the OM, distinct CSPGs showed preferential and non-overlapping distribution patterns, for instance, CS56-IR was found only superficially, exclusively surrounding ORN axon bundles but not the glomeruli, while WFA-IR showed opposing medial expression patterns. Conclusion: Our results show that non-overlapping CSPGs form channel-like structures that surround ORN axon bundles. Although preliminary, our results suggest that, in the human olfactory system, distinct CSPGs guide these ORN axon bundles to their corresponding odor-specific glomeruli. If so, disruptions of CSPG expression in the olfactory system of patients with SZ may contribute to the pathophysiology underlying odor identification deficits observed in this disorder. These results provide useful insights into the role CSPGs play in regulating axon guidance during brain development.

Title: Abnormalities in P300 reveal impaired working memory processing in subjects at high-risk of psychosis

Authors: R. I. CASTILLO[1,2], R. MAYOL[3], S. A. CORRAL[2], B. ABURTO[2], V. DE ANGEL[1], H. SILVA[1,4], D. GONZALEZ[2], *P. A. GASPAR[5,1,4,2];

Abstract: Background: Working memory (WM) abnormalities represent a core cognitive dysfunction in Schizophrenia (SZ). The decrease of the P300 visual evoked-potential (VEP) component is considered a physiological phenomenon when increasing WM load. Abnormalities of P300 amplitude have been classically associated to neurophysiological abnormalities of WM processing in SZ. However, little is known about these abnormalities in high-risk state psychosis (HR) population. Methods: To further investigate this topic, we performed a 64-channel electroencephalogram (EEG) while executing a Sternberg WM task in 6 HR subjects and in 6 matched healthy controls (HC). Then we did a VEP analysis in order to study the neurophysiological mechanisms underlying the WM cognitive processing in this population. We also compared these data to WM behavioral scores in all subjects. Results: Controls showed an inverse correlation between P300 amplitude and WM load. In contrast, HR subjects showed a lower amplitude in all conditions. Lower WM behavioral scores were also correlated with P300 amplitude abnormalities in HR subjects. Conclusions: These VEP P300 findings are consistent with previous research in SZ patients. Lower WM behavioral scores and their correlation with P300 abnormalities might explain in part the social difficulties seen in these subjects.

Title: The predictive power of early treatment response in first-onset psychosis: a randomized controlled trial of haloperidol versus olanzapine

Authors: *S. RASMUSSEN, P. I. ROSEBUSH, M. F. MAZUREK;
McMaster Univ., Hamilton, ON, Canada

Abstract: Background: Early response to antipsychotic treatment has emerged as a powerful predictor of treatment outcome, but there is some evidence that the predictive value of early response is poor for patients treated with olanzapine. Additionally, it is unclear whether the predictive value of early response persists throughout long-term treatment. Methods: We prospectively studied a cohort of antipsychotic-naive, first-episode psychosis patients randomized to treatment with haloperidol or olanzapine. All patients were assessed at baseline and twice weekly thereafter using the Brief Psychiatric Rating Scale (BPRS), Hamilton Depression Rating Scale (HAM-D), Hamilton Anxiety Rating Scale (HAM-A), and Young Mania Rating Scale (YMRS). Regression analyses were used to determine whether improvements on these measures at week 2 predicted improvements at discharge and at long-term follow-up. Results: 93 patients were assessed throughout hospitalization and at discharge. Length of hospital stay and overall treatment response were similar between treatment groups. In the haloperidol group, week 2 improvement was associated with improvement at discharge for BPRS total ($p<.001$), BPRS psychotic symptom subscale ($p=.010$), HAM-D ($p<.001$), HAM-A ($p=.019$), and YMRS scores ($p=.008$). In the olanzapine group, by contrast, week 2 improvement predicted improvement at discharge only for HAM-D scores ($p=.034$). 64 patients were assessed at follow-up between 14 and 39 months after their initial admission (mean=25 months). In this cohort, early response to haloperidol predicted long-term changes in BPRS total ($p=.001$), BPRS psychotic symptom subscale ($p<.001$), HAM-D ($p=.050$), and YMRS scores ($p=.049$), but not HAM-A scores ($p=.263$). Early response to olanzapine did not predict long-term outcomes on any measure. Conclusion: Early response after 2 weeks of treatment with haloperidol was predictive of improvement at discharge and at long-term follow-up 1-3 years after the initial admission. Early response to olanzapine, on the other hand, did not predict treatment outcome at either time point. These results demonstrate for haloperidol the long-term prognostic value of assessing early response to antipsychotic treatment, but suggest that, in the case of olanzapine, a more prolonged therapeutic trial may be required to assess long-term treatment efficacy.

Title: Study for the effect of carbonyl stress makers on cognitive impairment of schizophrenia

Authors: *A. KOBORI[1], S. HATAKEYAMA[1], Y. HORIUCHI[1], K. TORIUMI[1], M. MIYASHITA[2], M. ITOKAWA[1], H. ARAI[3], M. ARAI[1];

[1]Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan; [2]Shinsyu Univ. Sch. of Med., Nagano, Japan; [3]Juntendo Univ. Grad. Sch. of Med., Tokyo, Japan

Abstract: We investigated association between cognitive impairment and carbonyl stress with high plasma pentosidine and low serum vitamin B6 (pyridoxal) in schizophrenia. We divided 44 subjects with schizophrenia into 4 groups by levels of carbonyl stress markers (Group I: normal pentosidine & pyridoxal, Group II: normal pentosidine & low pyridoxal, Group III: high pentosidine & normal pyridoxal, Group IV: high pentosidine & low pyridoxal), and assessed the symptom severity by the Manchester Scale Japanese version and the cognitive function by Wechsler Adult Intelligence Scale 3rd (WAIS-III) and Wisconsin card sorting test (WCST). Data showed that schizophrenics with carbonyl stress (Group IV) had lower score of "picture completion" on WAIS, suggesting their impairments of long-term memory with visual attention in the trial. Performance Intelligence Quotient (PIQ) is a score resulting from a test that assesses capacity in dealing with non-verbal skills. "Picture completion" and "Picture arrangement" subtests of PIQ which is a non-verbal ability to perceive visual details. Our preliminary data suggest that schizophrenic patients with carbonyl stress might be associated with impairment of eye-hand coordination via visual working memory as visual attention.

Title: Detection of brain correlates of Schizophrenia deficits with a novel electroencephalography mobile system

Authors: *R. GIL-DA-COSTA[1,2], R. FUNG[2], M. CASWELL[2], T. P. COLEMAN[3], G. LIGHT[4]; [1]Systems Neurobio. Labs., Salk Inst. for Biol. Studies, LA JOLLA, CA; [2]Neuroverse, Inc., San Diego, CA; [3]Depart. Bioengineering, [4]Depart. Psychiatry, UCSD, San Diego, CA

Abstract: According to the National Institute of Mental Health, neuropsychiatric disorders will continue to affect approximately 46.4 percent of the U.S. adult population, with approximately 22.3 percent of these cases classified as "severe" (Statistics: Any Disorder Among Adults, National Institute of Mental Health). However, unlike electromyography biosensors for cardiac monitoring or diabetes glucose sensors, where a wide range of efficient commercial solutions are available, there are no adequate general public technological solutions for brain monitoring and evaluation. In a society currently affected by a wide range of mental disorders that impose

exponentially growing heavy penalties at both the individual and societal levels, the need for such systems is paramount. Currently available cognitive monitoring solutions that can assist in early detection, diagnosis and treatment efficacy are cumbersome and ill-suited for regular use, and impossible for use at home by patients and caregivers. This leads to an almost complete lack of use by clinicians and the impossibility of individual regular monitoring, which is key in today's prevention and understanding of mental illnesses. Here, we present a case-study with schizophrenia patients and healthy subjects, where we used a novel mobile forehead electroencephalographic (EEG) sensing system, with a software application for testing and analysis in mobile platforms (e.g. smartphones and tablets). We compared modulations of brain function associated with well-studied brain markers in healthy individuals, and correlated with deficits in schizophrenia. Namely, three event-related brain potentials (the mismatch negativity (MMN), P3a and reorienting negativity (RON)), recorded using this novel mobile system in 60 subjects (30 schizophrenia patients and 30 healthy controls) during an auditory oddball paradigm task. Our results show significantly reduced amplitudes for all three ERPs in schizophrenia patients, as compared to both young and age-matched healthy subjects. This findings are consistent with previous reports associating these ERP modulations to deficits in cognitive updating and attention orientation in schizophrenia. Thus, this study presents evidence of the outstanding efficacy of a novel user-friendly mobile system that can open new avenues for much needed large-scale applications in neuropsychiatric deficit detection and evaluation, clinical outcome predictability and drug efficacy evaluation.

Title: Sensory-motor control underpinnings of a baseline-pointing task in patients with schizophrenia and in neurotypical controls

Authors: *J. NGUYEN, S. M. SILVERSTEIN, T. V. PAPATHOMAS, E. B. TORRES; Grad. Program in Neurosci., Rutgers Univ., New Brunswick, NJ

Abstract: Little is known about sensory-motor integration in patients with schizophrenia (SZ). SZ is a disorder characterized by hallucinations, delusions, perceptual abnormalities, and cognitive dysfunctions. Although motor disturbances have been reported in the literature, how these symptoms relate and translate to sensory motor processes is largely unexplored (Kent et al., 2012). Moreover, clinical assessments of SZ often rely on subjective observational inventories, such as PANSS and DSM-V, to diagnose a widely heterogeneous population. It is therefore imperative to develop objective metrics that can help subtype levels of severity within SZ to serve as biomarkers for better diagnosis and treatment strategies. We examine the signatures of motor output variability of continuous reaching motions in patients with SZ in relation to typically developing controls. An established baseline-pointing task is implemented to look for underlying micro-movement motor signatures using a novel statistical platform for behavioral analyses (Torres, 2011, 2013; Torres et al., 2014). Specifically, we study motions with different levels of intent: the goal-directed reach deliberately aimed at the target, and the transitional, uninstructed retraction of the arm as subjects bring their hand to rest. The signal-to-noise patterns embedded in the motor output variability of these continuous motions are a form of kinesthetic re-afference. From trial to trial, their modulation and central control depend on the continuous returning afferent stream, which those motions themselves cause. Current research indicates that these kinesthetic parameters detect disruptions in proprioception that were previously overlooked in neurological disorders such as autism and Parkinson's disease (Torres et al., 2013; Yanovich, et al., 2013). Additionally, the Frontal Systems Behavioral Scale is administered to assess patients' abilities to manage cognitive control processes such as planning and cognitive flexibility. Preliminary results suggest that stochastic signatures of motor output variability in patients with SZ differ from neurotypical controls, particularly in the uninstructed motions that supplement each goal-directed action. These findings help characterize sensory-motor perturbations in SZ that may play a role in the onset and presence of core symptoms of SZ. By identifying these aberrations in sensor-motor processing, we gain a better understanding of the role of sensory-motor integration on executive functions, which can improve existing diagnostic tools and therapeutic interventions.

Title: The augmentation effect of electroconvulsive therapy on the antipsychotic action of medications and functional corticostriatal connectivity in patients with schizophrenia

Authors: *P. LI[1], R.-J. ZHAO[2], L. SHI[1,3], S.-Q. MENG[1,3], H.-Q. SUN[1], L. LU[1,3];
[1]Peking Univ. Sixth Hosp., Beijing, China; [2]Dept. of Alcohol and Drug Dependence, Beijing Hui-Long-Guan Hospital, Peking Univ., Beijing, China; [3]Natl. Inst. on Drug Dependence, Peking Univ., Beijing, China

Abstract: Background: Studies have demonstrated that combination of electroconvulsive therapy (ECT) and antipsychotic drugs may be more effective than drugs alone for patients with schizophrenia. However, its precise mechanism of action is stillunclear. Functional dysconnectivity of corticostriatal circuitry has been implicated as a risk phenotype for psychosis. Furthermore, the antipsychotic effects of drug treatment might result from the increased functional connectivity of the striatum with prefrontal and limbic regions. In the present study, we used resting-state functional magnetic resonance imaging (rs-fMRI) to explore the longitudinal effect of combined use of ECT and antipsychotics on functional corticostriatal circuitry in patients with schizophrenia. Methods: Twenty nine patients with schizophrenia and 30 healthy control subjects were included in this study. Patients with schizophrenia were then randomly assigned into two groups, the antipsychotics group (n=16) and ECT plus antipsychotics group (n=13). Functional connectivity of striatal regions was examined via functional magnetic resonance imaging using a seed-based approach, and patients were scanned at baseline and after 6 weeks of treatment. Results: The study finally included 39 participants (ECT plus antipsychotics group, n = 10; antipsychotics group, n =15; healthy control group, n=30). Both treatments lowered the Positive and Negative Syndrome Scale (PANSS) scores of the patients, and the combination of ECT and antipsychotics seems to be more effective against positive symptoms than antipsychotics alone ($p=0.08$). ANOVAs and subsequent post hoc t tests demonstrated significant between-group differences in functional connectivity between ventral striatum and anterior cingulate cortex, prefrontal cortex, and Inferior parietal lobule ($p<0.001$, $k>5$). The analysis also revealed a main effect of ECT plus antipsychotics on brain connectivity. The amelioration of positive symptoms by ECT plus antipsychotics was significantly correlated with increased neural activity in orbital prefrontal cortex. There was no discernible difference between groups on global cognition. Conclusion: We demonstrated that drug treatment and ECT produced antipsychotic effects by modulating corticostriatal activity, and ECT augmented the effects of antipsychotics via increasing the functional connectivity between prefrontal cortex and ventral striatum. These findings contribute to understanding the mechanisms underlying the enhancing effect of ECT on the antipsychotic actions of medications.

Title: Processing bimodal altered in individuals at high risk for psychosis: An ERP study

Authors: ***M. B. ABURTO**[1,2], R. CASTILLO[2], S. CORRAL[2], R. MAYOL[2], V. DE ANGEL[2], D. GONZÁLEZ[2], M. J. VILLAR[2], J. CORTÉS-BRIONES[3], H. SILVA[2], P. GASPAR[2,4]; [1]Univ. of Chile, Santiago, Chile; [2]Translational Psychiatry Laboratory, Dept. of Psychiatry and Mental Health, Clin. Hospital, Univ. of Chile, Santiago, Chile; [3]Yale University, West Haven, CT, United States, Santiago, Chile; [4]Biomed. Neurosci. Inst., Santiago, Chile

Abstract: Alterations in unimodal perception are symptoms frequently observed in patients with schizophrenia and individuals with the ultra high risk (UHR) syndrome of psychosis. However, the alteration in multimodal stimulus integration has not been as evaluated in patients with UHR. This multimodal integration can be studied through sensory stimuli that generate a sensory illusion, such as the double flash illusion. This occurs when a flash of light is presented between two auditory stimuli separated by 60- 100 ms - in this situation healthy people report seeing a second flash. The characteristic components of event-related potentials (ERP) evoked by this stimulus are a positive component between 60-120 ms (PD180) and a negative component between 252-284 ms (ND270). In this study we performed an ERP analysis by means of a 64-channel electroencephalogram during the execution of the double flash task in UHR subjects and healthy controls (HC). Subjects with UHR syndrome (N = 6) showed both behavioral and ERP alterations in the characteristic components of the double flash illusion. The UHR group showed a lower percentage of correct answers in the perception of the double flash illusion compared to HC. An increase in the latency of emergence of the ERP evoked by this stimulus was also observed, that is, components PD180 and ND270. These results suggest an altered processing of bimodal stimuli in the early stages of the disease. The study of multimodal alterations can be a potential biomarker for early detection in psychosis.

Title: Prevalence of psychoactive substance use and its effects on mental health of students of abubakar tafawa balewa university, bauchi, Nigeria

Authors: *Y. M. MAHMUD[1], K. A. AYANDA[2], D. SULYMAN[2];
[2]Psychiatry, [1]Abubakar Tafawa Balewa Univ. Teaching Hospita, Bauchi, Nigeria

Abstract: Alcohol and substance use are prevalent in this part of the world. Excessive alcohol intake and use of illicit drugs and substances of addiction have been associated with increased psychiatric morbidity and psychosocial problems in different populations. Studies had shown relationship between substance uses and different types of psychiatric disorders such as mood disorders, anxiety disorders, psychotic disorders as well as dementias. These disorders have been divided into substance use disorders and substance related disorders. Psychosocio-economic problems resulting from use of substances could be family discord, unemployment, conflict with law and financial difficulties. Studies have been done on the use and effects of psychoactive substances on mental health of adolescents and young adults in different settings such as motor park, schools and community. There is dearth of studies in this part of the country especially with the increase level of insecurity in this part of the country and involvement of youth in this act of violence. This present study therefore aimed to find the prevalence of psychoactive substance use among the students of Abubakar Tafawa Balewa University, Bauchi, Nigeria. It also examined types of psychiatric disorders among them and factors associated with the presence of psychiatric morbidities among youths using psychoactive substances. Pro formal questionnaire designed to obtain the socio-demographic and risk factors for psychiatric morbidity from the respondents and student substance use surveys questionnaire was administered to the students to assess their psychoactive substance use among the respondents. They were also required to complete the twelve-items, General Health Questionnaire (GHQ-12). Of the one thousand, forty seven students of the institutions given questionnaire, nine hundred and eighty three respondents returned completed questionnaires. Part of the result shows there is high prevalence of substance use among the students which likely predispose to their mental health problems. Research is still ongoing to evaluate the determinant factors for the use of these drugs and the predominant psychiatric disorder due to a particular psychoactive substance use.

Title: Aberrant activity in coherent motion perception at high risk Psychosis subjects

Authors: ***R. MAYOL**[1,2], B. ABURTO[1,2], R. CASTILLO[1,2], S. CORRAL[1,2], D. GONZÁLEZ[1,2], V. DE ANGEL[1,2], J. CORTES-BRIONES[3], H. SILVA[1,4], P. GASPAR[1,2]; [1]Univ. De Chile, Santiago, Chile; [2]Clínica Psiquiátrica Universitaria, Santiago, Chile; [3]Yale University, Dept. of Psychiatry, New Haven, CT; [4]Clínica Psiquiátrica Universitara, Santiago, Chile

Abstract: Visual Motion processing involves an integration of a distributed neural activity from long range brain areas. People with schizophrenia (Sz) have an impairment in the discrimination and detection of different kinds of motion processing such as coherent motion and biological motion. Current theories of schizophrenia have posited that abnormalities in coherent motion integration rely in difficulties in sensory processing. Little is known about the neural substrates of coherent motion perception in first episode and high risk psychosis. We hypothesized that subjects at high risk for psychosis (HRP) show deficits in the perception of coherent motion associated with late aberrant oscillatory brain activity. This research studied the electroencephalogram (EEG) activity in six high risk individuals and their corresponding healthy controls. The experiment included three motion conditions: coherent motion 100%, coherent motion 50%, incoherent motion and stationary. In the coherent condition, all dots moved from left to right within the stimuli window, and during the incoherent condition, all dots moved at randomly generated angles. Three ERPs were examined: P1, N1, and a late positive potential (LPP). In the control group we found no significant differences in ERP's P1 and N1 for within group comparison of all motion conditions studied. Moreover, a significant increase was found in the LPP ERP during the coherent motion conditions. However, the high risk group showed an aberrant pattern in the amplitude of LPP which is only elicited in the 50% coherence motion condition. These findings suggest that the behavioral dysfunctions in motion perception could be associated with late aberrant oscillatory brain activity a failure observed in LPP. These results allow an improvement in markers for early diagnosis in adults with psychosis.

Title: Early integration of visual and audio-visual information in schizophrenia as assessed by contour integration and sound induced flash illusion paradigms

Authors: *H. TURKOZER[1], E. KALE[2], Z. PAMIR[3], H. BOYACI[4], D. ONGUR[5], V. TOPCUOGLU[1];
[1]Dept. of Psychiatry, Marmara Univ., Istanbul, Turkey; [2]Brain Res. Ctr., Ankara Univ., Ankara, Turkey; [3]Neurosci. Grad. Program, [4]Dept. of Psychology, Bilkent Univ., Ankara, Turkey; [5]Dept. of Psychiatry, Harvard Univ. and McLean Hosp., Belmont, MA

Abstract: Visual perceptual organization and multi-sensory integration deficits have been observed in schizophrenia and are suggested to be related to the NMDA receptor hypofunction and reduced connectivity. Evidence suggests that both visual contour integration and sound induced flash illusion -an audio-visual integration paradigm- are associated with the activity of early visual areas (V1-V4). Here, we investigated integration deficits in schizophrenia in early levels of sensory processing, using a variant of contour integration paradigm, Jittered Orientation Visual Integration (JOVI) task and sound induced flash illusion. 18 patients with schizophrenia and 22 healthy control subjects participated in the study. Patients with schizophrenia showed significantly lower performance in the JOVI task than control subjects, which is consistent with prior studies. Contour integration performance was found to be negatively correlated with overall symptom severity and active social avoidance in patients, as measured by the Positive and Negative Syndrome Scale. We also demonstrated that poorer contour integration performance was associated with negative, disorganized and overall schizotypal traits in control subjects, as assessed by the Schizotypal Personality Questionnaire. No significant difference in illusory response rates for sound induced flash fission or fusion illusions were found between patients with schizophrenia and healthy controls. Sound induced flash illusion perception was not associated with symptom severity in patients or with schizotypal traits in the control group. No correlations were found between contour integration performance and sound induced flash

illusory response rates. These results suggest that multi-sensory convergence at early stages of visual processing is intact in schizophrenia although visual perceptual organization, another integration function of early visual cortex, is shown to be deficient. These data also suggest that JOVI task performance, which is associated both with symptom severity and schizotypal traits, has both state and trait-dependent characteristics.

Title: Mismatch negativity is associated with plasma levels of glutamate in patients with first-episode psychosis

Authors: *D. KOSHIYAMA[1], T. NAGAI[1], K. KIRIHARA[1], M. TADA[1], S. KOIKE[2], M. SUGA[1], T. ARAKI[3], K. KASAI[1];
[1]Dept. of Neuropsychiatry, Grad. Sch. of Med., The Univ. of Tokyo, Tokyo, Japan; [2]Office for Mental Hlth. Support, the Univ. of Tokyo, Tokyo, Japan; [3]Dept. of Youth Mental Health, Grad. Sch. of Medicine, Univ. of Tokyo, Tokyo, Japan

Abstract: Background: Mismatch negativity (MMN) is one of the event-related potentials. Many studies have shown that MMN amplitude is reduced in psychotic disorders and associated with cognitive dysfunction. Reduced MMN amplitude may reflect dysfunction of NMDA receptors in psychotic disorders because NMDA receptor antagonists reduce MMN amplitude. Therefore, MMN might be a marker that links molecular pathology to dysfunction in clinical settings. However, there are few studies to investigate a relationship between MMN and molecular pathology in patients with psychotic disorders. In this study, we examined plasma levels of glutamate, MMN amplitude, and cognitive functions to investigate their relationships in patients with psychotic disorders. We focused on early stages because clinical stages of psychotic disorders affect MMN amplitude and early stages are important periods for functional outcome of patients with psychotic disorders. Methods: Participants consisted of 19 patients with first-episode psychosis (FEP), 21 ultra-high risk (UHR) individuals, and 16 healthy control (HC) subjects. We measured plasma levels of glutamate and MMN amplitude. We also measured cognitive functions by BACS-J (Brief Assessment for Cognition in Schizophrenia Japanese version). Results: In FEP compared to HC, plasma levels of glutamate increased, MMN

amplitude was reduced, and cognitive functions were impaired. In FEP, MMN amplitude was positively correlated with plasma levels of glutamate and negatively correlated with cognitive functions. In UHR compared to HC, MMN amplitude was reduced. In UHR, MMN amplitude was significantly correlated with neither plasma levels of glutamate nor cognitive functions. Conclusion: FEP showed increased plasma levels of glutamate, reduced MMN amplitude, and impaired cognitive functions compared HC. Reduced MMN amplitude was associated with high plasma levels of glutamate and cognitive dysfunction in FEP. These findings suggest MMN can be a marker that links molecular pathology to dysfunction in clinical settings in early stages of psychotic disorders.

Title: Adjuvant pioglitazone for unremitted depression: clinical correlates of treatment response

Authors: K. WATSON LIN[1], T. WROOLIE[1], *N. L. RASGON[2];
[1]Stanford Univ., Stanford, CA; [2]Stanford Sch. of Medicine, Stanford Univ., Palo Alto, CA

Abstract: Abstract Background: Previous studies suggest that insulin-sensitizing agents could play a significant role in the treatment of major depression, particularly depression in patients with documented insulin resistance or those who are resistant to standard psychopharmacological approaches. This study aimed to assess the effects on depressive symptoms with adjuvant treatment with the PPARγ-agonist pioglitazone. Methods: Patients (N=37) with non-remitting depression receiving standard psychiatric regimens for depression were randomized across an insulin sensitivity spectrum in a 12-week double blind, randomized controlled trial of pioglitazone or placebo. Results: Improvement in depression was associated with improvement in glucose metabolism but only in patients with insulin resistance. An age effect was also shown in that response to pioglitazone was more beneficial in younger aged patients. Conclusion: Study findings suggest differential improvement in depression severity according to both glucose metabolic status and level of depression at baseline. A greater understanding of the reciprocal links between depression and IR may lead to a dramatic shift in the way in which depression is conceptualized and treated, with a greater focus on treating and/or preventing metabolic dysfunction.

Title: Off-label use of transmucosal ketamine as a rapid acting antidepressant: a retrospective chart review

Authors: *L. NGUYEN[1,2], C. B. WEAVER[1], K. J. CRAMER[3], S. E. POLLARD[2], P. J. MARSHALEK[2], R. R. MATSUMOTO[1,2,4];
[1]Pharmaceut. Sci., WVU Sch. of Pharm., Morgantown, WV; [2]Behavioral Med. and Pyschiatry, WVU Sch. of Med., Morgantown, WV; [3]WVU Schoof of Nursing, Morgantown, WV; [4]Touro Univ. CA Col. of Pharm., Vallego, CA

Abstract: The N-methyl-D-aspartate (NMDA) receptor antagonist ketamine administered at sub-anesthetic doses via an intravenous (IV) route can elicit robust, rapid and long-lasting antidepressant effect, even in treatment resistant patients. However, the need for IV administration limits the use of ketamine to an inpatient setting, requiring support services and monitoring. To minimize the adverse events associated with IV ketamine, including acute

dissociative and psychotomimetic effects and cardiovascular changes, recent investigations have attempted alternative routes of administration to elicit rapid antidepressant effects. This study evaluated the effectiveness and safety of sub-anesthetic doses of ketamine using an off-label, transmucosal administration route in patients with treatment resistant depression. A retrospective chart review was conducted to identify patients who met the inclusion criteria for treatment resistant major depressive disorder (MDD). Seventeen such patients who received sub-anesthetic doses of ketamine were included. Patient demographics, efficacy (drug refill, clinician notes), side effects, and concurrent medications were assessed. Benefit from low-dose transmucosal ketamine was noted in 76% of subjects (average age 48, 88% female), with a dose duration lasting 10-14 days. No notable side effects were noted. The most common classes of concurrent medications to which ketamine was added were serotonin norepinephrine reuptake inhibitors (59%), stimulants (47%), folate replacement (47%), and benzodiazepines (47%). Our results provide preliminary evidence of the effectiveness and safety of low-dose transmucosal ketamine in treatment resistant MDD patients. Formal prospective clinical trials are warranted to validate these findings.

Title: Cooling the forebrain in adults

Authors: *B. BARRERA-MERA;
Fac Med, UNAM, Mexico 04510 DF, Mexico

Abstract: The cooling of forebrain throughout the application of iced water on the skin of frontal and parietal regions, has been used to suppress of the consequences of mental fatigue, the major discomfort induced by the excessive ingestion of alcohol and also to relief of a paranoid syndrome. In all the cases the time of application of such a remedy lasted since minutes to some hours. This resource which is not only easy to applied but additionally innocuous and inexpensive, could be use to remedy some other mental pathologies i.e. depression, distress, and inclusively the severe changes in personality of that patients that suffers of inhalant addictions. .Presently we are intent to use the remedy in the last patients not by minutes or hours but during several days

Title: Development of a genetic risk score to index the integrity of somatostatin-positive GABA neurons in human cortex

Authors: *Y. S. NIKOLOVA[1,2], J. PIPITONE[2,3], E. SIBILLE[2,4];
[1]Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada; [2]Campbell Family Mental Hlth. Res. Inst. of CAMH, Toronto, ON, Canada; [3]Kimel Family Translational Imaging-Genetics Res. Lab, Res. Imaging Ctr., CAMH, Toronto, ON, Canada; [4]Departments of Psychiatry, Pharmacol. and Toxicology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Neurons expressing somatostatin (SST) constitute 20-30% of all GABA neurons in the human brain and mediate dendritic inhibition throughout the cortex. Results from studies in animal models and post-mortem human brain tissue suggest these neurons are impaired in depression and may be selectively vulnerable to stress. This vulnerability is reflected in changes in the neurons' transcriptomes potentially reflecting an increased susceptibility to endoplasmic reticulum and oxidative stress. Little is known about inter-individual variability in the functioning of these neurons in living humans. Common functional genetic variation can be used to bridge basic molecular and human *in vivo* work. Therefore, we sought to create a genetic risk score (GRS), using a gene co-expression network approach to index the relative integrity of SST-positive neurons based on combined post-mortem gene expression (mRNA) and single nucleotide polymorphism (SNP) data. Post-mortem gene expression and SNP data were available for 180 Caucasian individuals free of neuropsychiatric illness (35 women, mean age: 51.68 ± 14.64; range 16-96) and two brain regions - Brodmann areas 11 and 47 (BA11 and BA47). To create a gene co-expression network for SST, we selected the top 200 genes positively correlated with SST across both regions, after covarying for post-mortem interval, brain pH, RNA integrity number, and gender. To ensure the specificity of our results to SST neurons, we conducted parallel co-expression analyses for other subpopulations of GABA neurons expressing parvalbumin, cholecystokinin, and vasoactive intestinal peptide, and removed overlapping genes. To validate the resulting SST-specific co-expression network, we conducted a Gene Ontology (GO) term enrichment analysis using the Gene Ontology enRIchment anaLysis and visuaLizAtion tool (GOrilla; http://cbl-gorilla.cs.technion.ac.il/). Out of the top 200 genes showing a positive association with SST across both BA11 and BA47, 83 were uniquely co-expressed with SST. Among those, a GO term analysis demonstrated an enrichment of genes related to GABA A receptor function (p=7.84 x 10-5; genes: GABRB3, GABRA5, GABRA3),

consistent with the involvement of SST neurons in dendritic inhibition, and NADH dehydrogenase activity (p=6.42 x 10-4; genes: NDUFB7, NDUFS6, NDUFV1), consistent with a link between SST function and oxidative cellular processes. These preliminary results provide partial validation for our gene co-expression network approach. In a next step, SNPs regulating the expression of genes co-expressed with SST will be used to construct a GRS, which will subsequently be applied to *in vivo* neuroimaging data.

Title: In subjects with major depressive disorder CREB expression in the dentate gyrus correlates with number of granule neurons and decreases with aging

Authors: L. BONILLA[1], R. HEN[2], A. J. DWORK[2], G. B. ROSOKLIJA[2], V. ARANGO[2], J. J. MANN[2], *M. BOLDRINI[2];
[1]Barnard Col., New York, NY; [2]Psychiatry - Mol. Imaging and Neuropathology, Columbia Univ. - NYSPI, New York, NY

Abstract: Increased adult neurogenesis improves pattern separation (Sahay et al., 2011). In MDD there is a deficit in attention disengagement from negative material (Foland-Ross and Gotlib, 2012), with biased memories and judgments (Lemoult et al., 2012). Hippocampal atrophy is found even in first-episode MDD (Cole et al., 2011). Selective serotonin reuptake inhibitors (SSRI) increase neurogenesis in human DG (Boldrini et al, 2009, 2012) with unknown signaling mechanisms. The cAMP responsible element-binding (CREB) protein is a leucine zipper transcription factor (Borrelli et al., 1992) downstream of neurotrophin receptors, G-protein-coupled receptors and others (Carlezon et al, 2005), has a role in learning and memory (Silva et al, 1998), antidepressant action (Nibuya et al, 1996) and antidepressant-like effects (Chen et al, 2001). Conversely, mice with hippocampal CREB deletion respond faster to antidepressants and have increased neurogenesis (Gur et al, 2007), possibly due to up-regulation of CREB-family protein cAMP response-element modulator (CREM) (Gunderson et al, 2013). To assess

mechanisms of SSRI action on human adult neurogenesis, we quantified using immunohistochemistry and stereology CREB+ GN and glial cells in DG brain tissue from SSRI-treated (N=12), and untreated subjects with MDD (N=24) and controls with no psychiatric disease or treatment (N=24). We also assessed numbers of NPCs (nestin+), neuroblast (PSA-NCAM+) and GNs (NeuN+), and correlated their umber with CREB+ GNs and glial cells in the DG. Clinical data were obtained using psychological autopsy (Kelly and Mann, 1996), toxicology and neuropathology exams performed on all samples. Number of CREB+ cells decreased with increasing age in untreated MDD (r2= .778, F=17.503, p=.009), but not in controls and MDD*SSRI. In anterior DG, number of CREB+ GNs correlate with total number of GNs in untreated MDD (r2= .757, F=15.553, p=.011) and MDD*SSRI (r2= .703, F=11.824, p=.018), but not in controls. In anterior DG, CREB+ GNs were more in untreated MDD vs. controls (p=0.027) and MDD*SSRI ($p<0.05$). No group differences were found for CREB+ glial cell number. Fewer CREB+ GNs in older MDD suggests slower transcription processes. The correlation between CREB expression and GN total number in MDD suggests more maturation and or survival with more CREB expression. More CREB+ GNs in untreated vs. treated MDD and controls may be due to the fact that we are measuring non-phosphorylated CREB or to a compensating response or to an interaction with CREM that needs to be dissected. Further studies on CREB expression in NPCs and neuroblasts are needed to understand the regulation of neurogenesis by CREB.

Title: Sex differences in glutamate receptors in major depression and suicide

Authors: ***M. S. SODHI**[1], A. GRAY[2], A. DEEP-SOBOSLAY[3], T. HYDE[3], J. KLEINMAN[3]; [1]Col. of Pharm., Univ. of Illinois At Chicago, Chicago, IL; [2]Pharm. Practice, UIC, Chicago, IL; [3]Lieber Inst. for Brain Develop., Baltimore, MD

Abstract: Accumulating data indicate that the glutamate system is disrupted in major depression (MDD) and recent clinical research suggests that ketamine, an antagonist of the NMDA glutamate receptor, has rapid antidepressant efficacy. Here we report findings from gene

expression studies of a large cohort of postmortem subjects, including subjects with MDD and controls. Our data reveal higher expression levels of the majority of glutamatergic genes tested in the dorsolateral prefrontal cortex (DLPFC) in MDD ($F_{21, 59}=2.32$, $p=0.006$). Post-hoc data indicate that these gene expression differences occurred mostly in the female subjects. Higher expression levels of GRIN1, GRIN2A-D, GRIA2-4, GRIK1-2, GRM1, GRM4, GRM5 and GRM7 were detected in the female patients with MDD. In contrast, GRM5 expression was lower in male MDD patients relative to male controls. When MDD suicides were compared with MDD non-suicides, GRIN2B, GRIK3 and GRM2 were expressed at higher levels in the suicides. In addition, the suicides also had higher levels of GRIA2 RNA editing. Higher expression levels were detected for several additional genes but these were not statistically significant after correction for multiple comparisons. In summary, our analyses indicate a generalized disruption of the regulation of the GluRs in the DLPFC of females with MDD, with more specific GluR alterations in the suicides and in the male groups. These data reveal further evidence that in addition to the NMDA receptor, the AMPA, kainate and the metabotropic GluRs may be targets for the development of rapidly acting antidepressant drugs.

Title: VEGFR2 is increased in the dentate gyrus of antidepressant treated subjects and correlates with measures of angiogenesis, neurogenesis, and serotonin 1A receptor mRNA

Authors: *A. N. SANTIAGO[1,4], K. B. STEELE[5], T. H. BUTT[6], S. KASSIR[6], M. BAKALIAN[6], V. ARANGO[6,2], A. DWORK[6,2,3], G. ROSOKLIJA[6,2,7], J. MANN[6,2], M. York, NY; [7]Macedonian Acad. of Sci. & Arts, Skopje, Macedonia, The Former Yugoslav Republic of

Abstract: Adult neurogenesis is hypothesized to be impaired in major depressive disorder (MDD). Angiogenesis and neurogenesis in the hippocampal dentate gyrus (DG) are co-regulated by growth factors, including vascular endothelial growth factor (VEGF) in the neurogeneic niche. VEGF and its primary neural receptor (VEGFR2) have been shown to mediate increased cell proliferation in rodents following electroconvulsive seizure and treatment with selective serotonin reuptake inhibitors (SSRI). It is not known whether SSRIs increase VEGFR2 in the human brain, nor if this is a mechanism by which SSRIs increase neurogenesis. It is also unknown whether the serotonin 1A receptor (HTR1A), which has been implicated in antidepressant-mediated neurogenesis, is up-regulated with VEGFR2 in human subjects. To test the role of VEGFR2 in mediating adult neurogenesis in major depressive disorder (MDD) and in response to SSRI, we used immunohistochemistry and stereology to quantify numbers of VEGFR2-immunoreactive (IR) DG cells and endothelial cells in human postmortem hippocampus from psychiatrically healthy control, untreated MDD (MDD*U), and SSRI-treated MDD subjects (MDD*SSRI). We performed *in situ* quantification of the HTR1A mRNA. Additionally, we correlated VEGFR2-IR cell count with neural progenitor cell (NPC) number, mature granule neuron number, capillary surface area, dentate gyrus volume, and HTR1A mRNA density. We found that MDD*SSRI had a greater number of VEGFR2-IR DG cells than both control ($p = .02$) and MDD*U ($p = .001$) in the anterior DG, but not the mid or posterior DG. VEGFR2-IR endothelial cells in DG capillaries were more in MDD*SSRI vs. control ($p = .043$) and MDD*U (0.014). VEGFR2-IR DG cell number correlated with NPC number ($r2=.299$, $p=.015$), granule neuron number ($r2=.228$, $p = .021$), capillary surface area ($r2=.333$, $p=.010$), anterior DG volume ($r2=.349$, $p=.003$), and anterior DG HTR1A mRNA ($r2=.233$, $p=.020$). Our finding that VEGFR2 cell number is greater in SSRI-treated subjects supports a role for VEGF in antidepressant action. Correlations with NPC number, granule neuron number, and capillary surface area support the hypothesis that VEGFR2 plays an integral role in both angiogenesis and neurogenesis. Increased expression of HTR1A mRNA with VEGFR2-IR cell count suggests that SSRI treatment may induce neurogenesis and angiogenesis by up-regulating HTR1A mediated VEGF signaling. This conclusion is supported by rodent studies, which show that behavioral effects of SSRIs are diminished by VEGFR2 inhibitors.

Title: Oxytocin: A neurohormone link to the epigenetics of early life adversity and suicide

Authors: *D. ALMEIDA[1,2], L. FIORI[1], G. TURECKI[1,2,3,4];
[1]McGill Group For Suicide Studies, Verdun, QC, Canada; [2]Neurol. & Neurosurg., [3]Psychiatry, [4]Human Genet., McGill Univ., Montreal, QC, Canada

Abstract: Oxytocin is a mammalian neurohypophysial hormone which acts primarily as a neuromodulator in the CNS. The early development of secure attachments, relationship quality, and the ability to regulate and manage emotions are all instances of psychological resources influenced by the oxytocinergic system. Previous studies have shown that early life adversity might act to disturb the oxytocinergic system during critical developmental periods. A body of literature also supports alterations in the oxytocinergic system as a predisposing factor for suicidal behaviour. Our research looks into the expression of genes regulating the oxytocinergic system in the prefrontal cortex of suicide completers with a history of abuse, non-abused suicide completers, and healthy controls. Expression data from the prefrontal cortex of these subjects indicates an effect of abuse on genes involved in oxytocin metabolism and function. Specifically, suicide completers with a history of abuse show a significant upregulation of LNPEP (an enzyme responsible for the breakdown of neuropeptides in the brain), OXTR (oxytocin receptor), and AVPR1B (arginine vasopressin receptor 1 B), when compared to non-abused suicide completers and healthy controls. Recently, several studies have identified epigenetic mechanisms influencing the oxytocinergic system, with an emphasis on methylation. We are therefore also investigating methylation via targeted bisulfite sequencing of CpG rich regions within LNPEP, OXTR, & AVPR1B. The practical goals of this research are two fold, first they seek to strengthen the literature on child-abuse and CNS changes in psychiatric disorders, and secondly, to determine whether epigenetic modification of the oxytocinergic system represents a CNS biomarker of early life adversity and later suicidal behaviour.

Abstract: The World Health Organization (WHO) has been estimated that every 40 seconds one person commits suicide in one part of the world, in 2012 WHO estimated that nearly 1 million people die from suicide yearly. For these reasons, suicide has become a public health problem. Suicide risk is influenced by a wide range of factors such as the presence of psychopathologies like major depressive disorder, alcoholism, drug abuse, childhood adversity and stressful life events, all this exposure to stress can produce long lasting changes in brain circuits, behaviors and epigenetic behaviors. Some studies have reported an increase in the DNA methylation levels on the orbital prefrontal cortex. It is know that one of the brain region involved in the regulation of stress is the prefrontal cortex. Other results suggest Corticotropin-releasing hormone levels were elevated in frontopolar and dorsomedial prefrontal cortex, but not in the ventrolateral prefrontal cortex of suicide victims. Human tissue specimens were obtained according to an institutional approved protocol Tissue was coded and samples had no person identifiers. The brains were collected at forensic autopsies. With informed consent, family members were interviewed as part of a psychological autopsy to obtain demographic information and any evidence of psychiatric or somatic disease. Depressed-suicide cases were selected according to the following criteria: death by suicide, diagnosis of major depressive disorder *(DSMIV),* absence of psychotropic or illegal drugs on toxicological screens, death without prolonged agonal state or protracted medical illness. Controls did not have an Axis I psychiatric disorder, were drug-free and died suddenly without a prolonged agonal period from causes other than suicide. The aim of the present study was measure the changes in neuronal density by stereological processes, correlating by the measure of GFAP and protein nitration, in tissues of suicide victims in PFC. Our results suggest that suicide victims have a decrease in neuronal density and an increasing in astocytes and protein nitration in comparation to the control group. In conclusion the changes found in brains of suicide victims suggest a disruption in the neurons of the PFC and an inflammation process in the region. Title: Association between kynurenine metabolism and transcripts related to neuroinflammatory signaling in postmortem human brain

Authors: ***A. POCIVAVSEK**[1], A. W. LEE[2], A. ADBOURAHMAN[2], K. V. SATHYASAIKUMAR[1], J. A. TAMM[2], F. M. NOTARANGELO[1], J. WIEDEMANN[3], T. MÖLLER[2], G. TURECKI[4], R. SCHWARCZ[1], B. CAMPBELL[2];

Abstract: Inflammatory cytokines and subsequent dysregulation of kynurenine pathway (KP) metabolism may contribute to the development of depressive symptoms in a subset of major depressive disorder (MDD) patients. Though increased kynurenine production and elevated proinflammatory mediators in serum and plasma are relatively common findings in MDD studies, fewer reports have evaluated neuroinflammation or KP dysregulation in postmortem brain. A small number of studies reported elevated levels of quinolinic acid in the brain or cerebrospinal fluid in suicide attempters or victims (Erhardt S et al., 2013. Neuropsychopharmacology 38: 743-52; Steiner J et al., 2011. J Neuroinflammation 8: 94-102; Sublette ME et al., 2011. Brain Beh Immun 25: 1272-78). To better understand the role of inflammation and KP metabolism in MDD, the current study examined levels of KP metabolites, activity and expression of KP enzymes, as well as expression of neuroinflammation-relevant genes in dorsolateral prefrontal cortex from individuals with MDD who died of natural causes, those with MDD who died from suicide, and non-MDD controls. Levels of tumor necrosis factor receptor superfamily member 1A (TNFRSF1A) were higher in brains of MDD donors who died of natural causes compared to non-MDD controls. Moreover, levels of tumor necrosis factor alpha were lower in brains from donors who died from suicide compared to non-MDD controls, while there were no differences between groups in any of the other genes measured. Interestingly, we did not find significant differences between groups in KP metabolites and enzymes. However, there were correlations between levels of KP metabolites and several of the

transcripts associated with neuroinflammatory signaling, including interleukin-1 receptor (ILR1), TNFRSF1A, myeloid differentiation primary response gene 88 (MYD88), nuclear factor of kappa light polypeptide gene enhancer in B-cells 1 (NFKB1), and toll-like receptor 2 (TLR2). The expression of the KP enzymes kynureninase and 3-hydroxyanthranilate 3,4-dioxygenase was also positively correlated with transcripts associated with neuroinflammatory signaling, including interferon regulatory factor 9 (IRF9), macrophage migration inhibitory factor (MIF), toll like receptor 4 (TLR4), translocator protein (TSPO), ionized calcium-binding adapter molecule (IBA1) and am subunit of Mac-1 (CD11B). Thus, while our study did not reveal differences in KP metabolism, the data show that regardless of group status (e.g. control vs. MDD), markers indicative of microglial priming are associated with brain KP metabolites and enzymes within the quinolinic acid branch of the KP.

Abstract: MicroRNAs are a class of small, non-coding RNAs that canonically act as post-transcriptional regulators of gene expression. Given that microRNAs (miRNA) are heavily

enriched in the CNS and regulate many CNS processes, they have garnered intense interest, particularly in their relevance to CNS disorders. Multiple miRNAs have been shown to vary as a function of psychiatric disease state in several psychiatrically-relevant brain regions. However, these microRNAs have not been examined in any psychiatric disease state in the anterior cingulate cortex (AnCg), a brain region centrally involved in the regulation of mood and affect. Here we performed qPCR expression analyses of 29 miRNAs previously implicated in psychiatric illness (e.g. MDD, BP and/or schizophrenia) in AnCg of patients with MDD and BP versus control patients. Five microRNAs were differentially expressed in disease states: three in the BP cohort, one in the MDD cohort, and one across both states. In silico target prediction algorithms were used to identify putative targets of differentially expressed miRNAs and three mRNA candidates were selected based upon their previously published relevance to psychiatric illness. Luciferase reporter assays employing 3' UTRs of these candidate mRNAs were used to query miRNA/mRNA interactions. Site-directed mutagenesis of the putative seed domains alleviated each miRNA repression, validating these direct miRNA/mRNA interactions. Following target validations qPCR analyses were performed to determine whether changes in miRNA levels were correlated with changes in steady-state mRNA levels of these validated targets. Of the three mRNAs examined, one mRNA was overexpressed in our BP cohort, one was repressed in our MDD cohort, and one was unchanged in either disease state. In sum, this is the first study to demonstrate miRNA changes in AnCg as a function of psychiatric disease and 2) validate a miRNA as differentially expressed in both MDD and BP cohorts. Taken together, these findings support a mechanistic role for miRNAs in gene expression changes previously observed in psychiatric illness.

Title: Polyamine metabolic enzyme gene expression analysis of human amygdala of major depressive disorder samples

Authors: *V. SHARMA[1], M. HAGENAUER[1], S. CHAUDHURY[1], R. C. THOMPSON[1], R. M. MYERS[2], A. F. SCHATZBERG[3], J. D. BARCHAS[4], W. E. BUNNEY[5], H. AKIL[1], S. J. WATSON[1];
[1]Mol. and Behavioral Neurosci. Inst., Univ. of Michigan, Ann Arbor, MI; [2]Hudsonalpha Inst. for Biotech., Huntsville, AL; [3]Dept. of Psychiatry, Stanford Sch. of Med., Stanford, CA; [4]Dept. of Psychiatry, Weil Cornell Med. Col., New York, NY; [5]Dept. of Psychiatry, Univ. of California Irvine, Irvine, CA

Abstract: The polyamine pathways are important in cell growth as well as proliferation and are activated (or regulated) by G-proteins, protein kinases, nucleotide cyclases and receptors. Few recent studies have focused on the role of polyamines and their metabolic enzymes in the etiology and pathology of mental disorders. Altered levels of mRNA of polyamine enzymes arginase II (ARG2), S-adenosylmethionine decarboxylase (AMD1), and antizymes 1 and 2 (OAZ1 and OAZ2) have been observed in conditions like schizophrenia, major depressive disorder and bipolar disorder. The amygdala plays an important role in emotion, motivation and other higher cognitive functions which result in the addition of the subjective value to the stimulus. It appears to act as a neural gateway for binding the sensory representations with the neural correlates of emotional and motivational valence, thereby linking sensory information to adaptive responses and meaningful experiences. Because the human amygdala is a heterogeneous structure containing numerous nuclei that vary in size and shape through the anterior-posterior axis, we utilized laser capture microdissection to precisely dissect the nuclei from the human amygdala into ten divisions (Lateral (L), Basal (B), Accessory Basal (AB), Central (CE), Medial (M), Cortical (CO), Periamygdaloid Cortex (PAC), Amygdalohippocampal Area (AHA), Anterior Amygdaloid Area (AAA) and Paralaminar (PL) nuclei) followed by microarray gene expression analysis. Microarray data revealed the altered levels of the above said genes in the different sub-nuclei of amygdala which prompted us to further investigate the genes for polyamine metabolism. Thus, in the present study we assess the levels of gene expression of polyamine metabolic enzymes in various amygdala subnuclei of postmortem human brain of normal healthy and major depressive disorder subjects. The findings will help us in understanding the role of polyamines and their metabolic enzymes in the functioning of human amygdalar sub-nuclei in major depressive disorder.

Title: Expression of GABA(A) receptor trafficking molecules in schizophrenia brain

Authors: *T. M. MUELLER[1], V. HAROUTUNIAN[2], J. H. MEADOR-WOODRUFF[1]; [1]UAB, Birmingham, AL; [2]Mt Sinai Sch. of Med., Bronx, NY

Abstract: Schizophrenia is a complex neuropsychiatric illness of which the exact mechanisms remain unclear. Our lab has previously identified abnormalities of the gene and protein expression of some receptor subunits and associated trafficking molecules, disrupted N-glycosylation, and differences in subunit localization of glutamate receptor subunits. More recently, we have expanded these studies to determine if other neurotransmitter systems, such as the GABAergic system, exhibit similar alterations. We have previously measured the protein expression of GABA(A) receptor (GABAAR) subunits in postmortem human superior temporal gyrus (STG) between schizophrenia and comparison subjects, finding no difference between diagnostic groups. However, abnormalities of GABAAR subunit N-glycosylation of the α1, β1, and β2 subunits and atypical subcellular distribution of GABAAR β1 and β2 subunit isoforms have been identified in schizophrenia STG. Similar to the glutamatergic system, GABAARs must interact with a variety of other proteins in order to be correctly trafficked from the endoplasmic reticulum to the synapse. Our current study measures the expression of molecules necessary for the proper forward trafficking of GABAARs to determine if other factors, in addition to abnormal N-glycosylation, may contribute to the disrupted subcellular localization of GABAAR subunits in schizophrenia. To inform this question, we first measured the gene and protein expression of several molecules known to be necessary for GABA receptor trafficking in total STG homogenates and found reduced transcription of GABA receptor associated protein (GABARAP), gephyrin, and brefeldin A-inhibited guanine nucleotide exchange factor (ARFGEF2) mRNA in schizophrenia; however, we did not find any corresponding alteration in the relative abundance GABARAP or gephyrin protein. Furthermore, when assessed in a synapse-enriched subcellular fraction, gephyrin was found to be normally expressed in schizophrenia brain. These data demonstrate that protein levels of the trafficking molecules under investigation are not disrupted in schizophrenia STG. However, since N-glycosylation can play an important role in mediating protein-protein interactions by directly interacting with glycan binding proteins or by exerting steric effects affecting core protein conformation and/or binding site accessibility, the possibility remains that abnormalities of N-glycosylation may disrupt the integrity of protein-protein interactions between these molecules and intact GABAARs, thereby contributing to abnormal GABAAR subunit subcellular localization.

Title: GABAergic gene expression in the anterior cingulate cortex in schizophrenia

Authors: ***G. C. BRISTOW**[1], M. S. SODHI[2];
[1]Dept. of Pharm. Practice and Ctr. for Pharmaceut. Biotech., [2]Dept. of Pharm. Practice and Ctr. for Pharmaceut. Biotechnology, Dept. of Psychiatry, Univ. of Illinois At Chicago, Chicago, IL

Abstract: GABAergic dysfunction has been strongly implicated in the pathophysiology of schizophrenia. We have previously shown that sex differences in the expression of GABAA receptor subunits occur in the anterior cingulate cortex (ACC) in schizophrenia. These analyses revealed that in male groups, the expression of GABAergic genes was generally lower in schizophrenia cases compared to the controls, with significantly lower expression levels of GABAAα5, GABAAβ1, and GABAAε. In females, the expression of GABAergic genes was higher in the schizophrenia cases, with significantly higher expression of the GABAAβ1 and GAD67 genes. Analyses of the effects of medication in the male schizophrenia subjects revealed significantly higher expression of GABAAα1-3, GABAAβ2, GABAAγ2, and GAD67 in the medicated group compared to the unmedicated group, indicating that anti-psychotic treatment may have "corrected" the deficits in GABAergic gene expression observed. Investigations of the GABA transporter genes have not been reported in the ACC in schizophrenia. Here we have extended our study to analyse the expression of a gamma-aminobutyric acid transporter GAT2 in order to further examine the regulation of GABAergic neurotransmission in the ACC in schizophrenia. We have tested the ACC of post-mortem subjects with schizophrenia (n=21) and a comparison group of individuals without a history of psychiatric illness (n=18). Our data indicate that the expression of GAT2 does not differ in schizophrenia relative to controls, or between male and female groups. GAT2 expression is also not altered by medication status. In summary, our data indicate that there are sex differences in the expression of several GABAA receptor genes and GAD67, but not GAT2, in the ACC in schizophrenia. The authors thank Vahram Haroutunian, Director of the Alzheimer's disease and Schizophrenia Brain Bank, for post-mortem tissue, and John A. Bostrom for technical assistance. Title: Region and pyramidal cell level expression of glutamate transporters EAAT1 and EAAT2 and their splice variants in schizophrenia

Authors: *S. M. O'DONOVAN[1], K. HASSELFELD[1], D. BAUER[2], M. SIMMONS[3], P. ROUSSOS[4], V. HAROUTUNIAN[4], J. H. MEADOR WOODRUFF[3], R. E. MCCULLUMSMITH[1];

Abstract: Dysregulation of the glutamate transporters EAAT1 and EAAT2 and their isoforms have been implicated in schizophrenia. EAAT1 and EAAT2 expression has been studied in different brain regions but the prevalence of astrocytic glutamate transporter expression masks the more subtle changes in EAAT isoforms in neurons in the cortex. The mRNA levels of EAAT1, EAAT2 and the splice variants EAAT1 exon9skipping, EAAT2 exon9skipping and EAAT2b were analyzed by RT-PCR in an enriched population of pyramidal neurons. Region-level expression of these transcripts was measured in postmortem schizophrenia (n=25) and controls (n=25) in the dorsolateral prefrontal cortex (DLPFC) and anterior cingulate cortex. Using laser capture microdissection, pyramidal neurons were cut from the anterior cingulate cortex of postmortem schizophrenia (n=20) and control (n=20) subjects. The relationship between selected EAAT polymorphisms and EAAT splice variant expression was also explored. There were no changes in EAAT isoform mRNA levels in the DLPFC in schizophrenia compared to control subjects. EAAT2 exon9skipping mRNA was increased ($p<0.05$; 38%) at region-level in the anterior cingulate cortex with no significant change in other EAAT variants at region-level. Anterior cingulate cortex pyramidal cell expression of EAAT2b mRNA was significantly increased ($p<0.001$; 67%) in schizophrenia subjects compared to controls. There was no significant change in other EAAT variants. EAAT2 SNPs were significantly associated

with changes in EAAT2 isoform expression. To control for possible medication effects, rats were administered a chronic course (9 months) of haloperidol-decanoate, a typical antipsychotic drug. Neuronal EAAT2b mRNA levels were not significantly altered in these animals. The novel finding that EAAT2b levels are increased in populations of anterior cingulate cortex pyramidal cells further demonstrates a role for neuronal glutamate transporter splice variant expression in schizophrenia.

Title: Altered expression of adenosine system components in pyramidal neuron and glial cell populations in schizophrenia

Authors: *K. A. HASSELFELD[1], R. H. KOENE[1], S. M. O'DONOVAN[1], R. C. ROBERTS[2], R. E. MCCULLUMSMITH[1];
[1]Univ. of Cincinnati, Cincinnati, OH; [2]Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Schizophrenia is a debilitating and complex neuropsychiatric disorder that affects approximately 1.0% of the world's population. A leading hypothesis of the etiology of schizophrenia is a hypofunctioning glutamatergic system, which has been shown to produce negative and cognitive symptoms. The neuromodulator adenosine regulates glutamate transmission through its effects on neurons, both postsynaptically and presynaptically, and glial cells. We hypothesize that the adenosine system is differentially regulated in enriched populations of pyramidal neurons and glial cells in schizophrenia. The expression of adenosine pathway components were measured at region-level and in enriched populations of pyramidal neurons and astrocytes cut by laser capture microdissection from the dorsal lateral prefrontal cortex (DLPFC) of postmortem schizophrenia (n=10) and control (n=10) subjects. QPCR was used to analyze mRNA levels of adenosine 2a receptor (A2aR), adenosine deaminase (ADA), adenosine kinase (ADK), ectonucleoside triphosphate diphosphohydrodase 1 and 2 (ENTPD1/2), ecto 5'-nucleotidase (NT5E) and equilibrative nucleoside transporter 1 (ENT1). At the region-level in the DLPFC, ADA was increased ($p<0.05$; 60%) in schizophrenia while ENTPD1 mRNA levels were significantly decreased ($p<0.05$; 39%). There was no significant change in the other

transcripts at the region level. Expression of ADA mRNA was also increased in pyramidal neurons ($p<0.05$; 73%). ENT1 was significantly decreased ($p<0.05$; 29%) in pyramidal neurons in schizophrenia, while the other transcripts were not changed. ENTPD1 mRNA levels were significantly decreased ($p<0.05$; 37%) in astrocytes. There were no other significant changes between schizophrenia and control subjects at the astrocyte cell level. Components of the adenosine pathway were differentially expressed among control and schizophrenia subjects at region level and in both pyramidal neuron and astrocyte cell populations. This suggests an impairment of the adenosine system consistent with a loss of capacity to transport nucleosides and changes in adenosine metabolism.

Title: Expression of EAAT mRNA isoforms in Nissl-stained astrocyte populations in post-mortem schizophrenia

Authors: *R. KOENE[1], K. HASSELFELD[1], S. M. O'DONOVAN[1], R. C. ROBERTS[2], R. E. MCCULLUMSMITH[1];
[1]Dept. of Neurosci. and Behavioral Psychiatry, Univ. of Cincinnati, Cincinnati, OH; [2]Dept. of Psychiatry and Behavioral Neurobio., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Schizophrenia is a debilitating neurological disorder which has been linked to abnormalities in glutamatergic function in the brain. The main function of excitatory amino acid transporters (EAATs) is the reuptake and removal of glutamate from synapses. Astroglial transporters account for up to 90% of transport of glutamate in the forebrain. Astrocytes express high levels of EAATs as well as of glial fibrillary acidic protein (GFAP). We propose EAAT expression is decreased in schizophrenia. 14µm dorsolateral lateral prefrontal cortex (DLPFC)

sections were labelled with GFAP, an astrocyte marker, or stained with Nissl stain, which stains all nucleic acids (n=3 subjects/group). Astrocytes were then cut and captured by laser capture microdissection (LCM) based on visualization of GFAP labelled cells or cell morphology (Nissl). Gene expression of GFAP (astrocyte marker) was measured using QPCR in the enriched populations of astrocytes. Nissl-stained astrocytes had significantly higher expression of GFAP than GFAP-labelled astrocytes (t-test; $p < 0.01$). Based on these results, 14µm thick DLPFC tissue sections from control (n=10) and schizophrenia (n=10) subjects were stained with Nissl and an enriched population of astrocytes were captured. Gene expression levels of EAAT1, EAAT2 and their isoforms EAAT1 exon9 skipping, EAAT2 exon9 skipping , EAAT2b and EAAT2 intron7 retaining were measured using QPCR. EAAT1, EAAT2, EAAT1x9 skipping and EAAT2x9 skipping astrocytic mRNA expression was decreased 25-30% in schizophrenia subjects compared to controls. EAAT2intron7 retaining astrocytic mRNA decreased by 35% in schizophrenia subjects, and EAAT2b expression in schizophrenia was significantly decreased (44% compared to controls; t-test, $p \leq 0.05$). Astrocytes, identified by morphology using a Nissl staining protocol, had higher levels of GFAP expression, validating our astrocyte identification and LCM capture protocol. As a result, we applied this protocol to measure EAAT isoform mRNA expression levels in astrocytes in schizophrenia. This cell-specific approach found substantial decreases in EAAT levels, with EAAT2b expression being significantly decreased. These results support previous findings that show alteration in the glutamate reuptake system in schizophrenia.

Title: Altered expression of monocarboxylate transporter 1 in laser captured pyramidal neurons and astrocytes in schizophrenia

Authors: *C. R. SULLIVAN, S. O'DONOVAN, R. KOENE, K. HASSELFELD, R. MCCULLUMSMITH;
Psychiatry, Univ. of Cincinnati, Cincinnati, OH

Abstract: Schizophrenia is a complex and disabling illness characterized by impairments in attention, cognition, planning, and social function. There is evidence that abnormal lactate

metabolism and mitochondrial dysfunction might contribute to these deficiencies. In normal brain, lactate is rapidly synthesized from pyruvate in astrocytes and can be shuttled to neighboring cells via monocarboxylate transporters (MCTs). MCTs on neurons rapidly transport lactate into the neuron, where it is converted into pyruvate by LDH, which may enter the TCA cycle to generate ATP, suggesting a critical role for lactate in neuronal transmission. We hypothesize that lactate metabolism is differentially regulated in enriched populations of pyramidal neurons and astrocytes in schizophrenia. Enriched populations of pyramidal neurons and astrocytes were cut by laser capture microdissection from the dorsal lateral prefrontal cortex (DLPFC) in subjects with schizophrenia (n=10) and control (n=10) subjects. QPCR was used to analyze cell and region level expression of mRNAs for MCT1, MCT2, and MCT4. At the region level, MCT1, but not MCT2 or MCT4, mRNA was increased (p=0.00997) in subjects with schizophrenia compared to controls. MCT1 mRNA was also increased in pyramidal neurons (p=0.01298; 49%) and in astrocytes (p=0.02620; 39%) in subjects with schizophrenia compared to controls. There was no significant difference in MCT2 or MCT4 transcripts in pyramidal neurons or astrocytes. MCT1 transporters in the lactate shuttle pathway were differentially expressed among control and schizophrenia subjects at region level and in both Pyramidal neuron and astrocyte cell populations. A global increase in MCT1 transcripts might suggest an initial compensatory mechanism for decreased lactate production, inefficient lactate shuttling to neurons, or low transporter activity in schizophrenia. In conclusion, lactate metabolism is altered in schizophrenia by cell-type dependent changes possibly contributing to abnormal neuronal transmission.

Title: Analysis of the EAAT2 interactome coupling to metabolic function in schizophrenia

Authors: *A. E. GARDNER, S. M. O'DONOVAN, K. E. CLICK, A. J. FUNK, R. E. MCCULLUMSMITH;
Psychiatry and Behavioral Neurosci., Univ. of Cincinnati, Cincinnati, OH

Abstract: Schizophrenia is an often devastating neurodevelopmental illness characterized by positive, negative, and cognitive deficits that contribute to profound impairment in the afflicted.

We have previously reported changes in glutamate transporter expression in this illness, extending the NMDA receptor hypofunction hypothesis beyond the NMDA receptor. Our findings suggest a profound deficit in glutamate reuptake in multiple brain regions that may contribute to the deficits of neuroplasticity found in this illness. The excitatory amino acid transporter 2 (EAAT2) has a rich protein-protein interactome, which consists of a myriad of structural, signaling, and metabolic proteins. The function of this protein complex has a central role in the maintenance of sodium and potassium gradients, the production of energy intermediates including lactate and pyruvate, as well as facilitation of the glutamate/glutamine cycle. We hypothesize that the integrity of this protein complex is compromised in schizophrenia. We have developed an affinity purification-LC/MSMS protocol to isolate, characterize, and quantify the EAAT2 interactome in human postmortem brain tissues. Data will be presented from subjects with schizophrenia and a control group for key elements of the EAAT2 interactome. We will use a well-characterized bioinformatics workflow to normalize our data across subjects and quantify changes in the protein content between diagnostic groups. We anticipate that there are profound changes in the metabolic coupling of EAAT2 to metabolic function. We predict that changes in the EAAT2 interactome will reflect uncoupling of EAAT2 to mitochondrial function, with decreases in metabolic enzymes and increases in cytoplasmic proteins associated with trafficking away from the perisynaptic microdomain.

Title: Developmental molecular profiles of human choroid plexus epithelial cells determined by whole transcriptome rna sequencing

Authors: K. ATHANAS[1], E. KOHLBRENNER[1], S. JACKSON[2], K. VARMA[2], S. MAUNEY[1], K.-C. SONNTAG[3], S. BERRETTA[4], *T.-U. WOO[5];

Abstract: Increasing evidence from rodent studies has implicated the homeobox protein orthodenticle homeobox 2 (OTX2) as playing a critical role in orchestrating the postnatal maturation of neural circuitry of the cerebral cortex. In addition, it appears that the choroid plexus represents a major supply of OTX2 in the postnatal brain. In this study, we use whole transcriptome RNA sequencing (RNA-Seq) to determine the molecular profiles associated with human choroid plexus epithelial cells during postnatal development. Choroid plexus epithelial cells are obtained using laser capture microdissection (LCM). RNA is extracted from LCM caps using the Arcturus Picopure RNA purification kit. Libraries are constructed using the Ion Ampliseq Human Transcriptome kit, templated using Ion Chef, and sequenced on Ion Torrent Proton instruments using PI chips. Sequences are aligned using Ion Torrent Suite algorithms. Transcript abundance is analyzed by normalizing to reads per million reads using the Ampliseq RNA analysis plug-in available in the Torrent Suite software. Findings of this study will provide insight into the molecular underpinnings of the regulation of OTX2 production in the choroid plexus during postnatal human development. In this context, OTX2 deficit has recently been observed in subjects with schizophrenia and developmental events that are regulated by OTX2 also appear to be disturbed in this illness. As such, comparison of findings of this study and possible alteration in the molecular signature of choroid plexus epithelial cells in schizophrenia may shed light onto the pathophysiology of this illness and potential corrective strategies.

Title: Prefrontal cortical perineuronal net ensheathment of pyramidal neurons in schizophrenia

Authors: *K. M. ATHANAS[1], T.-U. W. WOO[1,2,3];
[1]Lab. for Cell. and Mol. Neuropathology, McLean Hosp., Belmont, MA; [2]Dept. of Psychiatry, Beth Israel Deaconess Med. Ctr., Boston, MA; [3]Dept. of Psychiatry, Harvard Med. Sch., Boston, MA

Abstract: Schizophrenia (SZ) is a debilitating psychotic disorder that typically onsets during late adolescence or early adulthood. Perineuronal nets (PNNs) are extracellular aggregates predominately composed of chondroitin sulfate proteoglycan (CSPG), tenascin-R, link proteins,

and hyaluronan that ensheath the somata and dendritic branchings of many neurons, including pyramidal neurons and the inhibitory neurons that contain parvalbumin (PV). We have recently found that the density of neurons ensheathed by PNNs appears to be significantly decreased in the prefrontal cortex (PFC) in SZ, but in that study we did not distinguish the specific cell types that might be involved. Here, we test the hypothesis that the ensheathment of pyramidal neurons by PNNs is deficient in SZ. In a cohort of SZ and 20 demographically matched controls (C) subjects, we use biotin-labeled lectin from Wisteria floribunda aggultinin (WFA) to histochemically visualize CSPG-containing PNNs in post mortem tissue of the PFC, followed by Nissl staining. Pyramidal neurons are identified based on morphological characteristics. In a blind fashion, we quantify the densities of pyramidal cells that are surrounded by and devoid of PNNs. PNNs are known to regulate neural circuitry formation, structural plasticity, synaptic maturation and stabilization, all of which are processes thought to be disrupted in SZ. Findings of this study will shed light onto the cell type-specific nature of PNN deficit in SZ and will provide insight into the pathophysiology of dysconnectivity of cortical excitatory circuits.

Title: UBE3B expression in the prefrontal cortex during development and in schizophrenia

Authors: *E. KOHLBRENNER[1], W. T.-U. WOO[2,3,4];
[2]Lab. for Cell. and Mol. Neuropathology, [1]McLean Hospital; Harvard Med. Sch., Belmont, MA; [3]Dept. of Psychiatry, Beth Israel Deaconess Med. Ctr., Boston, MA; [4]Dept. of Psychiatry, Harvard Med. Sch., Boston, MA

Abstract: The prefrontal cortex, a major site of dysfunction in schizophrenia, undergoes extensive developmental changes during adolescence, including the remodeling and pruning of circuitry in neuronal networks that eventually lead to enhanced cognitive decision making ability in adulthood. In most cases of schizophrenia, the manifestation of symptoms does not begin until late adolescence and early adulthood, suggesting that developmental events in the peri-adolescent period could contribute to the onset of this disorder. Our previous work explores gene expression regulation in normal, postnatal human development; specifically at layer 3 pyramidal cells that furnish corticocortical connections in the prefrontal cortex. We identified genes that are

both developmentally regulated and differentially expressed in schizophrenia. One of these genes is the ubiquitin ligase-encoding gene, UBE3B, a paralog to the widely studied UBE3A which has been previously correlated with autistic behaviors in mice. Ubiquitination influences cellular signaling cascades by posttranslational protein modification and regulates neuronal migration, neurogenesis, synaptic elimination and formation as a result. Alterations in the ubiquitination system are known to contribute to developmental neurological diseases such as Angelman Syndrome and other autism spectrum disorders. Previous protein and genetic expression analysis findings suggest that UBE3B expression increases developmentally and is decreased in schizophrenic samples, and thereby could contribute to the developmental pathophysiology of schizophrenia by disturbing periadolescent synaptic refinement of prefrontal cortical circuitry. We compared a cohort of schizophrenia versus control human post-mortem prefrontal cortex (Brodmann's area 9) (N=30 and 15, respectively), immunohistochemically stained and quantified in a blind fashion with an anti-ube3b polyclonal antibody and Nissl staining, to test the hypothesis that the density of UBE3B-expressing cells is decreased in schizophrenia. Preliminary results of this ongoing investigation indicate that schizophrenic samples have a lower percentage of ube3b-expressing cells, as also seen in our previous genetic analysis. Findings of this study will deepen our current understanding of the molecular pathophysiology of schizophrenia and its onset.

Abstract: Methods: We assessed transcription alterations in schizophrenia (SZ), bipolar disorder (BP) and major depression (MDD) as compared to controls (C) in hippocampus, dorsolateral prefrontal cortex (DLPFC) and dura in a large cohort of individuals (total number 470 subjects

for hippocampus, 691 for DLPFC and 150 for dura). RNA was extracted using RNAeasy Qiagen kits. Biotin labeled amplified RNAs were obtained with Affymetrix 3'IVT express kits and hybridized to the Illumina HumanHT-12_V4 Beadchips. The data were imported into R using the BeadArray package. VST and quantile normalization were performed. ComBat was used to remove batch effects. SVA was used for finding latent covariates. Quantitative PCR was used for validation of results in a large cohort of samples (~700). Results: Overall, not many genes were significantly different between controls and diagnostic groups (N=203, P <.05), and the fold changes were small (1%-18%). There were more DE genes in SZ than BP in DLPFC (N=138 and N=13 respectively), and vice versa in Hippocampus (N=16 and N=38 respectively). There were no differentially expressed genes in SZ vs C in dura. Variation was primarily associated with Diagnosis and not with confounders (pH, RIN, race, sex). More genes (60%) were downregulated in SZ in DLPFC than upregulated. ALDH1a1, known to be involved in dopamine metabolism, was validated by qPCR in DLPFC and Hippocampus. Conclusions: Data generated from postmortem brain tissue is a valuable resource for understanding the molecular nature of psychiatric disorders, and the validated gene, ALDH1A1, has potential clinical relevance due to its known role in dopamine metabolism.

Title: Decreased number of perineuronal nets in the reticular thalamic nucleus of individuals with schizophrenia and bi-polar disorder

Authors: *M. ARDELT;
McLean Hosp., Belmont, MA

Abstract: Background: Growing evidence shows that neuronal circuits linking the prefrontal cortex to the mediodorsal nucleus of the thalamus are disrupted in subjects with schizophrenia (SZ). The reticular nucleus of the thalamus (RTN) receives massive cortical projections and is connected to the mediodorsal and other thalamic nuclei; it is thus in a strategic position to gate the flow of cortico-thalamic information. A large number of RTN neurons are enveloped by perineuronal nets (PNNs), specialized extracellular matrix structures shown to regulate synaptic functions. Growing evidence shows that PNNs are markedly decreased in several brain regions

in SZ, including the medial temporal lobe and prefrontal cortex. Similar decreases in the RTN are likely to disrupt synaptic connectivity in SZ, thus impacting the information flow within cortico-thalamic circuits. With the present studies, we tested the hypothesis that PNNs in the RTN may be decreased in subjects with SZ. **Methods**: To visualize PNNs in serial sections which contained the thalamus from healthy controls (n=15), SZ (n=15) and bipolar disorder (BD; n=15) sections were labeled using *wisteria floribunda* agglutinin lectin (WFA). Stereology-based computer-assisted light microscopy was used to estimate numerical densities of PNNs. **Results**: Step-wise regression analysis shows a significant reduction of numerical densities of WFA-positive PNNs in the RTN of subjects with SZ ($p=0.010$; adjusted for antipsychotic exposure within the last six months of life) as well as in subjects with BD ($p=0.012$; adjusted for lifetime exposure to lithium) as compared to healthy controls. **Conclusions:** Our results show significant decreases in PNN number in the RTN of subjects with SZ and also BD. Such decreases may impact synaptic stability and regulation of glutamatergic inputs onto inhibitory RTN neurons, in turn disrupting thalamic connectivity. Parallel decreases of WFA-positive PNNs in SZ and BD were unexpected and raise the possibility of overlapping pathological findings in the RTN of subjects with major psychoses.

Title: CRH, CRH-R1, CRH-R2 and CRH-BP in the prefrontal cortex and hippocampus of teenage suicide victims

Authors: *X. REN, H. RIZAVI, G. N. PANDEY;
Psychiatry, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Suicide is a major public health concern, and in youth, it is the second most frequent cause of death in the United States. Although the neurobiology of adult suicide has been studied, the neurobiology of teenage suicide has been less studied. Recent studies suggest that there is a disturbance in hypothalamic -pituitary-adrenal (HPA) axis in depression and suicide. In order to determine the role of CRH, CRH-R and CRH-BP in teenage suicide victims, we studied CRH, CRH-R1, CRH-R2 and CRH-BP levels in the prefrontal cortex (PFC) and hippocampus of postmortem teenage suicide victims compared and control subjects. The protein expression of CRH, CRH-R1, CRH-R2 and CRH-BP was determined in the prefrontal cortex (PFC),

Brodmann area 9 (BA-9) and hippocampus obtained from 17 teenage (13-19 years) suicide victims and 17 control subjects by Western blot technique. Postmortem brain samples were obtained from the Maryland Brain Collection at the Maryland Psychiatric Research Center, Baltimore, Maryland. We found that the protein expression level of CRH was significantly increased, while the protein expression levels of CRH-R1, CRH-R2 and CRH-BP were significantly decreased in the PFC of teenage suicide victims compared with control subjects. However, there was no difference in the protein expression level of CRH, CRH-R1, CRH-R2 and CRH-BP in the hippocampus of teenage suicide victims compared to control subjects. These results suggest that the alterations of CRH, CRH-R1, CRH-R2 and CRH-BP in the PFC of teenage suicide victims may be related to the pathophysiology of teenage suicide. These results also suggest region-specific alterations of protein levels of CRH, CRH-R1, CRH-R2 and CRH-BP.

Title: The effects of smoking reduced nicotine cigarettes upon resting state functional connectivity, craving and withdrawal in young smokers

Authors: *P. FAULKNER, D. GHAHREMANI, C. COX, G. HELLEMANN, E. LONDON; Semel Inst. for Neurosci. and Human Behaviour, UCLA, Los Angeles, CA

Abstract: Smoking contributes to more than 540,000 premature deaths each year in the United States, and enacting a policy to reduce the nicotine content is viewed as a way to reduce cigarette use. This study examined whether the nicotine yield of a cigarette affects the response to smoking, measured as functional coupling between brain networks that have been shown to be related to cigarette craving, withdrawal and cognition - the executive control network (ECN), default mode network (DMN), and the salience network (SN) - along with behavioural measures of craving, withdrawal, and sustained attention. Fifteen participants (11 men, 4 women), 18-25 years of age, who smoked cigarettes daily, each completed testing on 5 days in two sessions: before and after the first cigarette of the day (after overnight abstinence). Testing included resting state fMRI scans, questionnaire measures including the Urge To Smoke (UTS) scale and the Shiffman-Jarvik Withdrawal (SJW) scale, and the Rapid Visual Information Processing (RVIP) task, a test of sustained attention. Participants smoked a research cigarette containing one

of four nicotine yields (0.027, 0.110, 0.231 or 0.763 mg), or their own preferred-brand. Independent Component Analyses of the fMRI data revealed 3 ECN networks, 5 DMN networks, and 1 SN network. Positive coupling between ECN and DMN networks and SN and DMN networks was reduced after smoking, with reduction in a greater number of networks after smoking the participants' preferred brand than the .027 mg cigarette. Smoking also enhanced sustained attention, as measured via RVIP hits and A' scores, with greater improvements in A' scores after smoking cigarettes with higher nicotine yields. Finally, smoking reduced cigarette craving and withdrawal, irrespective of the type of cigarette smoked or the nicotine yield. These results extend previous observations that both ECN-DMN coupling and SN-DMN coupling are reduced following cigarette smoking, by showing that these changes depend upon the nicotine yield of the cigarette. The results also suggest that improvements in sustained attention depend on the nicotine content of a cigarette, but that self-reported smoking-induced reductions in craving and withdrawal do not. The results suggest that RSFC may be a more sensitive index of response to smoking than subjective self-reports of craving.

Title: Effect of gender and estrous cycle phase on nicotine withdrawal syndrome in the rat

Authors: *M. HENCEROTH, J. R. CAMPBELL, M. L. CANDELARIO, C. L. AGUILAR, C. A. MADISON, E. A. ODOM, M. F. MERIANO, D. H. MALIN;
Univ. of Houston Clear Lake, Houston, TX

Abstract: Several studies have suggested differences in smoking cessation withdrawal syndrome as a function of gender and estrous cycle phase. There is a need to create rodent models of these effects so that they can be studied in the laboratory. While there is a large literature on nicotine withdrawal syndrome in the rat, there are very few studies with female subjects. The probable reason for this is female rats' four-day estrous cycle, which may cause variability in study results. The present research used histological examination to determine the precise estrous phase at the time of testing. The subjects were 16 female rats and 9 male rats, all five to six months old. Vaginal fluid was collected with a micropipette, placed on a glass slide, and stained with methylene blue. The slides were examined under a microscope for phase-identifying cell

types. Once the recurring patterns of estrous phases had been identified, experiments were scheduled for either the proestrus phase (n = 8), representing a follicular portion of the cycle, and the metestrus phase (n = 8) representing a luteal portion. The predicted estrous phases were histologically confirmed immediately after each experiment. For seven days before each experiment, rats were continuously infused with 9 mg/kg/day s.c. nicotine bitartrate. On the seventh day, each subject was challenged with 1 mg/kg of the nicotinic antagonist mecamylamine. This dose has been confirmed to precipitate a vigorous withdrawal syndrome in nicotine dependent rats only. Subjects were observed over 30 min. on a standard checklist of somatically expressed withdrawal behaviors. Male rats displayed 27.7 ± 3.4 withdrawal signs (M ± SEM), while female rats in their proestrus phase exhibited an almost identical 28.5 ± 2.8 signs (M ± SEM). Female rats in metestrus displayed 42.3 ± 5.1 signs (M ± SEM). One-way ANOVA revealed a significant difference among groups, p = .024. Post-hoc comparisons (Fisher's LSD test) revealed significant differences between metestrus females and proestrus females, p = .022 and between metestrus females and males, p = .013. There was no significant difference in withdrawal signs between proestrus females and males, p = .879. This confirms the interaction between gender and estrus cycle in modulating nicotine dependence and withdrawal. It also provides a laboratory model to study the biological basis and experimental treatment of this phenomenon.

Title: A subtype-specific NPFF receptor antagonist reverses nicotine dependence

Authors: ***D. H. MALIN**[1], M. M. HENCEROTH-CHOMIAK[2], J. J. IZYGON[2], D. J. MCGHIEY[2], K. M. BRIGHT[2], D. M. NGHIEM[2], P. GOYARZU[2], E. S. BURSTEIN[3]; [1]Human Sciences,, Univ. Houston-Clear Lake Mail Code 265, Houston, TX; [2]Univ. of Houston-Clear Lake, Houston, TX; [3]ACADIA Pharmaceuticals Inc., San Diego, CA

Abstract: The nicotinic receptor antagonist mecamylamine, 1 mg/kg, precipitates a vigorous withdrawal syndrome only in nicotine-dependent rats. Previous evidence suggests that this syndrome is mediated in part by adaptations of endogenous opiate mechanisms to chronic

nicotine exposure, which triggers release of endogenous opiate peptides. Neuropeptide FF (NPFF) and related neuropeptides contribute to opiate tolerance and dependence through anti-opiate actions, which appears to be primarily mediated by the FF1 receptor. Stimulation of the FF2 receptor primarily induces pro-opiate effects. AC-262620 is a systemically active, selective FF1 receptor antagonist of small molecular weight. Thirteen rats were infused for seven days with 9 mg/kg/day nicotine bitartrate via osmotic minipump, while six were infused with saline alone. Six of the nicotine-dependent rats were injected i.p. with 10 mg/kg AC-262620, while seven received only the saline/DMSO injection vehicle. The non-dependent rats were injected i.p. with saline only. One hour after i.p. injections, all rats were challenged with 1 mg/kg mecamylamine s.c. All subjects were then observed over 30 minutes under blind conditions on a standard checklist of somatically expressed nicotine withdrawal signs. The non-dependent/saline injected group averaged 19.17 ± 2.97 signs (M ± SEM), while the nicotine-dependent rats injected with saline averaged 50.00 ± 7.12 signs. In contrast, the nicotine dependent rats pretreated with AC-262620 averaged only 24.00 ± 4.84 signs. One-way ANOVA revealed a significant group effect, $p = .002$. The AC-262620-pretreated nicotine dependent group had significantly fewer mecamylamine precipitated signs than the nicotine dependent saline-pretreated group, $p = .011$ (Tukey's HSD post-hoc test), but was not significantly different from the non-dependent group, $p = .821$. The results implicate activation of the FF1 NPFF receptor in nicotine dependence and subsequent withdrawal syndrome.

Title: The effect of nicotine administration and withdrawal on sleep in mice

Authors: *H. L. MATHEWS[1], V. GRIMSHAW[2], J. A. STITZEL[3];
[1]Psychology & Neuroscience, IBG, [2]IBG, [3]Integrative Physiology, IBG, Univ. of Colorado - Boulder, Boulder, CO

Abstract: Sleep disturbances are a commonly reported symptom during tobacco cessation attempts. They are currently the only symptom of human nicotine withdrawal syndrome that has not been correlated in a rodent model. The current study investigates the effect of nicotine administration and withdrawal on sleep quantity and quality in a forced oral nicotine mouse model. Nine subjects were implanted with EEG and EMG recording devices using standard procedures. After a recovery and acclimation period, data was recorded continuously for a 4-week period, certain days were chosen over each condition for sleep scoring. Mice had ad libitum access to food and a drinking water solution containing .2% saccharin. Baseline sleep and wake data was scored for three consecutive 24 periods, and subsequently averaged. Immediately following baseline, five of the subjects began receiving 200µg/ml of nicotine for a period of 2 weeks (nicotine group). The control group did not experience any changes. Data for this condition was scored on days 1, 4, 8, 11, and 13. Withdrawal was precipitated spontaneously by excluding the nicotine from the drinking solution; the first two days of withdrawal were scored. Nicotine consumption tended to decrease total sleep. The effect was primarily seem during the lights off period and can mostly be explained by a decrease in time spent in NREM. Additionally, nicotine withdrawal appears to have an effect on the number of stage changes, both the number of awakenings from sleep and the number of total stage changes. The current data suggests of effect of nicotine consumption and withdrawal on the sleep wake cycle.

Title: Glutamate mediates p38-induced presenilin 1 activation

Authors: *M. E. JUNG, D. METZGER;
Univ. N Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: The mutation of presenilin 1 (PS1) genes is known to mediate age-associated brain disorders such as Alzheimer disease. However, little information is available about the interaction between PS1 and stress-activated kinase p38 in response to an excitatory stress. Our previous studies have demonstrated that repeated-withdrawal from a high dose of ethanol consumption provokes the overexpression of p38α (p38 isoform) in the rat brains. Here, we tested the hypothesis that p38α induces the activation of PS1 through glutamate in response to ethanol withdrawal insults. Young adult male rats received an ethanol program, consisting of 4-week-ethanol diet and 3-week-withdrawal per cycle for two cycles. At the end of the diet program, the protein and/or mRNA levels of p38α and PS1 were measured in the prefrontal cortex. Separately, HT22 (mouse hippocampal) cells were exposed to an ethanol program, consisting of 24-hour-ethanol and 4-hour-withdrawal per cycle for two cycles to measure p38α and PS1. Finally, HT22 cells were exposed to glutamate with or without a p38α inhibitor to measure PS1 level. Both ethanol withdrawn rats and HT22 cells show an increase in the protein and mRNA level of p38 and PS1. HT22 cells treated with glutamate also show an increase in the protein level of PS1 in a manner that is attenuated by a p38 inhibitor. These results suggest that p38α activates PS1 through glutamate upon EW. They also suggest that p38α-PS1 link is readily formed under a hyperexcitatory stress.

Title: Tissue hypothalamic-pituitary-adrenal axis responses to nicotine and mecamylamine following *in vivo* continuous nicotine administration and withdrawal

Authors: *M. E. RHODES[1], L. E. HARBAUGH[1], J. A. RUTKAUSKAS[1], R. T. RUBIN[2]; [1]St. Vincent Col., Latrobe, PA; [2]Psychiatry, VA Greater Los Angeles Healthcare Syst., Los Angeles, CA

Abstract: The hypothalamic-pituitary-adrenal (HPA) axis is a three-component endocrine system that modulates physiological responses to stress. To better understand the biology of nicotine (NIC) addiction, we developed an *in vivo* model of continuous NIC administration and withdrawal in laboratory rats, in order to study HPA axis stress responses to NIC. Our earlier studies demonstrated that HPA responses to NIC were reduced and transient following continuous NIC administration, but were enhanced and sustained following NIC "withdrawal"

by mecamylamine (a NIC receptor antagonist). In the present study, following *in vivo* continuous NIC administration and withdrawal, we determined HPA axis hormone responses to NIC and mecamylamine in a three-flask, *in vitro* model of the HPA axis. Hypothalami, pituitaries, and adrenal glands were collected from male rats under two dosing conditions: 1) immediately following 2-week continuous NIC via thrice daily injections plus voluntary consumption of NIC in drinking water (to model nicotine habituation), and 2) 24 h after cessation of 2-week continuous NIC (to model NIC withdrawal). For each axis studied, one-half hypothalamus, one-half pituitary, and one adrenal gland were placed individually into three temperature-controlled flasks connected by tubing and perfused in series with modified Bradbury buffer. Sampling ports between flasks were used to collect buffer at intervals before and after addition of NIC and mecamylamine, for measurement of corticotropin-releasing hormone from the hypothalamus flask, adrenocorticotropic hormone from the pituitary flask, and corticosterone from the adrenal flask. Hormones were measured by highly specific immunoassays. The *in vitro* system maintained stable temperatures, flow rates, pH and hormone baselines. *In vitro* HPA responses were significantly higher in the continuous NIC group than in the NIC withdrawal group. Mecamylamine addition to the hypothalamus flask decreased HPA axis activity in the continuous NIC group but had little effect in the NIC withdrawal group. These results suggest that *in vitro* HPA responses are enhanced and sustained following continuous NIC, and reduced following NIC withdrawal. The findings stand in contrast to our previous *in vivo* results with continuous NIC and its withdrawal, as described above. Further *in vitro* as well as *in vivo* studies addressing the complex relationships among NIC, stress, and the HPA axis may help elucidate new approaches to the understanding and treatment of nicotine addiction.

Title: Activation of the dynorphin-kappa system in the central nucleus of the amygdala mediates the negative emotional state of nicotine withdrawal but not escalation of nicotine intake

Authors: *M. KALLUPI[1], A. COHEN[1], T. E. GRIEDER[2], G. DE GUGLIELMO[1], O. GEORGE[1];
[1]Committee on the Neurobio. of Addictive Disorders The Scripps Res. Instit, Scripps Res. Inst., La Jolla, CA; [2]Inst. of Med. Sci. and Dept. of Mol. Genet., Toronto, ON, Canada

Abstract: Abstinence from nicotine often results in emergence of a negative emotional state that predict relapse and escalation of nicotine intake in humans and rats. Prodynorphin and activation of kappa receptors have been shown to produce withdrawal-like symptoms, suggesting that activation of the dynorphin-kappa system may be responsible for the emergence of a negative emotional state leading to escalation of nicotine intake. However, the causal role of activation of the dynorphin-kappa system on measures of negative emotional states and nicotine intake in dependent animals remains to be demonstrated. To test this hypothesis we tested the effect of systemic blockade of kappa receptors using a long-lasting kappa antagonist (nor-BNI), and downregulation of prodynorphin in the central nucleus of the amygdala using a viral vector (AAV-shPdyn) on withdrawal induced-pain, -conditioned place aversion, escalation of nicotine intake and stress-induced reinstatement. We found that withdrawal-induced hyperalgesia, conditioned place aversion to withdrawal and nicotine escalation, were prevented by nor-BNI (30 mg/kg). Immunohistochemical analysis showed that prodynorphin's content was increased in the CeA in nicotine dependent rats, but not in non-dependent rats. Downregulation of prodynorphin in the CeA using AAV-shPdyn did not affect nicotine escalation, but significantly decreased withdrawal-induced hyperalgesia, aversion to withdrawal and stress-induced reinstatement using the pharmacological stressor Yohimbine (1.25mg/kg). These results demonstrate that while activation of kappa receptors mediates both the negative emotional state of withdrawal and the increased motivation for nicotine after abstinence, increased prodynorphin levels in the CeA only mediates the negative emotional state of nicotine withdrawal, but does not affect the motivation for nicotine. This report provides preclinical evidence for the efficacy of kappa antagonists in reducing the motivational effects of nicotine withdrawal, and identify that upregulation of prodynorphin in the CeA is responsible for the emergence of the negative emotional state of nicotine withdrawal.

Title: Chronic ethanol enhances corticotrophin-releasing factor-dependent potentiation of glutamatergic transmission in lateral habenula neurons

Authors: *J. YE[1], W. ZUO[2];
[2]Anesthesiol., [1]Rutgers, New Jersey Med. Sch., Newark, NJ

Abstract: Background: The lateral habenula (LHb) in the epithalamus acts as an interface between stress- and addiction-related processes. Corticotrophin-releasing factor (CRF) is associated with stress-induced alcohol use disorders. This study was to determine: (1) whether CRF regulates excitatory drive onto LHb neurons; and (2) whether the effect of CRF is altered by chronic ethanol exposure. Methods: We recorded miniature EPSCs (mEPSCs) from the LHb neurons in brain slices from rats at 24-hour withdrawal from either chronic ethanol (CET, 2g/kg, i.p., twice/day, 2 weeks) or saline (SHAM). Results: Acute CRF or ethanol enhanced mEPSCs in LHb neurons in slices from both CET and SHAM groups. CRF (40 nM), which preferentially binds to CRF1 receptors (CRF1Rs), induced a greater mEPSC enhancement in the CET than SHAM group. This is mimicked by stressin 1 (a CRF1R-selective agonist, 1.5nM). Conversely, ethanol-induced a smaller mEPSC enhancement in CET than SHAM group. Interestingly, the CRF1R-selective antagonist (NBI 27914, 1 μM) attenuated the ethanol's enhancement of mEPSCs in both groups, whereas the CRF2-selective antagonist (astressin 2b, 20 nM) and urocortin2 (a CRF2-selective agonist, 1.5 nM) respectively potentiated or suppressed mEPSCs only in the CET group. These results suggest that CRF1R activation in the LHb contributes to CRF- or ethanol-induced mEPSC facilitation. CRF2Rs act opposite to the CRF1Rs after chronic ethanol exposure. This may contribute to the weaker effect of acute ethanol on mEPSCs on LHb during ethanol withdrawal. Conclusion: The CRF system modulates neuroadaptive changes in the LHb circuit during ethanol withdrawal, and both the CRF1 and CRF2 in this area mediate important mechanisms that contribute to ethanol withdrawal.

Title: CaV1.3 channels in inferior colliculus neurons are critical for alcohol withdrawal seizures

Authors: *P. N'GOUEMO;
Pediatrics, Georgetown University Medical Center, Washington, DC

Abstract: The inferior colliculus (IC) is critical in the initiation of acoustically evoked alcohol withdrawal seizures (AWSs), and L-type of voltage-gated Ca2+ (CaV1) channels are thought to contribute to AWS pathogenesis. We have previously reported that CaV1 channel current density was elevated in IC neurons during alcohol withdrawal. Molecular studies demonstrated that CaV1.2α1 subunit mRNA expression outlasted the finite period of AWS susceptibility, whereas CaV1.3α1 subunit mRNA and protein expression occurred before and paralleled the expression of AWSs. Suppresses AWS. Furthermore, pharmacological blockade of CaV1 channels within the IC suppresses AWS. Here I further evaluate the role of CaV1.2 and CaV1.3 channels in rat IC neurons in the pathogenesis of AWSs. Adult, male Sprague-Dawley rats received three daily doses of ethanol (30% v/v in Isomil solution) every eight hours for four consecutive days; control rats received vehicle. Selective siRNA anti-CaV1.2 or siRNA anti-CaV1.3 channels were administered intra-IC daily for four days during ethanol intoxication. Rats were tested for AWS susceptibility 20-24 hours after ethanol withdrawal. AWSs consisted of wild running (WRS) that evolved into generalized bouncing clonic seizures (clonus) and occasionally tonic forelimb extension (TFE). In the control group, the prevalence of WRSs, clonus and TFE was 83%, 58% and 42%, respectively. Quantification shows that intra-IC microinjections of siRNA anti-CaV1.2 reduced the prevalence of WRS, clonus and TFE to 40%, 30% and 20%, respectively. On another token, intra-IC microinjections of siRNA anti-CaV1.3 reduced the prevalence of WRS, clonus and TFE to 13%, 0%, and 0%, respectively. Thus, selective deletion of CaV1.3 but not CaV1.2 channels in IC neurons completely suppresses the occurrence of clonus and tonic seizures. These findings suggest that CaV1.3 L-type channels in IC neurons may play an important role in the pathogenesis of AWSs.

Title: Reduced dendritic complexity in the agranular insular cortex of rats following ethanol exposure and withdrawal

Authors: *M. E. FROST[1], C. W. BIRD[1], V. L. PETERSON[1], B. MCCOOL[2], D. A. HAMILTON[1];
[1]Univ. of New Mexico, Albuquerque, NM; [2]Wake Forest Sch. of Med., Winston-Salem, NC

Abstract: The agranular insular cortex (AID) plays a critical role in social behavior and behavioral flexibility. These behaviors require a distributed set of neural circuitry that includes the amygdala, hippocampus, AID, and other frontocortical regions. Previous work from our laboratory has observed effects of ethanol exposure and withdrawal on dendritic morphology within the nucleus accumbens (NAc) of the adult rat brain (Peterson et al., 2015). Chronic exposure to ethanol followed by a short-term withdrawal period led to decreased measures of neuronal morphological complexity in the NAc core and shell, while a long-term withdrawal period resulted in increased dendritic complexity in the NAc core. The NAc has reciprocal connections to AID, therefore it is reasonable to predict that similar changes in neuronal morphology may be observed within AID. The current study sought to examine the effects of short (24 hour) and long (7 day) withdrawal from chronic ethanol exposure on dendritic morphology in AID. Adult male Sprague Dawley rats were placed in airtight Plexiglas chambers in which they were exposed to ethanol vapor (~37mg/L air) during the light cycle (12hr/day) for 10 consecutive days. This type of exposure produces blood-ethanol concentrations in rats in the 150-200mg/dL range. Control animals only received room air but were otherwise housed in identical conditions for the 10 day exposure period. The ethanol exposed animals were euthanized either 24 hours or 7 days after the 10 consecutive days of exposure. Golgi stained layer II/III pyramidal neurons from AID were traced at 200x magnification. Branch and Sholl analyses were used to analyze dendritic morphology of both apical and basilar dendritic segments. There was a reduction in the complexity of apical branching in the 7 day withdrawal group, but no effects were detected in the basilar field or in length of apical dendrites. There were no significant reductions in dendritic morphology of the 24 hour withdrawal group, however, the numerical reductions in apical length and branching in the 24 hour withdrawal group were intermediate to the 7 day withdrawal group. These data suggest a relationship between withdrawal from ethanol and morphological alterations in dendritic apical length and branching.

Title: Acute alcohol withdrawal induces sex-dependent alterations in endocannabinoid mRNA expression and negative affect in alcohol dependent rats

Authors: *A. WILLIAMS, A. L. BERGER, R. J. MCLAUGHLIN;
Washington State Univ., Pullman, WA

Abstract: In alcohol dependent individuals, withdrawal is associated with severe affective, physiological, and cognitive symptoms, and research has shown that the endocannabinoid (ECB) system is an important regulator of stress-related affective behaviors observed during acute alcohol withdrawal. Clinical and preclinical evidence demonstrates sex differences in alcohol dependence development, as well as ECB regulation of alcohol dependence, though little research has examined sexually dimorphic changes in ECB related genes during withdrawal. Therefore, this study aimed to assess sex differences in negative affect and changes in ECB related mRNA expression during acute withdrawal in alcohol dependent rats. Specifically, we measured CNR1 and CNR2 mRNA, as well as mRNA for ligands responsible for the synthesis (a specific phospholipase D [NAPE-PLD] and DAG lipase [DGL]) and metabolism (fatty acid amide hydrolase [FAAH] and monoacylglycerol lipase [MGL]) of ECBs in the basolateral amygdala (BLA), medial prefrontal cortex (mPFC), nucleus accumbens (Acb), lateral habenula (LHb), and ventral tegmental area (VTA). Adult male and female rats were exposed to 6 weeks of chronic intermittent alcohol vapor. Following dependence induction, rats were assessed for negative affective behavior in acute withdrawal, and on the subsequent day at the same time point, rats were sacrificed and their brain tissue was harvested for rtqPCR. Compared to control males, alcohol dependent males expressed more air-puff induced 22-kHz ultrasonic vocalizations, an ethologically valid measure of negative affect in rats, and spent less time in the open arm of the elevated plus maze, suggestive of increased anxiety-like behavior. However, these endpoints were not significantly altered in alcohol dependent female rats. Compared to control males, alcohol dependent males also showed decreased CNR1, CNR2, MGL, and DGL mRNA in the BLA, decreased NAPE-PLD and CNR2 mRNA in the mPFC, decreased FAAH and CNR2 mRNA in the LHb, and decreased MGL, NAPE-PLD, DGL, and CNR2 mRNA in the Acb. Notably, these changes were not observed in alcohol dependent female rats. No significant alterations in ECB related genes were observed in the VTA of male or female alcohol-dependent rats. These results demonstrate that withdrawal from chronic intermittent alcohol vapor alters both negative affect and ECB related gene expression in a sexually dimorphic manner. Furthermore, the sex-specific effects seen in alcohol withdrawal-induced negative affect may be the result of sexually dimorphic ECB signaling, which significantly contributes to our understanding of the sex differences observed in alcohol dependence.

Title: Kappa opioid regulation of depressive-like behavior and ethanol self-administration following protracted withdrawal from ethanol

Authors: D. M. CHAPA, S. K. JARMAN, *G. R. VALDEZ;
Dept Psychol, Grand Valley State Univ., Allendale, MI

Abstract: Withdrawal from alcohol is often characterized by enhanced negative affect, such as symptoms of depression and anxiety. These behavioral changes can be long-lasting in nature, which further contributes to the challenge of the long-term management of relapse prevention. Recent evidence from animal models suggests that the increased activity of the dynorphin (DYN)/kappa opioid receptor (KOR) system leads to an increase in depressive-like behaviors and ethanol self-administration following withdrawal from ethanol. The objective of the present experiments was to determine the role of the KOR system in the regulation of ethanol self-administration and depression-related behaviors following protracted abstinence from ethanol. In the first experiment, male Wistar rats were trained to self-administer ethanol using a saccharin fading procedure. Following this procedure, rats were fed an ethanol or control liquid diet for approximately 4 weeks. Three weeks after removal of the liquid diet, the ability of KOR antagonist nor-BNI decrease ethanol self-administration was examined. At the conclusion of the 3 week withdrawal period, rats were injected with saline, and 24 h later, were allowed to self-administer ethanol. Immediately following this initial self-administration session, animals were pretreated with nor-BNI (20 mg/kg, i.p.), and were again allowed to self-administer ethanol 24 h later. To assess the ability of nor-BNI to attenuate increases in depressive-like behavior, animals were examined in the forced swim test. Male Wistar rats were exposed to an ethanol or control liquid diet as described above. Three weeks after removal of the diet, rats were injected with nor-BNI (20 mg/kg, i.p.), and 24 h later, were exposed to a 10 min session of forced swim stress. The following day, rats were given a 5 min forced swim session that was recorded and examined for time spent immobile. Although rats did not show increased ethanol self-administration during protracted withdrawal from ethanol following saline injections, nor-BNI selectively decreased self-administration in ethanol dependent animals. In the forced swim test, ethanol dependent rats displayed a characteristic increase in time spent immobile compared to control rats, an effect that was reversed by pretreatment with nor-BNI. These results suggest that long-term changes in KOR mechanisms may underlie the depressive-like behavioral changes as well as ethanol self-

administration associated with protracted periods of abstinence from ethanol. **DMC and SKJ contributed equally to this project.

Title: Protective role of delta opioid receptor in alcohol withdrawal-induced hyperalgesia

Authors: D. ALONGKRONRUSMEE[1], *R. M. VAN RIJN[2,1];
[1]Medicinal Chem. and Mol. Pharmacol., [2]Neurol., Purdue Univ., West Lafayette, IN

Abstract: Chronic pain and hyperalgesia are a major health issue for which adequate treatment options are still lacking. Withdrawal from long-term alcohol consumption can induce hyperalgesia in both humans and rodents. Yet, the molecular mechanisms underlying this phenomenon are not well understood, which stifles development of new therapeutics. We have previously shown that under naïve conditions, delta opioid receptors (DORs) are expressed at a low level in the spinal cord circuits mediating thermal nociception. However, prolonged alcohol exposure can promote a redistribution of DORs to the cell surface and increase potency of DOR selective agonists. We have also shown that DORs are present in mechanical pain-mediating circuits in naïve states. However, alcohol exposure does not increase DOR agonist potency in mechanical antinociception. Interestingly, we have found that alcohol withdrawal-induced mechanical hyperalgesia is exacerbated in DOR knockout mice. This suggests that DORs play a protective role in the establishment and/or expression of alcohol withdrawal induced hyperalgesia and thus could be a promising target for treatment of chronic pain induced by alcohol withdrawal. We hypothesize that DOR expression during withdrawal may be enhanced and that DOR agonists would showed increased potency in reducing mechanical sensitivity during alcohol withdrawal compared to naïve mice. To establish alcohol withdrawal-induced hyperalgesia, mice were exposed to alcohol by oral gavage for three weeks followed by a period of abstinence during which the mice resided in a stable hyperalgesic state lasting more than two weeks. We then intrathecally administered increasing doses of the DOR selective agonists SNC80 and TAN-67 and determined mechanical sensitivity using von Frey filaments. We found that both DOR agonists reduced alcohol withdrawal-induced mechanical hyperalgesia but had reduced potency compared to naïve mice. From our results it is not evident that after withdrawal

or during withdrawal DOR expression and/or function is increased. Therefore we believe that DORs are important during the establishment of alcohol withdrawal-induced hyperalgesia or very early in its expression. Further studies will need to be designed to explore DORs at these time points.

Title: Inhibitor-2 (I-2) , a regulator of protein phosphatase-1 (PP1), mediates alcohol withdrawal anxiety-like behavior in rats

Authors: *H. YANG[1], H. HOU[1], E. R. HELLARD[2], C. ITOGA[2], B. BAYNES[2], Y. TANG[3], N. W. GILPIN[2], H. XIA[1,3];

Abstract: Alcohol use disorder is a major health concern in the VA population and in the general population, exerting an enormous toll on the society. Anxiogenic effects of withdrawal after chronic alcohol consumption contribute heavily to the negative affect thought to drive subsequent alcohol-seeking behavior. Plasticity proteins such as the transcription factor CREB, activated via phosphorylation at Ser133 (pCREB), regulate anxiety-like behavior during withdrawal in alcohol-dependent rats by regulating gene expression in the central nucleus of the amygdala (CeA). Protein phosphatase-1 (PP1), a major plasticity gene itself, inactivates CREB by dephosphorylating CREB at Ser133 in neurons. PP1 is critical for memory processes, likely due to CREB-mediated gene expression in hippocampus, but the roles of PP1 and PP1 regulation in anxiety-like behavior and excessive alcohol drinking by alcohol-dependent animals have not been explored. Our recent work has discovered that PP1 inhibitor-2 (I-2) is an important endogenous regulator of PP1 in synaptic plasticity (LTD) and memory formation (novel object recognition and contextual fear conditioning). I-2 mRNA expression level is highest in amygdala, which suggests a critical role of I-2 in amygdala-mediated brain function. Indeed, our preliminary data show that I-2 knockdown in the rat CeA blocked the anxiogenic effect of

withdrawal in alcohol-dependent rats, which indicates that I-2 promotes anxiety-like behavior in the CeA. Moreover, we found that pCREB is increased in primary amygdala neurons when I-2 is knocked-down (KD), consistent with the proposed role of CREB in anxiety-like behavior. Finally we found that I-2 expression is reduced by chronic alcohol treatment, but alcohol withdrawal leads to the rebound of I-2 to control level. Scientific Impact: Our data show that I-2 in the CeA promotes anxiety-like behavior during alcohol withdrawal in alcohol-dependent rats, likely via positive regulation of PP1 function and inactivation of CREB-mediated gene expression. These data may provide insights into future therapeutic interventions in alcohol addiction in humans.

Federal de Ciências da Saúde de Porto Alegre (UFCSPA), Programa de Pós-Graduação em Ciências da Saúde, Porto Alegre RS, Brazil

Abstract: Anxiety and craving, during alcohol withdrawal, have been related to increased levels of corticosterone and leptin. We previously reported that N-acetylcisteine (NAC), a drug that modulates glutamatergic system and presents anti-addictive properties, prevents the alcohol withdrawal-induced increase in serum corticosterone and leptin when administrated for four days after alcohol cessation in rats. Given the relevance for its potential clinical application in alcoholics, the aim of this study was to verify the effects of NAC administered before withdrawal on anxiety behaviors, corticosterone and leptin biomarker in model of moderate alcohol intake in

rats. Male Wistar rats were treated with 2 g/kg of alcohol (20% w/v, n = 30) or glucose solution (n = 30), twice daily, by gavage, 5 days/week for 3 weeks. Four days before alcohol cessation, rats were treated (i.p.) with saline (n = 10) or NAC (60 or 90 mg/kg). Twenty-four hours after alcohol cessation and 20 h after the last NAC administration, rats were exposed to the open field test (OF) for 5 min and behaviors were video recorded. Blood samples were collected and centrifuged for serum corticosterone and leptin analysis by ELISA. A two-way ANOVA, followed by Tuckey test was used to determine differences and Pearson´s test, to verify correlations (behaviors × corticosterone or leptin). Significance was set at $P < 0.05$ and ethics committee approved this study (CEUA-UFRGS: # 23069). Our results showed that alcohol withdrawal decreased the time spent in the central area in the OF ($P = 0.002$), as well as serum corticosterone ($P = 0.019$) and leptin levels ($P = 0.038$). NAC prevented alcohol withdrawal-induced anxiety ($P > 0.05$), and increased serum corticosterone and leptin levels ($P > 0.05$). There was a weak negative correlation between the time spent in the central area in the OF and serum leptin levels ($r = - 0.40$, $P = 0.008$). Using a model of chronic moderate alcohol intake, we herein show that NAC prevented anxiety behaviors and enhanced serum biomarkers induced by alcohol-withdrawal in rats. Moreover, adding to results observed in alcoholics, leptin was inversely correlated with anxiety behaviors in rats suggesting that this hormone may be involved with the negative affect of alcohol withdrawal. Translationally relevant studies can assist in the design of the clinical studies needed to confirm the usefulness of NAC in the management of alcohol withdrawal.

Title: Failure of abstinent alcoholics to engage frontoparietal control systems when viewing alcohol beverage pictures: A task-activated fMRI study

Authors: *E. M. MULLER-OEHRING[1,2], W. CHU[2], E. V. SULLIVAN[1], A. PFEFFERBAUM[2], T. SCHULTE[2,3];

Abstract: Alcoholism is associated with attentional bias toward alcohol-related stimuli that have gained emotional relevance and processing priority and may have the potential to override attention to nonalcohol-related stimuli. To test this possibility, we used a Match-to-Sample task with functional MRI to identify neural correlates of alcohol and emotional stimulus interference during task processing in 26 participants with alcohol use disorder (AUD) (sober for median=86 days), and 26 age-matched controls. The task was to match the color of a patch to the color of a word by pressing a yes-key for color matches and a no-key for non-matches. Interference from alcohol and emotion stimuli was tested interspersing pictures of alcohol beverages and emotional faces (e.g., happy, angry) between color patches and words. Overall color matching performance (response times and error rates) did not differ between groups, but groups differed in their regional activation patterns that were related to the specific task conditions and clinical characteristics. When alcohol and emotion pictures were presented during color matching (relative to gray-patch trials), controls engaged a frontoparietal network including precuneus, inferior parietal, medial and dorsolateral frontal regions, whereas AUD activated midbrain, limbic, occipital, and cerebellar regions. More activity in visual occipital and parahippocampal regions to alcohol picture trials correlated with younger age at alcoholism onset (Rho=-.43), greater lifetime alcohol consumption (Rho=.41), and greater interference (longer RT difference between alcohol and control condition) from alcohol pictures during color matching (Rho=.44). Further, in AUD lower medial frontal and insula activation to happy faces correlated with longer sobriety (Rho=-.41, Rho=-.44), more depressive symptoms (BDI, Rho=-.45), and interference from positive facial expressions during color matching (Rho=-.46); greater midbrain activation to angry faces was related to higher anxiety levels. Finally, group-by-condition interactions revealed that AUD deactivated frontoparietal executive control areas to alcohol pictures more than to negative facial emotion, whereas controls showed greater activity with greater interference from alcohol beverage pictures (precunues Rho=.40; superior frontal gyrus Rho=.52). These findings provide evidence that AUD activate limbic areas serving emotion processing but do not activate attentional control systems that could help to overcome interference from alcohol-related stimuli. Title: Rostromedial tegmental nucleus (RMTg) mediates aversive consequences of spontaneous morphine withdrawal

Authors: *G. I. ELMER, K. E. RIEGGER, C. L. MAYO, H. PALACOROLLA, D. B. BELL, P. D. SHEPARD;
Psychiatry, Maryland Psychiatric Res. Center, Univ. of Maryland, Baltimore, MD

Abstract: Neuronal circuits that have electrophysiological control over midbrain dopamine (DA) neurons help govern motivated behavior along various positive and negative dimensions. The habenula - rostromedial tegmental nucleus - ventral tegmental area circuit (Hb-RMTg-VTA) plays a prominent role in modulating these neurons. Projections from Hb to RMTg excite RMTg neurons. These neurons in turn give rise to dense GABAergic projections to midbrain DA neurons, presumably signaling negative events. RMTg neurons are densely populated with μ-opioid receptors and play a role in opioid regulation of DA neurons via disinhibition. The RMTg has been implicated in mediating the rewarding effects of opioid agonists, however its role in the negative consequences of opioid withdrawal are unknown. In the present study we explored the influence of RMTg neurons on the negative consequences of spontaneous opioid withdrawal on the reward system using brain stimulation reward (BSR). Sham (n=6) and RMTg lesioned (n=8) (quinolinic acid; 0.4M in 166nl saline 0.9%) Sprague-Dawley rats were surgically implanted with monopolar electrodes into the medial forebrain bundle (MFB). Rats were trained to nose-poke for rewarding brain stimulation. Alterations in brain reward sensitivity were assessed using a rate-frequency protocol; the shift in the frequency that maintained half-maximal response rates (HMF) quantified the change in sensitivity. Equivalent rate-frequency curves were established in Sham and RMTg lesioned rats using similar currents (~200 μA). HMF values were assessed immediately following and 24hrs after morphine administration (0, 3.0, 5.6, 10.0 or 30.0 mg/kg s.c.). The reward potentiating effects of the low morphine dose was minimal in Sham and Lesioned rats. The aversive consequences of the higher doses were evident only in the Sham animals as evidenced by a dose-dependent increase HMF. Twenty-four hours following morphine administration (acute spontaneous withdrawal) there was a significant dose-dependent increase in HMF that was again only evident only in the Sham animals. Thus, RMTg lesion eliminated the aversive effects of acute high dose morphine and spontaneous morphine withdrawal. Previous studies have demonstrated a role for the RMTg in mediating behavioral reaction to aversive events. The present study highlights the role played by the RMTg in mediating the aversive consequences of acute high dose morphine and spontaneous morphine withdrawal. The results support the notion that RMTg may play a role in negative emotional states during drug-withdrawal and contribute to compulsive drug-seeking.

Title: Microglial P2X7 receptor activity is gated by morphine-induced phosphorylation

Authors: *H. L. LEDUC-PESSAH[1], N. L. WEILINGER[2], C. Y. FAN[3], N. E. BURMA[3], R. J. THOMPSON[2], T. TRANG[3];

Abstract: Morphine is indispensable in the treatment of acute and chronic pain. However, its use is limited by the development of analgesic tolerance, such that higher and more frequent doses are required to achieve the same level of pain control. Growing evidence suggests that microglia are critically involved in the development of morphine tolerance. In the present study, we examined the expression and function of microglial ATP-gated P2X7 receptors (P2X7Rs) after repeated morphine treatment, and their role in the development of morphine analgesic tolerance. In adult male Sprague Dawley rats, repeated morphine administration caused a progressive decline in morphine anti-nociception and a loss in morphine analgesic potency. The development of analgesic tolerance correlated with proliferation and activation of spinal microglia and an up-regulation of total spinal P2X7R expression. In the spinal dorsal horn we found that P2X7Rs are predominantly expressed on microglia using both immunohistochemical co-localization and flow cytometry. Intrathecal administration of the selective P2X7R antagonist, A740003, significantly attenuated of the development of analgesic tolerance. To further characterize the effects of morphine on microglial P2X7Rs, we used the BV2 microglial cell line and found an up-regulation of total P2X7R expression with repeated morphine administration consistent with our observation in spinal cord lysates. The morphine-induced increase in P2X7R protein expression was concomitant with a potentiation of BzATP evoked P2X7R calcium responses and inward current. Both the increase in P2X7R expression and potentiation of function were mediated by μ opioid receptor activation. We next tested whether receptor phosphorylation played a role in the potentiation of P2X7R function. Daily co-administration of a protein kinase inhibitor with morphine prevented the morphine-induced potentiation of P2X7R BzATP-evoked calcium influx and inward current. Taken together, our findings demonstrate that microglial P2X7Rs are causally involved in the development of morphine analgesic tolerance. In addition, we found that

repeated morphine increases total microglial P2X7R expression and induces a phosphorylation mediated potentiation of P2X7R ion channel function.

Title: Morphine withdrawal critically involves spinal microglial P2X7 receptors

Authors: *N. E. BURMA[1], H. L. LEDUC-PESSAH[2], Z. F. CAIRNCROSS[2], T. TRANG[2]; [2]Physiol. and Pharmacol., [1]Univ. of Calgary, Hotchkiss Brain Inst., Calgary, AB, Canada

Abstract: Opioids, such as morphine, are among the most effective and widely prescribed analgesics for the management of pain. However, their repeated use can lead to opioid physical dependence, which manifests as a withdrawal syndrome upon discontinuing drug use. Converging evidence suggests that opioid withdrawal is critically mediated by changes in the spinal dorsal horn, which is a primary site of action for opioid analgesia. The present study examines the importance of spinal ATP-gated P2X7 receptors (P2X7Rs) in the expression of morphine withdrawal. We treated rats with escalating doses of morphine for 5 days. On day 5, rats received a single injection of morphine and 2 hours later were challenged with an injection of the opioid receptor antagonist, naloxone, to rapidly precipitate withdrawal. We found that morphine treated animals displayed a robust naloxone precipitated withdrawal syndrome characterized by autonomic and somatic hyperactivity. Moreover, in morphine-withdrawn animals we detected a marked increase in spinal P2X7R protein expression. To assess the role of spinal P2X7Rs in morphine withdrawal, we intrathecally injected the selective P2X7R antagonist, A740003, 1-hour prior to naloxone challenge, and found that this acute injection significantly attenuated the morphine withdrawal syndrome. In morphine withdrawn rats we found an increase in spinal expression of CD11b, a cellular correlate of microglial activation. P2X7Rs are highly expressed on microglia within the spinal cord, so we next asked whether the up-regulation of P2X7Rs following morphine withdrawal was localized to microglia. Using flow cytometry, we found that in the CD11b positive population there was a significant increase in the mean P2X7R fluorescent intensity in morphine treated rats. This increase in P2X7R expression was not observed in the CD11b negative population. To further investigate the mechanism by

which P2X7Rs respond to morphine, we used primary rat microglial cultures and the immortalized BV2 microglial cell line. Following repeated morphine treatment, we found that both P2X7R expression and function were increased in primary and BV2 microglia. Collectively, our findings reveal a critical role for spinal microglial P2X7Rs in the expression of morphine withdrawal.

Title: Escalated alcohol drinking in socially stressed mice: CRF-R1 in the ventral tegmental area

Authors: ***L. S. HWA**, E. N. HOLLY, E. ZHANG, J. F. DEBOLD, K. A. MICZEK; Psychology, Tufts Univ., Medford, MA

Abstract: The stress neuropeptide corticotropin-releasing factor (CRF) and its two receptors type-1 and type-2 (CRF-R1 and CRF-R2) are activated during acute as well as repeated stress and alcohol (EtOH) withdrawal. We aimed to study extrahypothalamic CRF-R1/R2 in the dopaminergic ventral tegmental area (VTA) in EtOH drinking that was escalated by social defeat stress and intermittent access to EtOH. Adult, male C57BL/6J mice were exposed to 30 attack bites for ten consecutive days by an aggressive resident. After ten days rest, this first group of mice (group A) was tested for EtOH drinking using intermittent two-bottle choice to 20% EtOH (w/v) and water. Pretreatment with a CRF-R1 antagonist, 17 mg/kg CP376395 ip, before each confrontation was given to a second cohort of socially defeated mice (group B). Two groups of mice were not defeated but consumed EtOH on an intermittent or continuous schedule (groups C and D). After four weeks of EtOH drinking, group A, C and D mice were implanted with bilateral cannulae into the ventral tegmental area (VTA) for either microinjections of the CRF-R1 antagonist CP376395 (0-0.6 µg) or the CRF-R2 antagonist astressin2B (0-0.5 µg). Separate groups of mice were fitted with a probe in the nucleus accumbens for *in vivo* microdialysis of dopamine. Mice with a history of social defeat stress (groups A and B) increased their daily EtOH drinking (ca. 28 g/kg/day) further than the non-defeated controls. Also, pretreatment with CP376395 before confrontations reduced the increased EtOH drinking in mice with defeat experience (group B). The intermittent EtOH access mice (group C) significantly escalated EtOH

intake compared to those on a continuous schedule (group D). We found that CP376395 intra-VTA dose-dependently reduced intermittent EtOH drinking in the stressed and non-stressed mice, but did not affect continuous EtOH intake. Also, astressin2B microinjection into the VTA non-specifically reduced both EtOH and water drinking in the stressed intermittently drinking mice, but not in the non-stressed groups. Nucleus accumbens tonic dopamine levels were elevated in the mice that were socially defeated and given intermittent EtOH compared to the non-defeated drinking mice. After an intra-VTA 0.6 μg CP376395 microinjection, dopamine significantly increased compared to baseline, again only in the stressed condition. These experiments confirm a critical role for VTA CRF-R1, but not CRF-R2, in mediating stress-induced EtOH consumption. VTA CRF-R1 signaling in mesolimbic structures may be a critical node for both reward- and stress-related pathways.

Title: Stress modulation of alcohol consumption and anxiety-like behavior in specially bred alcohol-preferring and non-preferring rats

Authors: T. O'CONNOR[1], D. CRETHERS[1], *T. B. PATTON[2];
[1]Psychological Sci., [2]Psychology, Georgia Regents Univ., Augusta, GA

Abstract: Disorders characterized by significant symptoms of anxiety, such as post-traumatic stress disorder (PTSD), are often exacerbated by one or more co-occurring disorders. In particularly, alcohol use disorder (AUD) is reported with PTSD at alarming rates. In addition, the finding that exposure to trauma increases the subsequent risk for developing AUD has been well documented. Such high comorbidity of AUD and PTSD coupled with overlapping irregularities in certain neurotransmitters and brain structures suggests that a common underlying pathology exists between these two disorders. Indeed, studies show that certain brain regions and neurocircuitry, such as the prefrontal cortex, hippocampus, and amygdala appear to be dysregulated for both disorders. Distinct lines of research focusing on PTSD and AUD individually have demonstrated a link between impaired plasticity related immediate-early gene (IEG) expression and more severely affected individuals. These findings raise the possibility that such plasticity-related IEGs may be associated with susceptibility to both PTSD and AUD. However, the exact mechanisms that predispose an individual to develop PTSD and/or AUD remain elusive. Here, we wanted to know if a predisposition to drink alcohol would correlate

with impaired fear extinction. To study this, we exposed rats that have been bred to drink large quantities of alcohol to a stressor (tone paired with mild footshook). Alcohol consumption and freezing behavior was measured before and after the alcohol preferring (P) rats were exposed to the stressor. Comparisons were made to rats that have been specially bred to have a low affinity for alcohol, non-preferring (nP) rats. After behavior testing, all brains were processed for activity patterns of the IEG, Homer 1a one of several IEGs that appears to be involved with formation and maintenance of long term changes in synaptic act. As expected, the amount of alcohol consumed by P and nP rats was significantly different before and after exposure to the stressor. In addition, differences were found in the quantity and duration of anxiety-like behaviors between P and nP rats. Contrary to our hypothesis, nP rats displayed higher levels of freezing to the conditioned stimulus (tone) compared to P rats. Fluorescence *in situ* hybridization of the prefrontal cortex revealed clear differences between these two rat breeds. Analyses of hippocampus and amygdala IEG expression will be presented as well. These findings provide further insight into common neuropathaologies of PTSD and AUD.

Title: The effect of stress on the acquisition of ethanol self-administration in rats

Authors: *C. J. HEYSER, B. HOFF;
Neurosciences, UCSD, La Jolla, CA

Abstract: The hypothesis that stressful life experiences may contribute to an individual's vulnerability to drug and alcohol abuse has received considerable attention. However, to date the results in animal models has been mixed, with many studies reporting a reduction in ethanol intake following stress. Clearly this is a complex issue as the impact of stress can depend on the magnitude of stress, its predictability, the control an organism has over it and the social environment (context). Therefore, the present study was conducted to examine the effects of unpredictable stressor exposure on the acquisition of ethanol self-administration in male Wistar rats. All rats were given two-bottle (ethanol and water) access (1 hr/day or 24 hr/day) to gradually increasing sweetened (saccharin) ethanol concentrations over a 12-week period. The final concentration of ethanol was 10% w/v. The rats were either individually housed or group housed in pairs during their access to ethanol. Animals assigned to the stress condition were exposed to unpredictable mild stressors daily (e.g., cage crowding, forced swim, cage tilt, strobic light, etc) throughout the period of the experiment. Overall, the results showed that animals

exposed to stressful conditions drank significantly less ethanol than control animals, however this result was specific to the social environment. More specifically, the stress-induced reduction in ethanol intake was greatest in animals that were group housed during their access to ethanol. In contrast, stress had little to no effect on ethanol consumption in individually housed animals. Our working hypothesis is: 1) group housed rats form a fairly stable social structure (dominance hierarchy), 2) exposure to unpredictable stressors may alter the behavior of the rats, resulting in perturbations to the established dominance hierarchy, 3) instability in the social structure along with continued stressor presentation reduces ethanol intake during acquisition. These results strengthen the hypothesis that stress can modify ethanol consumption and that this influence is dependent on the organism's history of ethanol intake and its social environment.

Title: Stress promotes alcohol consumption and excitatory GABA transmission in the VTA

Authors: *A. OSTROUMOV, A. THOMAS, W. DOYON, B. KIMMEY, J. DANI;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Although stress has been shown to promote alcohol intake in humans, the synaptic and circuit-level mechanisms contributing to this interaction remain largely unknown. We examined the effect of a single restraint stress on alcohol self-administration and on alcohol-induced dopamine (DA) signaling via *in vivo* microdialysis and *in vitro* electrophysiology. Application of restraint stress 15 hours prior to alcohol exposure significantly increased alcohol self-administration over many days and decreased alcohol-induced DA signaling in the nucleus accumbens. *In vitro* patch electrode recordings showed that this decreased DA signaling was mediated by increased GABAergic inhibition onto DA neurons in the ventral tegmental area (VTA). Following stress, local VTA GABA neurons showed a higher firing rate in response to alcohol compared to non-stressed controls. The increase in alcohol-induced GABA neuron firing after stress was blocked by bath application of picrotoxin, suggesting GABAA receptor-mediated excitation. In support, we found that stress caused a positive shift in the reversal potential of GABAA receptors located on VTA GABA neurons, an effect that could contribute to cell excitability in the presence of alcohol. To test this hypothesis, we blocked GABAA receptor-mediated excitation with acetazolamide. Acetazolamide prevented the effect of stress on alcohol-induced neurotransmission *in vitro* and *in vivo*. These findings provide evidence that acute stress switches GABAA receptor function from inhibitory to excitatory in the presence of alcohol,

which significantly alters DA neuron signaling and may contribute to increased alcohol self-administration.

Abstract: The neurotrophic factor BDNF has been implicated in pharmacological and motivational effects of ethanol. Expression of BDNF is known to be modulated by multiple microRNAs (miRNAs), including miR-206 and miR-30a-5p. We have previously shown that a history of repeated cycles of chronic intermittent ethanol (CIE) vapor exposure significantly reduced Bdnf and elevated mir-206 mRNA levels in medial prefrontal cortex (mPFC) and hippocampus (HPC), with expression returning to control levels one week after the final CIE exposure. In separate animals, a similar profile was observed after acute forced swim stress (FSS) exposure; i.e. reduced Bdnf and increased miR-206 mRNA levels in both mPFC and HPC. The present study extends these findings by examining effects of combined CIE exposure and acute or repeated FSS exposure on miRNAs that modulate Bdnf mRNA expression. Adult male C57BL/6J mice received 4 consecutive weeks of CIE vapor exposure (EtOH group) or air exposure (CTL group) in inhalation chambers (16 hr/day x 4 days/week). Three days following the final (4th) CIE cycle, half of the subjects were subjected to FSS, with one group sacrificed

after a single 10-min FSS exposure and another group sacrificed after 5 daily FSS exposures. Stressed mice were sacrificed 30 min after the final FSS. The remaining non-stressed subjects were sacrificed at corresponding time points. mPFC and HPC samples were rapidly dissected on ice and miR-206 and miR-30a-5p expression determined by real time quantitative PCR (qRT-PCR), with U6 used as the miRNA reference RNA. In the mPFC, the combination of CIE exposure with either acute or repeated FSS exposure had no effect on miR-206 expression, whereas the combination of CIE exposure and repeated (but not acute) FSS exposure increased miR-30a-5p levels (63±26% increase). In the HPC, the combination of CIE exposure and FSS increased mir-206 expression, with the degree of increase similar for acute FSS (55±30% increase) and repeated FSS (55±24% increase). These results suggest that combined chronic ethanol (CIE) exposure and stress (FSS) challenge produce dynamic alterations in expression of miRNAs that target Bdnf expression, with effects dependent on brain region and acute vs. chronic stress experience. Samples are currently being analyzed to examine effects of combined CIE exposure with acute and repeated FSS exposure on miR-30a-5p expression in HPC. Studies also are planned to directly compare effects of CIE exposure alone, FSS exposure alone, and the combination of CIE and FSS exposure on Bdnf and miRNA expression in these brain regions.

Title: Optical stimulation of CRF-positive neurons in the pVTA decreases later ethanol drinking in mice

Authors: ***L. M. DARNIEDER**[1], K. GOBROGGE[2], L. C. MELON[3], J. MAGUIRE[3], K. A. MICZEK[2];

Abstract: Stress can escalate alcohol drinking in susceptible individuals and has been modeled preclinically by exposing mice to social stress. Underlying these effects are the actions of the

stress-induced neuropeptide, corticotropin-releasing factor (CRF), which both governs the HPA axis and has actions at extrahypothalamic sites. Critically, we have shown the importance of CRF signaling within the ventral tegmental area (VTA) to persistent, voluntary escalation of ethanol consumption. As the VTA is crucial to reward circuitry, CRF signaling in the VTA may be a critical region where stress and reward are integrated. However, the exact relationship between local CRF release within the VTA and later alcohol consumption is still unclear. To clarify the role of CRF within the VTA and its effects on later alcohol drinking, we employed an optogenetic strategy to specifically activate CRF neurons in the VTA. Two transgenic lines_floxed-Channelrhodopsin2 (ChR2) and CRF-Cre_were crossed to generate progeny expressing ChR2 specifically in CRF neurons. Male and female offspring were stereotaxically implanted at eight- to ten-weeks of age with optical fibers directed towards the ventral posterior medial VTA (pVTA). Both our lab and others have identified this subregion of the VTA as containing CRF and CRF receptor subtypes. After one week of recovery, ChR2-positive and Cre-negative littermate controls were given either 10 or 30 min of continuous, daily stimulation (5ms, 20 Hz, 473nm laser pulses) intermittently for 10 consecutive days. These parameters were chosen to simulate our social defeat protocol, which has been previously shown to escalate voluntary ethanol consumption. After 10 additional days of no stimulation, mice were subjected to a two-bottle choice, continuous access alcohol (20%, v/v) drinking protocol for six weeks. Results indicate that mice receiving more frequent optical stimulation of the pVTA had reduced ethanol drinking (4.5 g/kg/24h) when compared to optically stimulated, Cre-negative controls (15.49 g/kg/24h). Based on our results, we hypothesize that optically stimulating CRF-positive neurons within the VTA modulates mesolimbic dopamine pathways and mimics the effects of episodic social stress to affect later alcohol consumption.

Title: Alcohol programs the stress axis to hyper-response to a future stress challenge from prenatal to pre-pubertal period and not after puberty

Authors: S. MURUGAN[1], M. CABRERA[1], *L. G. CHASTAIN[2], D. K. SARKAR[1]; [1]Animal Sci., Rutgers, the State Univ. of New Jersey, New Brunswick, NJ; [2]The Endocrine Program, Dept. of Animal Sci., Rutgers, The State Univ. of New Jersey, New Brunswick, NJ

Abstract: Alcohol exposure (either prenatally or in the early postnatal period) can impact developmental pathways resulting in lasting structural and regulatory changes that predispose individuals to adulthood disease including long-term hyperresponsiveness to stress with exaggerated circulating glucocorticoids, enhanced anxiety, and depression-like behaviors. Recently, it has been shown that alcohol exposures during the adolescent period similarly predisposes individuals to adulthood stress abnormalities including long-term hyperresponsiveness to stress with exaggerated circulating glucocorticoids and enhanced anxiety. This raises the question of developmental timing, when does alcohol programming of the stress axis to hyper-response cease? To address this issue we fed young rats at various stages of reproductive development (postnatal period 2-7 days of age; juvenile periods, 15-20 days of age; prepubertal period; 23- 28 days of age; or pubertal period 50-54 days age) with a liquid diet containing 11.34% alcohol to raise blood alcohol levels at the range of 150-200 mg/dl. Control animals were pair-fed an isocaloric volume of maltose dextrin. These rats were maintained in the animal house and challenged with restraint stress around 70 days of age. The stress challenge was conducted in both sexes. For females, the stress study was conducted on diestrus. Determination of plasma glucocorticoid levels at various time points after restraint demonstrated an enhanced response to restraint stress in both male and female alcohol-fed animals until pre-pubertal period and not after puberty. These results identify a critical period for alcohol developmental programming of the stress axis.

Title: CRF1R antagonism reduces ethanol consumption in models of binge drinking, relapse drinking, and stress-induced drinking in adult male C57BL/6J mice

Authors: *R. I. ANDERSON[1], M. F. LOPEZ[2], H. C. BECKER[2];
[1]Ctr. for Drug and Alcohol Programs, [2]Charleston Alcohol Res. Ctr., Med. Univ. of South Carolina, Charleston, SC

Abstract: Stress-related neuropeptides, such as corticotropin releasing factor (CRF), have been strongly implicated in excessive alcohol consumption and the development of alcohol dependence. The present series of experiments was designed to characterize effects of CRF1R antagonism on binge-like drinking, relapse drinking, and stress-induced drinking in adult male C57BL/6J mice. Mice in Experiment 1 were subjected to multiple cycles of a drinking-in-the-dark (DID) procedure (access to a single bottle containing 20% ethanol for 2 hr on days 1-3, and 4 hr on day 4). During the final week of DID, mice were injected with MTIP (0, 20, 40 mg/kg, i.p.) 30 min prior to the day 4 drinking session. The same mice were also later tested for locomotor activity 30 min after the same doses of MTIP. The 40 mg/kg dose of MTIP produced a significant decrease in binge-like ethanol consumption and reduced resultant BEC by 50% without influencing locomotor activity. Mice in Experiment 2 were tested in a chronic intermittent ethanol (CIE) drinking paradigm, a model of ethanol dependence and relapse drinking. Once stable baseline ethanol intake was established in a 2-bottle (15% ethanol vs. water) limited access (2 hr/day) procedure, mice received chronic intermittent exposure (16 hr/day x 4 days/week) to ethanol vapor (CIE group) or air (CTL group). The weekly cycles of inhalation exposure were alternated with 5-day drinking test cycles. No drug treatment occurred during Tests 1-3. As expected, mice in the CIE group consumed significantly higher levels of ethanol than CTL mice. During Test 4, MTIP (0, 5, 10, 20, 40 mg/kg, i.p.) was administered 30 min prior to each daily drinking session. At doses of 10 mg/kg and higher, MTIP reduced ethanol consumption in CIE-exposed mice while not influencing consumption in CTL mice. Experiment 3 examined the effects of MTIP on stress enhancement of CIE-induced escalated drinking. Mice in the stressed condition were subjected to a 10-min forced swim 4 hr prior to each 2-hr drinking session. During Test 5, mice were administered a 40 mg/kg dose of MTIP 10 min prior to the forced swim. MTIP prevented stress-induced elevation of drinking in CIE mice (but not CTL mice). Overall, these results support a role for CRF antagonism not only in models of excessive ethanol consumption, but also in stress enhancement of drinking in the context of dependence. The CRF system appears to remain an appealing therapeutic target for potential treatment of alcohol use disorders.

Abstract: Maternal separation and its associated early life stress (MSS) affect the endocannabinoid system thereby facilitating alcohol consumption. The consequences of alcohol consumption in the brain cannabinoid and other systems of MSS rats has not been fully studied, therefore we decided to describe such potential changes. Results showed that maternal separation (MSS+W) increased CB1R compared to NMS+W. Alcohol increased CB1R in both NMS+EtOH and MSS+EtOH rats in the nucleus accumbens compared to NMS+W rats. Both maternal separation (MSS+W) ands alcohol (NMS+EtOH) induced a reduction in the expression of FAAH. In contrast, alcohol induced in MSS+EtOH rats a similar expression of FAAH than that observed in NMS+W. Maternal separation (MSS+W) induced an increased of GABA; while alcohol reduced GABA in both NMS+EtOH and MSS+EtOH. The MS+EtOH rats exhibited similar levels of GABA than those observed in NMS+W. Alcohol increased glutamate in both NMS+EtOH and MSS+EtOH in the nucleus accumbens compared with NMS+W. MSS+EtOH rats showed an increase in the expression of MeCP2 protein compared with NMS+W. Likewise, alcohol increased D2 receptor in NMS+EtOH while reducing it in MSS+EtOH. Maternal separation (MSS+W) reduced the expression of D3 receptors but alcohol (MSS+EtOH) reversed it to a level similar to NMS+W.All these maternal separation-induced changes seem to promote alcohol consumption, potentially seeking to reverse them.

Title: Acupuncture attenuates increases in anxiety-like behaviors and ethanol self-administration in dependent rats via activation of the endogenous opioid system

Authors: *C. YANG, S. CHANG, J. KIM, Y. GWAK, J. LEE, J. LEE, B. LEE, H. KIM; Daegu Haany Univ., Suseong-Gu, Daegu, Korea, Republic of

Abstract: Withdrawal from chronic ethanol reduces mesolimbic dopamine neurotransmission that may represent the mechanism, at least in part, underlying anxiety and depression that accompanies ethanol withdrawal and might also contribute to the intense ethanol craving experienced by addicts. Our previous studies have shown that acupuncture at Shenmen (HT7) points suppresses the reduction of extracellular dopamine levels in the nucleus accumbens (NAc) and withdrawal signs during ethanol withdrawal. The aim of this study was to evaluate the effects of HT7 acupuncture on anxiety-like behaviors and ethanol self-administration during acute ethanol withdrawal in dependent rats. A role for the endogenous opioid system in ethanol and acupuncture effects is also explored. Male Wistar rats were made dependent on ethanol via chronic exposure to ethanol containing liquid diet. Behaviors in the elevated plus maze and ethanol self-administration were measured after acupuncture at bilateral HT7 points followed by 2 h of ethanol withdrawal. The role of β-endorphin in acupuncture effects on these behaviors was examined by local injection of β-endorphin into the nucleus accumbens. Results showed that acupuncture attenuated increases in open-arm exploration behavior and ethanol self-administration during withdrawal in ethanol-dependent rats. Local injection of β-endorphin into the NAc enhanced open-arm exploration and ethanol self-administration behaviors in ethanol-withdrawn rats. HT7 stimulation reduced ethanol suppression of neuronal activity in the arcuate nucleus of the hypothalamus and the decrease in β-endorphin release in the nucleus accumbens in ethanol-withdrawn rats. Furthermore, HT7 acupuncture increased c-fos expression in neurons in the arcuate nucleus projecting to the NAc. Given opioid-dopaminergic interactions in the NAc, these findings suggest that acupuncture may attenuate anxiety-like behaviors and ethanol-seeking behaviors through activation of β-endorphinergic input to the nucleus accumbens from the hypothalamic arcuate nucleus.

Title: Sex differences in alcohol and corticosterone modulation of glutamatergic input from the basolateral to the central nucleus of the amygdala

Authors: *M. L. LOGRIP, C. OLEATA, M. ROBERTO;
Committee on the Neurobio. of Addictive Disorders, The Scripps Res. Inst., La Jolla, CA

Abstract: Alcohol use disorders are pervasive psychiatric conditions characterized by high rates of relapse. The propensity to relapse can be exacerbated by stress, and females show a greater association between past stress and likelihood of relapse (Hefner et al. 2011 Am J Addict 20:307). Greater sensitivity of females to stress effects on alcohol drinking suggests sexual dimorphism in stress-sensitive brain regions, like the amygdala. We previously presented data demonstrating sex differences in the ability of acute 44 mM alcohol treatment to reduce the amplitude of basolateral amygdala (BLA) -evoked glutamatergic potentials in the lateral (CeL) and medial (CeM) central amygdala (CeA). We showed that alcohol reduced the amplitude of BLA-evoked excitatory postsynaptic potentials (eEPSPs) in the CeL of males, but this effect was reduced in females. In addition, alcohol's reduction of eEPSP amplitude was less pronounced in the CeM of both males and females. While these studies demonstrated sexual dimorphism in alcohol's acute effects in the CeA, the basis for the more prominent link between stress and alcohol in females remains unknown. We investigated whether the stress hormone corticosterone, which females release at higher levels than males after stress, could modulate the neuronal response to alcohol in the CeA. To investigate sexual dimorphism in corticosterone and alcohol modulation of BLA-CeA activity, we performed intracellular recordings of BLA-eEPSPs in the CeA of male and female rat brain slices. We found that the maximal amplitude of CeL eEPSPs was significantly reduced by 100 nM corticosterone in females, occluding any further significant reduction in eEPSP amplitude upon co-application of 44 mM alcohol. This was not observed in the medial CeA of female rats, where corticosterone treatment did not significantly alter eEPSPs, whereas subsequent addition of alcohol did significantly reduce eEPSPs. Conversely, corticosterone slightly decreased eEPSP amplitude in both CeL and CeM neurons from male rats, although this effect was significant only in the CeM. Subsequent co-application of alcohol significantly reduced eEPSP magnitude in both the CeL and CeM. We found no significant treatment-related changes in paired pulse ratios, suggesting likely postsynaptic sources for the sex differences in corticosterone and alcohol effects. Together these data demonstrate that the female CeL displays great sensitivity to corticosterone, thereby blunting the subsequent response to alcohol. Sexual dimorphism in corticosterone's effects in the CeA implicates corticosterone as a possible moderator of sexual dimorphism in stress-alcohol interactions.

Title: Ventral subiculum is critical for context-induced relapse to alcohol seeking after punishment-imposed abstinence

Authors: *N. J. MARCHANT[1], K. KAGANOVSKY[1], E. J. CAMPBELL[2], J. M. BOSSERT[1], A. BONCI[1], Y. SHAHAM[1];
[1]Natl. Inst. On Drug Abuse, Baltimore, MD; [2]Sch. of Biomed. Sci. and Pharmacy, Univ. of Newcastle, and Hunter Med. Res. Inst., Newcastle, NSW, Australia

Abstract: Background: Alcoholics typically abstain because of negative consequences associated with excessive drinking and exposure to contexts previously associated with alcohol use often triggers relapse. We recently developed a rat model that captures some characteristics of this human condition: exposure to the alcohol self-administration environment (context A) after punishment-induced suppression of alcohol seeking in a different environment (context B) provokes relapse to alcohol seeking in alcohol-preferring P-rats. Here, we studied the role of ventral subiculum (vSub) and projections from vSub to nucleus accumbens (NAc) shell in this form of relapse. Methods: We first assessed the effect of reversible inactivation of vSub by GABAa+GABAb receptor agonists (muscimol+baclofen) on context-induced relapse to alcohol seeking. We then assessed neuronal activity associated with context-induced relapse by measuring Fos, a marker of neuronal activity. We combined Fos with the retrograde tracer cholera toxin subunit B (CTb, injected into NAc shell), to assess activation in neurons projecting to NAc shell. We assessed activation in glutamatergic inputs to NAc shell, including vSub, ventral medial prefrontal cortex (vmPFC), paraventricular thalamus (PVT), or basolateral amygdala (BLA). Results: Muscimol+baclofen injections into vSub decreased context-induced relapse after suppression of alcohol seeking by punishment. Double-labeling analysis of Fos+CTb demonstrated that context-induced relapse was associated with selective activation of NAc shell projecting neurons in vSub but not vmPFC, PVT, or BLA. Conclusion: These results demonstrate a critical role of vSub in context-induced relapse to alcohol seeking after punishment and suggest that vSub may promote alcohol seeking during relapse by activation of NAc shell.

Title: NMDA and GABAA receptor-mediated plasticity in the ventral tegmental area by acute and chronic ethanol

Authors: *A. NELSON, T. J. WOODWARD, H. PARK, S. I. SHIN, S. S. PISTORIUS, S. D. BAIR, S. C. STEFFENSEN;
Brigham Young Univ., Provo, UT

Abstract: Ventral tegmental area (VTA) GABA neurons are important substrates for alcohol effects in the mesolimbic dopamine (DA) system originating in the VTA and projecting to the nucleus accumbens (NAc). We have previously reported that VTA GABA neurons are sensitive to ethanol at physiologically-relevant doses, exhibit tolerance to acute ethanol, and evince marked hyperactivity during withdrawal from chronic ethanol, which may explain the deficits in DA transmission associated with alcohol dependence. We evaluated glutamate (GLU) NMDA and GABAA receptor-mediated synaptic transmission to VTA GABA neurons during withdrawal from acute and chronic ethanol. To accomplish these studies, we used standard whole-cell and cell-attached mode electrophysiological techniques to evaluate VTA GABA neuron responses in CD-1 GAD GFP mice. In naïve animals, withdrawal from an *in vivo* 24 hr intoxicating dose of ethanol (4 g/kg), enhanced the AMPA/NMDA ratio in VTA GABA neurons. In animals made dependent on ethanol by twice daily injections of 2.5 g/kg ethanol for 6 days, there was no change in the AMPA/NMDA ratio. Similar findings were obtained when animals were exposed to chronic intermittent ethanol (CIE) in alcohol vapor chambers, where they were exposed to 250 mg% blood alcohol levels for 12 hours/day during their dark cycle for 3 weeks. High frequency stimulation induced long-term depression (LTD) of evoked GABAA receptor-mediated IPSCs in VTA GABA neurons in air-exposed animals. Work is in progress to evaluate LTD(GABA) in mice exposed to CIE. These findings suggest that GLU NMDA receptor-mediated plasticity accompanies withdrawal from a single exposure to ethanol, but GABAA receptor-mediated plasticity is operational during withdrawal from chronic exposure to ethanol, suggesting that a switch occurs in GABAA receptor inhibition similar to what has been shown during opiate dependence. These findings have important implications for understanding the adaptations in the mesolimbic reward pathway along the continuum to alcohol dependence.

Title: Functional switch in GABA(A) receptors on VTA GABA neurons by acute and chronic ethanol

Authors: *H.-J. PARK, A. C. NELSON, T. J. WOODWARD, S. I. SHIN, S. S. PISTORIUS, S. D. BAIR, S. C. STEFFENSEN;
Brigham Young Univ., Provo, UT

Abstract: The motivational effects of opiates and ethanol switch from a dopamine (DA)-independent to a DA-dependent pathway during drug dependence. A corresponding change occurs in ventral tegmental area (VTA) GABA(A) receptors in opiate-dependent animals, which switch from a GABA-induced hyperpolarization of VTA GABA neurons to a GABA-induced depolarization. This effect occurs due to increased BDNF expression and corresponding activation of the trkB receptor on VTA GABA neurons. The aim of this study was to evaluate VTA GABA neuron excitability and GABA synaptic transmission to VTA GABA neurons under ethanol-naïve, acute and dependent conditions. To accomplish these studies, we used standard whole-cell and cell-attached mode electrophysiological techniques to evaluate acute and chronic ethanol effects on VTA GABA neurons in CD-1 GAD GFP mice. In saline-injected controls, superfusion of the GABA(A) receptor agonist muscimol (IC50 = 100 nM) decreased VTA GABA neuron firing rate in a dose-dependent manner. In animals given a single, *in vivo* 24 hr intoxicating dose of ethanol (4.0 g/kg), VTA GABA neuron firing rate was relatively resistant to the effects of muscimol. Similar findings were seen in mice made dependent on ethanol by twice daily injections of 3.0 g/kg ethanol for two weeks or chronic intermittent ethanol (CIE) vapor exposure (200 mg% BAL) for 2-3 weeks. BDNF expression was increased in both the VTA and the nucleus accumbens (NAc) during withdrawal from CIE. Work is in progress to evaluate the effects of blocking the trkB receptor on alcohol dependence and VTA GABA activity. These findings suggest that VTA GABA neurons undergo a switch in GABA(A) receptor function in ethanol-dependent animals, similar to opiate-dependent animals. There also appears to be some GABA(A) plasticity after an acute administration of ethanol. We suggest these changes occur through BDNF activation of the trkB receptor.

Title: Estrogen-potentiated reinstatement of cocaine seeking

Authors: *E. M. DONCHECK[1], J. J. TUSCHER[2], M. C. DEBAKER[1], L. A. URBANIK[1], L. E. MCCARTAN[1], E. E. HERDEMAN[1], K. M. FRICK[2], J. R. MANTSCH[1];
[1]Biomed. Sci., Marquette Univ., Milwaukee, WI; [2]Psychology, Univ. of Wisconsin-Milwaukee, Milwaukee, WI

Abstract: Although it is generally accepted that peak physiological levels of the ovarian hormone estrogen confer enhanced relapse vulnerability in female cocaine addicts, the underlying mechanisms are not yet well understood. To investigate this, we sought to determine whether the primary estrogen 17β-estradiol (E2), like the stress hormone corticosterone, can promote reinstatement of cocaine seeking in response to a "subthreshold" dose of cocaine that is otherwise insufficient for reinstatement. Sexually mature female Sprague Dawley rats (90 days old/280g minimum at study onset) were surgically implanted with intravenous catheters and underwent short access (2 hour) cocaine self-administration (0.5mg/kg/0.2mL i.v. infusion) for 14 days prior to extinction training. To avoid effects on self-administration and extinction and isolate effects on reinstatement and related responses, rats did not undergo surgical ovariectomy (OVX) until after reaching extinction criterion (<15 lever presses/2-hour session for 2 consecutive days). After allowing 7 days to recover and ensuring that responding still met extinction criterion, a counterbalanced design was used to administer the following tests to each rat: E2 (10ug/kg, i.p.; 1hr pretreatment) + saline, vehicle + saline, E2 + cocaine (various doses, i.p.), vehicle + cocaine. We determined that, under these conditions, both 0.625mg/kg and 1.25mg/kg cocaine were subthreshold doses, while 2.5mg/kg cocaine was a supra-threshold dose. Although pretreatment with E2 had no effect on 0.625mg/kg cocaine, potentiated reinstatement was seen with E2 + 1.25mg/kg cocaine. Furthermore, E2 potentiated responding to 2.5mg/kg cocaine, suggesting a synergistic effect between the hormone and psychostimulant. Although further testing is required to determine if higher physiologically-relevant doses of E2 may potentiate reinstatement, these results indicate that we have developed a model to study how estrogen may set the stage for relapse in female cocaine addicts. Further investigations into localized mechanisms are currently underway.

Title: Role of a crf receptor-regulated dopaminergic projection from the ventral tegmental area to the prelimbic cortex in stress-induced relapse

Authors: *O. VRANJKOVIC, T. M. KLOEHN, M. E. NORDNESS, D. A. BAKER, J. R. MANTSCH;

Abstract: Relapse to cocaine use is frequently precipitated by stress. It is well accepted that mesocortical dopamine (DA) neurons originating from the ventral tegmental area (VTA) and projecting into the prelimbic cortex (PL) are involved in drug-seeking behavior. However, the neural mechanism through which stress regulates VTA neurons remains elusive. We and others have implicated the neuropeptide corticotropin releasing factor (CRF) in stress-induced relapse. We hypothesize that CRF release into the VTA during stress activates a subset of VTA DA neurons that project into the PL, resulting in DA D1 receptor activation and, reinstatement of drug-seeking behavior. Here we show that electric footshock (EFS)-induced reinstatement is associated with an increase in PL Fos expression and is observed in animals with a history of long access (LgA; 6hr) but not short-access (ShA; 2hr) self-administration (SA). This is consistent with our previous finding that stress-induced reinstatement is dependent on history of LgA. In addition, using the retrograde tracer, cholera toxin b, we show that VTA cells that project into the PL are active during stress-induced reinstatement. Stress-dependent PL Fos activity is, in part, due to the activation of VTA CRFR1. Antagonism of CRFR1 with intra VTA antalarmin (250ng) prevented the increase in Fos expression within the PL and EFS-induced reinstatement of cocaine seeking. We also examined the role of VTA CRFR1-mediated activation of DA projections to the PL and, thereby, D1 receptor activation in the PL, in stress-induced reinstatement using a disconnection approach involving unilateral intra-VTA delivery of the CRFR1 antagonist, antalarmin and contralateral intra-PL injection of the D1 receptor antagonist, SCH 23390 (200ng). Disconnection of the PL-VTA pathway blocked stress-induced reinstatement of cocaine seeking. Ipsilateral control injections failed to block EFS-induced reinstatement. Thus, the increase in PL Fos is dependent on both a history of LgA SA, and activation of CRFR1 within the VTA, consistent with our previous report that reinstatement to intra-CRF (300ng) VTA is heightened following LgA SA. Heightened CRF-mediated drug seeking and activation of the mesocortical pathway following LgA SA is likely attributable to increased VTA CRFR1 expression, as VTA CRFR1 mRNA expression measured using *in situ*

hybridization is increased in LgA rats relative to ShA rats and saline controls. Our results suggest that VTA CRFR1 activation induces relapse to cocaine use by activating DA cells that project to the PL and that CRFR1 regulation of this pathway is heightened as a result of prior cocaine use.

Title: Corticosterone potentiates reinstatement of cocaine seeking through endocannabinoid-mediated inhibition of GABAergic neurotransmission in the prelimbic cortex

Authors: *J. R. MCREYNOLDS[1], E. M. DONCHECK[1], O. VRANJKOVIC[1], E. N. GRAF[1], Q.-S. LIU[2], C. J. HILLARD[2], J. R. MANTSCH[1];
[1]Biomed. Sci., Marquette Univ., Milwaukee, WI; [2]Pharmacol. and Toxicology, Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Stress is a powerful trigger for relapse and can not only induce relapse but can potentiate the response to other triggers for drug use. We have shown that under certain self-administration conditions, stress alone does not reinstate cocaine-seeking. However a stressor, electric footshock stress (EFS), can potentiate reinstatement when paired with low dose cocaine. This effect is corticosterone-dependent and the effect of EFS is mimicked by systemic or intra-prelimbic cortex (PL) corticosterone indicating that it is not only necessary but sufficient and the PL, a region critical for reinstatement, is a site of action. Exactly how corticosterone potentiates reinstatement is not fully understood but may involve interactions with the endocannabinoid (eCB) system. Stress increases eCB production in the medial prefrontal cortex, and, like stress-potentiated reinstatement, is glucocorticoid-dependent and we have shown systemically that eCB signaling mediates stress-potentiated reinstatement. The present study examined this effect further by assessing the potential mechanism of corticosterone action in the PL in this effect. Male SD rats self-administered cocaine (0.5 mg/kg/inf; 14 x 2 hrs/day) and then underwent extinction training followed by reinstatement tests. EFS paired with low-dose cocaine- (2.5 mg/kg, ip) induced reinstatement whereas either low dose cocaine or EFS alone did not. Intra-PL infusions of the cannabinoid receptor 1 (CB1R) antagonist, AM251 (0.3 µg) given 15 min prior to reinstatement tests blocked both EFS- and corticosterone-potentiated reinstatement suggesting that these effects are mediated through eCB signaling in the PL. In addition, the effect of EFS or

corticosterone can be mimicked by an intra-PL infusion of the CB1R agonist, WIN 55,212 (50 ng), suggesting that eCB signaling in the PL is not only necessary but sufficient for this effect. The contribution of specific eCBs to potentiated reinstatement is currently being tested. Altogether, these data suggest that glucocorticoid-endocannabinoid interactions in the PL mediate stress-potentiated reinstatement. As CB1Rs are located on GABAergic interneurons in the PL, corticosterone effects may be the result of eCB-mediated inhibition of GABA. In support of this, bath application of corticosterone to PL slices inhibits GABAergic neurotransmission in a CB1R-dependent manner. The involvement of intra-PL GABAergic signaling in corticosterone-potentiated reinstatement is currently being examined. These findings support the hypothesis that corticosterone acts in the PL, through eCB-mediated inhibition of GABA, to potentiate reinstatement of cocaine seeking.

Title: Exposure to anabolic androgenic steroids in adolescent male rats triggers changes in susceptibility to cocaine use in adulthood

Authors: *M. POMPILUS, S. SERRANO, J.-R. GESTE, G. SOTO, T. ORTIZ, T. ORTIZ, W. NORZE, C. S. MALDONADO-VLAAR;
Biol., Univ. of Puerto Rico-Rio Piedras, San Juan, PR

Abstract: Anabolic-Androgenic steroids (AAS) are derivatives of the male sexual hormone. Studies have shown that AAS have abuse potential and are implicated in behavior impairments and somatic dysfunction. Furthermore, many elite athletes take AAS in large doses for muscle growth and to enhance their athletic performance. Common misuse of AAS has recently increased in eight 8th grade and 12th grade students. Research has shown that AAS exposure can affect the dopamine brain reward pathway. The aim of this study is to investigate whether early exposure to AAS (nandrolone decaonate) in adolescent male rats potentiate cocaine self-

administration in adulthood and modulates long lasting neurochemical brain changes. We also assessed the role of androgen receptor (AR) within the mesolimbic dopamine system following AAS treatment. Two separate groups of Sprague Dawley adolescent male rats (P28) were treated with subcutaneously injections of either supra-physiologic doses (20mg/kp)/d nandrolone or Sesame oil (vehicle) for 10 consecutive days. At P72 days, animals were implanted with intravenous catheters and trained in cue induced- cocaine seeking behavior paradigm. Our preliminary data demonstrated that pre-exposure to nandrolone during adolescence, tends to increase cocaine self-administration and significantly decrease reinstatement of cocaine seeking behavior in adulthood. In addition, significant changes in the size of several organs were observed. This study suggests that previous use of AAS increases the propensity to cocaine use and morphologic organs changes in adulthood.

Title: A history of physical, emotional, or sexual abuse predicts higher mesolimbic response to drug cues in cocaine-dependent patients

Authors: *P. REGIER[1], Z. A. MONGE[1], J. J. SUH[1], K. JAGANNATHAN[1], Z. WANG[1], J. F. MAGLAND[2], A. TEITELMAN[3], T. R. FRANKLIN[1], R. R. WETHERILL[1], K. YOUNG[1], M. J. GAWRYSIAK[1,4], D. D. LANGLEBEN[1], C. P. O'BRIEN[1], A. R. CHILDRESS[1];

Abstract: Aims: Previous studies have reported that a history of adverse experiences is associated with higher rates of mental health issues, including addiction. Here, we investigated whether a history of physical, emotional, or sexual abuse in cocaine-dependent patients was associated with greater cocaine cue-triggered activity in nodes of the mesolimbic reward circuitry **Methods:** Treatment-seeking cocaine-dependent patients (n=26) were recruited as part of a 6 month treatment study. Before the start of the study, participants were administered the

Addiction Severity Index (ASI), which contains questions measuring prior abuse (emotional, physical, or sexual). After inpatient stabilization, participants were scanned with event-related blood-oxygen-level-dependent functional MRI during exposure to brief (500 msec) evocative (cocaine, sexual, aversive) vs. neutral cues. Forty-eight images of each cue type were presented in a quasi-random order. Imaging preprocessing (alignment, registration, normalization, smoothing, and motion correction) and first level analysis were conducted within a standard SPM8 pipeline. The responses to the abuse questions were used to create a split (abuse yes - abuse no) for the *cocaine-neutral* cue contrast. **Results:** From the ASI, there were 12 patients that reported a history of abuse and 14 that reported no abuse. As predicted, patients reporting abuse had greater brain activation to the cocaine (vs. neutral) cues in several mesolimbic regions, including the midbrain (VTA), ventral striatum, dorsal striatum, and caudal orbitofrontal cortex to drug cues compared to patients reporting no abuse ($2<t<5$). **Conclusions:** Individuals with adverse life events have been found to be more susceptible to drug addiction. In our study, even though all patients were cocaine dependent, our results provide initial evidence that a history of abuse could have a brain impact (i.e., heightened limbic response to drug cues) that drives drug seeking. Our results highlight heterogeneity within a cocaine-dependent population, indicating the need for individually-tailored treatment. Importantly, to our knowledge, this is the first evidence of a history of abuse on brain vulnerability that is linked to relapse.

Title: Corticotropin releasing factor and dopamine interactions in a heterogeneous ventral tegmental area: How can aversive experiences heighten cocaine self-administration?

Authors: *E. N. HOLLY[1], C. O. BOYSON[2], S. MONTAGUD-ROMERO[3], J. F. DEBOLD[1], K. A. MICZEK[1];

Abstract: Intermittent social defeat (on days 1, 4, 7, and 10) escalates later cocaine self-administration. Both rewarding and stressful stimuli increase extracellular dopamine (DA) in ventral tegmental area (VTA) projection targets_the medial prefrontal cortex (mPFC) and nucleus accumbens (NAc). Corticotropin releasing factor (CRF) and its receptors (CRFR1 and CRFR2) are located in the VTA and may influence DA activity during stress, resulting in later heightened vulnerability to addiction. These experiments explore how CRF acts on its receptors both during and after stress to influence mesocorticolimbic DA and cocaine self-administration. *In vivo* microdialysis on d 1 and 10 of social defeat showed phasic CRF release in the VTA. In the rostral VTA, CRF was phasically increased on d 10, but not d 1. In the caudal VTA, CRF was phasically increased on both d 1 and d 10, with greater increase on d 1. Additionally, baseline CRF concentration was increased on d 10 compared to d 1 regardless of probe placement. This CRF release in the VTA affected extracellular DA in both the mPFC and NAc, mediated by CRFR2. Rats were microinjected with a CRFR1 or CRFR2 antagonist into the VTA prior to each defeat, and microdialysis for DA in the mPFC and NAc conducted concurrently on d 1 and 10. Extracellular DA was significantly increased in both regions during both acute and repeated social defeat. On d 1, intra-VTA CRFR2 antagonism prevented the DA increase in the NAc, while not affecting mPFC DA. CRFR1 antagonism had no effect. On d 10, intra-VTA CRFR2 antagonism prevented the DA increase in both the mPFC and NAc, while CRFR1 antagonism still had no effect. Intra-VTA antagonism of both CRFR1 and CRFR2 during each defeat prevented later escalated cocaine self-administration during a 24 h “binge”. CRFR1 antagonism in the caudal, but not rostral, VTA prevented escalated “binge” cocaine self-administration in stressed rats, while the converse was found for CRFR2 antagonism. VTA CRF also played a role in later cocaine seeking. Rats acquired cocaine self-administration and were placed in forced abstinence for 15 d, followed by context-induced reinstatement testing. Previously stressed rats pressed the previous active lever significantly more than controls, which was blocked by both intra-VTA CRFR1 and CRFR2 antagonism. *In vivo* microdialysis found no phasic increase in CRF during reinstatement, although tonic levels were significantly higher in previously stressed rats compared to controls. In conclusion, CRF in the VTA plays a key role in DA function during stress, promoting neuroadaptations driving later increased drug taking and seeking.

Abstract: Corticotropin releasing factor (CRF) signaling in the ventral tegmental area (VTA) regulates stress-induced psychostimulant self-administration. However, the source of VTA-CRF and the molecular mechanisms underlying this drug-seeking behavior remain unclear. Thus, we used viral-vector-based tract-tracing by stereotaxically infusing an AAV-Flex-ChR2 virus bilaterally in the ventral-posterior-medial (VPM) region of the VTA in CRF-Cre mice. CRF neurons in the lateral hypothalamus (LH) and dorsal raphe nucleus (DRN) projected to and from the paranigral (PN) and parainterfasicular (PIF) subnuclei of the VTA. DRN-VPM CRF dendrites form putative synapses on subsets of dopaminergic (DA-ergic) neurons co-expressing CRF1/2 receptors in the VPM while LH-VPM CRF processes did not. Both of these circuits were activated, evident by c-FOS-immunnoreactivity (-ir), following a single 30-minute restraint or 15-minute social defeat stress. Although this circuit is activated by chronic stress (i.e., 10 days of social defeat), there are fewer synapses double-labeled with PSD95 and VGLUT1. Thirty-minutes of restraint stress increased CRF-ir fibers in the PN/PIF, consistent with microdialysis studies demonstrating CRF release in the VPM of intruder rats experiencing social defeat stress. Specifically activating the PN/PIF using either optogenetics or Gq-DREADD in CRF-Cre mice was sufficient to mimic chronic social defeat stress-induced drug-seeking behavior. Daily 30-minute activation of CRF signaling in the PN/PIF for 10 consecutive days followed by 10-days of rest induced behavioral sensitization to a single intra-peritoneal injection of dextro-amphetamine (d-AMPH, 1.5mg/kg). Together, these data suggest that CRF neurons in the DRN are activated by stress, releasing CRF in the PN/PIF, which modulates behavioral sensitization to d-AMPH. This research was supported by an NIMH R01 research grant NS073574 to J.M., a NIDA grant 031734 to K.M., and the Tufts Center for Neuroscience Research grant P30 NS047243. Title: Prevention of escalated cocaine self-administration and cocaine seeking by CRF R1 antagonist in socially defeated mice

Authors: *X. HAN, K. A. PEREZ, A. J. LOTSTEIN, J. F. DEBOLD, K. A. MICZEK;
Dept. of Psychology, Tufts Univ., Medford, MA

Abstract: Social defeat stress can result in escalated cocaine self-administration and cocaine seeking in rodents. Corticotrophin releasing factor (CRF) represents the initial step in the stress cascade that leads to escalation of drug use and drug seeking behaviors. However, the contribution of CRF receptor subtypes to cocaine reinstatement and their role during different phases of stress-induced cocaine self-administration still remains to be defined. The current study examines the effects of CRF R1 antagonist on escalated intravenous cocaine self-administration and cocaine reinstatement as a result of exposure to social defeat stress in mice. (1) The CRF R1 antagonism (CP 376,395, 15mg/kg) given 30 min prior to each social defeat episode prevented stress-induced cocaine self-administration in mice. (2) Administration of CP 376,395 (5 mg/kg and 15 mg/kg) 10 days after the last episode of social stress, dose-dependently reversed the escalation of cocaine intake. (3) In addition, we showed that CP 376,395 administration prior to reinstatement test decreased stress-induced cocaine seeking behaviors. (4) To further explore the role of CRF R1 in specific brain sites, CP 376,395 (0.5 µg/ 0.2 µl and 1 µg/ 0.2 µl) was delivered directly into the ventral tegmental area (VTA) before cocaine self-administration session 10 days after the last stress episode. Intra-VTA antagonism of CRF R1 was sufficient to reverse stress-induced escalated cocaine self-administration. These findings suggest that CRF R1 exerts multiple roles during initial reaction to social stress and in long-term neuroadaptations that are relevant to escalated cocaine self-administration and cocaine seeking, providing a potential target for therapeutic inventions for stress-induced drug use disorders.

Title: Increased sensitivity to cocaine-induced relapse to drug-seeking behavior in organic cation transporter 3 knockout mice

Authors: *P. J. GASSER, J. R. MCREYNOLDS, O. VRANJKOVIC, O. DERRICKS, B. NINO, T. AMBROSIUS, J. R. MANTSCH;
Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: Cocaine addicts report that craving responses to drug-associated stimuli are intensified during periods of stress, resulting in heightened susceptibility to relapse of drug use. These reports are paralleled by findings that stress can potentiate the reinstatement of cocaine-seeking behavior by drug-associated cues in rodents. Together, these studies suggest that stress may act as a "stage-setter", inducing state-dependent changes in the sensitivity of brain reward circuits to the reinforcing properties of drugs, and enhancing the potency of drugs of abuse or drug-associated cues to induce relapse. Thus, interactions between pathways activated by stress and by cocaine-associated stimuli are likely to be critical determinants of relapse vulnerability. However, the mechanisms underlying these interactions are not completely understood. We recently demonstrated that corticosterone (CORT) acutely blocks dopamine clearance in the nucleus accumbens (NAc), likely mediated by the uptake2 transporter organic cation transporter 3 (OCT3), a high-capacity corticosteroid-sensitive monoamine transporter. We provided evidence that, through this mechanism, CORT potentiates the actions of cocaine on dopamine signaling and reinstatement of drug-seeking behavior in rats. We have hypothesized that decreased clearance of dopamine in the NAc, due to CORT-induced inhibition of OCT3, enhances dopaminergic neurotransmission, resulting in increased sensitivity to natural and cocaine reward, and heightened vulnerability to relapse of cocaine-seeking behavior. While OCT3 is the most likely mechanism underlying CORT effects on dopamine clearance and relapse, support for its role in these processes is based on pharmacological tools (CORT and normetanephrine) which can exert actions at other, non-OCT3, targets. To more definitively test the hypothesis that OCT3 inhibition underlies CORT-induced potentiation of relapse, the present studies examined the effects of CORT and normetanephrine, two inhibitors of OCT3, on cocaine-primed reinstatement of conditioned place preference in wild type and OCT3 knockout mice. Compared to wild-type mice, OCT3-knockout mice were more sensitive to low-dose cocaine-induced reinstatement of conditioned place preference. In wild-type mice, both CORT and normetanephrine potentiated low-dose cocaine-induced potentiation of CPP, while both OCT3 inhibitors were without effect in OCT3 knockout mice. These studies suggest that the previously-described effects of CORT on relapse to drug seeking behavior are mediated, at least in part, by inhibition of OCT3-mediated dopamine transport.

Title: Corticosterone potentiates the effect of cocaine on nucleus accumbens dopamine release and clearance

Authors: *D. S. WHEELER, A. L. EBBEN, A. T. BOHN, I. A. JASEK, D. A. BAKER, J. R. MANTSCH, R. A. WHEELER, P. J. GASSER;
Marquette Univ., Milwaukee, WI

Abstract: Stress and cocaine act synergistically to increase extracellular dopamine and drive cocaine seeking. This interaction is mediated in part by the effects of corticosterone in brain areas that receive dopamine innervation, such as the nucleus accumbens and medial prefrontal cortex. We have recently demonstrated that corticosterone acts to decrease dopamine clearance in the nucleus accumbens via a dopamine transporter (DAT)-independent mechanism likely involving the inhibition of organic cation transporter 3 (OCT3)-mediated transport. We have also demonstrated that corticosterone potentiates the effects of cocaine on nucleus accumbens dopamine signaling and drug-seeking behavior. However, it is not known whether the corticosterone-induced reduction in clearance is accompanied by an increase in dopamine release events, or whether corticosterone affects clearance in the absence of DAT blockade. We examined the effect of acute corticosterone treatment on dopamine release and clearance in the nucleus accumbens core and shell of behaving rats to examine how the stress hormone acts centrally to augment the dopamine response to cocaine. Using fast scan-cyclic voltammetry, we measured naturally-occurring transient dopamine release events during a baseline period, after a systemic injection of corticosterone (2 mg/Kg, ip) or vehicle (2.5% EtOH, ip), and after a subsequent systemic injection of low-dose cocaine (2.5 mg/Kg, ip). Results show that corticosterone potentiates cocaine's effect on dopamine transient frequency and amplitude, suggesting that the reduction in dopamine clearance increases the number of spontaneous release events. Furthermore, preliminary findings indicate that corticosterone alone produces a mild increase in extracellular dopamine, suggesting that the inhibition of OCT3 modulates dopamine signaling in the absence of DAT blockade. Ongoing studies are investigating the potential impact of corticosterone on phasic dopamine encoding of natural rewards in order to determine whether the effects of corticosterone extend beyond situations in which the DAT is blocked by cocaine.

Title: Effects of cannabidiol on cocaine self-administration and cue-induced cocaine seeking in male rats

Authors: A. MAHMUD, S. GALLANT, T. D'CUNHA, *U. SHALEV;
Concordia Univ., Montreal, QC, Canada

Abstract: Drug abuse, a chronic disorder involving uncontrollable drug seeking, abstinence, and relapse, causes 47,000 deaths in Canada each year. For cocaine, a psychostimulant drug, a staggering 61.9% of abstinent users relapse and deaths related to its use have increased by 29% from 2001 to 2013. Despite this, adequate treatment has yet to be developed. Recent research in rats demonstrated that cannabidiol (CBD), one of the non-psychoactive compounds in cannabis, attenuated cue-induced heroin-seeking 24 hours after injection, thus suggesting that CBD may be a potential treatment option for opiate use. CBD has also been shown to enhance the extinction of cocaine-induced conditioned place preference. Here, we investigated the effects of CBD on cocaine self-administration and cue-induced cocaine seeking. In experiments 1 and 2, rats were trained to self-administer cocaine in operant chambers and then exposed to a 14 days withdrawal period while housed in the animal colony. Exp. 1: To investigate the effects of CBD on cocaine self-administration, rats were trained to self-administer for 5 days on a fixed ratio 1 (FR-1), followed by 12 days of a progressive ratio schedule of reinforcement. Rats were then injected with three doses of CBD (0.0 mg/kg, 5.0 mg/kg, and 10 mg/kg; i.p.) 30 min before the self-administration session. Exp. 2: To investigate the effects of CBD on cue-induced cocaine seeking, rats were trained on FR-1 schedule for 10 days. Following a 14 day withdrawal period, rats were returned to the operant conditioning chambers and tested for cocaine seeking under extinction conditions. Rats received one of three doses (0.0 mg/kg, 5 mg/kg, or 10 mg/kg), 24 hours prior to the test. Exp. 3: As CBD has been shown to have anxiolytic properties, the efficacy of CBD treatment (0.0 mg/kg and 10 mg/kg) was evaluated using an elevated plus-maze anxiety test. CBD did not attenuate cocaine self-administration or cue-induced cocaine seeking following prolonged withdrawal. In fact, CBD treatment appeared to augment cue-induced cocaine seeking and could thus be a risk factor in cocaine relapse. CBD treatment produced a clear anxiolytic effect in the elevated plus-maze, validating the efficacy of CBD as used in the present experiments. Overall, our findings suggest that CBD may not be a potential treatment option for cocaine addiction. Future studies should investigate the effects of repeated administration and higher doses of CBD, as well as the effects of CBD on cocaine seeking induced by re-exposure to cocaine (priming) or exposure to stress.

Title: Cannabinoid exposure in adolescence modulates cocaine reward in adulthood

Authors: *J. M. WENZEL[1], J. F. CHEER[1,2];
[1]Anat. & Neurobio., [2]Dept. of Psychiatry, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Marijuana is the most commonly abused illicit drug among adolescents, and regular use of cannabinoids (CBs) in this vulnerable population is associated with the development of psychiatric disease including drug abuse. Human research indicates that adolescent CB use predicts future cocaine (COC) abuse, however, the underlying cause of this phenomenon is unclear. Adolescent CB exposure disrupts the dopaminergic response to COC in adulthood suggesting that CB use may disturb the subjective experience of COC. It is well documented that immediate euphoria produced by COC administration is subsequently replaced by feelings of dysphoria and anxiety. Thus, it is likely that an individual's experience of either of these opposing processes may motivate successive COC use. Here we utilize a modified place conditioning test to assess how CB exposure in adolescence affects COC's dual positive and negative effects. In this test rats are conditioned to associate a unique environment with the effects of COC present either immediately or 15 min after IV COC injection. Characteristically following place conditioning rats exhibit a preference for the environment paired with COC's immediate/positive effects (a CPP), and an aversion for the environment paired with COC's delayed/negative effects (a CPA). Therefore, we assessed the impact of CB exposure in adolescence on adult COC reward and aversion. Adolescent male rats were treated with one of three doses of the synthetic CB WIN 55,212-2 (WIN; 0.5mg/kg, 2mg/kg, 5mg/kg) or its vehicle (VEH) once per day for eight days (PND35-42). Following treatment rats were left in their home cages until they reached adulthood at which point they underwent place conditioning for either the immediate/positive or delayed/negative effects of COC (PND77-86). Interestingly, while rats treated with VEH during adolescence developed the typical pattern of COC CPP and CPA, exposure to WIN during adolescence dose-dependently resulted in the development of CPA for the immediate effects of COC (an outcome opposite to the canonical COC CPP), while not disrupting CPA for COC's delayed/negative effects. These data suggest that CB exposure in adolescence diminishes COC's rewarding effects in adulthood and, in fact, results in a predominantly negative experience within the first 5 min after administration (i.e. the length of

each conditioning trial). It remains unclear how these alterations in COC reward translate to COC seeking in adulthood. In animal models, however, reduced COC reward is associated with increased COC intake, suggesting that these observed decrements in COC reward might contribute to increased COC administration.

Title: Pituitary adenylate cyclase activating polypeptide (PACAP) increases neuronal excitability in the bed nucleus of the stria terminalis (BNST)

Authors: *K. R. LEZAK[1], V. MAY[2], S. E. HAMMACK[1];
[1]Psychological Sci., [2]Neurolog. Sci., Univ. of Vermont, Burlington, VT

Abstract: The bed nucleus of the stria terminalis (BNST) has been implicated in mediating many of the consequences of exposure to stressful stimuli. Pituitary adenylate cyclase- activating polypeptide (PACAP) and its cognate PAC1 receptor have been associated with several mental health disorders that are related to stressor exposure and/or the dysregulation of the HPA axis, including mood and anxiety disorders. We have previously demonstrated increased PACAP and PAC1 receptor expression in the BNST following stressor exposure, and increased BNST PACAP signaling is necessary and sufficient for many of the behavioral and endocrine consequences of stressor exposure. These effects may be, in part, mediated by excitatory effects of PACAP on BNST neurons. In the present studies, we used whole-cell patch-clamp electrophysiological techniques in BNST slices to demonstrate that exogenous PACAP application enhances excitability in a subset of BNST neurons in a manner consistent with an enhancement of the hyperpolarization activated cation current, I_h. BNST neurons have been previously characterized into several physiological cell types; the PACAP response occurred primarily in type 2 neurons, which are characterized by the presence of both I_h and the low-threshold calcium current, I_T. The BNST response to PACAP was blocked by the I_h channel blocker, ZD7288, but not the I_T channel blocker, $NiCl_2$, suggesting that PACAP-induced

excitability was mediated by I_h, but not I_T, enhancement. These results support converging data suggesting that BNST PACAP signaling plays a key role in regulating stress and anxiety-like responding, and maladaptations in BNST PACAP systems may lead stress- related psychopathologies.

Title: Intra-bed nucleus of the stria terminalis (BNST)pituitary adenylate cyclase activating peptide (PACAP)infusion reinstates cocaine seeking in rats

Authors: *O. MILES[1], E. A. THRAILKILL[1], V. MAY[2], M. E. BOUTON[1], S. E. HAMMACK[1];
[2]Dept. of Neurolog. Sci., [1]The Univ. of Vermont, Burlington, VT

Abstract: The tendency of users to relapse severely hinders adequate treatment of addiction. Physical and psychological stressors often contribute to difficulties in maintaining behavior change, and may play a significant role in relapse. We have previously shown that the activation of pituitary adenylate cyclase activating peptide (PACAP) systems in the bed nucleus of the stria terminalis (BNST) mediate many consequences of chronic stressor exposure. Hence, chronic stress substantially increased BNST PACAP levels, intra-BNST PACAP infusions produced the behavioral and endocrine consequences of stressor exposure, and BNST PACAP antagonism blocked many of the consequences of chronic stress. In the present set of studies, we investigated the role of BNST PACAP in stress-induced reinstatement of cocaine seeking. All rats self-administered cocaine (3mg/ml; 0.5mg/kg/infusion, i.v.) for 1hr daily over 10 days followed by extinction training in which lever pressing no longer resulted in cocaine delivery. In the first experiment we showed that intra-BNST PACAP infusion (1 μg; 0.5 μl per side) could reinstate previously extinguished cocaine seeking behavior. In the second experiment we found that intra-BNST infusions of the PAC1/VPAC2 antagonist, PACAP 6-38 (1 μg; 0.5 μl per side) blocked reinstatement following stressor exposure (5 sec 2mA footshock). Overall, these data suggest that BNST PACAP systems mediate stress-induced reinstatement to drug seeking. Understanding the neuropharmacology of BNST PACAP in stress-induced reinstatement and the role of PACAP systems may lead to viable targets for relapse prevention.

Title: Antagonism of dopamine D4 receptors in the lateral habenula reduces the anxiogenic response to cocaine in a runway model of drug self-administration

Authors: ***K. SHELTON**[1], K. BOGYO[2], T. SCHICK[2], A. ETTENBERG[1];
[1]Dept. of Psychological and Brain Sci., [2]Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Human users of cocaine report that the initial "high", or period of euphoria, that results from taking the drug is temporally replaced by an aversive "crash" that is characterized as a period of agitation, anxiety and anhedonia. Our laboratory has previously reported that self-administered cocaine in rats produces behavioral effects consistent with the human report - that is, an initial experience of reward followed by a period of anxiety and anhedonia. While the positive motivating effects of cocaine have long been thought to require an intact mesolimbic dopamine (DA) system, the neural mechanisms that give rise to the negative effects of the drug remain less clearly defined. Recent literature points to the lateral habenula (LHb) as a site for the encoding of aversive or anxiogenic events and has also been shown to "gate" the activity of the DA reward system by inhibiting the activity of DA cells within the VTA. This "gating" is hypothesized to stem from a negative feedback loop originating in the VTA, and involving DA projections to the LHb and direct and indirect reciprocal connections back to the VTA. The current study investigated the putative modulatory effects of DA stimulation on the aversive/anxiogenic properties of cocaine as measured in a runway model of IV self-administration. Male rats were stereotaxically implanted with bilateral cannulae aimed at the LHb and then trained to run a straight alley for IV cocaine (1.0 mg/kg) delivered upon arrival in a goal-box. As we have previously reported, vehicle pretreated controls developed approach-avoidance conflict behaviors about goal-box entry that are reflective of the dual positive and negative effects of IV cocaine. The frequency of such behaviors was significantly diminished in animals pretreated with bilateral intra-LHb injection of the D4 receptor antagonist, L-745,870. These results suggest that DA neurons in the VTA may not only be involved in producing the positive-rewarding effects of cocaine, but also actively subduing the negative after-affects of the drug. Title: Activation of serotonin 1B autoreceptors in the Bed Nucleus of the Stria Terminalis attenuates the negative/anxiogenic effects of cocaine

Authors: ***A. KLEIN**, M. BRITO, N. LE, T. OHANA, A. PATIL, C. PROVENZANO, A. WEI, A. ETTENBERG;
Psychological and Brain Sci., UC Santa Barbara, Santa Barbara, CA

Abstract: Consistent with the Opponent Process Theory of motivated behavior, cocaine administration produces dual and opposing affective states: an initial rewarding "high" followed by a dysphoric/anxiogenic "crash". It therefore seems likely that the motivation to seek cocaine is dependent upon the organism's assessment of the positive relative to the negative consequences of its use. While the neurobiology of the reinforcing aspects of cocaine has been well established, less is known about the systems responsible for the drug's negative actions. In this context, the current study involved an assessment of serotonergic (5-HT) function, which is enhanced by cocaine administration and has been linked to the presence of anxiogenic and depressive states in human and animal studies. In particular, we investigated the role of 5-HT within the bed nucleus of the stria terminalis (BNST) - a structure within the extended amygdala that is activated during periods of stress and during the negative affective state associated with the withdrawal from drugs of abuse. The present study tested the hypothesis that increased 5-HT release in the BNST contributes to the anxiogenic effects of cocaine. A runway self-administration paradigm was employed in which animals were trained to traverse a straight alley in order to earn an infusion of IV cocaine (1.0mg/kg) delivered upon goal box entry. Testing consisted of 16 single daily trials. In this task, animals develop ambivalence about goal box entry (reflected by the development of approach/avoidance "retreat" behaviors) that we have shown to reflect the dual positive (rewarding) and negative (anxiogenic) associations that subjects form with the cocaine-paired goal-box. To assess the involvement of 5-HT signaling within the BNST on this conflict behavior, prior to each trial rats received bilateral intracranial injections of CP94,253 (0.0µg, 0.5µg, or 1.0µg/side in 0.5/µl), a potent and selective 5-HT1B agonist that inhibits local 5-HT release via activation of terminal autoreceptors. Results indicated that CP94,253 did not alter the positive incentive properties of cocaine (start latencies were unaffected) nor did it alter gross motor behavior (as revealed in subsequent locomotor activity

testing). Treatments did, however, selectively attenuate the negative effects of cocaine, as indicated by a dose-dependent decrease in the frequency of approach-avoidance "retreat" behaviors. We therefore conclude that 5-HT signaling within the BNST likely contributes to the negative/anxiogenic effects of cocaine. This work supported by NIDA grant DA-033370 awarded to AE.

Title: Role of anterior dorsal lateral hypothalamic area perineuronal nets in the acquisition of cocaine-induced conditioned place preference

Authors: ***J. M. BLACKTOP**[1], L. CHURCHILL[2], R. P. TODD[1], M. SLAKER[1], B. A. SORG[1]; [1]Dept. of Integrative Physiol. and Neurosci., Washington State Univ. Vancouver, Vancouver, WA; [2]Dept. of Integrative Physiol. and Neurosci. (IPN), Washington State Univ., Pullman, WA

Abstract: Addiction involves drug-induced neuroplasticity of the circuitry of motivated behavior, which includes the medial forebrain bundle and the lateral hypothalamic area. Emerging at the forefront of neuroplasticity regulation are specialized extracellular matrix structures that form perineuronal nets (PNNs) around certain neurons, mainly parvalbumin positive (PV+) fast-spiking interneurons (FSINs), making them a promising target for the regulation of drug-induced neuroplasticity. Despite the emerging significance of PNNs in drug-induced neuroplasticity and the well-established role of the lateral hypothalamic area (LHA) in reward/reinforcement/motivation, very little is known about how PNN-expressing neurons control drug-seeking behavior. The goals of this experiment were: 1) to determine areas of high PNN expression within the LHA, and 2) whether PNN expression within the LHA is necessary for the rewarding effects of cocaine exposure, measured by conditioned place preference (CPP). A discrete region of the anterior dorsal LHA (LHAad) was found to exhibit robust PNN expression, while the anterior ventral LHA (LHAav) exhibited comparatively sparse PNN expression. Compellingly, PNN removal via chrondroitinase ABC (Ch-ABC) administration in the dorsal but not the ventral anterior LHA prior to conditioning abolished acquisition of cocaine-induced conditioned place preference, highlighting the importance and specificity of PNN removal within this subregion of the LHA. Consistent with previous findings, it was determined approximately that 87% of WFA positive neurons co-expressed parvalbumin in the LHAad of drug naïve rats. Additionally, removal of PNNs in the LHAad did not affect total

locomotor activity or high-fat food intake in a separate group of cocaine naïve animals. In summary, preliminary data indicate that PNN expression in the LHAad: 1) is necessary for acquisition of cocaine-induced CPP, 2) is predominantly co-localized with parvalbumin, and 3) is not necessary for normal locomotor or ingestive behavior.

Title: Fos and dopamine activation in reward pathways of rats selectively bred for enhanced drug self-administration

Authors: *H. XU, S. HE, K. GRASING;
Lab. of Substance Abuse, Kansas City VA Med. Ctr., Kansas City, MO

Abstract: Background: Vulnerability to psychostimulants varies greatly among different individuals, with genetic factors contributing to these differences. In one comparative analysis of humans with substance abuse disorders, heritability was highest for cocaine relative to other forms of drug abuse.The LS and HS rat lives were developed by selective breeding for low and high levels of intravenous drug self-administration in our laboratory. For low-dose cocaine, HS rats self-administer approximately five-fold more injections than LS animals. Here, we explored cocaine-induced dopaminergic activation in brain reward circuitry of LS and HS animals. Methods: Conditioned-place preference (CPP) testing was performed in three-chamber shuttle boxes using an un-biased procedure. Rats were conditioned with low dose (daily intraperitoneal injections of 0.7, 1.3, 2.7, and 5.3 mg/kg) or high dose (daily injections of 2.0, 4.0, 8.0, and 16.0 mg/kg) cocaine under an ascending-dose protocol for CPP, with cocaine preference tested three days after conditioning. Subsequently, animals were euthanized and brains examined for c-fos, dopamine d1 (D1R) as well as D2 (D2R) receptor activation in nucleus accumbens core (NAc) and shell (NASh), caudate putamen (CPu), ventral tegmental area (VTA) and dentate gyrus (DG) by immunofluorescent-staining analysis. Results: Both low and high dose cocaine induced CPP in both strains. Preferences were significantly larger in HS animals, with no significant interaction between strain and cocaine dose. Relative to the LS strain, both cocaine doses produced greater c-fos expression and activation of D1R and D2R neurons in HS rats, for all five

brain regions. Compared to high-dose cocaine, D2R activation was significantly elevated in HS rats that received low-dose cocaine, but not LS animals. A similar of pattern of increased D1R activation for low-dose treated HS rats was observed in NASh, CPu, and VTA only. Conclusion: HS rats exhibit greater cocaine-induced CPP, fos activation, and activation of D1R and D2R relative to LS animals in various brain regions including the NAc, NASh, CPu, VTA and DG. HS rats are more sensitive to drug-induced activation of the dopamine system by low-dose cocaine in a subset of brain reward regions. This mechanism may underlie their enhanced sensitivity to cocaine.

Title: Extended cocaine-seeking produces a shift from goal-directed to habitual responding in rats

Authors: *K.-C. LEONG, C. R. BERINI, S. M. GHEE, C. M. REICHEL;
Dept. Of Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Cocaine addiction is often characterized by a rigid pattern of behaviors in which cocaine users continue seeking and taking drug despite negative consequences associated with its use. As such, full acquisition and relapse of drug-seeking behavior may be attributed to a shift away from goal-directed responding and a shift towards the maladaptive formation of rigid and habit-like responses. This rigid nature of habitual responding is typically characterized by insensitivity to changes in outcome value, which can be developed with extended training. Rats given extended access to self-administered cocaine are considered to have transitioned from a recreational or limited drug access to chronic use patterns indicated by an escalation of intake and higher reinstated behaviors. Additionally, extended access protocols offer an extensive number of drug trials that provides a nice framework to study drug-seeking habits following transition from recreational to chronic drug use. The present study determined whether cocaine (primary reinforcer) and cocaine associated cues (secondary reinforcer) could be devalued in rats with different histories of cocaine self-administration. All rats received one-hour cocaine self-administration sessions for 7 days, followed by either 14 days of six-hour sessions (long-access) or 14 days of continued one-hour sessions (short-access). Following acquisition, rats received outcome devaluation before undergoing a 7 day period of abstinence. The paired group received

cocaine (administered i.v. through a playback program based on the number of infusions received on the last day of self-administration) immediately followed by an aversive compound lithium chloride (LiCl; 0.6 M, 5 ml/kg, i.p.) before being placed into a holding cage. The unpaired group received LiCl injections 6 hours prior to cocaine infusions. Rats were given two reinstatement tests, the first in which they were exposed to the cocaine-paired cues only and the second in which rats were exposed to cocaine itself via a contingent lever response. Cocaine history did not have an impact on devaluation of cocaine-associated cues. However, only rats on a short-access cocaine schedule displayed devaluation to the reinforcing properties of cocaine, but rats trained on a long-access schedule did not. Taken together this pattern of results suggests that, in short access rats, devaluation is specific to the primary reinforcer and not associative stimuli such as cues. Importantly, rats that received extended training during self-administration displayed insensitivity to outcome devaluation of the primary reinforcer as well as all associative stimuli.

Title: Chronic stress exposure during early withdrawal from extended access cocaine self-administration facilitates incubation of cue-induced cocaine craving

Authors: ***J. A. LOWETH**[1], R. M. GLYNN[1], J. A. ROSENKRANZ[2], M. E. WOLF[1]; [1]Neurosci., [2]Cell. and Mol. Pharmacol., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: A major challenge for treating cocaine addiction is the propensity for abstinent users to relapse. Two important triggers for relapse are cues associated with prior drug use and stressful life events. Human studies indicate that exposure to chronic adverse life events is associated with increased relapse vulnerability, indicating a need for animal models that explore interactions between chronic stress and drug withdrawal. However, the majority of studies investigating stress-induced relapse vulnerability have examined the effects of acute stressors on the reinstatement of previously extinguished drug seeking behavior, a model which may not

accurately depict the situation of addicts, who typically do not undergo extinction training and may relapse after a long drug-free period. To study the effect of chronic stress on withdrawal-dependent changes in relapse vulnerability, we used the incubation model of craving and relapse in which cue-induced drug seeking progressively intensifies ("incubates") during withdrawal from extended-access cocaine self-administration. Food restriction or repeated restraint stress were used as chronic stressors. Rats self-administered cocaine under extended-access conditions (6 h/d for 10 d) that have been shown to produce incubation of craving. On the day after the last self-administration session [withdrawal day (WD) 1], rats received a test for cue-induced cocaine seeking, during which nose-pokes resulted in presentation of the light cue but not cocaine. Rats were then divided into 2 groups destined for either control or stress conditions. In the food restriction studies, rats underwent a 2 week period of mild, chronic food restriction stress starting on WD2 (body weight maintained at 90% of their baseline weight). Control rats had ad libitum access to food. On WD15, rats underwent a second seeking test. In the repeated restraint studies, rats underwent 7 daily restraint sessions (20 min) over a 9 day period from WD6 to WD14 and received a seeking test on WD15, a day after the last repeated restraint session. Controls were placed in a cage with bedding on the same schedule. As expected, we found that controls showed greater cue-induced cocaine seeking on WD15 compared to WD1 (i.e. incubation of craving). Interestingly, rats in both stress groups showed a more robust increase in seeking on WD15, indicating acceleration or facilitation of incubation. Separate studies showed that the enhanced cocaine seeking observed was due to chronic and not acute stress. These data indicate that chronic stress during early withdrawal facilitates incubation of cocaine craving, which is thought to contribute to enhanced relapse vulnerability.

Title: Rats that experience footshock-induced abstinence from methamphetamine self-administration exhibit increased prodynorphin mRNA in the nucleus accumbens

Authors: *M. T. MCCOY, O. V. TORRES, B. LADENHEIM, I. N. KRASNOVA, J. CADET; Mol. Neuropsychiatry Res. Br., DHHS/NIH/NIDA/IRP, Baltimore, MD

Abstract: Methamphetamine (METH) is an illicit psychostimulant that is abused worldwide. Despite the longterm problem of METH addiction, cellular and molecular mechanisms involved in the transition from occasional to habitual drug use remain to be elucidated. Towards this end, our laboratory has investigated the effects of METH self-administration (SA) on the expression of neuroplasticity-associated genes within the dorsal striatum. Here we examined the influence of footshock on METH SA. We also measured potential changes on gene expression in the nucleus accumbens (NAc) of rats self-administering METH. Male Sprague-Dawley rats were trained to self-administer METH (0.1 mg/kg/injection, i.v.) or saline during twenty-two (9-hr drug access) sessions. After that time, foot-shocks were administered in increasing intensity over a period of thirteen sessions. The rats were then tested for cue-induced drug craving at 2 and 21 days post-shock and euthanized 9 days after the second extinction test. We extracted RNA from the nucleus accumbens (NAc), made cDNA, and ran quantitative polymerase chain reaction (PCR). Foot-shock caused the separation into two distinct SA groups: shock-resistant (SR) rats that continued to press the lever for METH despite the negative consequence and the shock-sensitive (SS) rats that significantly reduce their lever pressing. Our PCR results reveal that the SS group had a significantly increased expression of prodynorphin, but not of proenkephalin, mRNA levels, relative to the rats in the control and the SR groups. The increase expression of this neuropeptide in the SS group suggests that the two groups of rats that respond differently to footshocks also differ in their expression of this kappa receptor agonist. Our data suggest that this model of METH SA with adverse consequences may provide greater insight into the mechanisms of relapse to METH in clinical situations. Title: Phentermine induces the conditioned rewarding effects via the activation of PI3K/Akt signaling pathway in the nucleus accumbens

Authors: *S.-I. HONG, S.-X. MA, J.-Y. HWANG, J.-Y. SEO, Y.-H. KO, S.-Y. LEE, C.-G. JANG;
Sungkyunkwan Univ., Suwon, Korea, Republic of

Abstract: Phentermine is similar to methamphetamine in structure and the most widely used anti-obesity drug in the United States. Phentermine has been raised as an abuse potential, however, the mechanism of phentermine dependence has not been established. The aim of this study was to investigate whether phentermine produces the conditioned rewarding effects via the activation of PI3K/Akt signaling pathway in nucleus accumbens (NAc) of mice. In this study, we investigated the abuse liability of phentermine by using conditioned place preference (CPP) and climbing behavior in mice. In addition, we observed changes in expression of DAT and phosphorylation of Akt in NAc. As a result, phentermine 3 mg/kg significantly increased CPP and climbing behavior in mice. Moreover, repeated treatment with phentermine significantly increased expression of DAT protein and phosphorylation of Akt in the NAc. Furthermore, we examined whether LY294002, a specific PI3K/Akt inhibitor, could block phentermine-induced CPP and climbing behavior in mice. LY294002 (3 μg/site, i.c.v.) not only reduced CPP and climbing behavior but also decreased expression of DAT protein and phosphorylation of Akt in the NAc. These findings suggest that phentermine induces the conditioned rewarding effects via the activation of PI3K/Akt signaling pathway in NAc.

Title: BDNF-TrkB signaling in the nucleus accumbens plays a key role in methamphetamine withdrawal symptoms

Authors: *Q. REN, M. MA, C. YANG, J.-C. ZHANG, W. YAO, K. HASHIMOTO;
Chiba Univ. Ctr. Forensic Mental Hlth., Chiba, Japan

Abstract: Depression is a core symptom of methamphetamine (METH) withdrawal during the first several weeks of abstinence. Several lines of evidence suggest the key role of brain-derived neruotrophic factor (BDNF) and its specific receptor, tropomyosin-related kinase (TrkB), signaling in the pathophysiology of depression. In this study, we examined whether BDNF-TrkB

signaling plays a role in the METH withdrawal symptoms (depression and behavioral sensitization). In the tail-suspension test, forced swimming test, 1% sucrose preference test, repeated administration of METH (3 mg/kg/day for 5 days) caused depression-like behaviors in mice, and depression-like behavior persisted more than 2-weeks after the final administration of METH. Western blot analysis showed that levels of BDNF and phosphorylated-TrkB in the nucleus accumbens (NAc) of METH treated mice were significantly higher than those of control mice although levels in the other regions, including prefrontal cortex, hippocampus, were not different. Furthermore, METH-induced depression and behavioral sensitization could be improved after subsequent repeated administration of TrkB antagonist ANA-12, but not TrkB agonist 7,8-dihydroxyflavone (7,8-DHF). Interestingly, METH-induced depression and behavioral sensitization could be improved after a single bilateral infusion of ANA-12 into NAc. These findings suggest that BDNF-TrkB signaling in the NAc plays a key role in the withdrawal symptoms in mice after repeated METH administration, and that TrkB antagonists would be potential therapeutic drugs for METH withdrawal symptoms in humans.

Title: Acid-sensing ion channels control locomotor and rewarding effects of amphetamine

Authors: *X. CHU[1], Q. JIANG[2], C. HASSANZADEH[2], A. JIVAN[3];
[1]Basic Med. Sci., Univ. Missouri-Kansas City, Kansas City, MO; [3]Anesthesiol., [2]Univ. of Missouri-Kansas City, Kansas City, MO

Abstract: Drug addiction is a persistent mental illness and there is no effective therapy for patients. The precise mechanisms underlying addictive responses have not been completely deciphered. New evidence has been shown that ion channels in the brain reward circuits are believed to play a vital role in drug addiction. Acid-sensing ion channels (ASICs) are highly expressed in brain with ASIC1a and ASIC2 channels being the predominant subtypes. These channels are enriched at synaptic sites and are central for the regulation of normal synaptic transmission. Moreover, increasing evidence is linking ASICs to the pathogenesis of various neurological and neuropsychiatric disorders. We and others have shown that ASICs are involved in cocaine addiction. Here, we hypothesized that amphetamine, a psychostimuland similar to

cocaine, may also impact the function of ASICs. Following IACUC approval, adult wild-type (WT) C57BL/6J, ASIC1 and ASIC2 knock-out (KO) mice were placed in individual test chambers to allow accommodation to novel environment for 60 minutes. They then received a single intraperitoneal (i.p) injection of amphetamine at 3.0 mg/kg, and their locomotor activities were recorded for 150 minutes. The experiment was repeated daily for a total of 5 days. After a 2-week withdrawal period, the mice were brought back to the behavioral chamber followed by a final challenge i.p injection of amphetamine at 1.5 mg/kg. Locomotor activity to this challenge dose was measured for 150 min. Acute amphetamine injection induced a typical dose-dependent increase in locomotor activities in WT, ASIC1 and ASIC2 KO mice. However, the increase in locomotor activities were attenuated in ASIC1 and ASIC2 KO mice as compared to WT mice. Both WT, ASIC1 and ASIC2 KO mice showed sensitization to amphetamine. However, ASIC1 KO mice showed more, while ASIC2 KO mice showed less behavioral sensitization to amphetamine. Our data provides new understanding of the complex genetic and molecular mechanisms of ASICs in response to amphetamine exposure.

Title: Individual differences in methamphetamine self-administration model methamphetamine-addicted phenotype and are associated with cellular alterations in dentate gyrus of hippocampus

Authors: *M. H. GALINATO[1,2], M. FANNON[2], J. C. SOBIERAJ[2], A. GHOFRANIAN[2], A. I. NAVARRO[2], S. CHAING[2], S. S. SOMKUWAR[2], C. MANDYAM[2];
[1]UCSD, La Jolla, CA; [2]Committee on the Neurobio. of Addictive Disorders, The Scripps Res. Inst., La Jolla, CA

Abstract: The hippocampus is important for the relapse stage of addiction, and maladaptive patterns of methamphetamine intake result in altered levels of neurogenesis in the dentate gyrus during withdrawal. Individual differences in methamphetamine intake during extended-access self-administration were used to model the methamphetamine-addicted phenotype. These individual differences allowed us to test whether specific patterns of methamphetamine-intake

differentially altered proliferation and survival of neural stem cells, and granule cell neuron activation and structural plasticity in the dentate gyrus of the hippocampus. Male outbred Wistar rats were trained to self-administer methamphetamine 6 hr/day for 17 sessions (FR 1 schedule, 0.05mg/kg per IV infusion). Rats with higher levels of methamphetamine intake (high responders, n = 15) exhibited escalating patterns of drug intake across sessions, whereas the rats with lower levels of methamphetamine intake (low responders, n = 13) maintained a stable pattern of intake without escalation. High responders exhibited a vertical and rightward shift in the self-administration dose-response function and higher breakpoints on a progressive ratio schedule compared to low responders, indicating a preferred higher intake level and higher motivation. BrdU was injected during withdrawal and after three weeks of withdrawal, high responders demonstrated greater latency to extinguish drug-seeking behavior, greater drug-context-induced reinstatement and greater cue-induced reinstatement, indicating higher propensity for drug relapse compared with low responders. Brain tissue was processed for Golgi-Cox staining, and hippocampal sections were processed for Ki-67 (cell proliferation), BrdU (17-day-old surviving cells), AC3 (apoptosis), and cFos (neuronal activation) immunohistochemistry. Stereological analysis of cell numbers in the dentate gyrus resulted in an increase in expression of Ki-67, BrdU, and cFos in high responders, and an increase in AC3 in low responders compared to controls. 3D Sholl analysis of preexisting dentate gyrus granule cell neurons demonstrated no differences in dendritic complexity. The changes in behavior and associated cellular effects were not due to differential metabolism or bioavailability of methamphetamine since hippocampal methamphetamine levels were identical 45 min after a methamphetamine challenge in low and high responders. These findings suggest that methamphetamine addiction is related specifically to differential alterations in granule cell neurogenesis, and these alterations may be able to modulate methamphetamine-seeking behavior.

Title: Investigating the role of nucleus accumbens core astrocytes in reinstated methamphetamine seeking

Authors: M. D. SCOFIELD, K.-C. LEONG, C. GARCIA-KELLER, S. M. GHEE, C. A. THOMAS, P. W. KALIVAS, *C. M. REICHEL;
Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Astroglial cells play an important role in the regulation of synaptic plasticity in the nucleus accumbens core (NAcore) through the regulated release and uptake of glutamate. Numerous studies show that exposure to various drugs of abuse causes reductions in the expression and or function of key components of the glial glutamate release (cystine-glutamate exchanger, system Xc-) and uptake (glial glutamate transporter, GLT-1) machinery. Importantly, these drug-induced neuroadaptations have been linked to relapse vulnerability. Consistent with other stimulants, methamphetamine (meth) self-administration followed by extinction training reduces extracellular glutamate in the NAcore leading to a potentiation of corticoaccumbal synapses, which underlies the enhanced glutamate release following exposure to drug-paired cues responsible for the initiation of drug seeking. We hypothesized that meth self-administration followed by extinction would also decrease expression and/or function of GLT-1. Strikingly, we did not observe any reduction of GLT-1 expression or glutamate uptake. Further, ceftriaxone, a β-lactam antibiotic, which has been shown to restore Xc- and GLT-1 expression, normalize glutamate uptake, and inhibit reinstated cocaine seeking, had no effect on cued meth seeking. However, restoration of NAcore glutamate tone via chronic N-acetylcysteine treatment during extinction inhibited cued-induced meth reinstatement. Additionally, activation of Gq-coupled designer receptors exclusively activated by designer drugs (DREADDs) in NAcore astrocytes prior to cue-induced reinstatement stimulated glial glutamate release and inhibited cued meth seeking, while having no impact on cued sucrose seeking. In summary, our data demonstrate that meth self-administration and extinction training did not impact accumbens glutamate uptake and that ceftriaxone treatment did not inhibit cued meth reinstatement. In contrast, restoration of extrasynaptic glutamate tone with N-acetylcysteine or activation of astroglial Gq-DREADD receptors reduced cue-induced meth seeking. Combined, our data indicate that similar to other dugs of abuse, potentiated synaptic glutamate release following exposure to meth-paired cues is responsible for the initiation of drug seeking and despite the lack of alterations in glutamate uptake, cued reinstatement of meth seeking is inhibited by the normalization of extrasynaptic glutamate tone provided by enhanced glial glutamate release.

Title: Neuron-specific modulation of dendritic spine dynamics in nucleus accumbens by amphetamine-paired contextual stimuli

Authors: *P. VEZINA[1], N. BUBULA[1], D. LI[1], V. BINDOKAS[2], B. F. SINGER[3];
[1]Dept Psychiatry and Behavioral Neurosci., [2]Dept Neurobiology, Pharmacology, and Physiol., The Univ. of Chicago, Chicago, IL; [3]Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Repeated exposure to amphetamine leads to both associative conditioning and nonassociative sensitization. Here we assessed the contribution of immunohistochemically identified cFos+ and FosB+ medium spiny neurons (MSNs) in the nucleus accumbens (NAcc). Compared to saline exposed rats, animals exposed to amphetamine IP or in the ventral tegmental area (VTA) showed the expected sensitized locomotor response when challenged with amphetamine weeks later. Both exposure routes also increased FosB levels in medial aspects of the NAcc, suggesting a role for FosB+ MSNs in this site in the accrual and maintenance of sensitization. Further characterization of these FosB+ neurons with single-cell injections of the neuronal tracer DiI, however, revealed no differences between saline and amphetamine exposed rats in dendritic spine density or in spine tip diameter, indicating that these neurons do not undergo changes in dendritic spine morphology that accompany the expression of nonassociative sensitization. As drugs are necessarily administered in the presence of a large number of environmental stimuli, conditions favoring the formation of drug-stimulus associations, additional experiments determined how NAcc MSNs contribute to the expression of associative conditioning. In these experiments, a discriminative learning paradigm was used to expose rats to IP or VTA amphetamine either Paired or Unpaired with an open field. In addition, Paired rats received saline and Unpaired rats amphetamine in the home cage. Control rats received saline in both environments. As expected, Paired rats administered amphetamine IP showed a conditioned locomotor response and an increase in the number of cFos+ neurons in medial NAcc when subsequently challenged with saline in the open field. Paired rats previously exposed to VTA amphetamine showed no evidence for conditioned locomotion and no evidence for an increase in the number of cFos+ neurons. An increase in FosB+ neurons was observed in both Paired and Unpaired rats, again consistent with a role for these neurons in the accrual of sensitization but not in the expression of conditioning. Further characterization of the activated cFos+ MSNs revealed that IP amphetamine exposed Paired rats, compared to rats in the other groups, showed an increase in the density of dendritic spines and spine tips as well as in the frequency of medium-sized spine tip diameters. These findings suggest a role for cFos+ MSNs in the medial NAcc and specifically for rapid changes in the morphology of their dendritic spines in the expression of conditioned responses evoked by amphetamine-paired stimuli.

Title: Therapeutic potential of perirhinal cortex DREADDs on methamphetamine-induced deficits in novelty recognition and relapse

Authors: *J. PETERS[1], M. D. SCOFIELD[2], S. M. GHEE[2], J. A. HEINSBROEK[2], C. M. REICHEL[3];
[1]Dept. of Neurosciences, [3]Neurosciences, [2]Med. Univ. of South Carolina, Charleston, SC

Abstract: Background: Long-term methamphetamine (meth) abuse has been linked to certain cognitive impairments in humans. Similarly, in rats, chronic meth self-administration leads to deficits in novel object recognition memory, which relies upon the perirhinal cortex. One central question is: how do these cognitive deficits impact reinstated meth seeking? Here, our purpose was to determine whether synthetic activation of the perirhinal cortex with DREADDs could repair meth-induced novelty recognition deficits and to investigate the impact of these cognitive enhancing effects on relapse using a novel cue-choice reinstatement test. Methods: We used a viral-mediated gene transfer approach to infect perirhinal neurons with designer receptors exclusively activated by a designer drug (DREADDs of the hM3Dq variant) in order to activate neurons. All rats were infused with AAV2-hSyn-HA-hM3Dq-IRES-mCitrine vector (UNC Vector Core) bilaterally into the perirhinal cortex prior to meth self-administration, therefore allowing at least 4 weeks for DREADD expression to peak. Rats self-administered meth (0.02 mg/infusion, i.v.) along an FR1 schedule of reinforcement. After 7 daily 1-h sessions, rats were switched to 6-h daily access sessions for 14 days, and then underwent drug abstinence. Rats were tested for object recognition on abstinence day 7 and 8 or 14 and 15, and tested for novel cue-choice relapse on abstinence day 7 or 14. Neuronal activation was achieved by administering the designer drug clozapine-N-oxide (CNO, 10 mg/kg, i.p.); control rats received vehicle. Results: Chronic meth self-administration resulted in an escalation of meth intake over time and pronounced object recognition deficits. CNO administered immediately after object familiarization effectively restored object recognition in meth rats 90 min later. Twenty-four hours later, however, the therapeutic effects were no longer evident. In contrast, CNO had no impact on novel cue-choice reinstatement when administered 30 min prior to testing. Discussion: The data suggest that synthetic activation the perirhinal cortex is capable of restoring novelty recognition in chronic meth-exposed rats. However, these therapeutic effects did not extend to reduced relapse in a model incorporating choice between a novel cue and a meth cue. Further research is needed to determine whether CNO dose or pharmacokinetics can account for the lack of effect on relapse. Nonetheless, restoring cognitive function in meth addicts using a DREADD approach is a translationally attractive means to help sustain abstinence.

Title: Amphetamine affects reward-related behavior but not reward-evoked dopamine signals

Authors: ***D. R. SCHUWEILER**, J. M. ATHENS, J. M. THOMPSON, S. T. VAZHAYIL, P. A. GARRIS;
Sch. of Biol. Sci., Illinois State Univ., Normal, IL

Abstract: Dopamine (DA) transients in the nucleus accumbens (NAc) are brief increases in DA that are critical for reward-related learning. They are elicited by unpredicted rewards and learned cues that predict rewards but not predicted rewards. Thus, learning correlates with a "transfer" of NAc DA transients from rewards to their predictive cues. The DA transfer deficit theory of attention deficit hyperactivity disorder (ADHD) proposes that symptoms are caused by insufficient "transfer" and that psychostimulant medications compensate for this by enhancing cue-evoked DA transients. At therapeutic doses, amphetamine (AMPH) is the most efficacious treatment for ADHD; however, at larger doses AMPH is rewarding and can cause addiction. Rewarding doses of AMPH enhance DA transients, an effect thought to contribute to addiction via over-learning of drug-predictive cues. The effect of therapeutic doses of AMPH on DA transients has not been investigated; therefore, it is unclear if AMPH-induced enhancement of DA transients is specifically a mechanism of reward learning or also a therapeutic mechanism. We employed a Pavlovian autoshaping paradigm to examine AMPH dose effects in rats. This paradigm uses insertion of a lever and illumination of a light on one side of the chamber as a CS+; insertion of a lever and illumination of a light on the opposite side is used as a CS-. Some rats, goal-trackers, approach the food-trough when the cue is present while other rats, sign-trackers, approach the lever. Prior to the second of ten conditioning sessions, rats received an i.p. injection of saline or AMPH (0.25 or 1.36mg/kg d-amphetamine hemi-sulfate). Rats treated with the high dose increased sign-tracking and tended to require more sessions to learn to respond to the CS+ and not the CS-. We also combined fast-scan cyclic voltammetry with an unpredicted food reward paradigm to determine if alterations in reward-evoked DA transients might contribute to these behavioral outcomes. A carbon-fiber microelectrode was lowered into the

NAc until reward-evoked DA transients could be reliably recorded. 30 food pellets were delivered on a variable schedule both before and after administration of 0.25 or 1.36mg/kg AMPH. Additionally, electrically evoked phasic-like DA signals were recorded before and after the behavioral task. Only rats treated with the high dose exhibited increased electrically evoked signals. Surprisingly, the high dose had no significant effect on reward-evoked transients yet it tended to cause the rats to cease consuming the rewards. Taken together, these experiments suggest rewarding doses of AMPH alter learning by a mechanism that does not alter reward-evoked DA transients.

Title: Inhibition of AKT phosphorylation in the rat ventral tegmental area prevents intermittent social defeat stress-induced weight gain deficits and the expression of amphetamine cross-sensitization

Authors: *C. E. JOHNSTON[1], R. P. HAMMER, Jr[2,1], E. M. NIKULINA[2,1];
[1]Arizona State Univ. - Neurosci. Program, Tempe, AZ; [2]Basic Med. Sci., Univ. of Arizona Col. of Med., Phoenix, AZ

Abstract: Intermittent social defeat stress is an unpredictable stressor that produces cross-sensitization to amphetamine and a corresponding upregulation of mu-opioid receptors (MORs) in the ventral tegmental area (VTA). A population of VTA gamma-aminobutryic acid (GABA) neurons express MORs, which inhibit GABA release onto local dopamine neurons, and their expression is necessary for social stress-induced cross-sensitization to amphetamine. We previously showed that social stress increases the labeling of phosphorylated AKT (pAKT) preferentially in VTA GABA neurons, and that this effect is dependent on VTA MOR expression. We hypothesize that intra-VTA inhibition of pAKT during social defeat stress will prevent stress-induced amphetamine cross-sensitization and weight gain deficits. Adult male Sprague Dawley rats received bilateral cannulas directed at the VTA. Social defeat stress consisted of exposure to both threat of defeat and a brief physical defeat by an aggressive Long-Evans rat. Either saline vehicle or NVP-BEZ235 (10 μM in 1 μl per side), a dual inhibitor of phosphoinositide 3-kinase/mTOR signaling used to inhibit AKT phosphorylation, were infused 1

hr prior to each episode of social defeat stress or control handling, which occurred 4 times in 10 days. Intra-VTA inhibition of pAKT significantly blocked the development of long-term weight gain deficits observed in vehicle-treated stressed rats. Ten days after the last episode of defeat, all rats received an amphetamine challenge (1.0 mg/kg, i.p.). Intra-VTA inhibition of pAKT during stress did not alter the development of stress-induced amphetamine cross-sensitization, however when inhibitor was infused one week later prior to a second amphetamine challenge, it completely blocked the expression of cross-sensitization, as locomotor activity of stressed rats did not differ from handled animals after VTA pAKT inhibition. Taken together, these data implicate MOR-induced pAKT in the metabolic and behavioral effects of stress, suggesting that VTA pAKT may mediate stress-induced weight gain deficits and vulnerability to psychostimulants. Furthermore, that intra-VTA inhibition of pAKT blocked the expression, rather than the induction, of amphetamine cross-sensitization suggests that pAKT inhibition may provide a novel therapeutic approach for the treatment of substance abuse.

Title: Social play behavior in juvenile rats after neonatal exposure to methamphetamine

Authors: *M. SEVCIKOVA, A. HOLUBOVA, I. HREBICKOVA, R. SLAMBEROVA; Charles Univ. In Prague, Third Fac. of Med., Prague, Czech Republic

Abstract: Methamphetamine (MA) belongs to the most abused drugs. The popularity of this drug among women, and pregnant women as well, seems to be due its psychostimulant and anorectic effects. Suckling neonates can also be exposed to MA postnatally since MA is secreted in the mother´s breast milk. The neonatal period in rats corresponds in the development of the nervous system to the third trimester in humans. The aim of our study is to determine the effect of MA exposed during 11 days after birth to the social play. Social play is an integral part of the development of social behavior, marker of creating the hierarchy and cohesion of the group. Additionally, social play is known to be modulated by neurotransmitters system involved in

reward and motivation. Pups receiver MA during postnatal days (PD) 1-11 either directly (in dose of 5mg/kg s.c.) or indirectly via the breast milk of the mother (the same dosage). The control groups received saline in the same way. On the PD 28 and 29, the pups were individually habituated to the test cage for 10 min. Subsequently, the animals were socially isolated during the night before the testing day. On the PD 30, the pups were treated with MA (acute dose of 1mg/kg s.c.) or saline 45 minutes before testing. The test consisted of placing 2 similarly treated animals of the same sex into the test cage for 15 min. The frequency of social play behavior, which consists of pinning and pouncing, was significantly higher in the group of females receiving saline directly in comparison to MA group of the same type of application. Pups who received neonatal saline or MA directly played more compared to indirect application of saline or MA respectively. The acute application of MA eliminated social play in all the groups. Due to the psychostimulant effect of MA, animals of all the groups with acute application of MA displayed increased exploratory behavior such as rearing, sniffing, locomotion. Thus it seems that exposure of MA in neonatal period affects the social play behavior of the pups more when MA is administered via the maternal breast milk and the acute dose of MA suppresses the social play.

Title: Sex dimorphic effect of acute methamphetamine treatment on behavior of adult rats exposed to the same drug throughout gestation and early neonatal period

Authors: *I. HREBÍCKOVÁ, M. SEVCIKOVA, R. SLAMBEROVA;
Charles University, Third Fac. of Med., Praha, Czech Republic

Abstract: Methamphetamine (MA) is a street drug causing potent psychomotor activation. Our previous studies demonstrated that effect of MA exposure on behavior of adult rats prenatally exposed to MA is sex-depended. The aim of the present study was to examine the effect of acute treatment of MA in adult rats that were exposed to MA during different phases of gestational and

early neonatal periods. Female rats were daily injected with MA (5 mg/kg) or saline during first (gestational day (GD) 1-11) or the second (GD 12-22) half of gestation period. These periods correspond to the human first and the second trimester of gravidity. The third trimester in humans corresponds to postnatal day (PD) 1-12 in rats. Therefore, MA was injected to rat mothers also in early lactation period. Their pups were exposed to the effect of drug indirectly via breast milk or directly with MA injection. Thus, four types of pre/postnatal administration periods were used in the present study. In adulthood, half of animals from each group were injected prior to the testing with MA (1mg/kg), second half received saline. Spontaneous locomotor activity and exploratory behavior were tested in Laboras apparatus (Metris B.V., Netherlands) for 1 hour. Our results demonstrated that acute administration of MA in all groups increased both, locomotion and exploration. Sex dimorphic effect of acute MA exposure was present in all groups. The females displayed more locomotion and more exploratory rearing than males in dependence of the time and kind of the application. Thus, our results indicate that adult MA injections affect behavior of adult rats in sex-, treatment- and time-exposure-specific manner.

Title: Differential rearing alters amphetamine self-administration: role of mGluR2/3 activation

Authors: *D. ARNDT, E. GARCIA, G. ERICKSON, M. ULMER, M. CAIN;
Psychological Sci., Kansas State Univ., Manhattan, KS

Abstract: Previous research has demonstrated that rats reared in an enriched environment self-administer less amphetamine at low unit doses than rats reared in isolation. We have recently demonstrated that differential rearing influences the function of post-synaptic metabotropic glutamate receptors (mGluRs) that contribute to the maintenance of glutamate homeostasis. The current study sought to determine if differential rearing also influences the function of presynaptic mGluRs critical for glutamate homeostasis, as research suggests that maintaining homeostatic glutamatergic function may be a protector against drug abuse. Male rats arrived to the lab at 21 days of age and were assigned to enriched (EC), isolated (IC), or standard (SC) conditions. EC rats were handled by experimenters and lived with cohorts and novel objects. IC rats lived with neither cohorts nor novel objects. SC rats lived in pairs in shoebox cages to

provide a lab standard for comparison. At 52 days of age, rats were trained to lever press for 20% sucrose on a fixed-ratio schedule (FR-1). Rats were then implanted with indwelling jugular catheters. Following surgery recovery, rats self-administered intravenous amphetamine (0.1 mg/kg/infusion) on a FR-1 schedule during 60 min daily sessions. After reaching stable responding, rats were injected with three doses (0, 0.3, and 1.0 mg/kg, i.p.) of the mGluR2/3 agonist, LY-379268 (LY), 30 min prior to self-administration sessions. Following FR-1 testing with all three doses, rats were tested with the same doses of LY on a progressive-ratio (PR) schedule following the same design as the FR-1 phase. Results revealed that LY generally decreased amphetamine self-administration under both FR-1 and PR schedules of reinforcement. Differential rearing influenced the attenuation of FR-1 self-administration. Specifically, EC rats given both 0.3 and 1.0 mg/kg LY earned significantly fewer amphetamine infusions than IC rats given the same doses. Furthermore, time course analyses revealed that LY led to a greater suppression of FR-1 and PR amphetamine self-administration in EC rats compared to IC rats. 1.0 mg/kg LY suppressed early-session FR-1 amphetamine self-administration in EC rats compared to IC rats, with no time course differences observed during vehicle FR-1 self-administration sessions between any of the environmental groups. These findings suggest the mGluR2/3 receptor may play a role in altering amphetamine self-administration among differentially reared rats, and differential rearing alters the function of pre- and post-synaptic mGluRs that maintain glutamate homeostasis.

Title: Exposure to amphetamine during development changes drug response, histone methylation, and reduces dopamine uptake in Caenorhabditis elegans progeny

Authors: *T. J. MCCOWAN, B. D. SAFRATOWICH, L. CARVELLI;
Dept. of Basic Sci., Univ. of North Dakota, Grand Forks, ND

Abstract: Amphetamine (AMPH) is a psychostimulant which is well known to increase dopamine (DA) in the synaptic cleft. *C. elegans* have been used in previous research to study AMPH because it possesses a well conserved dopaminergic system and display a well characterized behavioral response known as Swimming Induced Paralysis (SWIP), which results

from an increase in DA within the synaptic cleft. This behavior was used to investigate the young adult animals' response following embryonic AMPH exposure, as well as their progenies' response as young adult animals. Results show that animals who were exposed as embryos to AMPH (F0 AMPH) exhibited a higher SWIP response for the first 7 minutes when challenged with AMPH as young adults, with respect to control animals (F0 M9). Interestingly the progeny originating from animals previously exposed to AMPH (F1 AMPH) also exhibited a higher SWIP response during AMPH challenge with respect to the progeny of control animals (F1 M9). Western blots were performed to investigate histone methylation changes, as previous research has shown this epigenetic mechanism plays a role in addiction. A significant decrease was observed in histone H3 lysine 4 trimethylation (H3K4me3) in F1 AMPH with respect to F1 M9. Additionally a significant increase was observed in histone H3 lysine 9 dimethylation (H3K9me2) in F1 M9 with respect to both F1 AMPH and F0 M9. We are currently investigating whether AMPH changes these histone markers specifically in the dopaminergic neurons by performing staining in animals expressing GFP fused to the dopamine transporter (DAT). Previous data showed DAT plays a vital role in the SWIP response. To explore changes in the DAT as a potential mechanism for the changes we observed in SWIP, DA uptake assays were performed. Primary cell cultures were made from embryos of animals that were previously exposed to AMPH during development, as well as embryos of animals exposed to control solution. Our results show a significant decrease in DA uptake in cultures made from the embryos (F1) of animals previously exposed to AMPH during development, with respect to control cultures. As many of the components of the dopaminergic system as well as epigenetic mechanisms are highly conserved between *C. elegans* and mammals, these experiments could be critical for our understanding of how drugs of abuse affect future generations.

Title: Estimation of contribution of newly synthesized dopamine to amphetamine-induced increases in extracellular dopamine

Authors: *L. J. WALLACE, K. E. ROONEY, M. T. JANSON;
Ohio State Univ., Columbus, OH

Abstract: Amphetamine, a drug used to treat ADHD and narcolepsy and often used for non-medical reasons, increases extracellular dopamine. Data from both behavioral and micro-dialysis experiments suggest that newly synthesized rather than stored dopamine contributes a major

proportion of the increase in extracellular dopamine involved in the effects of amphetamine. The goal of this study is to determine the proportions of newly synthesized and stored dopamine contributing to amphetamine-stimulated increases in extracellular dopamine levels and to hypothesize a mechanism of secretion for newly synthesized dopamine. A representation of extracellular space associated with a single dopamine release site and 2,500 dopamine transporters was developed using MCell. Rates of dopamine secretion required for the model output to match published data for levels of extracellular dopamine after various doses of amphetamine were determined. These rates were separated into a stored (exocytotic) and non-stored (newly synthesized) component, with the stored component decreasing with increasing dose of amphetamine to account for drug induced decrease in firing rate of dopamine neurons. The non-stored component showed a biphasic dose response, with maximum at 1-2 mg/kg amphetamine, a pattern similar to that for published data on effects of amphetamine on rate of dopamine synthesis. A postulated mechanism for moving newly synthesized dopamine to extracellular space utilizes a membrane-associated complex of enzymes that convert tyrosine into DOPAC for export into extracellular space. Amphetamine inhibits monoamine oxidase in the complex, and the resulting accumulated dopamine is secreted in place of DOPAC. When this complex utilizes 20% of baseline and all of the amphetamine-stimulated increase in rate of dopamine synthesis, estimated dopamine secretion rates match the non-stored release rate determined in the model for doses of amphetamine up to 5 mg/kg. For higher doses of amphetamine, dopamine secretion from the proposed complex was not sufficient to provide high levels of extracellular dopamine needed to match published micro-dialysis data. Inclusion of decreased availability of active dopamine transporter for the highest dose of amphetamine does provide a model output that matches published data. The overall conclusion is that amphetamine-stimulated release of newly synthesized dopamine coupled with amphetamine competitive inhibition of dopamine transporter can account for measured levels of increased extracellular dopamine for most doses of amphetamine. At higher doses, however, the additional effect of decreased transporter availability is required.

Title: The effect of reactive oxygen species scavengers in methamphetamine-taking behaviors and dopamine release in the nucleus accumbens

Authors: *E. JANG[1], S. P. KIM[2], D. M. HEDGES[1], J. Y. LEE[2], T. EKINS[1], A. PEREZ[1], C. FREEMAN[1], A. LAMPRECHT[1], D. BRADSHAW[1], H. Y. KIM[2], C. H. YANG[2], S. C. STEFFENSEN[1];

Abstract: Methamphetamine (METH), a powerful and commonly used psychostimulant, has been shown to induce reactive oxygen species (ROS) formation, leading to oxidative stress, by dopamine (DA) auto-oxidation at DAergic terminals. Recently, we and others have implicated ROS in the development of behavioral sensitization following repeated contingent and non-contingent administration of psychostimulants such as cocaine. In this study, we evaluated the involvement of ROS in METH self-administration behavior and acute METH enhancement of DA release in the nucleus accumbens (NAc) using fast scan cyclic voltammetry (FSCV) *in vivo*. To evaluate the effect of ROS scavengers, rats received N-tert-butyl-α-phenylnitrone (PBN, a nonspecific ROS scavenger; 50 or 75 mg/kg, IP) or 4-hydroxy-2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPOL, a SOD mimetic; 50 or 100 mg/kg, IP) 10 minutes prior to beginning of METH self-administration (0.05 mg/kg/infusion) and IV injection of acute METH (0.1 mg/kg). Systemic administration of PBN or TEMPOL significantly decreased METH self-administration without affecting food intake. Using 8-OHG immunohistochemistry, increased oxidative stress was found in the NAc of rats self-administering METH compared to sham controls. Acute administration of TEMPOL (100 mg/kg, IP) had no significant effect on the enhancement of DA release produced by acute METH. However, in preliminary studies, repeated administration of TEMPOL (25 mg/kg, 4 days, IP) decreased DA release produced by acute METH. Taken together, these findings indicate that enhancement of ROS production contributes to the reinforcing effect of METH.

Title: Acute methamphetamine induces hydrogen peroxide formation in dopamine terminals of the nucleus accumbens

Authors: *D. HEDGES[1], E. JANG[2], A. W. PEREZ[2], N. D. SCHILATY[3], E. S. SCHRIEVER[1], N. FOLEY[1], B. R. BLUMELL[2], J. T. YORGASON[4], F. P. BELLINGER[5], J. D. UYS[6], S. C. STEFFENSEN[2];
[2]Psychology, [1]Brigham Young Univ., Provo, UT; [3]Ohio State Univ., Columbus, OH; [4]Oregon Hlth. & Sci. Univ., Portland, OR; [5]Univ. of Hawaii, Manoa, HI; [6]Med. Univ. of South Carolina, Charleston, SC

Abstract: Methamphetamine (METH) is a powerful psychostimulant known to both reverse the dopamine (DA) transporter (DAT) and inhibit the monoamine vesicular transporter (VMAT-2). Ultimately, METH facilitates DA release by causing reverse transport of DA through the DAT while simultaneously interfering with VMAT-2 pumping of DA into vesicles. Dopamine is subject to auto-oxidation and enzymatic degradation via MAO, resulting in formation of reactive oxygen species (ROS), specifically hydrogen peroxide (H2O2). The aim of this study was to evaluate the role of ROS in the effects of acute METH on phasic and basal DA release in the NAc. Utilizing a fluorescent dye sensitive to peroxide formation and fast-scan cyclic voltammetry (FSCV), superfusion of METH (1-100 uM) induced H2O2 production in the NAc. Using FSCV and the antioxidants glutathione (GSH) and 4-hydroxy-2,2,6,6-tetramethylpiperidin-1-oxyl (TEMPOL), we evaluated the role of ROS in acute METH enhancement of both phasic (modeled by electrical stimulation) and basal DA release. Superfusion of METH (0.1-100 μM) dramatically increased phasic DA release in the NAc slice preparation (330% at 100 μM METH). However, the enhancement was transient, for within 15 min of continuous superfusion of METH DA release returned back to baseline, suggesting desensitization. This effect was difficult to wash out - over an hour later a similar challenge dose of METH was unable to raise the signal more than 5%. Glutathione (100 μM) was unable to attenuate the transient increase in phasic DA release, but was able to prevent METH's enhancement of basal DA release. Similarly, TEMPOL, a SOD mimetic, had no effect on phasic release, but attenuated basal release. Inhibiting DAT with GBR 12909 was unable to impact the effects of METH on phasic DA release, but inhibiting VMAT-2 with tetrabenazine reduced the effects of METH on phasic DA release. Since VMAT-2 appears to be playing a primary mechanistic role in basal release and a small role in phasic release, protein mechanistic studies are underway to show interactions between GSH and cysteine residues on VMAT-2.

Title: Selenium deficiency alters dopamine transmission and response to methamphetamine in the mouse nucleus accumbens

Authors: D. J. TORRES[1], S. M. BARAYUGA[1], R. H. L. H. RUELI[1], D. M. HEDGES[2], N. D. SCHILATY[2], J. T. YORGASON[3], M. A. ANDRES[4], S. C. STEFFENSEN[2], *F. P. BELLINGER[1];

Abstract: Selenium (Se) is an antioxidant trace element that is important for normal brain function. Se is incorporated into selenoproteins, a family of proteins with multiple functions that include protection from oxidative stress. Methamphetamine (METH) increases dopamine (DA) signaling by inhibiting DA reuptake, resulting in increased oxidative stress from oxidized DA, and eventual degeneration of DAergic terminals. Previous studies have indicated that Se protects against METH-mediated neurotoxicity, potentially through the antioxidant actions of the glutathione peroxidase (GPx) selenoenzymes. Conversely, Se-deficiency potentiates METH toxicity. To investigate the mechanisms of how dietary Se deficiency alters METH toxicity, we investigated DA concentrations and reuptake kinetics in the nucleus accumbens (NAc). We used fast-scan cyclic voltammetry (FSCV) to measure changes in extracellular DA in NAc brain slices following evoked release and changes following METH application. Se-deficiency impaired initial DA reuptake kinetics compared with slices from mice raised on a normal Se diet. This indicates reduced function of the dopamine active transporter (DAT). Se-deficiency did not alter the METH-induced increase in peak extracellular DA concentration. However, Se-deficiency did attenuate METH-induced impairments of DA reuptake kinetics. We additionally measured protein changes in the brains of Se-deficient mice compared to mice on a normal diet. Western blots demonstrated that Se-deficiency decreased levels of DAT and GPx compared to controls. These results suggest that Se-deficiency results in less availability of DA reuptake machinery, promoting DA toxicity and impairing responses to METH.

Title: Effect of preexposure on methylphenidate-induced taste avoidance and related BDNF/TrkB activity in the insular cortex of the rat

Authors: *B. WETZELL[1,2], M. M. MULLER[2], S. M. FLAX[2], H. E. KING[2], K. DECICCO-SKINNER[1], A. L. RILEY[2,1];

Abstract: Exogenous brain-derived neurotrophic factor (BDNF) in the insular cortex (IC) is known to influence conditioned taste avoidance (CTA) learning, but little is known of its endogenous role in the phenomenon. A history with many abusable compounds attenuates their ability to induce CTA (known as a preexposure effect), thus providing a possible platform from which to examine the endogenous role of IC BDNF in CTA. In the present study, this role was examined by assessing the effect of preexposure to methylphenidate (MPH) on MPH-induced CTA, followed by an analysis of changes in expression between preexposure groups of BDNF and its primary receptor, the tropomyosin-related kinase receptor type B (TrkB) in the IC, central nucleus of the amygdala (CeA) and the nucleus accumbens (NAc). Specifically, following preexposure to 18 mg/kg MPH, CTAs induced by 0, 10, 18 and 32 mg/kg MPH were assessed in adult male Sprague Dawley rats (n = 64). In separate groups of rats (n = 31), differences in BDNF and TrkB were assessed using Western blots following similar preexposure and conditioning procedures. In line with previous research with psychostimulants, preexposure to MPH significantly blunted MPH-CTA compared to preexposure to vehicle. Although there were no significant effects of MPH on BDNF activity following CTA conditioning, animals preexposed to MPH exhibited decreased BDNF/TrkB activity in the CeA and enhanced activity in the IC and NAc. Thus, preexposure to MPH attenuates its aversive effects on subsequent presentations, and BDNF's endogenous impact on CTA learning may be dependent upon its temporal relation to other CTA-related intracellular cascades.

Title: Homer2 regulates sensitivity to methamphetamine reward

Authors: *C. BROWN[1], S. G. QUADIR[2], D. M. FLAHERTY[2], K. K. SZUMLINSKI[2]; [1]UCSB Psychological and Brain Sci., Santa Barbara, CA; [2]UCSB, Santa Barbara, CA

Abstract: Homer2 is a post-synaptic scaffolding protein involved in regulating glutamate receptor function, which has been highly implicated in drug-induced neural plasticity. Withdrawal from repeated methamphetamine injections increases Homer2 protein expression within the shell, but not the core, subregion of the nucleus accumbens, although vulnerability to high MA reward is associated with elevated Homer2 expression within both accumbens subregions. Herein, we employed 2 strategies to test the hypothesis that Homer2 regulates the motivational valence of methamphetamine. The first study employed constitutive Homer2 gene knock-out (KO) mice and demonstrated that KO mice expressed conditioned place-aversion to an environment paired repeated with low-dose methamphetamine (1 mg/kg). The second study employed an shRNA knockdown approach to selectively lower Homer2 expression within either the shell or core subregion of C57BL/6J mice. Homer2 knock-down within the shell, but not the core, attenuated the expression of a methamphetamine-conditioned place-preference and this effect was observed when animals were tested in under methamphetamine-free and -primed states. Together, these results indicate that Homer2, particularly within the nucleus accumbens shell, contributes to the rewarding properties of methamphetamine.

Title: vmPFC infusion of mGlu2/3 receptor agonist during protracted withdrawal does not prevent incubation of cocaine-seeking

Authors: *C. B. SHIN, M. A. RUPPERT-MAJER, M. M. SERCHIA, J. R. SHAHIN, T. E. KIPPIN, K. K. SZUMLINSKI;
Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Relapse to drug-taking is a reoccurring phenomenon impairing addiction recovery that can be triggered by the elicitation of intense drug craving upon re-exposure to drug-paired cues. Cue-elicited drug-craving increases in a time-dependent manner during drug abstinence - a phenomenon termed “incubation of craving”. The neural substrates of this phenomenon are not fully understood but are thought to involve glutamate mechanisms in the ventromedial prefrontal cortex (vmPFC) as the capacity of cocaine-paired cues to increase glutamate release within vmPFC incubates during protracted withdrawal in concert with behavior. We hypothesize that incubated cue-elicited glutamate release within vmPFC might drive incubated behavior. To test this hypothesis, male Sprague-Dawley rats were trained to lever-press for cocaine (0.25 mg/infusion; 6 h/day) for 10 consecutive days. At 30 days withdrawal, animals were infused intra-vmPFC (0.5 µl /side) with either vehicle or 50µM of the mGlu2/3 autoreceptor agonist APDC and underwent a 30-min test for cue-elicited cocaine-seeking. A control group was infused with vehicle at 3 days withdrawal to provide a base-line response. Vehicle-infused animals exhibited a time-dependent intensification of cue-reinforced responding, indicating incubation. However, the magnitude of this incubation was not influenced by 50µM APDC. As mGlu2/3 receptor down-regulation is reported within the medial PFC of rats withdrawn from non-contingent cocaine treatment, current studies seek to characterize mGlu2/3 expression within the vmPFC following a history of excessive cocaine intake to better understand the molecular mechanism(s) underpinning the cue hyper-reactivity of vmPFC glutamate that presumably drives incubated cocaine-seeking.

Title: Withdrawal-dependent incubation of anxiogenesis and dipsomania following a history of binge alcohol drinking during adolescence

Authors: *K. M. LEE, M. A. COEHLO, N. R. SOLTON, T. E. KIPPIN, K. K. SZUMLINSKI; Univ. of California At Santa Barbara, Santa Barbara, CA

Abstract: Binge alcohol drinking is the most prevalent form of alcohol abuse exhibited by adolescents and young adults, yet little is known regarding the short- or longer-term impact of binge drinking during this sensitive period of neurodevelopment upon brain and behavior. Herein, we characterized the short- and longer-term effects of a relatively short (14-day) period of binge alcohol drinking during adolescence upon emotionality, in comparison to adults with equivalent binge-drinking experience. Male C57BL/6J mice binge-drank alcohol under 4-bottle-choice procedures (5, 10, 20, 40% v/v) for 2 hrs/day, starting 3hrs into the dark cycle. Adolescent bingers commenced drinking on PND 28, while adults commenced on PND 56. A subset of adolescents were tested for behavior in early withdrawal (PND42), while all the other animals underwent behavioral testing on PND 70, followed by an additional 5 days of drinking. There was no age difference in the average alcohol intake over the initial 14-day period, although adolescents preferred 40% alcohol, while adults preferred 20% alcohol. When tested in early withdrawal, adult drinkers exhibited hyper-anxiety in the defensive marble burying test and, corroborating published data from humans and rat, "hang-over"-related anxiety was absent in adolescent bingers. However, when assayed for behavior in protracted withdrawal (PND70), the hyper-emotionality and subsequent alcohol intake exhibited by adolescent bingers was greater than age-matched adults. These data provide evidence that both anxiety and dipsomania "incubate" with the passage of time during alcohol withdrawal in individuals with an early life history of binge drinking and further the argument that binge drinking during adolescence perturbs the developmental trajectory of neurocircuits underpinning emotional control and control over alcohol intake.

Title: Rottlerin and psychostimulant-induced conditioned place preference.

Authors: *T. LIAO[1], L. YU[2];
[1]Inst. of Behavioral Medicine, Natl. Cheng K, Kaohsiung, Taiwan; [2]Natl. Cheng Kung University, Col. of Medicine, Inst. of Behavioral Med., TAINAN, Taiwan

Abstract: Brain-derived neurotrophic factor (BDNF) has been known to modulate cocaine conditionings. Systemic rottlerin (RO) administration can increase hippocampal BDNF levels in a long-lasting manner. Accordingly, we hypothesized that systemic pretreatment with RO may affect psychostimulant-induced conditioned place preference (CPP). To test this hypothesis, 8-week-old male C57BL/6 mice were used to receive an intraperitoneal RO injection (5 mg/kg) approximately 15 hour prior to the first bout of the saline-environment conditioning. Our CPP training protocol consisted of 3-day conditionings [saline-environment conditionings were in the morning, while psychostimulant-environment conditionings were in the afternoon at an 8-hour inter-conditioning interval]. We found that such RO treatment decreased methamphetamine (MA) (1 mg/kg/conditioning)- and cocaine (10 mg/kg/conditioning)-induced CPP. Likewise, pretreatment with 7,8-dihydroxyflavone (10 mg/kg, i.p.), a selective BDNF TrkB receptor agonist, before each saline-, cocaine-conditioning was effective in decreasing the cocaine(10 mg/kg/conditioning)-induced CPP. In an attempt to assess the modulating effects of RO on the maintenance of psychostimulant-induced CPP, a single RO injection was given approximately 24 hours before the 3-day forced extinction protocol [two saline-environment conditionings for each day]. We found that RO (5 mg/kg) did not affect the forced extinction protocol-produced decreases in the MA- or cocaine-induced CPP magnitude. Nevertheless, RO seemed to effectively abolish the MA-primed reinstatement of the extinguished MA-induced CPP. These results, taken together, suggest that systemic rottlerin administration may be beneficial in facilitating the erasure of the methamphetamine-supported memory.

Title: Sex differences in novel object recognition after a binge methamphetamine treatment

Authors: ***A. KLAMBATSEN**[1,2], S. NYGARD[3], V. QUINONES-JENAB[1], S. JENAB[1]; [1]Psychology, Hunter Col., New York, NY; [2]The Grad. Center, CUNY, New York, NY; [3]Washington Univ., St. Louis, MO

Abstract: Methamphetamine is a well-established neurotoxin that selectively damages dopaminergic cells, causing cell death and destruction of dopamine terminals. Behavioral evidence also indicates an effect on dopamine-dependent activities, as exemplified by the novel

object recognition task. However, few studies have examined the effects of methamphetamine on females. This study sought to test the sex differences in memory impairment using the novel-object recognition task. A four-dose methamphetamine “binge” dosage paradigm (4 x 5mg/kg, 2 hours apart) was used to compare memory performance between males, intact females, and ovariectomized females. Drug-treated males and ovariectomized females, but not intact females, exhibited memory impairments compared to saline animals. No differences in total exploration time were observed based on sex or drug condition. Methamphetamine toxicity-induced behavioral deficits therefore appear to differentially impact individuals based on sex.

Title: Methamphetamine-induced aberrant neurogenesis: protection by exercise

Authors: *M. TOBOREK, H. LEVINE, M. PARK;
Biochem. and Mol. Biol., Univ. of Miami Sch. of Med., Miami, FL

Abstract: While no effective therapy is available for the treatment of methamphetamine (METH) induced neurotoxicity, behavioral interventions, including aerobic exercise, are being used to improve depressive symptoms and substance abuse outcomes. The present study focuses on the effect of exercise on METH-induced neurotoxicity in the hippocampal dentate gyrus (DG) in the context of the blood-brain barrier (BBB) pathology. METH or saline (vehicle) was administered three times per day for 5 days with an escalating dose regimen at 3 h intervals. One set of mice was sacrificed 1 day post last injection of METH and the remaining mice were divided into two major groups: a) the exercise group and b) the sedentary group. After chronic METH administration, the expression of tight junction (TJ) proteins was decreased in the hippocampus. Importantly, BBB permeability was significantly increased and remained elevated

even 20 days after the withdrawal of METH. Moreover, neuronal differentiation was significantly decreased in METH-exposed hippocampal DG, suggesting impaired neurogenesis. Most importantly, voluntary exercise protected against this effect, enhanced the protein expression of occludin, and inhibited induction of inflammatory cytokines. These results suggest that exercise can attenuate METH-induced neurotoxicity by protecting against the BBB disruption and related microenvironmental changes in the hippocampus.

Title: The effect of exercise on the neurochemical consequences of methamphetamine abuse

Authors: ***M. MURRAY**, Z. VLASTOS, K. VARLEY, A. N. FRICKS-GLEASON;
Regis Univ., Denver, CO

Abstract: Abuse of methamphetamine (METH) in the Unites Stated has increased significantly in the past 15 years, and use is now endemic in the Western states. Colorado currently ranks 7th in the nation for total number of METH users over the age of 25. Overall, the economic cost of drug abuse is high. METH abuse alone costs the U.S. $23.4 billion annually due to crime, lost workplace productivity, foster care, and other social problems stemming from abuse. In addition to the known health risks associated with psychostimulant abuse, METH use carries the additional danger of permanent brain injury. One well-known animal model of METH use utilizes binge METH administration, where repeated doses of METH are given to rats in a single day. This dosing regimen has been shown to cause long-lasting damage to dopaminergic nerve terminals and serotonergic nerve terminals similar to that seen in human METH abusers. In humans, it has been suggested that METH-induced monoaminergic damage may lead to the development of Parkinson's disease. Exercise is a non-pharmacological treatment being explored for use in treating Parkinson's disease and this work has recently been extended to the study of METH-induced monoaminergic neurotoxicity. It has been shown that when rats exercised for 3 weeks before and 3 weeks after a binge treatment of METH, this exercise significantly attenuated METH-induced decreases in striatal dopamine. Interestingly, if the exercise regimen was limited to only 3 weeks before a binge treatment of METH, it did not protect against striatal dopamine damage. This suggests that pre-METH exercise does not help with prevention of neurotoxicity, but perhaps post-METH exercise aids in recovery. This study specifically tested

the effects of 3 weeks of exercise after a METH binge on the recovery of dopaminergic nerve terminals in the striatum and serotonergic nerve terminals in the prefrontal cortex. By examining the timing of the intervention, the results presented here provide important information about the therapeutic relevance of exercise as a potential treatment for METH-induced neurotoxicity and the concomitant cognitive deficits.

Title: Consequences of self-administered methamphetamine throughout pregnancy on rat dams and their offspring

Authors: *D. RÜEDI-BETTSCHEN, S. CHAWLA, C. S. WASHINGTON, D. M. PLATT; Psychiatry and Human Behavior, Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Methamphetamine (METH) abuse in women of childbearing age and those who are pregnant is an urgent health concern. While the harmful effects of METH are well described for adults, there is only limited knowledge of the effects of METH use during pregnancy on the developing child. In the present study, we investigated how daily METH self-administration throughout pregnancy affected rat dams, as well as how the resulting *in utero* METH exposure affected offspring development through weaning. Yoked saline control dams and their offspring served as controls. Female rats (n=6/group) were trained to self-administer METH (0.08 mg/kg/infusion) under a fixed-ratio schedule such that every injection of METH by a dam also resulted in a saline injection to her yoked control dam. When stable levels of self-administration were reached, all females were mated. Daily self-administration sessions continued until litters were born. General health and weight was assessed daily in dams and pups. In addition, pups were evaluated for achievement of age-appropriate developmental milestones. METH females self-administered 2-3 mg/kg/day prior to mating and throughout gestation. This level of METH self-administration had no effect on dam health, dam behavior or pregnancy outcome. Weight gain throughout pregnancy (and after) did not differ between METH dams and saline controls. All females produced viable litters, and litter size, composition and pup weight at birth did not differ between saline and METH dams. Similarly, maternal pup-directed behavior was not affected by prior METH self-administration experience. In contrast to the dams, pups were

negatively affected by *in utero* METH exposure. Compared to saline-exposed pups, METH exposed pups were delayed in reaching developmental milestones, including righting reflex, eye opening, incisor eruption and negative geotaxis. These results demonstrate the feasibility of using self-administration of METH by dams as a means to expose developing pups to the drug. More importantly, the results indicate that *in utero* exposure to low-to-moderate METH doses can profoundly affect offspring development, suggesting that even moderate or recreational METH use during pregnancy adversely affects offspring development.

Title: Differential dopaminergic toxicity of bath salt intermediates in mice: Implications for the mechanism of methamphetamine toxicity

Authors: *J. H. ANNEKEN[1,3], M. ANGOA-PEREZ[1,3], G. SATI[2], D. CRICH[2], D. M. KUHN[1,3]; [2]Dept. of Chem., [1]Wayne State Univ., Detroit, MI; [3]John D. Dingell VAMC, Detroit, MI

Abstract: “Bath salts” are a relatively novel class of stimulants, which consist of cathinone and its derivatives (e.g., cathinone, mephedrone, and methylone). These exhibit a close structural similarity to corresponding amphetamine class compounds (amphetamine, methamphetamine, and MDMA, respectively). Despite this similarity, the bath salts have been shown to lack the reduction in dopaminergic markers elicited in mice by methamphetamine and other neurotoxic amphetamines. The difference in toxicity between these closely related compounds presents a unique opportunity to better understand the mechanisms by which methamphetamine elicits its toxic effects in the brain. The bath salt mephedrone differs from methamphetamine by both a β-keto group and a 4-methyl group on the phenyl ring of its structure. In order to assess which of these additions may be responsible for the observed loss of dopaminergic toxicity, the intermediate compounds, methcathinone (MeCa) and 4-methylmethamphetamine (4MM), were administered at a range of doses to mice every 2 h in the standard binge regimen for a total of 4 injections, and dopaminergic markers were assessed in the striatum 48 h following treatment. In comparison to methamphetamine, 4MM lacked any striatal dopaminergic toxicity with the sole exception of a slight but significant decrease in dopamine at 40 mg/kg, which was the highest dose mice were able to tolerate. 4MM also exhibited significant, dose-dependent

hyperlocomotion, increased stereotyped behavior, and hyperthermia, similar to methamphetamine. As has been observed with other bath salt compounds, 4MM significantly enhanced the dopaminergic toxicity of a mildly toxic dose of methamphetamine (2.5 mg/kg) at 20 and 40 mg/kg, but not 10 mg/kg. In contrast with 4MM, MeCa exhibited significant reductions in striatal dopamine, DAT, and TH at the higher doses tested (20-80 mg/kg), as well as a significant increase in the inflammatory marker GFAP. MeCa induced hyperthermia and hyperlocomotion at lower doses, but at 80 mg/kg, induced significant hypothermia. The higher doses tested also elicited increased stereotyped behavior. These data support the view that while both the β-keto and 4-methyl substitutions lead to a lower neurotoxic potency when compared to methamphetamine, it is the 4-methyl ring-substitution on mephedrone that primarily prevents dopaminergic toxicity. Future experiments will investigate the mechanism by which this substitution leads to a loss of toxicity.

Title: Neurotoxic consequences of serial exposure to alcohol and methamphetamine

Authors: *A. L. BLAKER, B. K. YAMAMOTO;
Neurosciences, Univ. of Toledo, Toledo, OH

Abstract: Methamphetamine (Meth) and alcohol have an established comorbid relationship in drug abuse. Despite the widespread co-abuse of these drugs, little is known about the consequences arising from their serial exposure. Glutamate signaling is altered by alcohol and Meth administered independently, and glutamate-induced excitotoxicity mediates Meth neurotoxicity. Therefore, we tested the hypothesis that the serial exposure to alcohol and Meth will alter glutamatergic transmission and result in greater brain monoamine depletions than either drug alone. Male Sprague Dawley rats were exposed to a one week chronic binge of ethanol (6g/kg/day) via oral gavage followed by one day of binge Meth administration (10mg/kg x 4 injections). One week after treatment, the monoamine neurotransmitter content of the prefrontal cortex, striatum, and hippocampus was measured. Ethanol alone did not result in any monoamine depletions, while rats treated with Meth alone showed a 50% depletion of dopamine in striatum, as well as a 25% depletion of serotonin in striatum, hippocampus, and prefrontal cortex.

Importantly, ethanol significantly enhanced the neurotoxicity observed after Meth alone in that rats treated with both drugs showed 90% dopamine depletions within the striatum and 75% serotonin depletions in the striatum, hippocampus and prefrontal cortex. Other markers of monoamine terminals, such as dopamine transporter (DAT), serotonin transporter (SERT) and tyrosine hydroxylase (TH) immunoreactivities in the striatum were also measured one week after treatment. Western blot analysis showed that DAT, SERT and TH immunoreactivities were decreased 80% in the striatum of ethanol + Meth rats, compared to 40% decreases in rats exposed to Meth alone and no changes after ethanol alone. This enhanced effect after serial exposure to ethanol and Meth suggests a potential synergism between the drugs. To determine a role for glutamate in mediating monoamine depletions, the excitatory amino acid transporter 1 (EAAT1) was examined. EAAT1 immunoreactivity in the prefrontal cortex was decreased by 24% at one day after a week of ethanol alone. These results suggest a potential role for diminished glutamate uptake in mediating a vulnerability to excitotoxicity produced by ethanol, which could potentially be enhanced by Meth. Future studies will examine the role of excitotoxicity in mediating neurotoxicity after alcohol and Meth.

Title: P47 phox contributes to induce methamphetamine dopaminergic neurotoxicity

Authors: D.-K. DANG[1], Y. NAM[1], T.-V. TRAN[1], C.-G. JANG[2], E.-J. SHIN[1], *H.-C. KIM[1]; [1]Col. of Pharmacy, Kangwon Natl. Univ., Chunchon, Korea, Republic of; [2]Sch. of Pharmacy, Sungkyunkwan Univ., Suwon, Korea, Republic of

Abstract: Accumulating evidences suggest that oxidative stress mediates MA-induced dopaminergic neurotoxicity. Since recent reports emphasized emerging role for NADPH oxidases as a source of ROS, we investigated whether involvement of NADPH oxidase in MA-induced proapoptosis (i.e., TUNEL-positive cells), microglial activation, and dopaminergic impairment in the striatum of the mice. As the p47 phox subunit of NADPH oxidase acts as a connector between the components of the membrane and the cytoplasm, we performed

intracerebroventricular infusion of p47 phox antisense oligonucleotides (p47 phox ASO) before a single injection of MA (35 mg/kg, i.p). Treatment with MA resulted in a significant increase in TUNEL-positive cells in the striatum of Taconic ICR mice. Application of p47phox ASO significantly attenuated the increase in TUNEL-positive populations induced by MA. Furthermore, p47 phox ASO significantly protected reactive microgliosis (as labeled by Iba-1) and reductions in tyrosine hydroxylase-positive immunoreactivity and dopamine level in the striatum of Taconic ICR mice. Consistently, reactive microgliosis and dopaminergic loss induced by MA were less pronounced in p47 phox knockout mice than in wild type mice. Our results suggest that p47 phox mediates acute dopaminergic neurotoxicity induced by MA.

Title: Comparison of C57 B6N versus C57 B6 (NCTR strain) mice response to methamphetamine-induced seizures gives insights into the role of temperature, BBB breakdown and seizures on neurotoxicity

Authors: *J. F. BOWYER[1], K. M. TRANTER[1], S. SARKARA[1], J. RAYMICK[1], L. C. SCHMUED[1], J. P. HANIG[2];
[1]Neurotoxicology, NCTR/FDA, Jefferson, AR; [2]CDER/ FDA, Silver Spring, MD

Abstract: C57 B6 mice were used to further determine whether the blood-brain barrier (BBB) break down that occurs after a 40 mg/ kg methamphetamine (METH) s.c. is necessary for generating the status epilepticus and prominent neurodegeneration seen in limbic regions. Charles River (CR) C57 B6 mice were selected in lieu of the NCTR sub strain of C57 B6 (no longer available). Unexpectedly, differences in the seizuregenic and neurotoxic effects of METH in the C57 B6N mice from CR compared to the NCTR mice gave new insights into processes underlying these two events. BBB breakdown was evaluated in mice histologically at time points ranging from 15 min to up to 3 d after a single dose of D-METH. Fluoro-Gold (F-G, 30 mg/ kg i.p.) was given to some mice prior to sacrifice to help identify BBB breakdown. IgG immunoreactivity in brain was also used to detect BBB damage. In the C57 B6N, some mice had signs of continuous (10 to 30 min) seizure activity (SA) ranging in intensity from tremors to

Racine scale level 3 seizures but had body temperatures (BT) of only 39.6°C and 40.3°C. When BTs were <40.3°C there was no evidence of BBB damage at time points between 15 and 60 min after METH and no neurodegeneration at 1 or 3 d post METH. In mice with BTs of ≥ 40.9°C, IgG and F-G localization (intense spots < 1 mm in dia.) were seen in the anterior bed nucleus of the stria terminalis (BSTMA), anterior thalamus and hypothalamus, and amygdala nuclei of the accessory olfactory system (PLCo, PMCo) at 15 to 40 min after the first appearance of Racine scale 5 seizures and/ or status epilepticus. In this group of mice, with more intense SA, signs of neurodegeneration occurred within 4 h in the same areas where IgG appeared 15 to 40 min post METH. However, the only intense areas of neurodegeneration seen at 3 d in the C57 B6N were in the PLCo, PMCo and BSTMA. The maximal intensity and area of IgG immunoreactivity and neurodegeneration in the limbic regions of the C57 B6N was much less than that previously observed in the NCTR C57 B6J mice. Conclusions: in C57 B6N mice 1) METH can induce repetitive (≤30 min) mild to moderate SA in the absence of severe hyperthermia (<40.0°C); 2) However, under these conditions BBB breakdown does not occur and little or no forebrain neuronal cell death is detected; 3) when body temperatures are reach ≈ 41°C an early BBB breakdown in the BSTM, anterior hypothalamus and thalamus and amygdala nuclei occur which in turn likely exacerbates seizure activity and increases neurodegeneration. Additional studies are necessary in Jackson Laboratories original C57 B6J to determine whether the intensity and regional distribution of BBB breakdown 15 to 60 min after METH explain their greater sensitivity to METH neurotoxicity.

Title: Amphetamine addiction produces neuronal death in dorsal hippocampus and an increase of metabolites related with oxidative stress

Authors: ***L. ARROYO GARCÍA, SR**[1], H. TENDILLA BELTRAN[1], R. A. VÁZQUEZ-ROQUE[1], A. D. DIAZ FONSECA[1], E. BRAMBILA COLOMBRES[1], E. MONJARAZ GUZMÁN[1], F. DE LA CRUZ LÓPEZ[2], G. FLORES ALVARES[1];

[1]Benemerita Univ. Autonoma De Puebla, Puebla, Mexico; [2]Inst. Politecnico Nacional, México Df, Mexico

Abstract: There are different addiction theories that try to explain the human behavior in this alteration, one of these is the sensitization theory of addiction which propose that drugs produce alterations in the mesocortical limbic system that attribute in the reward-stimuli, become hypersensitive the circuits involve in drug-seeking and cause the pathological incentive motivation. Amphetamine (AMPH) has been commonly used to produce this theory, which is known like amphetamine-sensitization, this drug induces an enhanced in dopaminergic tone in the mesocortical limbic system. In another hand now around 1.2% of the world population is AMPH addicted, this represent a social problem inducing a pathological state of neuronal mechanism of learning and memory. In our previous results using the same protocol, we found a decreasing for the long-term memory by the novel object recognition (NOR), and changes in some oxidative stress metabolites like oxide nitric (NO) and Zinc (Zn), which was correlated with the changes in neural morphology to the dorsal hippocampus (DH), since this region has an important role in memory and learning behaviors, required for the development in the human life. Now we know DH changes can be relevant, highlights the fact to understand the processes that affect this region, like changes in metabolites related with oxidative stress, in consequence with a decreasing in neural density and neuronal connectivity. The aim of the present study was measured the changes in neuronal density by stereological methods, neuronal connectivity, presence of astrocytes and quantify malonilaldehyde (MDA), metallothioneins (MTs) and caspase 3 (CASP3). Our results suggest that amphetamine sensitization in rats shown an altered relation between in MDA and MTs levels, which we correlate with an increase in GFAP and CASP3 with a decrease in SYP and neuronal density in hippocampal region. In conclusion, this study demonstrates that the damage caused by AMPH addiction produce neuronal death in hippocampus regions that is involved in behaviors required for the daily life. Title: MDMA reduces markers for GABAergic neurons in the hippocampus and increases seizure susceptibility: Role of glutamate mediated excitotoxicity

Authors: *C. L. HUFF[1], J. P. HERMAN[1], B. K. YAMAMOTO[2], G. A. GUDELSKY[1]; [1]Univ. of Cincinnati, Cincinnati, OH; [2]Univ. of Toledo Sch. of Med., Toledo, OH

Abstract: MDMA is a unique psychostimulant that continues to be a popular drug of abuse. It is well documented that MDMA produces persistent reductions in markers of 5-HT axon terminals in rodents, as well as humans. To date there has been little recognition of potential MDMA neurotoxicity to neuronal populations beyond 5-HT axon terminals in brain regions, such as the hippocampus, in which damage may account for the neurologic/cognitive effects associated with repeated exposure to MDMA. In the present study, we examined the hypothesis that MDMA produces glutamate-dependent damage to GABAergic neurons, as assessed from GAD67-positive neurons in the hippocampus, which results in an increase in seizure susceptibility. Repeated exposure to MDMA (3x10mg/kg, ip) resulted in a marked reduction in the number of GAD67 positive cells in the dentate gyrus, as well as in the CA1 and CA3 regions. Repeated administration of MDMA also resulted in an increased susceptibility to kainic acid-induced seizures that persisted for at least 30 days following MDMA treatment. Kainic acid (9 mg/kg, sc) produced seizures in approximately 20% of control animals, whereas approximately 85% of MDMA-treated animals exhibited kainic acid-induced seizures. The MDMA-induced increase in seizure susceptibility was not evident in rats treated with either MK-801 (a NMDA antagonist) or ceftriaxone (an inducer of GLT-1). In further support for a role of glutamate-mediated excitotoxicity in the MDMA-induced loss of hippocampal GABA neurons and increase in seizure vulnerability, is the finding that repeated treatment with MDMA results in an increased extracellular concentration of glutamate in the hippocampus that is also prevented in rats treated previously with ceftriaxone.

Title: MDMA decreases paired-pulse depression and afterdischarge threshold in the dentate gyrus: Roles of 5HT2a and EP1 receptor activation

Authors: *S. A. COLLINS[1], G. GUDELSKY[2], B. YAMAMOTO[1];
[1]Dept. of Neurosciences, Univ. of Toledo, Toledo, OH; [2]James Winkle Col. of Pharm., Univ. of Cincinnati, Cincinnati, OH

Abstract: MDMA is a widely abused psychostimulant which causes the release of serotonin through its actions on the serotonin transporter. Recent findings in our lab demonstrated that MDMA causes an increase in extracellular glutamate concentrations within the dentate gyrus, which was dependent upon local activation of 5HT2A receptors. These increases in glutamate were also dependent upon local activation of EP1 receptors, suggesting a role for PGE2 signaling in mediating these glutamate increases. Here we report that local administration of MDMA (100 μM) causes a significant increase in PGE2 concentrations within the dentate gyrus (246%, p=.016) of rats. PGE2 increases were inhibited when MDL100907, a 5HT2a receptor antagonist, was administered with MDMA. Previously, we reported a significant decrease in parvalbumin (PV) interneurons in the dentate gyrus following MDMA exposure, which could be prevented by inhibition of either 5HT2a or EP1 receptors during MDMA exposure. Given the previously demonstrated decreases in PV interneurons following MDMA exposure, we investigated whether MDMA alters inhibition within the dentate gyrus. Perforant path evoked field potentials in the dentate gyrus of MDMA treated rats exhibited a reduced paired-pulse depression at 40, 50 and 65 ms interstimulus intervals (41.5, 47.2, 36.4%, p=.001, .003, .006 respectively), 10 days following MDMA exposure (7.5 mg/kg x 4, ip). Decreases in paired-pulse depression were prevented by treatment during MDMA exposure with either MDL100907 or SC-51089, an inhibitor of EP1 receptors. Further experiments revealed a decrease in the stimulus amplitude needed to drive perforant path induced afterdischarges in the dentate gyrus of MDMA treated rats (19.4%, p=.001). Reductions in afterdischarge threshold were prevented when rats were treated during MDMA exposure with either SC-51089 or MDL100907. These findings suggest that MDMA causes a decrease in inhibition within the dentate gyrus, which may disrupt the excitatory/inhibitory balance. Furthermore, these findings suggest that MDMA-induced reductions in PV interneurons are responsible for decreases in inhibition. Further studies are needed to characterize the changes in GABAergic inhibition within the hippocampus of MDMA treated animals and whether these changes mediate known deficits in hippocampal function caused by MDMA.

Title: Clinically-relevant pharmacological strategies that reverse MDMA-induced brain hyperthermia potentiated by social interaction

Authors: *E. A. KIYATKIN, S. REN, K. T. WAKABAYASHI, M. H. BAUMANN, Y. SHAHAM;
Behavioral Neurosci Br., NIDA-IRP, NIH, DHHS, Baltimore, MD

Abstract: MDMA-induced hyperthermia is highly variable, unpredictable, and greatly potentiated by the social and environmental conditions of recreational drug use. Current strategies to treat pathological MDMA-induced hyperthermia in humans are palliative and marginally effective, and there are no specific pharmacological treatments to counteract this potentially life-threatening condition. Here, we injected rats with a moderate non-toxic dose of MDMA under conditions modeling recreational drug use (i.e., social interaction) that led to the dramatic enhancement of MDMA-induced brain hyperthermia. We tested the effectiveness of mixed adrenoceptor blockers carvedilol and labetalol, and the atypical antipsychotic clozapine in reversing MDMA-induced hyperthermia. To mimic the clinical situation of drug intoxication, we injected the treatment drugs after MDMA had already caused robust hyperthermia (>2.5°C). Brain temperature was our primary focus, but we also simultaneously recorded temperatures from the deep temporal muscle and skin, allowing us to determine the basic physiological mechanisms of the treatment drug action. Carvedilol induced skin vasodilation and was modestly effective in attenuating MDMA-induced brain and body hyperthermia, whereas labetalol was ineffective. In contrast, clozapine induced a marked and immediate reversal of MDMA-induced hyperthermia via inhibition of brain metabolic activation and blockade of centrally-mediated vasoconstriction. Our findings suggest that clozapine, and related centrally acting drugs, can be highly effective for reversing MDMA-induced brain and body hyperthermia in emergency clinical situations, with possible life-saving results. Title: Sex-differences in rodent methamphetamine self-administration

Authors: *A. JOHANSEN, A. E. FLECKENSTEIN, A. E. FLECKENSTEIN, L. M. MCFADDEN;
Univ. of Utah, Salt Lake City, UT

Abstract: Methamphetamine (METH) is a widely abused psychostimulant that can cause persistent alterations in brain neurochemistry. METH is abused in both females and males. Research has shown that women exhibit higher co-morbid neuropsychiatric disorders and prefer METH to other drugs compared to their male counterparts. However, little research has been conducted to understand these sex-differences. The purpose of the present study was to investigate possible sex-differences in the behavioral and neurochemical effects of METH self-administration. Male and female rats were subjected to 7 days of self-administration (8 hours/day) of either METH or saline and were sacrificed one hour after the last self-administration session. METH-induced changes in hippocampal brain derived neurotrophic factor (BDNF) and expression of the striatal dopamine transporter (DAT) were assessed. Similar METH self-administration occurred between the sexes; however, METH-induced hyperthermia was significantly greater in females. METH self-administration decreased striatal DAT immunoreactivity in both females and males. METH-induced increases in hippocampal BDNF immunoreactivity occurred in males but not in females. In conclusion, there are similar drug-taking behaviors between the sexes, but sex-differences exist in the neurochemical consequences of METH self-administration. These findings may have clinical implications to sex-differences observed in human METH users.

Title: Sex differences in the developmental and behavioral effects ofchronic oral methylphenidate in rats

Authors: *M. MICHAELOS[1], L. S. ROBISON[1], J. GANDHI[1], E. MIAO[1], C.-Y. LAM[1], A. MAUCERI[1], M. VITALE[1], J. LEE[1], S. PAENG[1], D. E. KOMATSU[1], M. HADJIARGYROU[2],

P. K. THANOS[1];
[1]Stony Brook Univ., Stony Brook, NY; [2]NYIT, New York City, NY

Abstract: Background: Methylphenidate (MP) is a widely prescribed psychostimulant for the treatment of Attention Deficit Hyperactivity Disorder (ADHD), that has received attention for its abuse potential and side effects which may persist after treatment cessation. Previously, we developed a dual dosage oral MP drinking paradigm for rats that mimics the pharmacokinetic profile of treated patients (Thanos et al. 2015). This study aims to follow up on previous data on the skeletal effects of chronic MP (Komatsu et al 2012) and to determine the developmental and behavioral effects of chronic oral MP treatment in both male and female rats. Methods: Male and female Sprague Dawley rats were assigned to 1 of 3 treatment groups (n=12/group) at 4 weeks of age: control (water), low dose (LD) MP, and high dose (HD) MP. Using the dual bottle-drinking paradigm, rats would drink 4 mg/kg MP (LD) or 30 mg/kg MP (HD) for one hour, and 10 mg/kg (LD) or 60 mg/kg MP (HD) for seven hours each day. Throughout the 3 months of treatment, rats in each group were monitored for body weight, food and fluid intake, as well as tested for open field activity behavior, circadian sleep-wake activity, novel object recognition, and social interaction behavior. Results: Chronic MP treated rats exhibited reduced fluid intake during treatment weeks. MP dose-dependently decreased body weight accrual for both genders, while not influencing overall food intake. MP dose-dependently increased locomotor activity in both sexes, and to a greater extent in females. MP-induced hyperactivity was observed during the dark cycle of their circadian dark cycle without affecting light cycle activity. MP had an anxiolytic effect that was similar in males and females. Chronic MP treatment had no effect on novel object recognition or social behavior for either sex. Conclusions: Chronic oral MP treatment at clinically-relevant doses was found to have significant effects on development and behavior, including body weight, locomotor activity, and anxiety. Particularly marked sex differences were most apparent for locomotor activity, with females being more sensitive to the hyper-activating effects of the drug. The lack of effects seen in novel object recognition and social behavior may be the result of neuroadaptations that occurred under chronic MP treatment. These findings suggest that chronic MP exposure beginning in adolescence can have significant behavioral effects that are both drug and sex-dependent. These findings raise concerns regarding the reversibility of these effects post-discontinuation of treatment, as well as how MP may influence the dopamine mesolimbic reward system and subsequent vulnerability for addiction.

Title: Segregated effects of 4-methylethcathinone on CPP, locomotor sensitization and anxiety-like behavior

Authors: P. XU[1], Y. QIU[2], P. XU[1], Y. LIU[1], *H. SHEN[2];
[1]Drug Intelligence and Forensic Center, Ministry of Publ. Security, Beijing, China; [2]Natl. Inst. On Drug Dependence, Peking Univ., Beijing, China

Abstract: Background: A second generation of synthetic cathinones 4-Methylethcathinone (4-MEC) has ranked among the most popular "legal highs" recently. Although 4-MEC appears to have similar neurochemical actions like cocaine mixing with MDMA *in vitro*, its behavioral profiles in human and experimental animals were little known Methods: This study investigated the addictive potential and psychomotor stimulation of 4-MEC (1-30 mg/kg) by measuring the conditioned place preference (CPP) and locomotor activity, while methamphetamine (METH, 1-3 mg/kg) was used as positive control. Because synthetic cathinones often cause adverse psychiatric sequelae, we then assayed the acute and chronic 4-MEC-induced anxiety/restlessness-like behavior using the elevated plus maze (EPM). Results: We found CPP was induced by 4-MEC at 10mg/kg after trainings and was able to reinstate after two weeks withdrawal. Although the last dose elicited an acute increase on locomotor activity, 4-MEC failed to induce locomotor sensitization with 3, 10 or 30 mg/kg. Rats treated by chronic 4-MEC with 30 mg/kg daily spent remarkably less proportion of open arm time compared to chronic saline group, while METH-treated rats showed augmentation in exploratory behavior. Interestingly, two weeks withdrawal after chronic 4-MEC or METH, all rats emerges to show more exploratory behavior rather than anxiety-like behavior. Conclusions: Taken together, these results revealed that 4-MEC-associated reward is segregate from its effects on locomotor stimulation. And, the effects of 4-MEC on addictive potential and restless behavior will be enduring even after long-term withdrawal.

Title: Cocaine-paired cues contribute to the acquisition, but not escalation, of intravenous cocaine self-administration in rats

Authors: ***P. A. VIEIRA**[1,2], L. BUBALO[1], K. L. PLOENSE[1], J. BAGLEY[1], C. SHIN[1], K. NOVICK[1], R. BOZADJIAN[1], T. E. KIPPIN[1,2];

Abstract: Cocaine addiction is a major health concern which is associated with excessive cocaine use. A leading animal model of excessive drug use is the expression of escalated cocaine intake during extended (6 h or greater) daily sessions of self-administration. Emerging evidence indicates that drug-related contextual cues are important in the maintenance of escalated cocaine intake as well as reinstatement of drug-seeking behavior. Similarly, discreet cocaine-paired cues have been extensively examined in the reinstatement of drug-seeking behavior as well as acquisition of cocaine taking but the role of these cues in the development and maintenance of escalated cocaine self-administration has not been examined. Here, we examined the impact of cocaine-paired cues on the acquisition and escalation of cocaine self-administration in a rat model. Rats were implanted with a permanent jugular catheter and then allowed to lever press to self-administer cocaine (0.25 mg/0.1 ml infusion, FR1, 20s time-out) during 5 daily acquisition (1-h) sessions followed by 15 extended-access (6 h) sessions. For one group, each cocaine infusion was paired with a 20s presentation of cue light above the active lever and, for a second group, no cue light was presented. Rats that received presentation of the cue light exhibited higher intake levels throughout the acquisition phase than those that did not ($P < 0.05$), but no differences were detected between groups during the escalation phase (cue rats exhibited 25.5±16.5% and no cue rats exhibited 30.7±8.3% escalation of intake across extended access sessions; $P > 0.05$). Further, following development of escalated cocaine intake, reversal of cue conditions failed to impact cocaine self-administration in either group. The present findings indicate that cocaine-associated discrete cues facilitate initial drug taking under limited access conditions but do not appear to contribute to the escalation of cocaine intake which contrasts with the reported role of contextual cues in the control of escalated cocaine intake.

Title: Extended-access to cocaine has a distinct behavioral and molecular profile from yoked- and limited-access to cocaine

Authors: *K. PLOENSE[1], L. BUBALO[2], A. CARR[3], T. KIPPIN[2];
[1]Univ. of California Santa Barbara, Goleta, CA; [2]Univ. of California Santa Barbara, Santa Barbara, CA; [3]Neurosci., Wake Forest Univ., Salem, NC

Abstract: Cocaine addiction is a chronic disorder that involves escalation of intake over time. Approximately 10% of the US population has used cocaine by the age of 18, yet, only about 1% of US citizens meet the criteria for cocaine addiction. Both humans and rodents will self-administer escalating doses of cocaine when the drug is readily available. However, when cocaine access is restricted, escalation of intake is not apparent in rodents. Here, we investigated escalation of cocaine intake and active lever responding in rats as a function of control over intake. Rats were implanted with a permanent jugular catheter and then allowed to lever press to self-administer (FR1, 20s time-out with a 20s light cue paired with each infusion) saline vehicle (0.1 ml/infusion) cocaine (0.25 mg/infusion) under 4 conditions: limited-access (1 h/ day) to saline, limited-access to cocaine, extended-access (6 h/day) to cocaine condition, and limited-access + yoked-access (1h/day + 5 h/day, respectively) to cocaine. Based on the first 10 min and first hour of daily access, we observed rapid escalation of cocaine intake in both the extended-access and limited-access + yoked conditions (ps < 0.05). We also observed a delayed escalation of cocaine intake in the limited-access condition within the first 10 min of self-administration ($p < 0.05$), but not within the first 1 h of self-administration. Interestingly, there was an immediate escalation of active lever responding in the limited + yoked-access condition during the first 10 minutes of daily self-administration which preceded the escalation of responding observed in the extended-access condition. A similar pattern of escalation for active lever responding was observed during the first 1 h of daily self-administration for all cocaine conditions. However, relative to the other cocaine conditions, the limited-access + yoked group exhibited markedly less efficient self-administration (i.e. more non-reinforced relative to reinforced lever responses) during both the first 10 min and 1 h of daily self-administration (ps<0.05). . Additionally, post-mortem quantification of *homer2* (a gene implicated in cocaine cued learning) mRNA expression within the dmPFC indicated elevation only in the extended-access conditions ($p<0.05$). Together, these findings indicate that either contingent or non-contingent "excessive" cocaine exposure supports escalation but has distinct effects on the temporal patterning of operant responsiveness as well as molecular correlates of escalation.

Title: Chronic cocaine disrupts angiogenesis and cerebral blood flow in the mouse brain

Authors: *K. PARK[1,2], J. YOU[1], J. CHOI[1], N. D. VOLKOW[2], C. DU[1], Y. PAN[1];
[1]Stony Brook Univ., Stony Brook, NY; [2]Natl. Inst. on Drug Abuse, NIH, Bethesda, MD

Abstract: Cocaine-induced stroke is among the most serious medical complications associated with its abuse. However, the extent to which chronic cocaine-induced reductions in cerebral blood flow (CBF) and micro-ischemia affects cerebral blood vessels has not been investigated, in part, because of the lack of tools with high spatiotemporal resolution and sensitivity that can simultaneously measure cerebral blood flow velocity (CBFv) quantitatively and morphology with single vascular resolution over large fields of view. Recently, we developed novel optical imaging techniques that permitted the quantitative CBF imaging of cerebrovascular networks along with the imaging of cortical vascular angiography simultaneously. Our study showed that CBF was decreased in response to cocaine and the micro-ischemia was observed in the cortex of the animal after repeated cocaine administration. Here we extend the study to investigate the effects of chronic cocaine on CBF and in the morphology of cerebral blood vessels. To monitor the neurovascular changes from chronic cocaine exposure in mice, a cranial window was implanted on the cortex of each individual mouse. Two groups of animals were used; a control group (saline, ~0.1cc/10g/day, i.p. 35 days) and a cocaine group (30mg/kg/day, i.p. 35 days). Each animal was periodically scanned to image CBFv and angiography of the cortical vascular network simultaneously till the end of treatment. Our repeated imaging of the cortex through the implanted cranial window showed vasoconstrictive effects of cocaine on the brain vessels with chronic cocaine treatment. Vessel constriction induced decreases in CBFv as compared to their baseline (prior to cocaine treatment). The diameters of vessels were decreased ~ 25-35% after 35 days of cocaine exposure compared to baseline, whereas CBFv in these vessels was decreased ~ 40-50%. Interestedly, angiogenesis surrounding the constricted vessels was observed by 12-14 days of cocaine treatment. Blood flow gradually developed in these new growing vessels and 7-8 days later blood flow to the local area had increased 20-30% and was maximal at the end of 35 days of our experiment. These results indicate that the angiogenesis is a response to repair the local micro-ischemia of brain induced by cocaine. Although the angiogenesis intends to improve blood perfusion into the ischemic brain area, the limited CBFv within these vessels makes them difficult to fully compensate for cocaine-induced cerebrovascular dysfunction.

Title: Amphetamine and morphine may produce aspects of acute withdrawal by initially affecting a common pathway

Authors: *W. WHITE, R. WARD, I. WHITE;
Psychology, Morehead State Univ., Morehead, KY

Abstract: When separate groups of rats are administered 2.0 mg/kg amphetamine or 5.0 mg/kg morphine near light onset of a 12-12 hour light-dark cycle, activity is reduced 18 to 24 hours later. This longer-term hypoactivity may be an indicator of an acute withdrawal. If a dopamine D1 receptor antagonist is given shortly after amphetamine or morphine, the reduction in activity appears to be blocked. The similar time courses with which amphetamine and morphine produce hypoactivity, and the similar effects of D1 antagonist on the occurrence of the hypoactivity, suggest that the drugs produce it by initially activating a common circuit. This study sought additional evidence that amphetamine and morphine produce longer-term hypoactivity via a common pathway. Though all rats show longer-term hypoactivity following amphetamine or morphine, the magnitude differs across subjects. If amphetamine and morphine produce longer-term hypoactivity by initially activating a common circuit, then the magnitude of hypoactivity following amphetamine and morphine might be expected to be correlated, the hypothesis assessed in the present study. Adult male Wistar rats were individually housed in open field arenas (43 cm X 43 cm X 30 cm high), equipped with grids of infrared emitters and detectors. Beam interrupts were used to monitor distance moved per unit time, our measure of activity. The animals were in a 12-12 hour light-dark cycle and had free access to water and food (Purina rodent chow). After animals had habituated to the arenas and entrained to the light-dark cycle, they were tested at intervals of five days. On the first day of a test (Day 1), near light onset, animals received a saline administration. Two days later (Day 3), near light onset, they received 2.0 mg/kg amphetamine or 5.0 mg/kg morphine. Station maintenance occurred at the time of a treatment. Activity was monitored for 24 hours following Day 1 and Day 3 treatments. Activity following drugs was compared to activity following saline. During the first six tests, amphetamine was administered, and during the final tests, morphine was administered. The magnitude of hypoactivity that different animals showed following amphetamine and morphine appeared to be qualitatively similar.

Title: Disruption of the hubs of the connectome in cocaine addiction. A multimodal approach

Authors: *A. ZILVERSTAND[1], R. O'HALLORAN[1,2], P. KUNDU[1,2], M. A. PARVAZ[1], S. J. MOELLER[1], G. GAN[1], F. D'OLEIRE UQUILLAS[1], N. ALIA-KLEIN[1], R. Z. GOLDSTEIN[1]; [1]Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Radiology, Mount Sinai, New York, NY

Abstract: Brain networks or 'connectomes' are organized around highly connected processing 'hubs', which are particularly valuable for efficient information processing. Disruptions of these crucial information processing hubs have been linked to impairments in multiple neuropsychiatric disorders, including dementia, schizophrenia, and post-traumatic stress disorder. A recent meta-analytic study has demonstrated that structural microlesions in hub regions predict disruptions of these regions in resting-state functional connectivity. Using a novel multimodal neuroimaging approach, we aim to investigate both if the functional resting-state connectome in cocaine addiction shows disruptions specifically in brain processing hubs, and if these disruptions are predicted by structural microlesions. We acquired structural, diffusion-weighted and functional resting-state data in cocaine users (n=30) and healthy controls (n=33), matched on race, gender and intelligence. Per individual, a whole-brain functional connectome was derived from the resting-state data following standard procedures: parcellating the data according to an anatomical template, calculating functional connectivity between each pair of regions, and thresholding each connectome to contain only the strongest connections. Diffusion-weighted data were parcellated using the same template, and the number of fiber tracts connecting each pair of regions was computed. Brain connectivity (or degree) was defined as the number of connections between each region with all other brain regions. Structural data was processed using the same template, computing changes in gray matter volume by voxel-based morphometry. Functional and structural connectomes of cocaine addicts were contrasted with controls', controlling for age (p<0.05, uncorrected). Ongoing work is using logistic regression to

determine associations between structural and functional connectome abnormalities. Cocaine users showed disruptions of resting-state connectivity in processing hubs, such as the anterior cingulate cortex (ACC), dorsolateral prefrontal cortex (dlPFC), hippocampus, putamen and caudate that have previously been implicated across brain disorders. The ACC, dlPFC, and hippocampus also showed reduction in structural brain connectivity. We expect these disruptions to correlate with abnormalities in gray matter volume. Results support functional and structural abnormalities in brain network hubs within the cognitive control network in cocaine addiction. Evidence of their correlation could advance a multimodal systems-level account of the neural circuitry involved in compulsive behavior.

Title: Characterizing atherosclerosis in asymptomatic cocaine addicted individuals

Authors: *K. BACHI[1], V. MANI[2], R. Z. GOLDSTEIN[1], Z. A. FAYAD[2], N. ALIA-KLEIN[1]; [1]Psychiatry and Neurosci., [2]Translational Mol. Imaging Inst. (TMII), Icahn Sch. of Med. MSSM, New York, NY

Abstract: Cocaine use is involved in 40% of emergency department visits, where positive toxicology for illicit drugs have been associated with stroke, coronary artery disease and myocardial infarction, resulting in severe impairments or sudden mortality, even in absence of prior vascular disease symptoms. Indeed, cocaine, a powerful vasoconstrictor and a sodium channel blocker, decreases basal anti-inflammatory markers (Interleukin 10) and increases pro-inflammatory cytokines (Tumor necrosis factor alpha), contributing to progressive vascular inflammation (atherosclerosis). The carotid arteries supply blood to brain regions that are implicated in the higher-order cognitive impairments documented in individuals with cocaine use disorder (iCUD). Hence, structural and/or functional damage in the carotid arteries may impact cognitive and behavioral functioning even before substantial arterial narrowing results in clinical

symptoms. We hypothesized that iCUD have significant vascular inflammation, which is modulated by history of drug use. Therefore, using Positron Emission Tomography/Magnetic Resonance (PET/MR), we imaged the internal carotid arteries to assess atherosclerosis in 10 healthy iCUD aged 43 to 58 with cocaine lifetime use of 22.6±7.3 years and without a history of neurological or cerebrovascular disease (CVD). We compared results to findings in a sample at risk for CVD, aged 64.6±7.8. Amount of inflammation, measured with PET with 18F-fluorodeoxyglucose (18F-FDG), was calculated by the maximum arterial wall (target) to background (blood) ratio (TBR). To measure enlargement of wall area and thickness of the vessel, we used MR with 3-Dimensional dark-blood sequence. Results show that 78% of iCUD had inflamed plaque in arteries [TBRmax. (mean, SE) right (1.89, .12) left (1.7, .11); notably, TBR $\geq$ 1.6 is indicative of inflamed plaque]. Furthermore, in one sample t-tests using the comparison group's mean values, iCUD had thicker wall (mm; 1.63, .03 versus 1.27, .04, $t(8)=8.84$, $p=.00$) and larger wall area (mm2; 38.45, 1.48 versus 32.28, 1.43, $t(8)=3.34$, $p=.01$) indicating the presence of more plaque in the carotid than the much older comparison sample at risk for CVD. These PET/MR findings correlated significantly with cocaine use indices (lifetime use, craving, and addiction severity) and with nicotine and alcohol lifetime use where the more severe the drug use, the greater the carotid abnormalities ($.53 \leq r \leq .85$, $p<.01$). These preliminary results show markers of carotid disease in CVD-asymptomatic iCUD, which may exacerbate cognitive and behavioral impairments, of paramount clinical significance for combating silent disease progression.

Abstract: Alterations of the endocannabinoid system (ECS) are involved in the pathophysiology of neuropsychiatric disorders including autism spectrum disorders (ASDs). The interaction between genes and environmental factors including immune system dysregulation are associated with ASDs. The ECS consists of the cannabinoid receptors (CB1Rs and CB2Rs), endocannabinoids (eCBs), and the synthesizing and degradation enzymes of eCBs. ECS are involved in embryo neurodevelopment and growth and is a key regulator of the immune system via CB2Rs which are expressed on macrophages, microglial cells and neurons. We used the BTBR T+tf/J mice that have been shown to exhibit autism-like behavioral phenotypes to 1). Determine brain expression of CB2Rs throughout neurodevelopment in BTBR T+tf/J and C57BL/6J mice and also to measure the levels of eCBs, anandamide (AEA) and 2-arachidonlyl glycerol (2-AG) in frontal cortex, cerebellum and the rest of the brain by LC-MS using isotopic dilution method. 2). Evaluate the neurochemical and molecular basis of cannabinoid-induced behavioral effects and 3). Determine impact of SERT, DAT, MOR, and DAT-CI gene knock out on CBR-induced behaviors in motor function and emotionality tests. We report that CB2Rs are present and essential during neurodevelopment and its enhanced brain expression in the adult BTBR mice might be associated with the differential cannabinoid-induced behavioral effects when compared to the C57BL/6J mice. But [^{3}H] CP55,940 binding to CB1Rs did not differ between BTBR and C57BL/6J mice in the amygdala and parietal cortex. CB2R agonist, JWH133 and ACEA- CB1R agonist reduced motor activity in both BTBR and C57BL/6J mice. ACEA induced aversive behavior in both the BTBR and C57BL/6J mice while CB1R antagonist-AM251 reduced aversive behavior in both BTBR and C57Bl/6J strains. In the transgenic mice, the effect of JWH133 was genotype and gender dependent in the motor function and emotionality tests. SERT ko mice were more active in the wheel running activity (WRA) and this was enhanced by JWH133 in the male but not female SERT ko mice. Similar reductions in WRA were recorded for the male and female DAT, DAT-CI and MOR ko mice. In MOR and DAT-CI ko mice, JWH133 induced aversions but reduced aversions in SERT and DAT ko male mice in the two chamber black and white box. AEA but not 2-AG levels in the BTBR mice were reduced in the brain areas analyzed. The data indicate that dysfunction in the ECS may in part contribute to ASDs and other neuropsychiatric disorders. Further studies are required to determine the contribution of the different elements of the ECS involvement in the etiology of ASDS.

Title: Mechanisms and signaling downstream the cannabinoid receptor 1/beta-arrestin

Authors: *F. DELGADO-PERAZA[1], K. H. AHN[2], K. MACKIE[3], D. A. KENDALL[2], G. A. YUDOWSKI[1];
[1]Inst. of Neurobio., San Juan, PR; [2]Dept. of Pharmaceut. Sci., Univ. of Connecticut, Storrs, CT; [3]Dept. of Psychological and Brain Sci., Gill Ctr. for Biomed. Sciences, Indiana Univ., Bloomington, IN

Abstract: G protein-coupled receptors (GPCRs) are transmembrane proteins that transduce external stimulus into intracellular effector pathways. When activated by ligands, they can elicit multiple signaling cascades that are mediated by G proteins or by multifunctional scaffold proteins known as beta-arrestins. While G protein pathways are well defined, the mechanisms and pathways downstream from beta-arrestin signaling are less understood. Here, we sought to investigate the mechanisms and signaling cascades downstream from the cannabinoid 1 receptor (CB1R)/beta-arrestin. First, we tested the hypothesis that the duration of the interaction between CB1R/beta-arrestins during the endocytic process, can control beta-arrestin signaling. We characterized ligand-induced endocytosis of the CB1R in real time by total internal reflection (TIRF) microscopy at the single endocytic level in human embryonic kidney (HEK)293 cells and hippocampal neuronal cultures. Cells were transfected with the CB1R tagged with super-ecliptic phluorin (SEP). Endocytosis was initiated by bath application of different ligands and the endocytic dwell time, which is the time receptors are clustered with beta-arrestins at the endocytic pits before endocytosis, for each ligand was analyzed. We identified ligand-specific endocytic dwell times. The endogenous eicosanoid, 2-arachidonoylglycerol (2-AG), elicited prolonged dwell times (>120 seconds) and strong beta-arrestin signaling, whereas the synthetic agonist WIN 55,212-2 (WIN) elicited short ones (<120 seconds) and no beta-arrestin signaling. Furthermore, chemical inhibition of endocytosis significantly increased beta-arrestin signaling. In addition, by using antibody arrays and siRNA technology, we identified specific signaling pathways controlled by beta-arrestins. Our results indentify the signaling network downstream from CB1R/beta-arrestins and propose a molecular mechanism controlling this type of signaling. Furthermore, we propose modulation of receptor trafficking as a novel approach to control beta-arrestin mediated signaling.

Title: Elucidating cannabinoid biology in zebrafish

Authors: *R. G. KRUG, M. O. PETERSEN, K. J. CLARK;
Mayo Clin., Rochester, MN

Abstract: Although the number of annual cannabis users exceeds 100,000,000 globally and an estimated 9% of these individuals will suffer from dependency, a dearth of knowledge exists about the potential consequences on public health. However, the psychoactive constituents of cannabis are known to signal through the endocannabinoid (eCB) system, and to disrupt features of vertebrate physiology and behavior. While studies have revealed that the eCB anandamide (AEA) regulates stress response system (SRS) activity, little is known about the pathological consequences of disrupted AEA signaling. Our central hypothesis is that disruptions in the AEA signaling system have pathological consequences on vertebrate behavior and physiology, including dysregulation of the SRS. Herein, we use a preclinical zebrafish model to clarify the ramifications of disturbances in the AEA signaling system. Using qRT-PCR and *in situ* hybridization we show that the genes encoding enzymes that synthesize (*abhd4*, *gde1*, *napepld)*, enzymes that degrade (*faah*, *faah2a*, *faah2b*), and receptors that bind (*cnr1*, *cnr2*, *gpr55-like*) AEA are expressed throughout development. We show that disruptions of this system via exogenous cannabinoid administration results in altered behavior and physiology, including increased secretion of glucocorticoids in our stress response reporter line. We are developing a zebrafish AEA signaling mutant library using transcription activator-like effector nucleases (TALENs). Currently, we are identifying our first mutant lines and will share the preliminary results of behavioral assays using our first mutants. Collectively, these results establish zebrafish as a viable model for studying AEA signaling, and lay a foundation for informing a better understanding of the toxicological and therapeutic potential of the eCB system.

Title: Cannabinoid cb1 and cb2 receptors mediate the classical tetrad effects of delta9-tetrahydrocannabinol in mice

Authors: *Z. XI[1], X.-F. WANG[2], Y. HE[2], G. BI[2], E. GARDNER[2];
[1]NIDA, IRP, Baltimore, MD; [2]NIDA, Baltimore, MD

Abstract: In animals, cannabinoid agonists such as delta9-THC produce a characteristic combination of tetrad symptoms - hypothermia, analgesia, hypoactivity, and catalepsy. However, the receptor mechanisms underlying these actions are incompletely understood. When cannabinoid CB1 and CB2 receptors were first cloned in 1990s, CB1 receptor was found in the brain and periphery, while CB2 receptor was found only in periphery. Therefore, it is believed that brain CB1, not CB2, receptor mediates the action produced by cannabis. This view has been challenged by recent finding that functional CB2 receptor is expressed in the brain and in midbrain dopamine neurons. This new finding inspired us to re-examine whether brain CB2 receptor is also involved in the action produced by cannabis such as delta9-THC. To address this issue, we first compared the behavioral response to delta9-THC under the same experimental conditions between wild-type (WT) and CB1 receptor-knockout (CB1-KO) or CB2 receptor-knockout mice (CB2-KO). We found that delta9-THC, at 10 or 30 mg/kg (i.p.), produced dose-dependent analgesia (as assessed by hot-plate test), hypothermia, catalepsy and rotarod performance impairment in WT mice, but not in CB1-KO mice. Surprisingly, deletion of CB2 receptor in CB2-KO mice also blunted delta9-THC-induced analgesia and catalepsy. We then observed the effects of the selective CB1 receptor agonist (ACEA) or CB2 receptor agonist (JWH133) in WT mice. We found that, systemic administration of ACEA (1-10 mg/kg, i.p.) or JWH133 (1-10 mg/kg, i.p.) alone failed to produce significant effects in the above measurements, while co-administration of ACEA and JWH133 produced significant analgesia, hypoactivity and catalepsy. These findings suggest that 1) brain CB1 receptor plays a predominant role in mediating delta9-THC-induced tetrad effects; 2) brain CB2 receptor also play an important role in mediating delta9-THC-induced analgesia and catalepsy; and 3) co-activation of brain CB1 and CB2 receptors are required in mediating the behavioral effects produced by cannabinoid ligands. Title: Differential tolerance produced by daily administration of Δ^9-THC and JWH-018 in rhesus monkeys

Authors: *M. L. COCKE, L. R. MCMAHON;
Pharmacol., Univ. of Texas Hlth. Sci. Ctr. At San A, San Antonio, TX

Abstract: The *Cannabis* derivative Δ^9-tetrahydrocannabinol (Δ^9-THC) and the synthetic cannabinoid naphthalen-1-yl-(1-pentylindol-3-yl) methanone (JWH-018) are both CB_1 receptor agonists; however, unlike Δ^9-THC, JWH-018 has been linked to adverse effects such as seizures and hypertension. The disparity between adverse effects could be due to JWH-018 having higher CB_1 receptor efficacy than Δ^9-THC, evidenced most commonly by greater maximum stimulation of inhibitory G proteins. In a previous study, daily Δ^9-THC treatment produced tolerance and cross-tolerance to JWH-018 in a non-human primate model of subjective effects; however, tolerance to Δ^9-THC was greater than cross-tolerance to JWH-018, consistent with a difference in CB_1 receptor efficacy. What remains unclear is the extent to which daily JWH-018 administration alters sensitivity to JWH-018. This study tested the hypothesis that tolerance to Δ^9-THC is greater than tolerance to an equally effective dose of JWH-018, as would be predicted for chronic treatment with a low versus a high efficacy agonist. Rhesus monkeys (*Macaca mulatta*) discriminated Δ^9-THC (0.1 mg/kg i.v.) from vehicle under an FR5 schedule of lever pressing to avoid a noxious stimulus. Both Δ^9-THC and JWH-018 produced dose-dependent increases in Δ^9-THC lever responding to 100%; the respective ED_{50} values were 0.026 and 0.0084 mg/kg, a difference of 3-fold. The time courses of discriminative stimulus effects following subcutaneous administration were compared: Δ^9-THC (1 mg/kg) produced 80% Δ^9-THC lever responding for 8-12 h, whereas the duration of action of JWH-018 (0.32 mg/kg) was 4-8 h. According to these time courses, Δ^9-THC (1 mg/kg s.c.) was administered once daily and JWH-018 (0.32 mg/kg s.c.) was administered twice-daily 6 h apart. Δ^9-THC treatment produced a 3.8-fold loss of sensitivity after three days and a 16-fold loss of sensitivity after 7 days. JWH-018 treatment produced a 2.1-fold loss of sensitivity after three days and a 4.7-fold loss of sensitivity after 7 days. Consistent with the hypothesis, tolerance to the low efficacy CB_1 receptor agonist Δ^9-THC was greater than tolerance to the high efficacy CB_1 receptor agonist JWH-018. The differential development of tolerance among CB_1 receptor agonists as a function of efficacy might underlie the greater incidence of adverse effects following use of synthetic cannabinoids as compared with *Cannabis*.

Title: Increased cortical inhibition in autism-linked neuroligin 3 r451c mice is due to loss of tonic endocannabinoid signaling

Authors: ***H. E. SPEED**[1], I. MASIULIS[2], J. GIBSON[3], C. POWELL[4];
[1]Neurol., UT Southwestern Med. Ctr., Dallas, TX; [2]Quantitative Morphology Core, [3]Neurosci., [4]Neurol., Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: A single, maternally inherited, X-linked point mutation leading to an arginine to cysteine substitution at amino acid 451 (R451C) of Neuroligin 3 is a likely cause of autism in two brothers. Knockin mice expressing the $NL3^{R451C}$ mutation in place of wild-type NL3 demonstrate increased inhibitory synaptic strength in somatosensory cortex, resulting in an excitatory/inhibitory (E/I) imbalance that is potentially relevant for autism-associated behavioral deficits characteristic of these mice. We have replicated the increase in evoked inhibitory postsynaptic currents (eIPSCs) onto layer II/III cortical pyramidal neurons. We also find that increased frequency of spontaneous IPSCs in $NL3^{R451C}$ mice occurs in the absence of action potential-driven transmission. This suggests the E/I imbalance is due to changes at the synapse level, as opposed to the network level. Next, we use paired whole-cell recordings in an attempt to identify specific interneuron subtypes affected by the $NL3^{R451C}$ mutation. Curiously, we observe no change in the amplitude of cell-to-cell, unitary IPSCs from parvalbumin-positive (PV) or somatostatin-positive (SOM) interneurons onto pyramidal neurons. We also observe no change in the number or density of PV and SOM interneurons in LII/III of somatosensory cortex. This effectively rules out a role for these particular interneurons in the increased inhibitory synaptic transmission, pointing to perhaps alternative interneuron subtypes. Lastly, impaired endocannabinoid signaling has been implicated in hippocampal synaptic dysfunction in $NL3^{R451C}$ mice, but has not been investigated at cortical synapses. We find that bath application of the CB1 antagonist, AM 251 in WT mice eliminates the $NL3^{R451C}$ increase in evoked IPSC amplitude and mIPSC frequency, indicating that increased inhibitory transmission in mutant mice is due, at least in part, to a loss of tonic endocannabinoid signaling through CB1 receptors likely acting at interneurons other than PV or SOM.

Title: Morphine and ethanol reward, tolerance, and dependence in mice expressing a desensitization-resistant form of the cannabinoid receptor 1 (CB1)

Authors: M. L. ZEE[1], D. J. MARCUS[2], M. GONEK[3], A. H. REDMOND[1], *D. J. MORGAN[1]; [1]Dept. of Anesthesiol., Penn State Col. of Med., Hershey, PA; [2]Vanderbilt Univ., Nashville, TN; [3]Virginia Commonwealth Univ., Richmond, VA

Abstract: The focus of this study was to investigate whether enhanced endocannabinoid system (ECS) signaling modulates reward, tolerance, and dependence for morphine and ethanol. Preference and consumption of ethanol is attenuated in CB1 knockout mice using a two-bottle choice voluntary drinking paradigm. Studies also demonstrate involvement of the CB1 receptor in the modulation of reward, dependence and tolerance to morphine. We produced S426A/S430A mutant mice expressing a desensitization-resistant form of CB1 to study the importance of desensitization for tolerance to cannabinoid agonists. During the characterization of these novel mutant mice, we found that they also display an exaggerated and prolonged acute response to Δ9-THC and endogenous endocannabinoids. Given the important role of CB1 in modulating the effects of opioid and ethanol reward and dependence, we decided to use the S426A/S430A mutant mice as a novel model to examine the effect of enhanced ECS signaling on these processes. Ethanol intake was measured using a 24-hour, continuous-access voluntary drinking paradigm. We found that S426A/S430A mice consumed significantly more 6 and 9% ethanol. Tolerance to ethanol-induced ataxia was examined using the rotarod, while tolerance to morphine-induced antinociception was assessed using the hotplate and tail-flick tests. Despite differences in ethanol intake, S426A/S430A and wild-type mice exhibit equivalent ethanol and morphine tolerance. Likewise, S426A/S430A also develop normal and robust CPP for morphine and cocaine. Morphine dependence was determined by counting naloxone-precipitated withdrawal symptoms in mice implanted with 75mg morphine pellets. Both genotypes displayed similar severity of morphine dependence; however, we found that S426A/S430A mutants recovered from precipitated withdrawal more quickly than wild-type littermates. These findings suggest that CB1 modulation of reward for, tolerance to, and dependence on ethanol and morphine is not heavily impacted by elevated ECS sensitivity due to disruption of CB1 desensitization. Although the S426A/S430A mice may indeed possess enhanced sensitivity to

exogenously administered cannabinoids, our data suggests that they have limited utility for drug addiction research.

Title: Antinociceptive effects of synthetic tetracycline compound and influence of Cx3cr1 in inflammatory pain

Authors: *J. GUINDON, B. SEEGMILLER, C. BEZBORUAH, P. C. MARQUADT, J. M. MARTINEZ, S. E. BERGESON;
Dept. of Pharmacol. and Neurosci., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: Tetracycline compounds are broad-spectrum antibiotics used against different bacterial infectious diseases. Synthetic tetracycline compounds have been developed and are able to reduce infection as well as inflammation. However, the effect on alleviation of pain, and more specifically reduction of inflammatory pain, has not been investigated. The goal of the study is to evaluate the effect of synthetic tetracycline compounds using an inflammatory pain model and mechanical and cold allodynia responses. The formalin test (10 µl at 2.5 % intraplantar) was use to evaluate pain threshold differences between male wild-type C57BL/6 mice and male GFP Cx3cr1 +/- mice. First, our preliminary data demonstrate that male GFP Cx3cr1 +/- mice show lower pain threshold in both (acute and inflammatory) phases of the formalin test. Second, we evaluated the effect of a synthetic tetracycline compound on inflammatory pain and on mechanical and cold allodynia. Our data indicate that mechanical and cold allodynia remains unchanged after administration of a synthetic tetracycline compound meaning values are similar to baseline levels. However, synthetic tetracycline compound lower pain threshold in both phases of the formalin test from 4 hours up to 20 hours after its administration and showed antinociceptive effects to mechanical and cold allodynia following the formalin test (60 minutes after injection of formalin). Moreover, mechanical and cold allodynia responses return to baseline levels 2 hours after the formalin test. These results demonstrate potential antinociceptive properties of synthetic tetracycline compound with long lasting effect up to 20 hours after its administration. Further studies are needed to investigate the mechanism underlying this

antinociceptive effect of synthetic tetracycline compounds. We will also evaluate potential stronger antinociceptive effect of the synthetic tetracycline compound in Cx3cr1 +/- male mice and evaluate if there is any gender specific differences. Antinociceptive properties of synthetic tetracycline compound could be a great alternative avenue to relieve inflammatory pain and improve alleviation of pain in patients.

Title: Tolerance to the antinociceptive effects of Δ9-THC in the formalin model of inflammatory pain

Authors: *M. B. YUILL[1], D. J. MORGAN[2,3], J. GUINDON[4];
[2]Dept. of Anesthesiol., [1]Penn State Hershey Col. of Med., Hershey, PA; [4]Dept. of Pharmacol. and Neurosci., [3]Texas Tech. Univ. Hlth. Sci. Ctr. Sch. of Med., Lubbock, TX

Abstract: The use of cannabinoids to manage pain is of interest given the rise of opiate abuse among the general population. Δ^9-THC produces potent antinociceptive effects but, like opiates, is subject to tolerance. The objective of this study was to examine the complete time-course of Δ^9-THC tolerance in a model of inflammatory pain. The effect of Δ^9-THC was assessed in male wild-type C57BL/6 mice subjected to inflammatory pain using formalin (10 µl at 2.5 % intraplantar). Experimental groups were subjected to the formalin test after receiving chronic daily injections of Δ^9-THC (6 mg/kg), or vehicle, for periods of time starting from zero consecutively up to eight days. We also examined the effect of JNK inhibitor SP600125 on Δ^9-THC. Control groups injected with saline for 1, 4, and 8 days were examined. Mice tested after one day of exposure showed the greatest level of antinociception while mice treated for eight days showed almost no antinociception. Preliminary data suggest that co-administration of SP6 (3 mg/kg) with Δ^9-THC prolongs the onset of full tolerance from 8 to 12 days. In phase I (acute pain), tolerance develops gradually across eight days, with the largest jump between two and three days of chronic administration. While also gradual across eight days, in phase II of the

formalin test, the largest increase seems to occur between three and four days of chronic administration. These results are consistent with the findings in other models such as acute pain showing onset of tolerance by three days of daily administration. Further studies are needed to investigate the longer retained efficacy of Δ^9-THC appearing in inflammatory pain relative to acute pain in the tail-flick test. The findings of this study reinforce the validity of the formalin model as a pathologically relevant tool to assess cannabinoid tolerance in mice models. Also, it provides a detailed day-by-day map of the progression of Δ^9-THC tolerance. Preliminary results also suggest that JNK signaling is involved in this observed tolerance. Title: Development of a novel rodent model of THC self-administration

Authors: *S. M. SPENCER[1], C. GARCIA-KELLER[2], M. D. SCOFIELD[2], N. ALLEN[2], D. SCHWARTZ[2], P. W. KALIVAS[2];
[1]Neurosci., [2]Med. Univ. of South Carolina, Charleston, SC

Abstract: Cannabis is the most frequently used illicit drug worldwide, but preclinical research on its effects has been hampered by lack of an animal model since rats will not maintain self-administration of isolated Δ^9-tetrahydrocannabinol (THC), the drug's main psychoactive component. THC on its own may produce unpleasant side effects including increased anxiety, but cannabis contains over 60 cannabinoids and more than 400 additional chemicals. Cannabidiol (CBD), a non-psychoactive cannabinoid, may counter some of the aversive properties of THC by producing anxiolytic and anti-psychotic effects. Thus in the present investigation, one strategy that was employed to promote drug taking in male Sprague-Dawley

rats was by combining CBD with THC in a ratio of 10:1, a proportion previously demonstrated to neutralize a THC conditioned place aversion. Moreover, we used a Volcano vaporizer to pre-expose rats to THC:CBD vapor (10 mg THC vapor per pad) for 5 days prior to initiating intravenous THC:CBD self-administration (4 g/kg/0.05 ml infusion) as it has previously been demonstrated that THC pre-exposure facilitates formation of a THC conditioned place preference rather than aversion. We determined that our THC vapor pre-exposure provided a physiologically relevant dose of THC as we were able to measure a decrease in core body temperature after exposure. During self-administration, clear lever discrimination was observed with greater than 2-fold preference for the drug-associated lever. The rats sustained low levels of responding with an average of 6 infusions per 2-hr session although there was high inter-individual variability. We generated a dose response curve in (1.27, 4, and 12.64 g/kg) and found that highest responding was observed at 4 g/kg/infusion. Importantly, we also demonstrated both cue-induced and THC-primed (1 mg/kg, ip) reinstatement in animals extinguished from THC:CBD. This affords the opportunity to initiate a reverse-translational investigation of n-acetylcysteine (NAC) to test its effects on reinstatement as this drug has recently demonstrated efficacy in clinical studies of marijuana dependence. Additional studies will examine biomarkers of altered glutamatergic synaptic plasticity in the nucleus accumbens after THC self-administration. In summary, we have established a rodent model of THC self-administration allowing us to evaluate THC-dependent brain changes relevant to addiction and relapse.

Title: Cannabinoid withdrawal-induced adaptations in the habenulomesencephalic pathway

Authors: *A. MUNTONI[1], S. ARONI[2], C. SAGHEDDU[2], M. PISTIS[2,1];
[1]CNR Neurosci. Institute-Cagliari, Monserrato, Italy; [2]Dept. of Biomed. Sciences, Div. of Neurosci. and Clin. Pharmacol., Univ. of Cagliari, Cagliari, Italy

Abstract: The mesolimbic reward system arising from dopamine (DA) neurons of the midbrain ventral tegmental area (VTA) shows a profound reduction in its function during cannabinoid withdrawal. This hypoactivity, a common feature of several abused drugs, is thought to underlay the withdrawal-induced aversive affective states eventually leading to compulsive drug seeking and relapse. The lateral habenula (LHb) exerts a negative control over the VTA via the GABA rostromedial tegmental nucleus (RMTg), encoding aversion-related stimuli. In fact, both RMTg

and LHb cells are activated by negative/unpleasant events, and inhibited by rewarding/positive stimuli. Therefore, these nuclei represent a potential convergence point for drug-evoked reward and aversive opponent processes. On these bases, we hypothesized that the LHb-RMTg pathway might be causally involved in the hypodopaminergic state which occurs during cannabinoid withdrawal. To address this question, we performed single unit extracellular recordings from either VTA, RMTg and LHb neurons in anesthetized male Sprague-Dawley rats. To induce Δ^9-tetrahydrocannabinol (Δ^9-THC) dependence, rats were chronically treated (15 mg/kg, i.p.) twice daily for 6.5 days. Administration of the cannabinoid antagonist rimonabant (5 mg/kg, i.p.) precipitated a robust behavioural withdrawal syndrome, while abrupt Δ^9-THC suspension caused milder signs of abstinence. Electrophysiological experiments confirmed that Δ^9-THC withdrawal is accompanied by a marked decrease in the discharge frequency and burst firing of VTA DA neurons. Remarkably, in Δ^9-THC withdrawn rats the duration of RMTg-evoked inhibition lasted longer than controls. In contrast, the spontaneous activity of RMTg GABA neurons was reduced in cannabinoid-withdrawn rats. Consistent with results, we also found that the firing rate of RMTg-projecting LHb neurons was strongly depressed during cannabinoid withdrawal. These data support the hypothesis that enhanced GABA inputs from the RMTg might contribute to the hypodopaminergic state induced by cannabinoid withdrawal. They also confirm that functional changes in the habenulomesencephalic circuit are implicated in the mechanisms underlying drug dependence and addiction.

Title: Modulation of CB1 cannabinoid receptor signaling and adaptation by D2 dopamine receptors

Authors: D. E. SELLEY[1], L. S. MIDDLETON[1], J. J. BURSTON[2], D. K. GRANDY[3], *L. J. SIM-SELLEY[1];
[1]Virginia Commonweatlh Univ., Richmond, VA; [2]The Univ. of Nottingham, Nottingham, United Kingdom; [3]Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Gi/o-coupled CB1 receptors (CB1R) in striatum produce motor suppression and catalepsy and regulate motivation. Repeated CB1 agonist administration produces tolerance that

is associated with CB1R desensitization and downregulation in the CNS, however CB1Rs in striatal circuits are somewhat resistant to these adaptations. CB1Rs co-localize with D2 receptors (D2R) on striatopallidal medium spiny neurons, and interaction between these receptors affects their activity and expression. CB1R and D2R can heteromerize, which switches their G-protein coupling from Gi/o to Gs. We examined D2R-CB1R interactions in G-protein activation using [35S]GTPγS binding in wild-type (WT) or D2R knockout (KO) mice and CHO cells stably expressing CB1R (CB1-CHO) or CB1 and D2R (CB1/D2-CHO). Maximal CB1R mediated G-protein activation was reduced in both dorsal and ventral striatum of D2R KO compared to WT mice. In dorsal striatum of WT but not D2R KO mice, incubation with both the CB1 agonist WIN55,212-2 (WIN) and D2 agonist quinelorane (Quin) produced less G-protein activation than WIN alone. Despite reduced CB1R mediated G-protein activation in D2R KO mice, adenylyl cyclase (AC) inhibition by WIN was enhanced in dorsal and unchanged in ventral striatum of D2R KO mice, suggesting that D2R might switch a subset of CB1Rs from Gi to Gs protein activation. Interestingly, maximal G-protein activation by D2R did not differ between CB1R KO and WT mice in dorsal or ventral striatum, but the Quin EC50 value in dorsal striatum was greater in CB1R KO mice. Because D2R alters CB1R signaling, co-expression with D2R might contribute to resistance of striatal CB1R to agonist-induced adaptation. This was tested in a model cell system. CB1-CHO and CB1/D2-CHO cells were treated for 24 hr with WIN or Quin alone or in combination. WIN treatment desensitized CB1R mediated G-protein activation in CB1-CHO cells without downregulating CB1Rs. Importantly, CB1R desensitization by WIN was reduced in CB1/D2-CHO cells, but co-treatment with WIN + Quin did not further reduce CB1R desensitization. Treatment of CB1-CHO cells with WIN + the AC activator forskolin attenuated CB1R desensitization compared to WIN alone, suggesting that heteromer coupling to Gs could play a role in D2R mediated attenuation of CB1R desensitization. Quin treatment of CB1/D2-CHO cells desensitized D2R, but enhanced CB1R mediated G-protein activation, whereas WIN treatment did not affect G-protein activation by D2R. These results demonstrate asymmetric interactions between CB1R and D2R in G-protein signaling and receptor adaptation.

Title: Involvement of endocannabinoid system on cognitive dysfunction during withdrawal of repeated methamphetamine administration in mice

Authors: R. FUKUMORI, S. YAMADA, *T. YAMAGUCHI, T. YAMAMOTO;
Nagasaki Intl. Univ., Sasebo, Nagasaki, Japan

Abstract: Repeated administration of methamphetamine causes reverse tolerance and/or behavioral sensitization in mice. However, the cognitive deficits induced by withdrawal after repeated methamphetamine administration have not been sufficiently studied until now. On the other hand, endocannabinoid systems play important roles in physiological functions in the central nervous system, such as pain perception, appetite, psychomotor behavior, emotion, reward system and cognitive function. Furthermore, we previously reported that the involvement of cannabinoid CB1 receptors in the reinstatement of methamphetamine-seeking behaviors in rats. In this study, we investigated relationship between cognitive deficits and development of behavioral sensitization by using the cannabinoid CB1 receptor knockout mice. Mice were subcutaneously administered methamphetamine at dose of 0.1-1.8 mg/kg or saline, every other day for 30 days (15 injections). In wildtype mice, locomotor activity was enhanced by the repeated administration of methamphetamine at dose of 1.0 and 1.8 mg/kg. 10 or 30 days after withdrawal, the mice were tested cognitive functions. In novel object recognition test, approach time to novel object has decreased during withdrawal of repeated 1.8 mg/kg methamphetamine administration. In addition, prepulse inhibition had been suppressed during withdrawal of repeated methamphetamine administration at dose of 1.0 and 1.8 mg/kg. On the other hand, in cannabinoid CB1 receptor knockout mice, the locomotor activity was not enhanced by repeated administration of methamphetamine. Furthermore, cannabinoid CB1 receptor knockout mice were not shown dysfunctions of cognition and prepulsee inhibition by repeated administration of methamphetamine. Our data suggest that the cannabinoid CB1 receptor is involved in the development of behavioral sensitization and cognitive/sensorimotor gating deficits during withdrawal of repeated methamphetamine administration.

Abstract: We have recently reported that brain cannabinoid CB_2 receptors (CB_2Rs) regulate midbrain dopamine (DA) neuronal activity, nucleus accumbens DA release and intravenous cocaine self-administration in mice and rats (Xi et al., Nature Neuroscience, 2011; Zhang et al., PNAS, 2014). These findings appear to conflict with anatomic evidence that brain CB2 gene level is very low (~50-fold) compared to that in the periphery - e.g., spleen. We hypothesized that acute or chronic use of drugs of abuse may up-regulate brain CB2 receptor expression, and produce significant effects on brain function. To test this hypothesis, we first treated animals with a single injection or repeated injections of cocaine, or chronic cocaine self-administration, respectively, and then measured brain CB2 mRNA levels using quantitative real-time PCR (qRT-PCR) and *in situ* hybridization (ISH) assays. We found that: 1) chronic intravenous cocaine self-administration (1 mg/kg/infusion × 50 infusions/day × 4 weeks) significantly up-regulated (4-5 fold) CB_2 mRNA expression in the prefrontal cortex (PFC) and striatum of mice compared to that observed in oral sucrose self-administration (control) mice or drug naïve mice. In contrast, a single injection (10, 20, 30 mg/kg, i.p.) or repeated injections of cocaine (10 mg/kg, i.p. per day, for 7 days) (i.e. locomotor sensitization dose regimen) failed to alter brain CB_2 mRNA expression as assessed by qRT-PCR; 2) ISH assays show similar findings - CB_2 mRNA is significantly up-regulated in cortical and striatal neurons as well as VTA DA neurons. To determine the cell types of striatal GABAergic medium-spiny neurons (MSNs) expressing CB2Rs, we used D1- versus D2-eGFP transgenic mice and fluorescence activated cell sorting (FACS) techniques, and found that CB2 mRNA is mainly expressed in D2-MSNs (3~4-fold higher in D2-MSNs than in D1-MSNs) in normal subjects. Repeated cocaine administration (20 mg/kg, i.p. per day for 7 days) significantly up-regulated CB2 mRNA expression in D1-MSNs, but not in D2-MSNs. Taken together, these findings suggest that brain CB_2 receptors are inducible and responsive to chronic cocaine abuse or repeated large doses of cocaine. Thus, these findings not only well explain the anti-addictive effects of CB2R agonists observed in cocaine self-administration mice, but also suggest that brain CB_2Rs may constitute a new target in medication development for the treatment of drug addiction and possible other CNS disorders.

Title: Elevation of kynurenic acid levels suppresses Δ9-tetrahydrocannabinol-induced excitation of mesolimbic dopamine and prefrontal cortex pyramidal neurons

Authors: *M. PISTIS[1,2], M. MELIS[1], A. MUNTONI[2], C. SAGHEDDU[1];
[1]Univ. of Cagliari, Monserrato, Italy; [2]C.N.R. Neurosci. Inst., Cagliari, Italy

Abstract: Δ9-tetrahydrocannabinol (THC), the major psychoactive component of Cannabis extracts, like most drugs of abuse, enhances dopaminergic (DA) transmission by increasing both DA neuron firing rate and DA release in the nucleus accumbens shell (shNAc), an effect that underlies the rewarding and dependence-inducing effects of marijuana. We have recently demonstrated that elevations of brain levels of kynurenic acid (KYNA), an endogenous product of the normal metabolism of amino acid L-tryptophan, suppresses THC-induced behavioral and neurochemical effects, in rats and monkeys [1]. On these bases, we carried out *in vivo* electrophysiological single cell recordings in anesthetized rats to investigate how KYNA modulates THC-induced electrophysiological actions on DA neurons in the ventral tegmental area (VTA) and pyramidal neurons in the medial prefrontal cortex (mPFC). Neurons were selected as projecting to the shNAc by antidromic stimulation. According with previous studies, THC (0.3-2.4 mg/kg), increased firing activity of DA (137.1 ± 4.1 %) and mPFC (306.2 ± 75.6 %) cells projecting to the shNAc. To enhance brain levels of KYNA, the kynurenine-3-monooxygenase inhibitor, Ro 61-8048 (Ro, 30 mg/kg, i.p.) was administered 40 minutes before recordings. Consistent with microdialysis and behavioral studies, THC-induced increase in firing activity was completely abolished in DA (103.6 ± 3.3 %) as well in mPFC (119.4 ± 28.1) cells recorded from rats pretreated with Ro. *Ex vivo* patch clamp experiments confirmed that KYNA prevents THC-induced depression of excitatory post-synaptic potentials in DA neurons. KYNA was suggested to act as a negative allosteric modulator of α7 nicotinic acetylcholine receptors (α7-nAChRs), therefore, to prevent Ro effects we administered a positive allosteric modulators of α7-nAChRs, PNU120596. PNU120596 partially prevented the effects of Ro on mPFC pyramidal neurons, suggesting that the electrophysiological effects of KYNA might be dependent on α7-nAChR. The involvement of α7-nAChR was confirmed also with patch clamp experiments. Patients seeking help for Cannabis dependence are increasing worldwide but specific pharmacological treatments are lacking. Together with recent neurochemical and behavioral studies, our results support the hypothesis that specific modulation of KYNA levels might represent an innovative therapeutic approach to treat Cannabis dependence. Title: The novel dopamine D3 receptor antagonists CAB02-015 and BAK4-54 inhibit oxycodone self-administration and reinstatement of drug-seeking behavior in rats

Authors: *Z.-B. YOU, G.-H. BI, C. BOATENG, A. BANALA, E. E. GARDNER, Z.-X. XI, A. H. NEWMAN;
Mol. Targets and Medications Discovery Br., NIDA-IRP/NIH/DHHS, Baltimore, MD

Abstract: The use of prescribed opioid analgesics such as oxycodone has been increased dramatically in recent years, which parallels the increases in prescription opioid abuse and drug-related deaths worldwide. Thus, understanding the rewarding properties of prescription opioids, and accordingly, developing effective pharmacotherapies for treatment of prescription opioid abuse has become a critical matter of public health. In the present study, we studied the rewarding and reinforcing properties of oxycodone in animal models of drug addiction, and the potential roles of the novel dopamine D3 receptor antagonists CAB02-015 or BAK4-54 in mediation of these effects in rats. We have found that animals rapidly acquired oxycodone self-administration in a dose range of 0.03 -0.24mg/kg/infusion, with a pattern that is similar to those of heroin or cocaine. Pretreatments in drug trained rats with either CAB02-015 or BAK4-54 (0.4~10mg/kg, i.p.) inhibited oxycodone self-administration dose-dependently. In addition, repeated treatments with CAB02-015 (0.4, 4 mg/kg, i.p. for 7 days) during the extinction sessions (in which oxycodone was replaced by saline) dose-dependently accelerated the extinction of drug-seeking behavior (as indicated by the accelerated decline in responding on the lever previously associated with oxycodone in CAB02-015 versus vehicle treated groups) and inhibited reinstatement of oxycodone-seeking induced by oxycodone priming injection (1 mg/kg, i.p.). Taken together, these findings indicate that 1) oxycodone possesses similar addictive properties as heroin and cocaine; and 2) the novel D3 receptor antagonists CAB02-015 and BAK4-54 may have therapeutic potential for addiction treatment associated with prescription opioid use.

Title: Effects of the non-opioid (+)-naltrexone and the peripherally active (+)-N-methylnaltrexone in rats self-administering the mu agonist remifentanil

Authors: C. ZANETTINI[1], T. HIRANITA[2], *L. R. WATKINS[1], B. R. SELFRIDGE[3], K. C. RICE[3], J. L. KATZ[2];
[1]Dept Psychology & Neurosci., Univ. Colorado At Boulder, Boulder, CO; [2]Psychobiology, NIDA Intramural Res. Program, Baltimore, MD; [3]Drug Design and Synthesis Section, NIDA Intramural Res. Program, Rockville, MD

Abstract: Toll-like receptor 4 (TLR4) is a protein that detects lipopolysaccharide from gram-negative bacteria and is involved in activation of innate immune responses to foreign substances. TLR4 is expressed centrally and peripherally. It was recently reported that the non-opioid TLR4 antagonist, (+)-naloxone, decreases self-administration of remifentanil, a short acting mu-opioid agonist, in rats, suggesting an involvement of TLR4 in the reinforcing effects of mu-opioids (J. Neurosci. 32: 11187). Using the CNS-active and peripherally acting TLR4 antagonists (+)-naltrexone and (+)-N-methylnaltrexone, respectively, the present study compared i) central vs peripheral components of this effect, and ii) the specificity of the effect by comparing effects on responding maintained under comparable schedules of remifentanil or cocaine injection, and food presentation. One group of rats was trained to self-administer remifentanil (0, 0.1-3.2 µg/kg/inj, IV) under a fixed ratio 5-response schedule of reinforcement in sessions comprised of five 20-min components. The dose of remifentanil per-ratio completed was increased during successive components of the session to determine dose-effect curves. A second group was trained under a comparable schedule with cocaine injections (0, 0.03-1.0 mg/kg/inj), and a third group with food reinforcement using 0 to 4 food pellets per ratio completed in the successive components. The TLR4 antagonist, (+)-naltrexone (3.2-56 mg/kg, sc), its peripherally acting analog, (+)-N-methylnaltrexone (32-100 mg/kg, sc), or vehicle were administered before selected daily sessions. Control response rates were an inverted U-shaped function of remifentanil or cocaine dose or amount of food, with maxima at 1.0 µg/kg/inj, 0.32 mg/kg/inj, or 2 pellets/presentation, respectively. (+)-Naltrexone dose-dependently decreased the self-administration of remifentanil, cocaine, and rates of responding maintained by food presentation. In contrast, (+)-N-methylnaltrexone, at doses greater than active doses of (+)-naltrexone, did not significantly alter remifentanil self administration. The potency of (+)-naltrexone in decreasing behavior was slightly greater with cocaine self administration than with responding maintained by either remifentanil or food reinforcement, for which there was no difference in potency. Overall the present study suggests that the (+)-naltrexone produced decreases in self-administration of remifentanil and cocaine are centrally mediated though generalized to behaviors maintained by various reinforcers. Supported by NIDA IRP (JLK, BRS, KCR) and a DoD Contract PR110146 (LRW).

Title: Reversal of the sleep/wake cycle in heroin self-administering rats

Authors: ***A. A. COFFEY**, Z. GUAN, P. S. GRIGSON, J. FANG;
Penn State Col. of Med., Hershey, PA

Abstract: Addiction is a chronic, relapsing disease. In the United States, heroin abuse is increasing dramatically. Drug abuse and sleep disturbances interact to form a vicious cycle where drug abuse disrupts sleep, and sleep deficits spur on drug abuse. Rodents have been shown to entrain their activity to the availability of cocaine or methamphetamine during the light cycle, but there have been no assessments of sleep patterns. Alcoholism has been linked to an inverted circadian rhythm of melatonin secretion, providing some evidence for circadian disruptions in humans. With opioid abuse, a decrease in rapid eye movement (REM) sleep during withdrawal is the most commonly cited sleep deficit. Here, we used electroencephalography (EEG) and electromyography (EMG) to measure sleep patterns in male Sprague-Dawley rats over 20 days of acquisition of heroin self-administration, 14 days of abstinence, and a single day of extinction and reinstatement. The results showed that rats entrain their sleep/wake patterns to heroin availability during the light cycle as evidenced by a complete inversion of sleep/wake patterns compared to the saline controls. Over the first 36 hours of abstinence, the circadian patterns of wakefulness and NREM sleep are lost in heroin self-administering rats, after which the patterns re-entrain to the light/dark cycle. In addition, individual differences were evident whereby a reduction in REM sleep was found during the first three days of abstinence for high vs low drug takers. Ultimately, characterization of the drug-induced dysregulation of sleep and circadian rhythm may reveal new avenues for treatment.

Title: Attenuating reinstatement of drug-seeking using selective kappa opioid receptor antagonists

Authors: *E. R. DUNN-SIMS[1], C. TYSZKIEWICZ[1], A. SAWANT-BASAK[2], J. HEDDE[2], Z. HUGHES[2], A. N. MEAD[1];
[1]Pfizer Inc, Groton, CT; [2]Neurosci. Res. Unit, Pfizer Inc, Cambridge, MA

Abstract: Dysregulation of the brain-reward system has been associated with numerous psychiatric and neurological disorders and co-morbidity exists between mood disorders and addiction. Exposure to stress is associated with drug addiction in humans and can induce relapse and craving. Similarly, a variety of stressful stimuli can reinstate drug-seeking in animal models. Converging evidence have demonstrated that the kappa-opioid receptor (KOR) pathway plays a critical role in regulating dopamine release in areas of the brain highly associated with reward-related learning and are implicated in reward, stress and mechanisms underlying stimulus-controlled drug-seeking behavior. The objective of these studies was to investigate the dynorphin-KOR system and its involvement in stress-induced drug relapse using the novel selective KOR-antagonist, PF-04455242, and the prototype KOR-antagonist LY-2456302 in a reinstatement model of drug-seeking. Male Sprague-Dawley rats were initially trained to self-administer nicotine or fentanyl, I.V., under a fixed ratio schedule of reinforcement using a standard 2-lever choice design, with infusion-paired cues. Following acquisition, an extinction period commenced to dissociate the act of lever pressing from delivery of the drug. Reinstatement tests were then conducted using a within-subjects design, with reinstatement induced by the pharmacological stressor, yohimbine administered alone and in combination with drug-paired (nicotine or fentanyl) cues. For reinstatement tests, animals were treated with PF-04455242 or LY-2456302, S.C., prior to each session. Congruent with the literature implicating KORs with the rewarding/reinforcing effects of drugs, and specifically the association between relapse to drugs of abuse and exposure to stress-inducing stimuli, the present findings suggest KOR-antagonists attenuate reinstatement of drug-seeking in rats and this effect appears specific to seeking induced by stress. The effect of these antagonists in blocking reinstatement of drug-seeking behavior was compared to their affinity to bind to, and occupy, the KOR. Taken together, these observations support the potential benefit of KOR-antagonism in relapse prevention.

Title: The neurobiological effects of acute oxycodone exposure: Data from BOLD, diffusion tensor, and manganese imaging in rats

Authors: *C. F. FERRIS, K. MOORE, W. KENKEL, D. MARINI, P. KULKARNI; Psychology, Northeastern University, Ctr. for Translational NeuroImaging, Boston, MA

Abstract: Oxycodone (OXY) is used clinically to treat severe acute or chronic pain; however, when inappropriately prescribed or misused can lead to severe addiction. Indeed, just a short exposure to OXY can lead to drug dependence. Consequently, studies were undertaken to examine the immediate effects of this opioid agonist on brain activity to a single exposure and to four consecutive days of drug given once daily (2.5 mg/kg). We were interested in two specific questions: 1) What are the brain areas activated by peripherally administered OXY? This was addressed with BOLD imaging in awake rats in response to a single dose of OXY and brain mapping with manganese (Mn) in response to four consecutive days of drug exposure. 2) Are there structural changes in the brain with OXY exposure? This was addressed by DTI and quantitative anisotropy. All studies used a 3D MRI atlas of the rat brain segmented and annotated into 171 brain areas. When combined with computation analysis it was possible to reconstruct OXY-driven integrated neural circuits for each of the imaging protocols. Sprague Dawley rats were acclimated to the imaging protocol before data collection. Experiments were conducted using a Bruker Biospec 7.0T magnet. Functional BOLD images were acquired in awake rats given saline or OXY IP during a 25 min imaging session. Manganese imaging was performed before and after four days of OXY administration. Diffusion tensor MRI data were acquired for indices of anisotropy (IA) for use in a novel method of analysis to detect changes in gray matter microarchitecture. IA values from over 20,000 voxels were registered into the MRI atlas to identify difference between control and drug exposed rats. Within 15 min of OXY injection there were significant changes in BOLD signal. Positive BOLD signal was localized primarily to the amygdala and thalamus, while negative BOLD was primarily associated with the olfactory system and hypothalamus. Four days of consecutive OXY showed enhanced Mn contrast primarily in the amygdala. Changes in IA values were most prominent in the olfactory system, hypothalamus and amygdala. Oxycodone when given to healthy adult male rats causes robust BOLD signal changes from olfactory bulbs to brainstem. The amygdala was particularly interesting because it showed long-term activation with repeated oxycodone and alterations in microarchitecture. Also of interest was the absence of activity in the pain neural circuit and only modest activity in the dopaminergic system, areas associated with analgesia and reinforcement, respectively. Molecular and cellular studies are underway to identify the microarchitectural changes identified with quantitative anisotropy.

Title: Comparison of the psychostimulatory effect induced by methadone, buprenorphine and morphine

Authors: ***J. M. ANDERSEN**, S. KABASHI, I. BERGSETEREN, J. MØRLAND; Norwegian Inst. of Publ. Hlth., Oslo, Norway

Abstract: Methadone and buprenorphine are synthetic opioid drugs used to treat heroin addiction because they effectively reduce consumption of illegal heroin and facilitates retention in treatment. However, replacing heroin with another opioid may be perturbing since the new drug also might be addictive and have harmful effects related to drug dependence. Behavioral sensitization seen following repeated exposure to a specific drug may be central in the development of drug addiction and involves changes in brain striatal dopamine transmission. Surprisingly, in methadone or buprenorphine therapy this aspect has received little attention both in human and animal studies. In this work, locomotor activity (used as a measure of a psychostimulatory effect), brain pharmacokinetics and western blot analysis of DARPP-32 in striatum, nucleus accumbens, frontal cortex and hippocampus were investigated in mice exposed (s.c.) to different doses of methadone (12.5-100 umol/kg), buprenorphine (0.25-2 umol/kg) or morphine (15- 60 umol/kg) either acutely or for prolonged periods (5-15 days). Methadone and morphine stimulated locomotor activity dose-dependently, while the effect of buprenorphine was less prominent. After repeated exposure a strong sensitization of the activity was seen. However, the pharmacokinetics of the drugs remained unaffected. DARPP-32 was expressed in all the brain areas investigated, but phosphorylation of this protein was only seen in nucleus accumbens and striatum, areas which are directly related to drug addiction. No clear relationship between the locomotor activity and pDARPP-32 was found. In this study, the psychostimulatory effect of methadone and morphine was more similar than the effect of buprenorphine. This may be related to the fact that methadone and morphine are agonists while buprenorphine acts a partial agonist on the mu receptor, suggesting a possible difference in the cellular responses triggered by these molecules.

Title: Activation of calmodulin-dependent kinase II protein in the hippocampus of oxycodone self-administered adult C57Bl/6 mice

Authors: *D. P. SIMON, Y. ZHANG, M. KREEK;
Lab. of Biol. of Addictive Dis., Rockefeller Univ., New York, NY

Abstract: An epidemic of prescription opioid and heroin addiction is occurring in the United States, characterized by: 1) wide-spread abuse amongst all age groups, but with especially high numbers amongst adolescents 2) frequent morbidity and mortality due to overdose and 3) a high rate of relapse and long-term persistence of drug addiction. The surge in abuse of opioids highlights the necessity for a greater understanding of this disease. An often underappreciated aspect of addictions is the role of learning and memory. For example, the hedonic aspects of the drug become associated with the act of drug taking. Also, neutral environments/stimuli that become associated with drug use can trigger drug craving_consolidation and retrieval of contextual memories. Indeed, it has been hypothesized that formation and persistence of contextual memories facilitates compulsive drug taking. The activation of calmodulin dependent kinase II (CamKII) in the hippocampus has been shown to be a critical molecular mechanism in memory formation. Furthermore, numerous drugs of abuse including the opioids, have been shown to require CamKII activity for maintenance of drug-taking. To examine the function of CamKII activation in the hippocampus during oxycodone-reward learning, we conducted a self-administration experiment. Adult C57Bl/6 male mice were implanted with an intravenous catheter and allowed to self-administer oxycodone or saline 2 hours/day for 14 days (0.25mg/nose poke). As a critical control, whenever an animal self-administered oxycodone, another animal passively received an infusion of oxycodone (oxycodone-yoked controls). Mice were then sacrificed and total hippocampal protein lysate was analyzed by Western blot. We found a statistically significant increase in the amount of phosphorylated-CamKIIα protein in the hippocampus of oxycodone-self administered mice when compared to the oxycodone-yoked or

saline controls, though no difference in phosphorylated CamKIIβ or total CamKII protein of either isoform was detected. Furthermore, mice that received investigator-administered oxycodone for 10 days (3mg/kg/day) did not exhibit any change in total or phosphorylated CamKII protein, as determined by Western blot analysis. Taken together, these data strongly suggest that activation of CamKIIα plays a critical role in opioid addiction-like settings specifically involving learning and memory, but not in the primary hedonic effects of the drug itself. Improved knowledge of hippocampal function in opioid addiction may help lead to the development of medications for either prevention and/or treatment of opioid addiction.

Title: Use of functional near-infrared spectroscopy to identify resting-state functional connectivity in heroin addicts

Authors: *H. IEONG[1,2], F. LU[1], X. LIN[1], Z. YUAN[1];
[1]Fac. of Hlth. Sci., Univ. of Macau, Macau Sar, Macao; [2]Inst. of Chinese Med. Sci., Univ. of Macau, Macau SAR, Macao

Abstract: Addiction is defined as a loss of control of substance use despite adverse consequences. In addition to intensive work done by the public health and social welfare, recent neuroimaging studies have revealed new findings on the abnormal functional connectivity in addicted brains during cognitive and emotional processing. However, many of the studies did not focus on the brains at rest. Moreover, not only did different drugs yield different findings, but also the relapse rate and treatment outcomes have not yet been significantly improved in the past 50 years. As such, a more comprehensive experimental approach such as examining the resting-state functional connectivity (rsFC) is thus needed to resolve this issue. In particular, it is widely recognized that dynamic rsFC strength could provide dramatic insights to identify and predict various psychiatric trajectories. In this study, cost-effective and non-invasive functional near-infrared spectroscopy (fNIRS) technique was utilized to capture and characterize the brain activity, then the dynamic rsFC was constructed based on the fNIRS recordings from 5 heroin

users and 6 normal control subjects in Macau. Our results provided novel information on the change of functional connectivity during resting-state in heroin abusers, particular in orbitofrontal cortex (OFC) and dorsolateral prefrontal cortex (DL-PFC). Our robust findings suggest that fNIRS is a valid neuroimaging tool for cognitive studies in establishing psychiatric profile in addiction.

Title: Differential effects of oxycodone, hydrocodone, and morphine on gene expression

Authors: *M. A. EMERY, M. BATES, P. J. WELLMAN, S. EITAN;
Psychology, Texas A&M Univ., College Station, TX

Abstract: Opioids (a term that refers to both opiates, the natural products obtained from the opium poppy, and synthetic opioids) are the most commonly used drugs for managing moderate-to-severe pain. However, their chronic use is complicated by the development of tolerance, hyperalgesia, dependence, reward, and abuse. Exposure to opioid analgesics has been associated with altered responses of D2-like dopamine receptors (D2DRs). Disturbances in the responses of the D2DRs would be expected to have important implications for the abuse potential of opioids, other drugs of abuse, and alcohol. Moreover, the D2DRs were also suggested to be involved in the pathophysiology of a wide range of affective and psychotic disorders. Our previous studies demonstrated that various opioids modulate the responses of D2DRs in differential degrees. Specifically, oxycodone, hydrocodone, and morphine differentially modulate baseline activation levels of signaling molecules. This in turn results in ligand-selective effects on both the signaling and behavioral responses to a D2/D3 dopamine receptor agonist. Mice pretreated with oxycodone showed significantly greater locomotor supersensitivity to quinpirole than did mice pretreated with equianalgesic doses of morphine, while mice pretreated with equianalgesic doses of hydrocodone showed sensitivity between that of mice treated with morphine and oxycodone. Additionally, morphine, oxycodone, and hydrocodone have differential efficacies in relieving burn pain and minimizing the development of chronic pain. These studies demonstrated a complex interplay between opioid receptors and D2DRs, and support the notion that various opioids carry differential risks to the dopamine reward system. Thus, in the current study we examined the differential effect of oxycodone, hydrocodone, and morphine on modulation of

striatal gene expression. This information highlights differences between opioids in modulating the responses of the reward system and should be considered when prescribing opioid pain medication, in order to balance effectiveness with minimal risk.

Abstract: Objective: The over activation of inflammatory cytokine and dysfunction of the neurotrophic system might be related to the development of opioid dependence. Recent studies show that proinflammatory cytokines might be related to the development of opioid dependence (physiological, psychological, or both). In addition, brain-derived neurotrophic factor (BDNF) may be important in synaptic plasticity and neuron survival, and may become a key target in the physiopathology of long-term opioid use. Thus, we investigated the expression of plasma cytokines and BDNF concentrations in heroin-dependent patients. Furthermore, the transforming growth factor (TGF)-β1, a key immunoregulatory factor for central nervous system was also evaluated. Methods: The pretreatment expression levels of plasma cytokines, TGF-β1 and BDNF levels in 142 heroin-dependent male patients and 75 male healthy controls were evaluated by the enzyme-linked immunosorbent assay. Results: Plasma TNF-α, Interleukin (IL)-6 (IL-6), IL-8 and CRP were significantly higher in patients with long term heroin used. However, plasma TGF-β1 and BDNF levels were significantly lower in patient with long term heroin used. The plasma BDNF levels were significantly positive correlated to the TGF-β1 levels and negative correlated to the IL-6 levels. Conclusion: Long term used heroin induced systemic inflammation and neurotrophic factor down regulation. Furthermore, plasma BDNF might modulate the inflammatory factors (TGF-β1 and IL-6) concentration. The systemic inflammation, downregulation of TGF-β1 and BDNF might caused the neuronal inflammation and less

neuronal protective effects after long term opioid used. Providing the anti-inflammatory and neuronal protective agents might benefit to the treatment of opioid dependence.

Title: Morphine modulates mouse hippocampal progenitor cell lineages via PKCε-dependent ERK activation and TRBP phosphorylation

Authors: **C. XU**[1], H. ZHENG[2], H. H. LOH[1], *P.-Y. LAW[1];

Abstract: Morphine regulates adult neurogenesis by modulating miR-181a maturation and subsequent hippocampal neural progenitor cell (NPC) lineages. By using NPCs cultured from PKCε or β-arrestin2 knockout mice and the MEK inhibitor U0126, we demonstrate that regulation of NPC differentiation via the miR-181a/Prox1/Notch1 pathway exhibits ligand-dependent selectivity. In NPCs, morphine and fentanyl activate ERK via the PKCε- and β-arrestin-dependent pathways, respectively. After fentanyl exposure, the activated phospho-ERK translocates to the nucleus. Conversely, after morphine treatment phospho-ERK remains in the cytosol and is capable of phosphorylating TRBP, a cofactor of Dicer. This augments Dicer activity and promotes the maturation of miR-181a. Furthermore, by using NPCs transfected with wild type TRBP, SΔA and SΔD TRBP mutants, we confirmed the crucial role of TRBP phosphorylation in Dicer activity, miR-181a maturation, and finally the morphine-induced astrocyte-preferential differentiation of NPCs. Thus, morphine modulates the lineage-specific differentiation of NPCs by PKCε-dependent ERK activation with subsequent TRBP phosphorylation and miR-181a maturation.
