Abstract: As many as one hundred million people may suffer from chronic pain and over two million Americans abuse opioid pain medications. Although morphine is a highly potent opioid analgesic used for pain management, its analgesic efficacy fades gradually during repeated administration. Thus, progressively higher doses of morphine are required to achieve comparable analgesic effects. Previous studies with rodents have reported that experimenter-administered repeated morphine induces tolerance to analgesic effects and morphine withdrawal increases pain sensitivity (hyperalgesia). However, it is not clear whether intravenous morphine self-administration also induces tolerance and hyperalgesia in rodents. Male Sprague-Dawley rats self-administered intravenous morphine (0.5 mg/kg/infusion) for three weeks (4 hrs per day, 5 days per week). Using a noxious (thermal) behavioral paradigm, antinociceptive effects of morphine, tolerance to repeated morphine and withdrawal-induced hyperalgesia were measured in morphine self-administered animals. On day 1, morphine self-administered animals showed antinociception to thermal pain and individual differences in antinociception. However, on day 3, morphine self-administered animals started to develop tolerance to antinociceptive effects of morphine. Spontaneous withdrawal from chronic morphine self-administration (MSA) induced hyperalgesia in these animals. Individual differences in initial morphine-induced antinociception were correlated with development of addiction-like behavior following chronic MSA. Our findings support the results from previous studies that used morphine injections and further suggest individual differences in analgesic responses and vulnerability to develop opioid addiction. This observation is important because poor responders to opioid medications require higher doses of opioids and other pain medications, which may increase probability of substance abuse in vulnerable individuals. Early identification and intervention of vulnerable individuals may improve the treatment strategy for pain management and opioid abuse.

Title: Altered nociception and morphine tolerance in neuropeptide FF receptor type 2 over-expressing mice

Authors: ***Y.-T. LIN**[1], S.-C. KAO[3], Y.-J. DAY[3], C.-C. CHANG[5], J.-C. CHEN[1,2,4];

[5]Dept. of Chem., Fu Jen Catholic Univ., New Taipei City, Taiwan

Abstract: The neuropeptide FF system is thought to act as an anti-opioid modulator and plays a role in nociception, morphine antinociception and dependence. Two receptor subtypes, NPFFR1 and NPFFR2, have been identified, but their respective roles in these processes remain uncertain. In the present study, the role of NPFFR2 was investigated using transgenic mice over-expressing NPFFR2 in addition to a selective NPFFR2 agonist AC-263093. NPFFR2 Tg mice exhibited increased sensitivity to both mechanical and thermal noxious stimuli compared to the WT mice, while the antinociceptive effects of morphine at three different doses (6.25, 12.5, and 25 mg/kg, s.c.) were similar in both strains. The development of tolerance to morphine antinociception after chronic morphine treatment (12.5 mg/kg, s.c.; twice daily × 5 days) was attenuated in NPFFR2 Tg mice when compared to WT mice. Similarly, WT mice receiving AC-263093 pretreatment (2.5 mg/kg, i.p.) showed attenuated morphine tolerance compared to vehicle controls. Most naloxone-precipitated morphine withdrawal symptoms were not attenuated in NPFFR2 Tg mice, with the exception that wet dog shake was significantly reduced. Both NPFFR2 Tg and WT mice displayed similar degree of morphine rewarding. Our results suggest that NPFFR2 is mainly involved in the modulation of nociception and tolerance to morphine antinociception.

Title: Modeling prenatal and postnatal oxycodone exposure using self-administration

Authors: F. M. VASSOLER, A. KUBEREK, C. WYSE, *E. M. BYRNES;
Tufts Univ. Cummings Sch. Vet Med., North Grafton, MA

Abstract: The abuse of opiates has emerged as a major public health issue. Of growing concern are the numbers of women abusing opiates during pregnancy, with a significant increase observed over the past decade. A large number of these women are using prescription opiates containing oxycodone. While neonatal abstinence syndrome is one consequence of prenatal opiate use, the long-term consequences associated with use have not been well-documented. Additionally, animal models of prenatal oxycodone exposure are lacking. To address this gap, we have established a prenatal oxycodone self-administration model in rats. The goal of these studies are twofold; 1) develop a model with high face validity that can be used to make informed predictions about potential long-term neurodevelopmental effects in offspring; and 2) utilize this model to better understand variations in female use patterns that may be a natural function of the reproductive state and environmental conditions. In the current set of studies cycling female Sprague-Dawley (200-225g) rats were fitted with indwelling jugular catheters. One week later females began daily 1h self-administration sessions in standard self-administration chambers (Med Associates) with one lever press resulting in one infusion of oxycodone (0.1 mg/kg/infusion). During this period, females were assessed daily for stage of estrous cycle. Following at least three weeks of daily sessions, proestrus females were placed overnight with breeder males. Pregnancy was confirmed by the presence of sperm in the vaginal lavage. Self-administration sessions continued throughout pregnancy and during the postpartum period with doses adjusted based on increasing and decreasing bodyweight. On postnatal day 1 (PND1), half of the subjects had their pups removed while the other half remained with their pups. Additionally on PND1, brains were harvested from one male and one female offspring from each litter. Data indicate that levels of responding for oxycodone increase during pregnancy and even more so during the postpartum period. Preliminary findings suggest that the presence or absence of pups influences the level of responding. Gene expression studies are ongoing in PND1 brains as are studies examining the effects of prenatal oxycodone on maternal behavior and pup ultrasonic vocalizations. These findings represent the initial phase of model development in the area of prenatal opiate abuse.

Title: A wireless electrophysiology system designed for the preclinical development of translatable biomarkers for treatment of substance use disorders

Authors: *J. K. DASILVA[1], S. KREUSER[3], T. CHAPPIE[2], P. TRAPA[4], A. N. MEAD[1], D. P. NGUYEN[4];
[1]Global Safety Pharmacology, Drug Safety Res. and Develop., Pfizer, Inc., Groton, CT; [2]Neurosci. Med. Chem., Pfizer, Inc., Cambridge, MA; [3]Worldwide Comparative Med., Pfizer, Inc, Groton, CT; [4]Translational Modeling and Simulation, Pharmacodynamics and Metabolism, Pfizer, Inc, Cambridge, MA

Abstract: Drug addiction is a widespread disorder with a large unmet need for treatment options. In the process of developing therapies, two major goals have been: 1) to understand how a potential therapy reduces the motivation to seek and take a drug, and 2) to develop a non-invasive biomarker that would be predictive of therapeutic efficacy in the clinic. The reinstatement model is a rodent model of drug-seeking and relapse, in which conditioned reinforcement drives relapse-like behavior, and has been used to investigate the efficacious properties of potential treatments for substance use disorders. In addition, event-related potentials (ERPs) have been shown to correlate with specific neural coding pathways in rodent models of decision making and attention, and thus when combined with the reinstatement model, provides a powerful tool for understanding how pharmacologically-based neural circuit modulation correlates with reduced drug seeking behavior. Simultaneously, the dose-response of ERP modulation may provide a non-invasive clinical endpoint for assessing an early sign of efficacy in the clinic. In order to achieve ERP recordings in the drug discovery setting, we designed a single system that could overcome a number of design constraints: 1) wireless recording to prevent interference with drug delivery catheters, 2) scalable to a large number of concurrently tested animals, 3) daily experiments are quick and easy to conduct, 4) easily retrofits with existing behavioral setups, and 5) has the temporal precision to resolve millisecond level features in the neuroelectrophysiology data. We demonstrate that we were able to observe, with high precision, ERPs that are driven by drug-associated cues, and observed clear alterations in ERP N1-P2 complex latency over the course of the reinstatement session, which may reflect real-time alteration in the motivation to self-administer a drug. Finally, we outline a translational strategy based on these ERP data in order to clearly demonstrate how these ERPs may inform and bridge, preclinical and clinical strategies.

Title: Stress-induced activation of amygdalar corticotropin releasing factor neurons projecting to the locus coeruleus in morphine dependent rats

Authors: ***B. A. REYES**[1], N. HELDT[1], M. HENRY[2], G. DROLET[2], E. J. VAN BOCKSTAELE[1];
[1]Pharmacol. & Physiol., Drexel Univ., Philadelphia, PA; [2]Neurosci., Univ. Laval, Ctr. de Recherche du CHU de Quebec, Quebec, QC, QC, Canada

Abstract: Chronic opiate exposure promotes the development of long-term adverse consequences including tolerance and physical dependence as a result of persistent alterations in brain neurons. The locus coeruleus-norepinephrine (LC-NE) system is implicated in arousal and cognition associated with the stress response. Previous electrophysiological studies have demonstrated that the LC-NE is sensitized to corticotropin-releasing factor (CRF) following chronic morphine exposure. While it is known that the LC receives CRF afferents from multiple brain regions including the central nucleus of the amygdala (CeA), the mechanism underlying enhanced sensitivity to stress following chronic opiate use remains unknown. In a first study, male Sprague-Dawley rats received morphine via subcutaneous delivery of pellets. Controls received placebo pellets. *In situ* hybridization labeling of CRF mRNA in the amygdala revealed a lack of statistical significance in expression levels across groups. To further characterize stress-induced neuronal activation of LC-projecting amygdalar CRF neurons under conditions of morphine dependence, male rats received microinjections of fluorescent latex microspheres (Retrobeads) into the LC. Five days later, rats were implanted with morphine or placebo pellets. Seven days post-implantation, a subset of rats was exposed to a single 15-minute swim. Cell counts revealed that c-Fos expression in the CeA was significantly increased in the swim stress groups irrespective of morphine exposure ($P < 0.05$). Morphine treatment further increased c-Fos expression ($P < 0.05$) when compared to placebo irrespective of stress exposure, and compared to morphine alone. Interestingly, more than half of the c-Fos labeled neurons in the morphine dependent stress-exposed group were observed in CRF amygdalar neurons that projected to the LC. These results indicate that morphine exposure increases CRF amygdalar responses to stress and that this increased activation impacts the LC. Such cellular adaptations have important

consequences for increasing brain noradrenergic tone and may predispose chronic opiate users to hyper-arousal, a symptom observed in many stress-related psychiatric disorders.

Title: Acute combined low/high burst stimulation of the lateral habenula attenuates cue-induced heroin seeking in rats

Authors: *F. ZHANG;
Ningbo Addiction Res. and Treatment Ctr., Zhejiang, China

Abstract: The lateral habenula (LHb) is critical for the modulation of rewarding process and drug addiction. The aim of the present study is to observe the effects of deep-brain-stimulation (DBS) in the LHb on heroin seeking behavior. An electrode was implanted in the LHb and rats were trained to establish stable heroin self-administration behavior (0.05 mg/kg/infusion) for daily 4h session under a FR1 schedule. Results showed that pretreatment with high- frequency (100Hz, 0.5ms, 0.2mA) or a combined low/high frequency (alternating between 10Hz and 100Hz, 0.5ms, 0.2mA) stimulation of the LHb for 15min could significantly enhance heroin self-administration, whereas no effect was observed with low-frequency (10Hz, 0.5ms, 0.2mA) stimulation. Cue-induced heroin seeking was tested after extinction of heroin self-administration for 14 days. After extinction, cue-induced reinstatement of heroin seeking could be attenuated only by acute pretreatment with the combined DBS. Microdialysis showed that dopamine level in the nucleus accumbens (NAc) could be decreased after low-frequency, while increased after high or combined DBS in the LHb. We postulate that the effect of combined DBS in LHB on heroin seeking may be via modulation of the neuronal activity of the ventral tegmental area and the NAc dopamine projections, suggesting the LHb might be a promising treatment target for drug addiction treatment.

Title: Role of projections from ventral subiculum to nucleus accumbens shell and ventral medial prefrontal cortex in context-induced reinstatement of heroin seeking

Authors: *J. M. BOSSERT[1], S. ADHIKARY[1], R. M. ST. LAURENT[1], N. J. MARCHANT[1,3], H. L. WANG[2], M. MORALES[2], Y. SHAHAM[1];
[1]Behavioral Neurosci., [2]Integrative Neurosci., NIH, NIDA, IRP, Baltimore, MD; [3]Florey Inst. of Neurosci. & Mental Health, Univ. of Melbourne, Parkville, Australia

Abstract: Background: In humans, exposure to contexts previously associated with heroin use can provoke relapse. In rats, exposure to heroin-paired contexts after extinction of drug-reinforced responding in a different context reinstates heroin seeking. We previously demonstrated a causal role for projections from ventral medial prefrontal cortex (mPFC) to accumbens shell in context-induced reinstatement of heroin seeking. Because ventral subiculum sends glutamate projections to both accumbens shell and ventral mPFC, we sought to determine whether these projections also contribute to this reinstatement. Methods: We trained rats to self-administer heroin in a distinct context and then extinguished lever pressing in a non-drug-associated context; infusions or lever presses were paired with a discrete cue. We then tested the rats in the heroin- and/or extinction-associated contexts under extinction conditions. We first used the retrograde tracer Fluoro-Gold in combination with Fos to assess whether the ventral subiculum→accumbens shell or ventral subiculum→ventral mPFC pathway is activated during context-induced reinstatement of heroin seeking. We then employed an anatomical disconnection procedure to determine whether these projections are functionally involved in this reinstatement. Results: Exposure to the heroin context, but not the extinction context, reinstated lever pressing. Context-induced reinstatement was associated with increased Fos expression in ventral subiculum neurons, including those that project to accumbens shell or ventral mPFC. Contralateral and ipsilateral disconnection of ventral subiculum from accumbens shell decreased context-induced reinstatement. We are currently examining whether disconnection of ventral subiculum from ventral mPFC inhibits this reinstatement. Conclusions: Results suggest that glutamatergic projections from ventral subiculum to accumbens shell play a critical role in context-induced relapse to heroin seeking.

Title: Machine learning identifies distinct behavioral markers for opiate and stimulant addiction

Authors: *J. L. VASSILEVA[1], W.-Y. AHN[2], F. G. MOELLER[2];
[1]Dept. of Psychiatry, [2]Psychiatry, Virginia Commonwealth Univ., Richmond, VA

Abstract: The development of objective markers for addiction can innovate its prevention and treatment. Abundant evidence indicates that drug addiction is characterized by personality, psychiatric, and neurocognitive manifestations of impulsivity, one of the most viable endophenotypic markers for addiction. However, it is unclear which of its various dimensions would have the highest predictive utility for addiction and whether addiction to different classes of drugs would be characterized by different impulsivity profiles. To address these gaps, we used a machine learning approach, which holds promise for discovering predictive markers of disease. We conducted two machine-learning studies, using different indices of impulsivity as predictors of stimulant and opiate dependence. In Study 1, we recruited current stimulant (cocaine) users and healthy controls (HCs) in USA who completed self-reports of trait impulsivity and neurocognitive tasks of impulsive choice and impulsive action. A machine learning model was fitted on the training set using 5-fold cross validation and we tested its out-of-sample classification accuracy in the test set. The area under the curve (AUC) of the ROC curve was 0.90 in the test set. In Study 2, we tested HCs and individuals with past mono-dependence on heroin or amphetamine, currently in protracted abstinence. The study was done in Bulgaria where poly-substance dependence is still uncommon. Machine learning analyses revealed that the AUC of the ROC curve in the test set was 0.85 and 0.75 for the classification of past heroin and amphetamine dependence, respectively. Heroin and amphetamine dependence were predicted by distinct multivariate personality and neurocognitive impulsivity profiles. Delay discounting predicted stimulant dependence in both studies. Our results demonstrate the promise of machine-learning approaches to extract features predictive of group membership with high degree of accuracy and drug-class specificity and highlight how decision science and advanced statistical methods can inform clinical science. The results suggest that behavioral measures of impulsivity and decision-making can be objective markers of drug addiction. Results suggest that delay discounting may be a viable endophenotypic marker for stimulant (but not opiate) addiction. Our findings suggest that different mechanisms may underlie stimulant and opiate addiction, challenging the unitary account of drug addiction. This line of work may shed light on the development of affordable and easy-to-administer standardized tests that can be used to assess individuals' risk to addiction to different classes of drugs in clinical settings.

Title: Examining protein synthesis in the nucleus accumbens after withdrawal from extended-access cocaine self-administration

Authors: ***M. T. STEFANIK**, M. MILOVANOVIC, M. E. WOLF;
Neurosci., Rosalind Franklin Univ. of Sci. and Medici, North Chicago, IL

Abstract: During withdrawal from extended-access cocaine self-administration, there is a progressive intensification (incubation) of cue-induced cocaine craving that is associated with numerous synaptic adaptations in the nucleus accumbens (NAc). Recent work from our lab suggests these adaptations are maintained by dysregulated local protein translation. Aberrant translation has a profound impact on cellular function and is a key feature in Fragile X syndrome and some other disorders of the nervous system. Treatments to normalize protein synthesis have proven successful in reversing some behavioral and cellular abnormalities in a mouse model of Fragile X. Currently, little is known about mechanisms regulating translation in the NAc. Furthermore, the possibility of long-term alterations in translation following cocaine exposure has been largely uninvestigated and provides an intriguing novel target for therapeutic intervention. We examined the hypothesis that incubation of cocaine craving is associated with dysregulation of protein translation in the NAc. Male Sprague Dawley rats underwent extended-access cocaine or saline self-administration (6hr/10days, 0.5mg/kg/infusion), followed by >40 days of withdrawal. We used 35S-Met/Cys incorporation to measure protein translation in NAc tissue. Preliminary data indicate that overall translation is not different between cocaine and saline groups, suggesting that translation of only a small subset of proteins may be differentially regulated. Work is underway to compare patterns of translation using bioorthogonal noncanonical amino acid tagging (BONCAT) of newly synthesized proteins to specifically examine translation rates of key synaptic targets either using immunoprecipitation or through an unbiased mass spectrometry approach. We are also comparing the regulation of translation in cocaine versus saline rats by mGluR and NMDA receptors. These studies are the first to characterize how synaptic transmission regulates protein translation in the NAc under basal

conditions and whether drugs of abuse cause persistent alterations in the synthesis of proteins linked to addiction.

Title: Cocaine self-administration alters calcium signaling mediated by NMDA and AMPA receptors in dendritic spines of rat nucleus accumbens neurons

Authors: *D. T. CHRISTIAN, C. A. BRIGGS, M. E. WOLF, G. E. STUTZMANN; Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: Cue-induced cocaine craving intensifies or incubates during withdrawal from extended-access cocaine self-administration. After prolonged withdrawal, incubated seeking is mediated by GluA2-lacking, Ca2+-permeable AMPARs (CP-AMPARs) that accumulate in the nucleus accumbens (NAc). The functional consequences of CP-AMPAR accumulation have been characterized using whole-cell patch-clamp recordings, but, to our knowledge, no studies have characterized Ca2+ entry through CP-AMPARs at the level of NAc dendritic spines following the incubation of cocaine craving. In addition to CP-AMPARs, NMDARs play a major role in Ca2+ signaling and have been increasingly implicated in cocaine-induced neuroadaptations. Here we measured Ca2+ entry into MSN dendritic spines in the rat NAc following >40 days of withdrawal from saline or cocaine self-administration. We utilized 2-photon microscopy, whole cell electrophysiology, and photo-uncaging of either MNI-L-Glutamate (in the presence of APV) to activate CP-AMPARs or MNI- NMDA to activate NMDARs. We found that cocaine rats exhibited an increase in the proportion of spines responding to MNI-Glutamate + APV, suggesting that some CP-AMPARs are added to spines that did not previously possess them. In addition, cocaine rats demonstrated a significant reduction in the percentage of spines responding to MNI-NMDA photolysis compared to saline

control rats. We are evaluating potential explanations for this effect. Support: DA034943 (G.E.S), DA015835, DA009621, DA029099 (M.E.W) and postdoctoral NRSA DA36963 (D.T.C.).

Title: Comparison of trafficking mechanisms of calcium-impermeable and calcium-permeable AMPA receptors in rat nucleus accumbens neurons co-cultured with prefrontal cortex neurons

Authors: *N. M. CHAUHAN[1], C. T. WERNER[1], C. H. MURRAY[1], J. M. REIMERS[2], J. A. LOWETH[1], M. E. WOLF[1];
[1]Neurosci., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL; [2]Tacoma Community Col., Tacoma, WA

Abstract: Glutamatergic transmission in the nucleus accumbens (NAc) is critical for motivated behaviors, including drug addiction. In an animal model of cocaine addiction called the "incubation" model, rats exhibit progressive intensification or "incubation" of cue-induced cocaine craving during withdrawal from extended access cocaine self-administration. We have shown that this cocaine regimen leads to the accumulation of GluA2-lacking, Ca2+-permeable AMPA receptors (CP-AMPARs) in the NAc and that these high conductance AMPARs mediate the expression of incubated cue-induced cocaine craving after prolonged withdrawal (Conrad et al., 2008). To understand how this occurs, it would be helpful to know whether different mechanisms regulate the trafficking of CP-AMPARs versus the GluA2-containing, Ca2+-impermeable AMPA receptors (CI-AMPARs) that normally dominate synaptic transmission in the NAc. Because receptor trafficking is difficult to study *in vivo*, we are using a model system consisting of rat NAc neurons co-cultured with prefrontal cortex (PFC) neurons from enhanced cyan fluorescent protein (ECFP)-expressing mice. The cortical neurons restore excitatory input onto the NAc neurons but can be distinguished based on their fluorescence. NAc medium spiny neurons (MSN) in this co-culture system express high levels of CP-AMPARs, recapitulating the

state of the NAc after incubation of cocaine craving (Sun et al., 2008). The goal of this study is to compare the regulation of CP-AMPARs (homomeric GluA1) and CI-AMPARs (GluA1A2) with respect to: 1) rate of receptor internalization and receptor cycling (rate at which tagged surface receptors are replaced by untagged receptors), 2) effect of protein synthesis inhibition on surface receptor levels and cycling, and 3) effect of increasing or decreasing synaptic activity on surface receptor levels and their cycling. So far, our results indicate that: 1) GluA1 and GluA2 exhibit similar rates of constitutive internalization and cycling. 2) Brief protein synthesis inhibition reduces surface levels of both CI-AMPARs and CP-AMPARs. 3) Following activity blockade (CNQX, 24 h), CI-AMPARs, but not CP-AMPARs, show increased surface expression and cycling. In contrast, increased activity (bicuculline, 24 h) decreases both CI-AMPAR and CP-AMPAR surface expression. These studies will better our understanding of mechanisms that shape excitatory transmission in the NAc, which has translational implications related to drug addiction and relapse.

Title: Regulation of protein translation following prolonged withdrawal from extended-access cocaine self-administration with or without cocaine memory retrieval

Authors: ***C. T. WERNER**, M. T. STEFANIK, M. MILOVANOVIC, M. E. WOLF; Neurosci., Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: Vulnerability to relapse in cocaine addicts is often attributed to craving evoked by exposure to cues previously paired with the drug. Studies in animal models of addiction have shown that drug memories, upon retrieval, become labile and must undergo reconsolidation to be returned to long-term storage, a process that represents a potential therapeutic target for treating addiction. It is therefore important to understand mechanisms mediating memory retrieval and reconsolidation. It has been shown that de novo protein synthesis is necessary for retrieval and/or reconsolidation of cocaine memories. In addition, numerous studies have implicated mTOR-

related signaling, a pathway that regulates protein translation, in cocaine-dependent plasticity. Lastly, previous work from our lab has shown that ongoing protein translation is required to maintain cocaine-dependent synaptic adaptations in the nucleus accumbens (NAc during prolonged withdrawal. The goal of this study was to determine if the regulation of protein translation, and particular the mTOR pathway, is altered following an extended-access cocaine self-administration regimen that produces progressive intensification, or "incubation", of cue-induced craving. To study this, we collected NAc tissue from rats that self-administered saline or cocaine and underwent ~50 days of withdrawal. Half the rats in each group experienced a cue-induced seeking test. In our first experiment, we prepared a P2 fraction and evaluated a number of proteins involved in regulation of translation, including two factors involved in translation initiation and elongation, eIF2 and eEF2, respectively. We found retrieval-dependent but treatment-independent increases in phosphorylated and total eIF2 and phosphorylated but not total eEF2. In our second experiment, we prepared NAc synaptoneurosomes to better isolate postsynaptic processes. Analysis of eIF2, eEF2 and other translational regulators is underway.

Title: Reinstatement to drug-seeking behavior following cocaine, cues, and stress results in synaptic depotentiation of glutamatergic synapses in the nucleus accumbens

Authors: *S. R. EBNER, M. C. HEARING, E. B. LARSON, M. J. THOMAS;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Relapse to drug-seeking behavior during abstinence, often precipitated by drug re-exposure, cues, or stress, is a major obstacle to long-lasting addiction recovery. Understanding the neurobiology of drug craving and relapse is likely to provide new means for addiction treatment. The nucleus accumbens (NAc), a key target for addictive drugs, is a critical interface of mesolimbic dopamine circuitry with excitatory cortical afferents in regulating motivation and

drug seeking. Plasticity of glutamatergic synapses in the NAc is induced by *in vivo* cocaine and appears to contribute to increased drug-seeking behavior. Repeated experimenter-administered cocaine potentiates synaptic strength in NAc medium spiny neurons (MSNs) following abstinence, while subsequent re-exposure to cocaine (temporarily) reverses this effect. The extent to which this pattern of plasticity occurs following self-administration of cocaine, and whether cue-, or stress-primed reinstatement elicits depotentiation is unknown. Using a combination of cocaine self-administration with NAc whole-cell recordings in an *ex vivo* brain slice preparation, we examined plasticity at glutamatergic synapses in NAc shell MSNs following reinstatement of drug-seeking behavior precipitated by saline, cocaine, stress, and drug-associated cues. Mice self-administered 0.5mg/kg/infusion cocaine for 10 days before 8-12 days of extinction training. To reinstate drug seeking, mice were exposed to a priming injection of saline, cocaine (10mg/kg), or yohimbine (2.5mg/kg) prior to, or drug-associated cues during reinstatement testing. As predicted, cocaine-, yohimbine-, and cue-primed animals exhibited greater reinstatement behavior than saline injected animals (228.2±55.9%, 268.0±42.8%, 169.0±21.0%, 95.6±10.2% of extinction responding respectively). In concordance with behavioral data, mice challenged with saline following cocaine self-administration and extinction exhibited elevated AMPA:NMDA ratios (1.53±0.11) in comparison to control animals (0.98±0.08). However, mice that reinstated drug-seeking behavior following a cocaine (1.00±0.04), stress (0.96±0.08), or cue prime (0.92±0.09) displayed de-potentiated AMPA:NMDA ratios down to control levels. Interestingly, AMPA:NMDA ratios were still potentiated in mice that failed to reinstate drug-seeking behavior (1.41±0.08). Collectively, these data indicate a common neurobiological response - AMPAR depotentiation in the NAc shell - to different stimuli that provoke a reinstatement of drug seeking. Future studies will determine the extent to which this response may modulate or mediate drug seeking.

Title: Optogenetic self-stimulation of the infralimbic-accumbens pathway: opposing effects of abstinence from repeated cocaine and cocaine re-exposure

Authors: *E. B. LARSON, A. J. ASP, M. ESGUERRA, M. C. HEARING, K. A. SILVIS, M. J. THOMAS;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Mice will actively self-administer optogenetic stimulation of glutamatergic inputs to the nucleus accumbens shell (Stuber et al. 2012; Britt et al. 2012). In drug-naïve animals, optogenetic self-stimulation is largely input-pathway independent, suggesting that glutamate non-discriminately supports behavioral reinforcement (Britt et al. 2012). However, it is unknown how cocaine experience may alter the ability of glutamatergic inputs to the nucleus accumbens shell to promote behavioral reinforcement. We have previously shown that abstinence from repeated cocaine and cocaine re-exposure produce bidirectional synaptic plasticity in the nucleus accumbens shell (Kourrich et al. 2007). Furthermore, while input-specific changes in glutamatergic synaptic function are apparent during cocaine abstinence (Pascoli et al. 2012), the effects of cocaine re-exposure in abstinence on input-specific plasticity is unknown. Therefore, to better understand how input-specific plasticity induced by cocaine experience may alter the ability of excitatory transmission in the NAcSh to reinforce behavior, we compared input-specific optogenetic self-stimulation behavior in animals with different histories of cocaine experience. C57BL/6J mice were infected with channelrhodopsin in either the infralimbic cortex (IL), ventral hippocampus (vHipp), or basolateral amygdala (BLA), and optical fibers were implanted over the NAcSh to allow for selective stimulation of these inputs. Mice were next treated with saline or a cocaine sensitization regimen (15 mg/kg i.p, 5 once daily injections) followed by 10-14 days of abstinence. A spatial optical self-stimulation task was used to assess behavioral reinforcement after cocaine abstinence, or after being re-exposed to cocaine in abstinence. We found that IL-NAcSh self-stimulation was more pronounced in cocaine-abstinent mice compared to drug-naïve controls (10 hz, 5 ms, 5 s max pulse per entry into the “active” zone). Interestingly, cocaine re-exposure dampened IL-NAcSh self-stimulation behavior to levels of control mice. In contrast, self-stimulation of vHipp-NAcSh inputs was enhanced by cocaine abstinence, and further augmented by cocaine re-exposure. Importantly, these different behavioral effects were paralleled by input-specific changes in synaptic plasticity as measured by whole cell patch clamp recordings in medium spiny neurons. Together, our findings suggest that input-specific changes in plasticity with cocaine abstinence and re-exposure directly modify the reinforcing effects of glutamate in the NAcSh.

Title: Synaptic depotentiation via mGluR5 activation and AMPAR internalization in the nucleus accumbens shell drives cocaine-primed reinstatement

Authors: *M. A. BENNEYWORTH, M. C. HEARING, A. J. ASP, A. E. INGEBRETSON, C. E. SCHMIDT, S. R. EBNER, M. ESGUERRA, M. J. THOMAS;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Relapse after periods of drug abstinence is a major obstacle to long-lasting recovery for many addicts. Understanding the neurobiological processes that incite drug craving and drive relapse has the potential to help target our efforts to treat addiction. The nucleus accumbens (NAc) serves as a critical interface of mesolimbic dopamine circuitry with excitatory cortical afferents in the regulation of motivation and drug seeking. Repeated cocaine exposure potentiates synaptic strength in the NAc medium spiny neurons, which is thought to promote addiction-related behavior. However, the present studies tested the hypothesis that reversal of that augmented synaptic strength, or depotentiation, in the NAc shell is the critical factor in relapse. In support of this hypothesis, we used cocaine conditioned place preference (CPP) behavior and *ex vivo* whole-cell electrophysiology to show that cocaine-primed reinstatement and synaptic depotentiation was disrupted by intra-NAc shell infusion of the tat-GluA23Y "interference" peptide (inhibitor of activity-dependent AMPAR internalization; Ahmadian et al., 2004). Metabotropic glutamate receptor subtype 5 (mGluR5) activation is one mechanism known to promote synaptic depression. Therefore, we investigated whether cocaine-primed reinstatement is driven by an mGluR5-dependent reduction in AMPA-type glutamate receptor signaling. Intra-NAc shell infusion of the mGluR5 antagonist MTEP blocked cocaine-primed reinstatement and corresponding depotentiation, while infusion of the mGluR5 agonist CHPG produced a dose-dependent reinstatement of CPP and depotentiated synaptic strength in the NAc shell. Using an optogenetic approach to look at the role of glutamatergic afferent signaling in the NAc shell, we observed that low frequency blue-light stimulation of the NAc (10 Hz, 5 min, 5ms pulse width) produces reinstatement of CPP in mice infected with AAV-ChR2. Interestingly, this effect was observed when ChR2 was expressed in either the infralimbic cortical or ventral hippocampal projections. This optical stimulation is modeled after electrical stimulation protocols that produce mGluR1/5-dependent LTD (Grueter et al 2010). These findings support a model in which mGluR5-mediated reduction in synaptic GluA2-containing AMPAR function in NAc shell medium spiny neurons can mediate the reinstatement of cocaine-primed behavior.

Title: Bidirectional ethanol-induced synaptic plasticity and reinstatement of place preference following a history of combined ethanol and cocaine exposure

Authors: ***M. ESGUERRA**[1], M. C. HEARING[1], C. E. SCHMIDT[1], A. E. INGEBRETSON[1], T. MACHEDA[1], M. A. BENNEYWORTH[1], M. J. THOMAS[1,2];

Abstract: Repeated exposure to drugs of abuse induces plasticity at excitatory synapses in the nucleus accumbens (NAc) that are central to the development and persistence of addiction-related behavior. An abundance of data indicates that experience-dependent plasticity in NAc glutamatergic synaptic transmission is primarily expressed via dynamic changes in AMPA-type glutamate receptors (AMPARs), making these receptors a key target for studying how drug experiences modify behavior in models of addiction. In humans, coabuse of drugs is pervasive, with concurrent cocaine and alcohol use being a frequently abused combination; however, to date, knowledge of drug-induced synaptic plasticity is often limited to single-drug regimens. Using a model of conditioned-place preference (CPP), our studies test the hypothesis that co-administration of cocaine and ethanol modulates NAc synaptic plasticity at glutamatergic afferents to MSNs in a way that may explain the potent effects of this drug combination on behavior. In wild-type mice, co-administration of cocaine (7.5 mg/kg ip) and ethanol (2 g/kg ip) as the conditioned stimulus reliably produced a modest conditioned place preference which extinguished rapidly. On re-exposure to ethanol alone (2 g/kg) after extinction, animals showed divergent behavioral responses, with one subpopulation displaying robust reinstatement of preference for the conditioned stimulus (580.40 ± 66.8 sec CS bias, n=16), while another showed dramatic aversion to the conditioned stimulus (390.97 ± 90.4 sec anti-CS bias, n=10) after ethanol primed reinstatement. A subset of mice was sacrificed immediately after the ethanol

reinstatement test to examine alterations in synaptic AMPA receptor-mediated transmission in the NAc using whole-cell recordings from MSNs in acute slices. In the NAc shell in animals with a strong preference for the conditioned stimulus, the amplitudes of miniature excitatory postsynaptic currents (mEPSCs) were similar to saline controls. However in animals with inverted preference, mEPSC amplitudes were increased by >16%, suggesting that synaptic plasticity in NAc may underlie aversion to the CS in this population. Our results suggest that re-exposure to ethanol induces bidirectional synaptic plasticity in nucleus accumbens, in parallel with divergent behavioral responses. Ongoing experiments will examine how cocaine modulates this divergence, and whether motor and sensory impairment contribute to bimodal reinstatement after ethanol priming.

Title: Cellular mechanisms and timing of cocaine-induced synaptic depotentiation in the nucleus accumbens

Authors: ***A. E. INGEBRETSON**[1], M. C. HEARING[2], S. R. EBNER[2], M. J. THOMAS[2]; [1]Neurosci., [2]Univ. of Minnesota, Minneapolis, MN

Abstract: Repeated exposure to cocaine can promote drug-seeking and -taking behavior. In rodent addiction models, enduring changes in glutamatergic synaptic transmission in the nucleus accumbens (NAc) appear to be important in driving this behavior. Repeated exposure to cocaine is known to potentiate AMPAR-mediated signaling in medium-spiny neurons (MSNs) in the NAc shell 10-14 days following the last drug exposure. This increase in synaptic function is reversed (or, “depotentiated”) by a single re-exposure to cocaine. However, the cellular mechanisms and the detailed timing of this drug-evoked plasticity are not well characterized. We investigated the onset and duration of NAc synaptic depotentiation as well as potential underlying mechanisms driving this plasticity, focusing on region-specific changes (shell versus core). Extending previous findings (which focused on NAc shell), we observed that in the NAc

core, AMPAR-mediated transmission was augmented following 10-14 d withdrawal, and reversed 24 h following drug re-exposure. In both NAc shell and core MSNs, challenge-induced depotentiation of AMPAR-transmission returned to control levels 5 d following drug re-exposure, indicating that this plasticity is transient. To determine the underlying mechanisms of the drug-induced depotentiation, we employed a novel *ex vivo* "bath challenge" model of drug re-exposure. *Ex vivo* re-exposure to cocaine induced depotentiation of AMPAR-mediated synaptic transmission in NAc shell and core MSNs within 30 min of drug exposure. In the NAc, activation of postsynaptic group I metabotropic glutamate receptors (mGluRs) has been shown to promote reduced presynaptic glutamate release probability and increased trafficking of AMPA-type glutamate receptors (McCutcheon et al., 2011; Robbe et al., 2002). Consistent with this, in the NAc shell, prior exposure to the mGluR5 antagonist MTEP blocked the *ex vivo* cocaine-induced reductions in mEPSC amplitude but not frequency_presumed measures of posysnaptic and presynaptic function respectively. In contrast, in the NAc core, prior exposure to MTEP did not influence the *ex vivo* cocaine-induced reductions on mEPSC amplitude or frequency. Interestingly, blockade of endocannabinoid signaling using the eCB1 receptor antagonist (SR-141716A), blocked cocaine-induced reductions in mEPSC frequency but not amplitude, suggesting the existence of multiple, independent forms of synaptic plasticity in response to drug re-exposure during abstinence. Using this approach to further delineate mechanisms and timing of drug-induced plasticity will help elucidate the neurobiology of susceptibility to addiction relapse.

Title: NMDA receptor subtypes control maturation of cocaine-generated silent synapse in nucleus accumbens

Authors: *Y. WANG[1], M. OTAKA[2], P. MU[2], M. ISHIKAWA[2], J. WANG[2], O. M. SCHLÜTER[4], Y. DONG[2], Y. H. HUANG[3];

Abstract: Exposure to cocaine induces adaptive molecular and cellular changes in the forebrain nucleus accumbens (NAc), leading to subsequent drug craving, drug seeking and drug taking behaviors. Using repeated i.p. injection procedure, we previously demonstrate in the NAc that exposure to cocaine generates AMPA receptor-silent excitatory synapses, which are enriched in GluN2B-containing NMDA receptors. These cocaine-generated silent synapses are likely immature synaptic contacts that evolve into fully functional synapses after cocaine withdrawal. Similar to the non-contingent procedure, after cocaine self-administration (2 h/session/day x 5 d) we also observed a substantial increase in the level of silent synapses in the NAc, enriched in GluN2B-containing NMDARs. Furthermore, the increased level of GluN2B-containing NMDARs returned to the basal levels after 7-day withdrawal, accompanied by the maturation of cocaine-generated silent synapses. In a mouse line in which the CaMKII-binding to GluN2B was compromised, exposure to cocaine generated silent synapse in the NAc, but these silent synapses remain silent after cocaine withdrawal without undergoing the maturation process. These results lead to our hypothesis that GluN2B-containing NMDARs control the maturation of these cocaine-generated silent synapses. Our future experiments will test this hypothesis by determining how GluN2B and its coupled signaling regulate maturation of cocaine-generated silent synapses and whether targeting NAc GluN2B is a strategy to reverse cocaine-induced circuitry remodeling.

Title: Cocaine self-administration generates silent synapses in thalamus to nucleus accumbens projection

Authors: *P. A. NEUMANN[1,3], N. GRAZIANE[2], Y. H. HUANG[2], W. XU[3], S. R. SESACK[1], E. J. NESTLER[4], O. M. SCHLÜTER[5], Y. DONG[1];

Abstract: Drug Addiction is characterized by maladaptive changes in signaling between brain regions which regulate rewards and motivated behaviors. The paraventricular thalamic nucleus (PVT) is a brain region which sends direct projections to the nucleus accumbens (NAc) and is increasingly being linked to addiction-related behaviors. We sought to characterize the molecular and cellular changes within the PVT-to-NAc pathway in response to cocaine self-administration. We used virally-mediated channelrhodopsin expression in the PVT of rats to isolate fibers from the PVT and recorded from neurons in the NAc shell. We found that cocaine self-administration increases silent synapses within the PVT-to-NAc pathway. Additionally, calcium-permeable AMPARs are present at PVT-to-NAc synapses under basal conditions, but are not additionally recruited to maturing silent synapses. Cocaine self-administration also leads to a greater probability of presynaptic vesicle release, which persists though long-term withdrawal. Disrupting PVT neurons that project to the NAc works to inhibit the acquisition of cocaine self-administration. These results characterize an array of cellular and molecular signaling changes along the PVT-to-NAc pathway in the context of cocaine exposure and demonstrate that this pathway plays a significant role in the acquisition of cocaine self-administration.

Title: Cocaine exposure alters thalamo-accumbens synapses

Authors: *M. E. JOFFE[1], B. A. GRUETER[2];
[1]Pharmacol., [2]Anesthesiol., Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract: Dysregulation of the mesolimbic system is a hallmark of the pathophysiology of drug addiction and other reward-related psychiatric diseases. The nucleus accumbens (NAc) is well known as a key biological substrate that modulates the incentive and hedonic properties of drugs of abuse. At least 90% of the neurons in the NAc are GABAergic medium spiny neurons

(MSNs). The MSNs, which provide the output of the NAc, can be divided into two classes anatomically and biochemically: one class of MSNs project primarily to the midbrain DA areas and express D1 DA receptors, while the other MSNs project to the ventral pallidum and express D2 DA and A2A adenosine receptors. MSNs rest at relatively hyperpolarized membrane potentials; therefore excitatory drive is essential to governing the output of the NAc and subsequent complex behavioral outcomes. The prefrontal cortex, ventral hippocampus, and basolateral amygdala, provide major excitatory inputs to the NAc and each have demonstrated relevance to drug exposure and subsequent behavioral abnormalities. However, the midline thalamic nuclei (thal) also send dense glutamatergic projections to the NAc core, but little is known about how these synapses may subserve conditioned reward-related behaviors. To gain a better understanding of the physiology and plasticity at thal-NAc synapses we virally expressed channel rhodopsin in the midline thalamic nuclei of D1-tdtomato BAC transgenic mice and performed targeted whole-cell patch-clamp electrophysiology in the NAc core. These experiments revealed that under basal conditions, thal-D1(+) and thal-D1(-) exhibit differential synaptic properties as assessed by ratiometric measures of ionotropic glutamate receptor (NMDAR and AMPAR) function. We then proceeded to assess the consequences of *in vivo* cocaine exposure on the thal-NAc circuit, following 2 weeks of abstinence from cocaine exposure. These experiments uncovered adaptations at both thal-D1(+) and thal-D1(-) synapses that are likely important for the behavioral changes observed at this stage of cocaine exposure. These novel findings point towards new potential avenues for DBS- or pharmacotherapy-assisted drug addiction treatments.

Title: Corticostriatal LTP is modulated by direct pathway co-release of dynorphin

Authors: ***S. L. HAWES**, K. T. BLACKWELL;
George Mason Univ., Fairfax, VA

Abstract: Synaptic plasticity adjusts behavior adaptively in the case of skill learning, or maladaptively in the case of addiction. Just as dopamine plays a critical role in synaptic plasticity underlying normal skill learning and addiction, endogenous and exogenous opiates modulate

learning and addiction related striatal plasticity. While the effect of opioids on LTD has been characterized, their effect on LTP remains unknown. This study investigates the effect of opioid neuropeptides co-released by direct pathway (D1) MSNs on corticostriatal LTP. We cross Ai32 female mice, which contain genes for channel rhodopsin 2 and EYFP downstream of a loxP-flanked STOP cassette, to Tg(Drd1a-cre) EY217 male mice. This generates Cre-positive offspring with optically-excitable D1-MSNs. In striatal brain slice from these offspring, we supply blue light through a 40x submersion objective to drive endogenous co-release from the D1-MSN population coincident with theta-burst stimulation of cortical afferents. First, we demonstrate that this afferent theta-burst stimulation (10.5Hz with 50Hz intra-burst) evokes corticostriatal LTP using the whole cell patch recording technique. Subsequently we show that optical activation of D1-MSNs during induction impairs LTP. We hypothesize that the opioid neuropeptide dynorphin, co-released exclusively by D1-MSNs, is responsible for this reduced TBS LTP. Dynorphin-activated kappa opioid receptors reside presynaptically on dopaminergic afferents and are capable of negatively regulating dopamine release, previously demonstrated to be essential for LTP in dorsomedial striatum. In support of this hypothesis, we demonstrate full rescue of LTP induced with optical activation of D1-MSNs by bath application of the kappa opioid receptor antagonist nor-Binaltorphimine dihydrochloride (1μM). Our findings illustrate a physiological phenomenon whereby heightened D1-MSN activity can regulate corticostriatal plasticity. Ongoing experiments will establish whether this indeed functions through regulation of dopamine availability, and will address whether LTP modulation by D1-MSN co-release differs between direct and indirect pathway MSNs. Our findings have important implications for learning in addictive states marked by elevated direct pathway activation.

Title: Incubation of methamphetamine craving is associated with selective increases in expression of BDNF and TrkB, glutamate receptors, and epigenetic enzymes in cue-activated Fos-expressing dorsal striatal neurons

Authors: ***X. LI**[1], F. RUBIO[1], T. ZERIC[1], J. M. BOSSERT[1], S. KAMBHAMPATI[1], H. M. CATES[2], P. J. KENNEDY[3], Q.-R. LIU[1], R. CIMBRO[4], B. T. HOPE[1], E. J. NESTLER[2], Y. SHAHAM[1];

Abstract: Cue-induced methamphetamine seeking progressively increases after withdrawal (incubation of methamphetamine craving) but the underlying mechanisms are largely unknown. We determined whether this incubation is associated with alterations in candidate genes in dorsal striatum (DS), a brain area implicated in cue- and context-induced drug relapse. We first measured mRNA expression of 24 candidate genes in whole DS extracts after short (2 d) or prolonged (1 month) withdrawal in rats following extended access methamphetamine or saline (control condition) self-administration (9-h/day; 10-days). We found minimal changes. Next, using FACS, we compared gene expression in Fos-positive dorsal striatal neurons, which were activated during 'incubated' cue-induced drug-seeking tests after prolonged withdrawal, with non-activated Fos-negative neurons. We found significant increases in mRNA expression of immediate early genes (IEGs: Arc, Egr1), Bdnf and its receptor (Trkb), glutamate receptor subunits (Gria1, Gria3, Grm1), and epigenetic enzymes (Hdac3, Hdac4, Hdac5, GLP, Dnmt3a, Kdm1a) in the Fos-positive neurons only. Using RNAscope® to determine striatal sub-region and cell-type specificity of the activated neurons, we measured co-labeling of Fos with Drd1 and Drd2 in three DS sub-regions. Fos expression was neither sub-region nor cell-type specific (52.5% and 39.2% of Fos expression co-labeled with Drd1 and Drd2, respectively). Finally, we found that DS injections of SCH23390, a D1-family receptor antagonist known to block cue-induced Fos induction, decreased 'incubated' cue-induced methamphetamine seeking after prolonged withdrawal. Results demonstrate a critical role of DS in incubation of methamphetamine craving and that this incubation is associated with selective gene-expression alterations in cue-activated D1- and D2-expressing DS neurons.

Title: Distinct glutamatergic inputs to nucleus accumbens medium spiny neurons control synaptic plasticity and its modulation by alcohol

Authors: *X. JI, S. SAHA, G. E. MARTIN;
Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract: In the core nucleus accumbens (NAc), a brain region involved in drug reward, it is accepted that long-lasting changes of synaptic strength mediate acute and chronic effects of most drugs of abuse, including alcohol. Yet, very little is known about this cellular phenomenon. Of particular interest is the fact that core NAc medium spiny neurons (MSNs) receive glutamatergic inputs from distinct brain regions, i.e. the prefrontal cortex, the amygdala and the hippocampus, each informing the NAc with a different types of information (e.g. spatial, emotional and cognitive). However, their respective role in shaping synaptic plasticity remains unknown. The role of each pathway in mediating the effects of alcohol on synaptic plasticity also has never been examined. Using patch clamp recordings and the optogenetic techniques to independently recruit each input, we show that stimulation of prefrontal cortex afferents consistently evoked spike-timing dependent tLTD but failed to induce tLTP. In contrast, stimulation of amygdala and hippocampal inputs led to both tLTP and tLTD. Comparison of the basic properties of AMPA/NMDA-mediated synaptic transmission revealed markedly different NMDA receptor properties and probability of release at amygdala, cortical and hippocampal synapses. Importantly, low 20 mM acute ethanol powerfully inhibited tLTP but had only a mild effect on tLTD. This study suggests that glutamatergic inputs to NAc medium spiny neurons are not identical, determine synaptic plasticity and its regulation by alcohol.

Title: Cognitive behavioral therapy rectified the altered functional connectivity of ventral striatum in Internet gaming disorder group

Authors: *S.-S. MA[1], J.-T. ZHANG[1], C.-S. R. LI[2], L. LIU[3], L.-J. WANG[1], B. LIU[1], Y.-W. YAO[1], X.-Y. FANG[3];

Abstract: Internet gaming disorder (IGD) is associated with the altered cortico-striatal activities. Resting-state functional connectivity (rsFC) of functional magnetic resonance imaging (fMRI) signals is a non-invasive and systems-level approach to assess functional interaction between brain areas and provides a powerful tool to identify biological markers of various psychiatric disorders, including addiction. Cognitive Behavioral Therapy (CBT) has been consistently found to be effective in ameliorating adverse impacts of Internet addiction. However, little is known about the neural bases of CBT and whether it can remediate cortico-striatal connectivity. We firstly conducted a cross-section study to examine the altered rsFC of the ventral striatum in 74 adolescent IGDs compared with 41 age- and gender-matched healthy controls (HCs). Then in the follow-up intervention study, 39 of the 74 IGDs were scanned twice, including 23 IGDs who accepted CBT (IGD-intervention) and 16 IGDs without CBT (IGD-control). IGDs showed greater functional connectivity of ventral striatum (NAc) with left inferior parietal gyrus, right inferior frontal gyrus and left middle frontal gyrus, which were positively associated with the clinical assessments. All of these indices showed more decrease in IGD-intervention group than in IGD-control group. Moreover, there is a significant interaction between intervention and group in functional connectivity between ventral striatum (NAc) and left inferior parietal gyrus, along with the clinical assessments. Results suggested that CBT can moderate the abnormality of cortico-ventral striatal connectivity, and the functional connectivity between ventral striatum (NAc) and left inferior parietal gyrus may be a stable and sensitive biomarker for diagnosis of IGD and detection of the effects of CBT.

Title: Neuroplasticity associated with individual sensitivity to a natural reward following cocaine exposure

Authors: *B. O'DONOVAN, P. I. ORTINSKI;
Pharmacology, Physiol. and Neurosci., Univ. of South Carolina, Columbia, SC

Abstract: Withdrawal from psychostimulants such as cocaine and amphetamine has been associated with reduced motivation for natural rewards in both rats and humans. Rats exhibit individual differences in their consumption of naturally rewarding sucrose. There is evidence to

suggest that rats with a high preference for sweet substances differ from rats with a low preference in their response to psychostimulants. However, a potential difference between these groups in neuronal plasticity in the NAc in response to cocaine has yet to be fully explored. This study examined the effect of a 'binge' cocaine treatment on the motivation to achieve sucrose reward and associated changes in neuronal excitability in the NAc shell of these animals. Rats were trained to respond for a sucrose reward on a progressive ratio (PR) schedule of reinforcement and divided into high and low responders based on their breakpoints. Breakpoints were then measured over 5 days of saline or 'binge' cocaine treatments (3 daily injections at 1 hour intervals, 15mg/kg i.p.) and for 2 days after the termination of drug delivery. Following the final PR session, slices containing NAc were prepared and whole-cell patch clamp recordings were taken in the NAc shell. In cocaine treated rats, breakpoints were reduced during the 5 days of cocaine treatment and up to 2 days following the termination of treatment. No difference in the magnitude of the reduction was seen between the high and low responder groups. In saline treated rats breakpoints remained stable for the duration of the experiment. Whole-cell patch clamp recordings from medium spiny neurons in the NAc shell indicated a pattern of differences between the high and low responder groups on measures of action potential firing and excitatory synaptic strength. These results demonstrate that exposure to the same cocaine regime reveals broad variability in excitability of NAc neurons associated with individual motivation for a natural reward. We are now exploring whether individual sucrose preference in the absence of cocaine similarly co-varies with measures of membrane and synaptic excitability.

Title: Reversal of morphine-induced cell-type specific synaptic plasticity in the nucleus accumbens shell blocks reinstatement

Authors: *M. C. HEARING, A. INGEBRETSON, S. EBNER, C. SCHMIDT, R. FISCHER, A. ASP, M. THOMAS;
Dept. of Neurosciences, Univ. of Minnesota, Minneapolis, MN

Abstract: Repeated exposure to drugs of abuse such as cocaine, induces plasticity at excitatory synapses in the nucleus accumbens (NAc). However, little is known of opiate-induced synaptic

plasticity in NAc and its relevance to drug-seeking. Medium spiny neurons (MSNs), the principal NAc cell-type, typically express either the dopamine receptor 1 (D1-MSNs) or dopamine receptor 2 (D2-MSNs), the presence of which plays a role in determining cell physiology and contribution to drug-related behaviors. To identify morphine-induced plasticity in glutamatergic signaling in the NAc, we used BAC transgenic mice expressing fluorescent proteins under the control of the D1R or D2R promoter, and a model of morphine sensitization to identify adaptations in glutamatergic signaling within the NAc shell (and core) following 10-14 d withdrawal. In the NAc shell, AMPAR/NMDAR (A/N) ratios and the amplitude and frequency of miniature excitatory postsynaptic currents (mEPSCs) are increased in D1R- but not D2R-MSNs, indicating synaptic potentiation in the D1R-MSNs. To test for morphine-induced changes in the subunit composition of synaptic AMPARs in D1R-MSNs, we assessed current-voltage relationships of evoked EPSCs and the effect of bath application of 1-naphthylacetylsperimine (Naspm), a selective blocker of GluA2-lacking AMPA receptors. The rectification index increased and Naspm decreased evoked EPSC amplitude in neurons recorded from the morphine-exposed mice_indicators of the presence of GluA2-lacking AMPARs. Given the morphine-induced changes in mEPSC frequency, we used paired-pulse stimulation to test for changes in glutamate release probability, we find significant increases and decreases in release probability within D1R-MSNs and D2-MSNs respectively. We next explored whether reversal of this plasticity is able to prevent drug-associated behavior using a conditioned place preference model. We found that repeated administration of the antibiotic, Ceftriaxone, which up-regulates expression of the glutamate transporter GLT-1, during withdrawal reversed increases in D1-MSNs AMPAR signaling, enhanced signaling in D2-MSNs, and blocked reinstatement of morphine place preference. Furthermore, using an AAV viral vector expressing hM3Dq (Gq) DREADD under control of the glial fibrillary acidic protein (GFAP), we demonstrated that repeated activation of DREADD-mediated signaling in the NAc shell during withdrawal attenuates reinstatement of morphine place preference. These data suggest that cell-type specific adaptations in NAc shell MSN synaptic strength are critical pathophysiological mechanisms underlying morphine-associated behavior.

Title: Drebrin signaling mediates opiate-induced plasticity in the nucleus accumbens

Authors: *J. A. MARTIN[1], Z.-J. WANG[1], M. HUMBY[1], A. CACCAMISE[1], L. E. MUELLER[1], R. NEVE[2], A. M. GANCARZ[1], D. M. DIETZ[1];
[1]State Univ. of New York At Buffalo, Buffalo, NY; [2]MIT, Cambridge, MA

Abstract: Opiate addiction has dramatically increased, becoming a worldwide epidemic with great societal and financial burdens. Drug addiction, defined as a chronic relapsing disease, involves the 'rewiring' of the brain through long-term changes, such as structural plasticity, in several key regions of the mesolimbic dopaminergic pathway. There is a great deal of evidence demonstrating that chronic psychostimulant exposure increases the number of dendritic spines on medium spiny neurons in the nucleus accumbens (NAc). In contrast, exposure to opiates, such as morphine and heroin which similarly induce behavioral sensitization, leads to a decrease in dendritic spine density. However, there are minimal data regarding the cellular neurobiology that regulates this opiate-induced plasticity. Following both morphine sensitization and heroin self-administration there is a decreased expression of the actin binding protein drebrin in the NAc. This decrease in drebrin results from an increase in HDAC2 expression and binding at the promoter of the transcriptional start site, accompanied by a decrease in pan-H3 acetylation. Overexpression of drebrin blunted the development of morphine sensitization (5 mg/kg, i.p.) and attenuated the expression of sensitization following a morphine challenge (2.5 mg/kg, i.p.) compared to HSV-GFP controls. In order to determine the role of drebrin in drug relapse, animals were trained to self-administer heroin (0.02 mg/kg/inf). Interestingly, following heroin self-administration, overexpression of drebrin in the NAc significantly decreased responding during heroin-primed reinstatement (0.25 mg/kg, s.c.), but not cue-induced reinstatement. Finally, overexpression of HDAC2 leads to a potentiation of behavioral response to low doses of morphine. Taken together, these data suggest that epigenetic regulation of drebrin is functionally regulated following exposure to opiates and may be a key molecular mechanism underlying opiate-induced behavioral plasticity.

Title: Dopamine D1 agonist treatment alters opiate reward extinction and accumbal dendritic complexity

Authors: *G. B. KAPLAN[1], K. L. KOBRIN[2], D. ARENA[3], S. C. HEINRICHS[3];
[1]Psychiatry and Pharmacol., [2]Pharmacol., Boston Univ. Sch. Med/VA Boston Healthcare, Boston, MA; [3]Res., VA Boston Healthcare Syst., Boston, MA

Abstract: The dopamine D1 receptor (D1R) mediates drug reward and morphology of accumbal neurons. We used a morphine conditioned place preference (CPP) mouse model to study the role of D1R in context-reward associative learning and related accumbal dendritic morphology changes. To acquire CPP, a morphine group received saline or morphine 10 mg/kg s.c. on alternate days, while CPP controls received saline on all days, immediately before 8 daily place conditioning sessions. Post-conditioning, morphine CPP mice expressed significantly higher place preference than saline mice. We examined the effects of D1R agonist on morphine reward extinction. To induce extinction, mice were repeatedly exposed to the place conditioning environment in a drug-free state. Morphine-conditioned mice were divided into three groups, receiving s.c.saline, 0.5 mg/kg SKF81297 (D1R agonist), or 0.8 mg/kg SKF81297 immediately after each extinction session, while saline sham-conditioned controls received saline. After every two days of extinction training mice were tested for place preference. D1R agonist treatment inhibited extinction of place preference in a dose-dependent manner. After the third post-extinction preference test, the 0.8 mg/kg SKF81297 group's mean preference score was twice as high as the mean preference score of the group of morphine-conditioned mice receiving saline during extinction. One day after the final place preference test brains were isolated and processed using Golgi-Cox staining followed by digital tracing of accumbal neuron morphology. Neurons of the accumbens core from mice treated with 0.8 mg/kg SKF81297 that were prevented from undergoing CPP extinction-related changes had signficantly greater dendritic complexity and spine density than controls that achieved CPP extinction. No differences were found in the accumbens shell. D1R agonist appears to activate drug reward memories, reverse extinction, and increase accumbal core dendritic complexity.

Title: Effects of chronic forced exercise on the mesolimbic dopamine pathway: Implications for addiction

Authors: *L. S. ROBISON[1], A. TUCCI[1], J. STAMOS[3], M. ANANTH[2], P. K. THANOS[1]; [1]Psychology, [2]Neurobio. and Behavior, Stony Brook Univ., Stony Brook, NY; [3]Psychology, Rutgers Univ., New Brunswick, NJ

Abstract: Substance abuse disorders affect over 20 million people in the United States and cost the nation over $700 billion annually. Therefore, identifying means of reducing the propensity for substance abuse is of great interest. Exercise has been identified as a natural and cost-effective means of both preventing and treating substance abuse. Both clinical and preclinical studies have found that exercise is associated with reduced behavioral reactivity, initiation of drug use, progression of use to addiction, withdrawal symptoms, and likelihood of relapse. Less is known, however, regarding the underlying neurobiological mechanisms driving these changes in behavior. Research has shown that vulnerability for substance abuse may be attributable to "reward deficiency", mediated by altered functioning of the brain's mesolimbic dopamine pathway, which functions in reinforcing both natural and drug rewards. One possibility is that exercise may alter the mesolimbic dopamine pathway in such a way to make drugs of abuse less salient and/or rewarding. Chronic use of drugs and vulnerability to substance abuse has been associated with an increase in excitatory dopamine D1 receptors (D1R) and a decrease in inhibitory dopamine D2 receptors (D2R). Therefore, it was hypothesized that exercise may decrease D1R and/or increase D2R in reward-related regions. Male and female Lewis rats were split into exercise and sedentary groups at 8 weeks of age. Exercise rats were run on a treadmill at 10m/min, five days per week, for six weeks. Sedentary rats received no exercise beyond normal cage ambulation. Following treatment, rats were euthanized and brains were flash-frozen until being cryosectioned and bound with [3H]SCH 23,390, [3H]spiperone, and [3H]WIN55,428 to quantify levels of D1R, D2R, and the dopamine transporter (DAT), respectively. ImageJ software was used to outline and quantify receptor and transporter levels in regions of interest, including the caudate putamen (split into four quadrants: dorsomedial, dorsolateral, ventromedial, and ventrolateral), nucleus accumbens core and shell, olfactory tubercle, and substantia nigra. Results show that exercise attenuates D1R binding in the olfactory tubercle and shell of the nucleus accumbens, while this trend approaches significance in the substantia nigra. Preliminary data suggests that exercise may also increase D2R binding across several regions measured. Analysis of D2R and DAT binding continues. These findings thus far support the hypothesis that exercise results in changes in the mesolimbic pathway that could mediate exercise-induced changes in drug-seeking behavior.

Title: Dopamine-acetylcholine interplay in the basal ganglia modulates AMPA glutamate receptors and behavior

Authors: *B. XUE, D.-Z. JIN, L.-M. MAO, J. WANG;
Dept. of Basic Med. Sci., UMKC Sch. of Med., Kansas City, MO

Abstract: Dopamine (DA) and acetylcholine (ACh) converge onto the protein kinase A (PKA) pathway in medium spiny neurons of the striatum and pyramidal output neurons of the medial prefrontal cortex (mPFC) to control the excitability of these neurons and thus behavior, although underlying molecular mechanisms are less clear. Here we measured phosphorylation of AMPA receptors (AMPARs) at a PKA site (S845) as an activation indicator of AMPARs in adult rat brains *in vivo* to explore how DA and ACh interact to modulate AMPARs and behavior. In a series of pharmacological experiments, we characterized GluA1 S845 responses to DA D1 receptor (D1R), D2 receptor (D2R) or muscarinic M4 receptor (M4R) agents in DA responsive regions (striatum and mPFC). The S845 responses support a local multitransmitter interaction model in which D2Rs inhibited an intrinsic inhibitory element mediated by M4Rs to enhance the D1R efficacy in modulating AMPARs. Consistent with this, selective activation of M4Rs through a positive allosteric modulator (PAM) resumed the cholinergic inhibition of D1Rs. In addition, D1R and D2R coactivation recruited GluA1 and PKA preferentially to extrasynaptic sites. Behaviorally, the M4R PAM inhibited the motor responsivity to co-injected D1R/D2R agonists. Our *in vivo* data support the existence of differential DA-ACh balances in the striatum and mPFC which actively modulate GluA1 AMPARs and behavioral sensitivity to changing DA input. A central signaling pathway in these balances involves PKA-dependent and S845-regulated trafficking of GluA1.

Title: Dopamine release and cocaine sensitivity differ between striosome and matrix compartments of the striatum

Authors: *A. G. SALINAS[1,2], M. I. DAVIS[1], D. M. LOVINGER[1], Y. MATEO[1];
[1]Natl. Inst. On Alcohol Abuse and Alcoholism, Rockville, MD; [2]George Mason Univ., Fairfax, VA

Abstract: The striatum is involved in a number of neural processes including learning and action control. Two major output pathways from striatum have been characterized: the direct and indirect pathways, which consist of D1 and D2 dopamine receptor-enriched neurons, respectively. The striatum can also be classified into striosome and matrix compartments, based on the expression of several proteins, including the mu opioid receptor, dopamine transporter (DAT), and Nr4a1 (nuclear receptor subfamily 4, group A, member 1). A number of functional differences between the striosome and matrix compartments have been implicated in neurological disorders including Parkinson's disease and addiction. Given the importance of dopamine signaling and the differences between striosome and matrix compartments in models of these conditions, we hypothesized that dopamine release would differ between striosome and matrix compartments. To test this hypothesis, we used Nr4a1-GFP mice to identify striosomes and fast scan cyclic voltammetry to measure evoked dopamine overflow from adjacent striosome and matrix compartment pairs. We found that electrically evoked dopamine overflow in striosomes in the dorsal striatum was reduced approximately 35% compared to the matrix compartment. We further found that in the ventral striatum, this pattern was reversed, such that evoked dopamine overflow in striosomes was approximately 64% greater than in the matrix compartment. We then examined three common mechanisms involved in modulating dopamine overflow. We started by examining the effect of quinpirole, a D2 dopamine receptor agonist, on autoreceptor-mediated inhibition of dopamine overflow and found no differences between compartments, neither in dorsal nor in ventral striatum. To examine the contribution of nicotinic receptors, we treated slices with DHBE and found that antagonism of nicotinic acetylcholine receptors inhibited dopamine overflow to a similar degree in both compartments. We then examined the role of DAT in the differences in dopamine release between compartments and found that cocaine enhanced dopamine overflow in striosomes to a greater degree than in the matrix at several concentrations. Modeling of the dopamine overflow kinetics showed that cocaine inhibited dopamine uptake in the matrix compartment to a greater degree than in striosomes. This difference in cocaine sensitivity was limited to the dorsal striatum. Together these findings demonstrate a strict regulation of striosomal dopamine relative to the matrix. The significance of this regulation remains uncertain but has implications for dopamine-related neurological disorders and addiction.

Title: Sleep disturbances predict reductions in striatal D2R availability in cocaine abusers

Authors: *C. E. WIERS[1], E. SHUMAY[2], E. CABRERA[3], E. SKARDA[2], E. SHOKRI-KOJORI[2], S. CUNNINGHAM[2], C. WONG[2], D. TOMASI[2], G.-J. WANG[2], N. D. VOLKOW[2]; [1]Lab. of Neuroimaging, Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD; [2]NIAAA, Bethesda, MD; [3]NIAAA, Bethseda, MD

Abstract: Sleep disturbances and substance use disorders are highly comorbid conditions, but the neural mechanisms underlying this comorbidity remain largely unknown. It has consistently been found that cocaine abusers have reduced striatal dopamine D2 receptor (D2R) availability compared to controls. Moreover, it was recently shown that direct sleep deprivation decreases striatal D2R availability in healthy volunteers. In this study, we therefore investigated whether durations of daily sleep are associated with DR2 availability in a group of 24 active cocaine abusers and 21 healthy controls (matched for age [mean cocaine abusers =44.78years ± 4.88SD; mean controls = 42.18 years ± 5.49SD), sex, education, BMI, handedness and ethnicity) using Positron Emission Tomography (PET) and [11C]raclopride. We found that compared to controls, cocaine abusers had shorter sleep durations (mean cocaine abusers = 6.17h ± 1.61SD; mean controls = 7.43h ± 1.12SD; t=3.01, p=.004), went to bed later (mean cocaine abusers = 00:14 am ± 1.6h SD; mean controls = 11:14pm ± 1.51h SD; t= 2.26, p=.029) and reported longer periods of sleep disturbances (mean cocaine abusers = 19min ± 42min SD, mean controls = 0; t=2.33, p=.029), but did not feel less rested in the morning (cocaine abusers: 19 yes/5 no, controls: 18 yes/3 no χ^2=.33, p>.1). Further, cocaine abusers showed lower D2R availability in striatal areas than controls (putamen [p=.021] and ventral striatum [p.1]). In cocaine abusers, duration of sleep predicted D2R availability in all striatal areas (putamen [r^2=.218, p=.021], ventral striatum [r^2=.209, p=.025], and caudate [r^2=.276, p=.008]), also when correcting for age (all p.1). Moreover, in cocaine abusers, last cocaine use correlated with duration of sleep (cocaine use in mg [r=-.495, p=.014] and in $ [r=-.543, p=.006]), but not with striatal D2R availability (all p>.1). These findings suggest that cocaine-induced sleep deprivation reduces striatal D2R availability. Alternatively, shorter sleep and lower D2R may be risk factors for cocaine abuse.

Title: Optogenetic activation of anterior cingulate cortex inhibits the heroin seeking behavior in rats

Authors: *W. ZHOU, M. LAI, H. ZHU, W. CHEN, H. LIU, F. ZHANG;
Ningbo Addiction Res. and Treat. Cent. Med. Sch. of Ningbo Univ., Ningbo, China

Abstract: The aims of present study were to investigate effects of optogenetic activation of anterior cingulate cortex (ACC) on heroin self-administration, heroin seeking behavior induced by cues or heroin priming and learning and memory in rats. The rats in ACC optogenetic activation group were microinjected with 1μl pAAV-CaMKIIα-hChR2-EYFP into ACC(AP:+2.7mm,ML:0.5mm,DV:2.5mm), then implanted optical fiber 0.5mm above site of microinjection. The rats in sham operation group were microinjected with AVV-EYFP into ACC. The rats were placed in operant chambers for a daily 4h heroin self-administration session under FR1 for consecutive 14 days. Then memory was taken eight-arms maze test. Optogenetic activation of ACC by illuminated by light(470 nm,5mW) decreased the enhancement of reference memory errors, working memory errors induced by heroin exposure. Moreover, optogenetic activation of ACC inhibited the heroin seeking behavior induced cues, which could be reversed partially by pretreatment with LY341495. While, Optogenetic activation of NAc core(AP:+1.2mm,ML:±3.2mm,DV:-6.7mm)also inhibited the heroin seeking induced by cues. In conclusion, these data demonstrate that activation of ACC can improve the cognitive dysfunction induced by heroin chronic exposure, and projective pathway from ACC to NAc core may be involved in the heroin seeking behavior induced by cues.

Title: Role of deep brain stimulation of medial prefrontal cortex on heroin seeking behavior in rats

Authors: *H. LIU[1,2];
[1]Ningbo Inst. of Microcirculation and Henbane,Ningbo Addiction Res. and T, Zhejiang, China;
[2]Lab. of Behavioral Neuroscience, Sch. of Medicine, Ningbo Univ., Ningbo, China

Abstract: Recent research in both animals and humans has indicated that deep brain stimulation (DBS) may have potential for the treatment of drug dependence and relapse, but few studies of DBS on the treatment of heroin dependence, in particular for relapse to heroin seeking, it is not yet entirely clear which brain and paradigm should be applied. In the present study, we used an animal model of heroin self-administration to investigate the role and possible mechanisms of DBS treatment for the two sub-regions (dorsal and ventral) of medial prefrontal cortex (mPFC) in the extinction and reinstatement of heroin seeking behavior. Cue-induced heroin seeking reinstatement test was conducted 24h after the last extinction training. In the DBS treatment with dmPFC, two-factor repeated ANOVA revealed that the H-DBS group had significantly lower active pokes in cue-induced reinstatement of heroin seeking compared with those of sham stimulation group, while there was no difference in active pokes between sham stimulation and L-DBS group in cue-induced reinstatement of heroin seeking; There was also no difference in active nose-pokes between stimulated and sham control groups during the extinction sessions. In the DBS treatment with vmPFC, two-factor repeated ANONA found the number of active pokes in H-DBS group were significantly higher than the sham control group in cue-induced reinstatement of heroin seeking or during day 4-7 extinction sessions. We also explored the effects of long-term high frequency stimulation of dmPFC on p-CREB ,p-AKT and p-ERK expression in the NAc core and NAc shell. Western blot and immunohistochemical analysis showed that the level of p-CREB in the NAc core significantly increased in the rats treated with H-DBS compared with the sham control. In contrast, the level of p-ERK and p-AKt in the NAc core significantly decreased in the rats treated with H-DBS compared with the sham control. We conclude that the high frequency stimulation of dmPFC can inhibit the reinstatement of heroin-seeking induced by conditioned cues, and its regulation of phosphorylated CREB, phosphorylated ERK and phosphorylated AKt expression in NAc core may contribute to the behavioral inhibition in cue-induced reinstatement. High frequency stimulation of the vmPFC can impair the extinction of heroin seeking and facilitate the reinstatement of heroin-seeking induced by conditioned cues ; Low frequency stimulation of either dmPFC or vmPFC have no influence on heroin seeking behavior during extinction and cue-induced reinstatement. The present studies demonstrated that chronic DBS treatment with mPFC may represent a useful treatment method for heroin addiction.

Title: AMPA/Kainate receptor modulation of glutamate transporters in the prefrontal-accumbens circuitry: impact of adolescent ethanol drinking

Authors: *G. E. SEALE[1], T. MERCED[2], E. P. RODRIGUEZ[2], L. ACOSTA[2], R. I. MELENDEZ[2];

Abstract: Glutamate transporters play an indispensable role in shaping synaptic glutamate transmission and plasticity. Alterations in the re-uptake of glutamate has been linked to a number of neurobiological disorders, including drug and alcohol addiction. Yet, the regulation of glutamate uptake systems by glutamatergic receptors remains not well understood. Here we examined the role of AMPA and kainate glutamate receptors in regulating glutamate uptake in the prefrontal cortex (PFC) and nucleus accumbens (NAC) of ethanol (EtOH) naïve and EtOH-drinking adolescent and adult C57BL/6J mice (n=4-6/group/age/drug). Mice were initially given 24 h two-bottle choice access to 15% EtOH and water for 2 weeks, which spans the adolescent period. Mean EtOH intake prior to glutamate uptake procedures was (in g/kg) 12.3 ± 0.6 for adolescent and 11.1 ± 0.5 for adult mice. Following EtOH drinking, crude (mixed) synaptosomal preparations were obtained from the PFC and NAC of all mice and subjected to a [3H]-glutamate uptake assay. In naïve mice, our results indicated that the maximal velocity or Vmax of glutamate uptake was significantly greater in PFC than NAC of both age groups, suggesting a greater number of glutamate transporters in PFC. The Vmax for glutamate uptake was (in pmol/mg protein/min) 18.1 ± 0.7 in PFC and 13.4 ± 1.2 in NAC, respectively. Interestingly, in both age groups, we revealed a significant (nearly 30%) enhancement of glutamate uptake following application of the AMPA/kainate antagonist, DNQX (50 μM) in NAC but not PFC. On the other hand, application of the AMPA-selective antagonist NBQX (50 μM) significantly reduced (nearly 50%) glutamate uptake in NAC particularly in adult mice, but not in PFC. In EtOH mice, we observed a significant reduction in the Vmax of basal glutamate uptake in NAC but not PFC, particularly in adolescent mice. Moreover, EtOH drinking experience significantly blocked the ability of DNQX to stimulate glutamate uptake in the NAC in both age groups, and further enhanced the ability of NBQX to inhibit NAC glutamate uptake, particularly in

adolescent mice. These findings indicate that AMPA and kainate receptors differentially modulate glutamate transporters particularly in the NAC of B6 mice. Moreover, EtOH drinking experience blocks DNQX-induced potentiation and enhances NBQX-induced inhibition of glutamate uptake, which may lead to major deficits in synaptic glutamate transmission and plasticity.

Title: Epigenetic alterations in medial prefrontal cortex and testis after chronic caffeine and cocaine administration in mice

Authors: *B. GONZALEZ[1], C. R. GONZALEZ[2], J. A. MUÑIZ[1], J.-L. CADET[3], E. GARCIA-RILL[4], F. URBANO[5], A. VITULLO[2], V. BISAGNO[1];

Abstract: There is growing evidence of epigenetic mechanisms contributing to the transgenerational transmission of stress, psychiatric disease and addiction vulnerability. Regarding paternal transmission, it has been proposed that environmental factors like chronic stress, nutritional status, toxins and drugs of abuse trigger epigenetic mechanisms in the testicular germ line that can lead to variations in offspring's development and behavior. Chronic psychostimulant intake also causes epigenetic changes and toxic consequences not only in dopaminergic brain areas but in peripheral organs as well, including the testis. From that perspective, several groups have reported epigenetic alterations in the medial prefrontal cortex

(mPFC) of cocaine-experienced sires that were present in the testicular germ line and were transmitted to the male offspring. Recreational use of cocaine (Coc) is often abused in combination with other psychostimulants like caffeine (Caf). Caf was reported to enhance cocaine-mediated effects in brain areas. In the present study, we measured epigenetic and functional markers in the mPFC and testis of adult mice treated with Coc (10 mg/kg), Caf (5 mg/kg), or the combination (Caf-Coc) (10 mg/kg Coc + 5 mg/kg Caf) compared to vehicle (Veh), in an intermittent binge protocol (3 i.p. injections, 1 h apart, one day on/off for 13 days. Mice were euthanized on day 14. Deacetylation by histone deacetylases (HDACs) at lysine residues are post-translational histone modifications that have been reported in various neuropsychiatric diseases including addiction. In our study, we found that Coc and Caf-Coc treatments caused a decrease of HDAC2 expression and a concomitant increase in histone 3 acetylation (H3ac) in both mPFC and testis. Morphometric analyses of the testis revealed reduced volume of the seminiferous tubules after Coc and Caf-Coc treatments, indicative of altered spermatogenic process. In addition, there was reduced mRNA expression of AMPA-type glutamate receptor subunit Gria1, adenosine receptor subunit Adora2a, scaffolding protein Psd95 and methyl CpG binding protein Mecp2 in the mPFC after Caf, Coc and Caf-Coc treatments. We are currently investigating whether these psychostimulants might differentially regulate gene expression in the testis. Our results further support that psychostimulant abuse can induce epigenetic marks in CNS and testis that could lead to impaired function with the possibility of affecting individuals from next generation.

Title: Monoamines alter neuronal excitability of lateral orbitofrontal cortex neurons: role of G protein-coupled inwardly-rectifying potassium channels

Authors: ***S. NIMITVILAI**, M. F. LOPEZ, P. J. MULHOLLAND, J. J. WOODWARD; Dept. of Neurosci. and Addiction Sci. Div., Med. Univ. of South Carolina, Charleston, SC

Abstract: The orbitofrontal cortex (OFC), a brain region within the prefrontal cortex, plays an important role in integrating sensory information, and participates in learning, prediction and decision making for emotional and reward-related behaviors. Many studies have revealed that

the OFC is extensively innervated by monoamines, including serotonin, dopamine and noradrenaline. Dysfunction of the OFC is associated with numerous neuropsychiatric disorders such as schizophrenia, obsessive-compulsive disorder as well as alcohol and substance abuse disorders, and drugs that target monoamine receptors have been used in the treatment of these psychiatric diseases. With whole-cell patch-clamp electrophysiology, we found that 5HT, DA or NE produced a dose-dependent decrease in spike firing of lateral OFC (lOFC) neurons. Pharmacological studies revealed that these effects were mediated via Giα-coupled 5HT1A, D2 or α2-adrenergic receptors, respectively. As activation of these and other Giα-coupled receptors has been linked to stimulation of G protein-coupled inwardly rectifying potassium (GIRK) channel, we examined whether the GIRK channel is a common target for monoamine-induced inhibition of spiking. In addition, we tested whether acute and chronic ethanol exposure (CIE) altered the spiking when GIRK channels were modulated. Inhibition of neuronal firing by 5HT, DA or NE was suppressed by a GIRK channel blocker barium, while the GIRK channel activator ML297 decreased firing when administered alone. In the presence of ML297 or barium, acute ethanol (33 mM) had no further effect on firing. In neurons from mice exposed to CIE, spike frequency was nearly doubled and these neurons were largely resistant to the inhibitory effects of acute ethanol or each monoamine for up to at least 7 days of withdrawal. ML297 also had little effect on spiking in neurons from CIE-treated animals, despite no change in GIRK channel expression. Since activation of GABA-B receptor is also known to stimulate GIRK channels, we tested whether the GABA-B receptor agonist baclofen affects lOFC excitability. In control animals, baclofen decreased spiking of lOFC neurons, and this inhibition was also diminished in neurons obtained from CIE-exposed mice. The results of these studies suggest that monoamines likely play a key role in modulating the intrinsic excitability of lOFC neurons, through activation of GIRK channels, and that this modulation is significantly disrupted following chronic exposure to alcohol. Dysfunction of one or more of these neuromodulators may contribute to impaired OFC function associated with various neuropsychiatric diseases including alcohol dependence.

Title: Pharmacological inhibition of monoacylglycerol lipase systemically and centrally in the amygdala and visceral insular cortex prevents establishment of a naloxone-precipitated morphine induced conditioned place aversion in rats

Authors: *K. L. WILLS[1], C. L. LIMEBEER[1], E. M. ROCK[1], M. J. NIPHAKIS[2], B. F. CRAVATT[2], L. A. PARKER[1];
[1]Univ. of Guelph, Guelph, ON, Canada; [2]The Scripps Res. Inst., La Jolla, CA

Abstract: Enhancement of endocannabinoid activity, through pharmacological inhibition of the catabolic enzyme fatty acid amide hydrolase (FAAH) or monoacylglycerol lipase (MAGL), has been shown to reduce somatic symptoms of morphine withdrawal in mice (Ramesh et al., 2011; Ramesh et al., 2013). However, the effect of such treatments on the affective properties of morphine withdrawal has not been investigated in rats. The conditioned place aversion paradigm represents an animal model capable of assessing the ability of pharmacological manipulations to alter affective morphine withdrawal. Specifically, a morphine induced conditioned place aversion is produced when naloxone is administered 24 hr following a single exposure to a high dose of morphine (Parker and Joshi, 1998). Our experiments demonstrate that systemic pretreatment with the monoacylglycerol lipase (MAGL) inhibitor, MJN110 (which selectively elevates the endocannabinoid 2-arachidonoylglycerol - 2-AG), but not the fatty acid amide hydrolase (FAAH) inhibitors, URB-597 and PF-3845 (which selectively elevate the endocannabinoid anandamide - AEA), interferes with the establishment of a naloxone-precipitated conditioned place aversion; a model of affective morphine withdrawal. Furthermore, central administration of MJN110 to regions of the amygdala or to the visceral insular cortex (VIC) also prevents the establishment of the place aversion. The effect of MJN110 to interfere with withdrawal was reversed with pretreatment of the CB1 antagonist AM251, and MJN110 administration alone did not possess rewarding or aversive properties in the place conditioning paradigm. Ultimately, these findings suggest pharmacological treatments that elevate 2-AG acting at the CB1 receptor may be useful in reducing the aversive effects of morphine withdrawal.

Nacional Autónoma de México, Facultad de Psicología. Área de Neurociencias, Mexico City, Mexico; [4]Univ. Nacional Autónoma de México, Facultad de Medicina, Clínica de Trastornos de Sueño, Mexico City, Mexico

Abstract: Introduction: Sleep disturbances are related with increased risk of depression, hearth diseases, cognitive decline and primary sleep disorders in elderly [1]. About 15 to 45% of older adults in the US reported difficult of initiate and maintain sleep [2] and in Mexico City about 63.2% of older people reports bad sleep quality [3]. Many risk factors are related to sleep disturbances in the elder [4]. It is also known that alcohol [5] and drug consumption [6] produces changes in sleep architecture, suppressing REM sleep and increasing arousal, but little is now about the relationship between aging, sleep disturbances and drug consumption. Method: A descriptive, retrospective, correlational study was performed. A methodological review of 148 files of patients who attended to a Sleep Clinic was done. Clinical history and polisomnographic report was analyzed, to assess differences between history of alcohol and drug consumption and polysomnographic variables. Descriptive statistics of the group were determined. Four groups were studied (caffeine use, alcohol use, polydrug use and no substance use). Means were compared between groups using ANOVA with DMS post-hoc test, and for robust mean comparison used Welch's and Brown-Forsythe statistic. Results: Mean age was 70 years old; we found differences in S1% (W=5.690, sig=.001), Apnea/Hypoapnea Index (W=6.454, sig<.001), O2% Total (B-F=3.391, sig=.014), and post-hoc analysis showed significant differences in alcohol consumption in Arousal%, caffeine in REM latency, caffeine in Total O2%, polydrug use in Minimum O2% and caffeine in apnea index. Title: Distinct neuronal ensembles in rat infralimbic cortex control food reward memories and extinction memories

Authors: *B. L. WARREN, M. P. MENDOZA, F. C. CRUZ, R. M. LEAO, D. CAPRIOLI, K. B. MCPHERSON, Y. SHAHAM, B. T. HOPE;
NIDA IRP/NIH, Baltimore, MD

Abstract: Animals can be trained to perform an operant response to receive a reward and then to extinguish the learned response when the reward is withheld. Reward memories and extinction memories are thought to be distinct and are likely encoded by different patterns of sparsely distributed neurons called ‘neuronal ensembles’. In a previous study, we found elevated Fos immunoreactivity in the infralimbic cortex in rats exposed to 2 days of extinction training, suggesting that neuronal ensembles within the infralimbic cortex encode extinction memory. To test this hypothesis, we first trained food-restricted transgenic cfos-lacZ rats to lever press for palatable food pellets for 7 days (60 min/day). Two groups of rats were subsequently exposed or not exposed (levers retracted) to 2 days of extinction training (60 min/day). On induction day, one day later, all rats were exposed to a brief induction session (15 min) under extinction conditions to induce Fos. After 75 additional minutes, we selectively inactivated infralimbic neuronal ensembles associated with either the food reward memory (no extinction group) or the extinction memory (extinction group) using the Daun02 inactivation procedure to determine the effects of inactivating ensembles on food seeking. We hypothesized that the ‘food reward ensemble’ is reactivated on induction day when there was no prior extinction training and that the ‘extinction ensemble’ is reactivated after 2 days of prior extinction training. Two days after Daun02 inactivation, rats in the no extinction group had decreased, while rats in the extinction group had increased their lever presses in a brief (15 min) test under extinction conditions. Here, we show that selective inactivation of extinction ensembles impaired extinction recall, while selective inactivation of reward ensembles disrupted reward recall. Results demonstrate that neuronal ensembles encoding reward and extinction memories can intermingle in the same brain area. This research was supported [in part] by the Intramural Research Program of the NIH, NIDA

Title: Fos-expressing neuronal ensembles in learned behaviors using the Fos-Tet-Cre transgenic rat system

Authors: *R. MADANGOPAL, B. L. WARREN, D. CAPRIOLI, B. LIANG, L. R. WHITAKER, R. M. LEAO, F. CRUZ, F. J. RUBIO, Y. ZHANG, C. T. RICHIE, D.-T. LIN, Y. SHAHAM, B. K. HARVEY, B. T. HOPE;
Natl. Inst. On Drug Abuse IRP, Baltimore, MD

Abstract: Since proposed by Hebb in 1949, evidence supporting the hypothesis that learned associations are encoded in sparsely distributed 'cell assemblies' (neuronal ensembles) has primarily been based on correlations between *in vivo* electrophysiological firing or two-photon calcium-imaging patterns during learning and memory tasks and learning-related post-mortem activity patterns of immediate early genes (IEGs) such as c-fos, arc and zif268. Until recently, the lack of ensemble-targeted approaches has made it difficult to examine whether this sub-population of neurons that is selectively activated during learned behaviors mediates these associations. Current methods target all neurons within a specific region or belonging to a specific cell-type, regardless of whether or not they were selectively activated during learned behaviors. Recently, the Hope lab developed a novel tool_the Fos-Tet-Cre transgenic rat system_that permits recombination of Cre-inducible genes in activated Fos-expressing neuronal ensembles within a 6-h time window following systemic tetracycline injections. The system was validated using a rat model of context-induced relapse to cocaine seeking using Cre-inducible YFP and Fos-immunoreactivity to assess context-specific reactivation of neuronal ensembles in ventral mPFC. Further, selective inhibition of these context-encoding neuronal ensembles using a Cre-inducible halorhodopsin decreased context-induced relapse. We are now pursuing high resolution mapping of neural circuit dynamics in freely behaving Fos-Tet-Cre transgenic rats using a combination of GRIN endoscope-based calcium imaging, two-photon microscopy, and viruses for cell-type and task specific expression of fluorescent reporter proteins.

Title: The neural substrates underlying ketamine addiction

Authors: *I.-M. LIAO[1], J.-C. CHEN[2];
[2]Dept. of Physiol. and Pharmacol., [1]Grad. Inst. of Biomed. Sciences, Chang Gung Univ., Taoyuan City, Taiwan

Abstract: Ketamine (KET), an NMDA receptor antagonist, displays a diverse pharmacological profile, in which the drug effects are differentiated based on the dosage used. High dose of KET leads to anesthesia, sub-threshold dose exhibits anti-depressant effect, while as sub-anesthesia dose with chronic consumption induces addiction, as well as symptoms that model for schizophrenia or KET psychosis. The action of anti-depressant effect of KET has been explored extensively in the recent years; however, the cellular mechanism of KET addiction has been rarely addressed. The specific aim of this study is to explore the neural substrates of KET addiction and its rewarding properties. In the present study, mice receiving daily 30 mg/kg intraperitoneal KET administration for 7 consecutive days developed locomotor sensitization. Dopamine and glutamatergic signaling cascades implicated in addiction progress were assessed accordingly in the nucleus accumbens (NAc). Increased phosphorylation of protein kinase B (PKB/Akt) and glycogen synthase kinase (GSK3) were observed in the NAc in mice after 7 days of KET treatment. In addition, the phosphorylation of extracellular signal-regulated kinase (ERK) 2 and AMPA receptor at GluR1 were also upregulated in the NAc after 7 days of KET treatment. These results imply the potential action of KET in modulating and converging both dopaminergic and glutamatergic neural transmission in the NAc at a sub-anesthesia dose. The enhanced GluR1 phosphorylation may represent a possible long-term potentiation (LTP) in accumbal synaptic strength contributing to addiction learning. The functional aspect of these signal changes in KET sensitization is currently under investigation to elucidate the neuroplasticity underlying KET addiction.

Title: Expression of Perineuronal Nets in the cerebellum after Prelimbic lesions in rats trained to acquire conditioned preference towards cocaine-related cues

Authors: *I. GIL MIRAVET[1,2], M. CARBO-GAS[1], C. SANCHIS-SEGURA[1], D. CARULLI[2], M. MIQUEL[1];
[1]Psychobiology, Univ. Jaume I, Castellon, Spain; [2]Dept. of Neurosci. Rita Levi-Montalcini. NICO, Universiti of Turin, Turin, Italy

Abstract: Pavlovian conditioning tunes the motivational drive for drug-associated stimuli, fostering the probability of those environmental stimuli to promote and trigger drug seeking and taking. The permanent capability of these cues to trigger drug consumption derives from an over-consolidation of such drug-dependent Pavlovian memories. Growing evidence supports that reorganization of the prefronto-striatal-limbic networks underpins storage of these drug-induced memories. For years, the cerebellum has been a neglected region in brain circuits holding these long-lasting drug-related memories. This is surprising because several decades of research have demonstrated that prefrontal-cerebellar loops are strongly compromised in drug addiction. Moreover, clinical data suggest that lesions and pathological conditions reorganize functions of the prefrontal-cerebellar circuitry. Recently, we have found two cerebellar hallmark signatures of conditioned preference for cocaine: an increase in cFOS expression in cells at the apex of the granule cell layer as well as strong expression of the perineuronal nets (PNNs) surrounding Golgi interneurons at the same region of the cerebellar vermis. No one of these cerebellar features was seen if mice did not develop preference for the cocaine-related cue. The present study aimed to evaluate the effects of prelimbic deactivations on the acquisition of cocaine-induced conditioned preference as well as on the expression of PNNs in the cerebellar vermis. Rats were infused with

6% lidocaine (1microl/2min) ten minutes before conditioning. Remarkably, the results indicated that deactivation of the prelímbic cortex increases up to 100% the percentage of animals acquiring conditioned preference for cocaine as compared to the control group (sham). Golgi interneurons of the prelimbic lesion group expressed stronger intensity of wisteria floribunda agglutinin labelling (WFA) than the sham group, pointing to stronger PNNs. Our findings suggest that prelimbic lesions promote the acquisition of cocaine-induced cue-related memories and the development of those cerebellar hallmark signatures associated with such memories.

Title: The effects of chronic adolescent toluene on behavioral flexibility and intrinsic excitability of mPFC neurons

Authors: *K. M. BRAUNSCHEIDEL[1], B. H. EATON[2], P. A. ZAMUDIO-BULCOCK[2], J. T. GASS[1], J. J. WOODWARD[1];
[1]Neurosci., [2]Psychiatry and Behavioral Sciences, Addiction Sci. Div., Med. Univ. of South Carolina, Charleston, SC

Abstract: Psychoactive inhalants such as toluene induce changes in neural connectivity, electrophysiology, and behavior that are similar to those produced by classic drugs of abuse. Toluene and other abused inhalants are predominantly used by adolescents, and exposure to these compounds may contribute to behavioral problems associated with drug use such as compulsivity and reduced executive control. While use of volatile solvents is associated with deficits in fronto-cortical dependent behaviors in humans, studies of solvents using well-validated animal models of behavioral flexibility are lacking. To address this issue, we treated male, adolescent Sprague-Dawley rats (P39 at first exposure) to ten minute, twice daily exposures to toluene (~5400PPM) for five consecutive days. After reaching adulthood (P60) rats were trained in operant boxes to lever-press in response to a light cue for 20% sweetened condensed milk. We then tested behavioral flexibility using an attentional set-shifting task followed by a reversal learning task. As predicted, rats that experienced chronic toluene exposure during adolescence took longer to learn the initial reward contingencies during training. Surprisingly however, the toluene exposed group reached criteria in significantly fewer trials

compared to air treated controls during the set-shifting task, a result driven by a marked reduction in perseverative errors. There were no significant differences between the two groups during the reversal learning task. Lesion and pharmacological studies have identified two subdivisions of the frontal cortex, the medial prefrontal cortex (mPFC) and orbital frontal cortex (OFC), as regions responsible for attentional set-shifting and reversal learning, respectively. We thus hypothesized that the behavioral alterations observed in toluene treated rats could be due to altered mPFC neuron electrophysiology and dendritic spine morphology. To test this idea, we performed current-clamp electrophysiology and spine imaging on separate cohorts of adult animals treated with toluene vapor during adolescence. To date, results from electrophysiology experiments reveal that chronic adolescent toluene exposure enhances measures of excitability including a hyperpolarized action potential threshold and reduced after hyperpolarization potential. These data suggest that toluene selectively alters mPFC-dependent behavior, which could be a result of enhanced neuronal excitability in this region. Understanding the effects of chronic adolescent toluene could provide further insight into the neural basis of both drug addiction and behavioral flexibility Supported by NIDA R01 DA013951.

Title: Neuronal activity in the orbitofrontal cortex predicts cocaine choices and preferences in addicted rats

Authors: *K. GUILLEM[1,2], S. H. AHMED[1,2];
[1]Univ. De Bordeaux, Bordeaux Cedex, France; [2]CNRS, Bordeaux Cedex, France

Abstract: Human neuroimaging research has consistently shown that cocaine addiction is associated with structural and functional changes within the orbitofrontal cortex (OFC). In view

of the important role of the OFC in value-based decision-making, these changes have been hypothesised to bias choice towards cocaine despite and at the expense of other competing pursuits, thereby explaining cocaine addiction. Here we report for the first time direct evidence for this hypothesis in a choice-based model of cocaine addiction where rats could choose between two actions, one rewarded by cocaine, the other by a nondrug alternative. Briefly, we used *in vivo* electrophysiology to record the neuronal correlates of individual choices and preferences in a minority of cocaine-preferring rats versus a majority of non-drug preferring rats. We first assessed action-coding selectivity of OFC neurons and then followed their firing activity before and during choice. We found that the relative proportion of OFC neurons encoding the cocaine-rewarded action versus the alternative action matched individual preferences. Specifically, in cocaine-preferring rats, the proportion of neurons encoding the cocaine-rewarded action was larger than that encoding the alternative action (38 versus 31%), while it was the opposite in nondrug-preferring rats (22 versus 53%). Moreover, pre-choice relative firing activity of both functional populations of neurons predicted several seconds in advance what animals will eventually prefer. Finally, to assess causality, we conducted a pharmacological intervention known to shift choices toward cocaine in the majority of nondrug-preferring rats. This induced reversal in preference was associated with a dramatic reversal of the predictive neuronal correlates of preference, mostly due to an overall and relatively selective suppression of firing activity in OFC neurons encoding the alternative action. Overall, this study demonstrates that OFC neurons play a critical role in influencing cocaine choices and preferences in addicted rats.

Title: New street drugs block NMDA receptor mediated synaptic excitation

Authors: *H. KANG[1], Z. A. BORTOLOTTO[2], S. LIGHTMAN[2], G. L. COLLINGRIDGE[2], J. WALLACH[3], S. D. BRANDT[3], D. LODGE[2];
[1]Med. and Dent., [2]Univ. of Bristol, Bristol, United Kingdom; [3]Liverpool John Moores Univ., Liverpool, United Kingdom

Abstract: Dissociative anaesthetics, such as ketamine and phencyclidine, induce a range of psychoactive effects in humans, and have been widely used as street drugs for recreational purposes. Since these drugs have been placed under legislative control, new designer drugs

related to diphenidine have appeared and have been associated with similar perceptual effects. In addition, intoxication has been reported to produce hypertension, confusion and psychosis as well as casualties. Beside diphenidine (DPH) itself, several derivatives including the 2-chloro (2-Cl-DPH) and 3-methoxy (3-MeO-DPH) are known and may, like ketamine, have N-methyl-D-aspartate (NMDA) receptor antagonist activity. To investigate the potential NMDA receptor antagonist properties of these three new street drugs, we have compared their actions with those of standard channel blockers, ketamine, memantine and dizocilpine (MK-801). Using adult rat hippocampal slices, isolated NMDA receptor-mediated field excitatory postsynaptic potentials (NMDAR-fEPSPs) were recorded from CA1 neurons following Schaffer collateral - commissural stimulation. DPH, 2-Cl-DPH and 3-MeO-DPH (all at 10 μM) like ketamine and memantine (10 μM) and MK-801 (0.3 μM) inhibited NMDAR-fEPSPs to a similar extent (70-90%). However, the time course of the inhibition was different. Ketamine reached a near plateau response in 2 h whereas fEPSPs decreased more slowly with all the other drugs, requiring some 5 h to reach near maximal effects. Interestingly, ketamine 1, 5 and 10 μM inhibited the NMDAR-fEPSP in a dose dependent manner, each concentration producing both a different rate of onset and a different maximum inhibition, whereas with 2-Cl-DPH, 1 μM the time course was notably longer than with 10 μM, requiring 10 hours but reached a similar maximal effect. In conclusion, these new DPH-related street drugs are effective blockers of NMDA receptor mediated synaptic transmission in the hippocampus.

Title: Menthol attenuates respiratory irritation responses to cigarette smoke and oral nicotine aversion in C57BL/6 mice: Role of TRPM8

Authors: *S. E. JORDT[1,2], S. BALAKRISHNA[2], L. FAN[2], A. I. CACERES[1], Y.-S. LIU[3], M. A. HA[4], G. J. SMITH[4], J. A. CICHOCKI[4], M. R. PICCIOTTO[2], J. B. MORRIS[4];
[1]Anesthesiol., Duke Univ., Durham, NC; [2]Tobacco Ctr. of Regulatory Science, Psychiatry, [3]Pharmacol., Yale Univ., New Haven, CT; [4]Pharmaceut. Sci., Univ. of Connecticut, Storrs, CT

Abstract: Addition of menthol to cigarettes may be associated with increased initiation of smoking, however, the mechanisms underlying this association are not known. Menthol, possibly through its effects on TRPM8 ion channels in cold-sensing peripheral sensory neurons, is known to inhibit the sensation of irritation elicited by respiratory irritants activating TRPA1, TRPV1 and other chemosensory irritant receptors. However, it remains unclear whether menthol modulates cigarette smoke irritancy and nicotine absorption during initial exposures to cigarettes, thereby facilitating smoking initiation. Using plethysmography in a C57Bl/6J mouse model, we examined the effects of L-menthol, the menthol isomer added to cigarettes, on the respiratory sensory irritation response to primary smoke irritants (acrolein and cyclohexanone) and smoke of reference cigarettes. We studied L-menthol's effect on blood levels of the nicotine metabolite, cotinine, immediately after exposure to cigarette smoke. We also examined the effects of menthol on oral nicotine aversion in mice in the two bottle drinking paradigm. L-menthol suppressed the irritation response to acrolein with an apparent IC50 of 4 ppm. Suppression was observed even at acrolein levels well above those necessary to produce a maximal response. Respiratory irritation caused by cigarette smoke was significantly suppressed by L-menthol even at smoke concentrations as high as 300 mg/m3. L-menthol's effects were abolished by treatment with a selective inhibitor of TRPM8, the neuronal cold/menthol receptor. Inclusion of menthol in the cigarette smoke resulted in a ~1.5-fold increase in plasma cotinine levels over those observed in mice exposed to smoke without added menthol. In the two bottle drinking paradigm addition of menthol reduced oral aversion to nicotine. This effect was reversed in Trpm8-deficient mice which showed an aversion to mentholated solutions. These findings document that, L-menthol, through TRPM8, is a strong suppressor of respiratory irritation responses, even during highly noxious exposures to cigarette smoke or smoke irritants, and increases blood cotinine. In addition to its effects on respiratory irritant sensing, menthol also suppressed aversion to oral nicotine, known for its irritating effects and bitter taste. The data suggest that L-menthol, as a cigarette additive, may promote smoking initiation and nicotine addiction.These effects may extend to other tobacco products, including electronic cigarettes and smokeless tobacco products.

Title: Protein Kinase C epsilon inhibitors as potential new therapeutics for alcohol use disorder

Authors: *A. BLASIO[1], D. WANG[2], R. O. MESSING[1,2];
[1]Univ. of Texas At Austin Col. of Pharm., Austin, TX; [2]Univ. of California, San Francisco, CA

Abstract: Although alcohol use disorder is a major public health problem worldwide, only three drugs have been approved by the FDA for treatment: Disulfuram, Naltrexone and Acamprosate. Our previous studies have provided strong evidence that the enzyme protein kinase C epsilon (PKCepsilon) promotes ethanol consumption and reward. We recently identified a lead compound derived from the commercially available Rho-associated coiled-coil forming protein kinase (ROCK) inhibitor Y-27632, which also inhibits PKCepsilon. This compound (named 12.0) and 3 analogs inhibited PKCepsilon with *K*i < 20 nM. All four compounds weakly inhibited conventional PKCgamma at 10 μM, while 2 compounds (12.3 and 12.7) showed almost no activity against atypical PKCzeta at that high concentration. All inhibited the highly related novel PKCs, PKCdelta and PKCteta, but showed some selectivity within the novel PKC subfamily being ~ 6 to 10-fold less potent in inhibiting PKCdelta and PKCteta than PKCepsilon. Two compounds (12.0 and 12.7) were screened against a panel of 395 non-mutant kinases using a binding competition assay (KINOMEscan™ Profiling Service from DiscoverRx) at a concentration of 200 nM. Both were potent and selective. Only twelve other kinases besides PKCepsilon were inhibited to <35% of control activity by these compounds and among these, only ROCK1 and ROCK2 were inhibited to less than 1% of control. A pharmacokinetic study with 12.0 (20 mg/kg) showed that it enters the brain and achieves a brain/plasma ratio of 0.53 at 4 hours, with a brain half-life of ~15.11 hours. We tested the ability of 2 compounds to reduce ethanol consumption in C57BL/6J mice using an intermittent access, two-bottle choice procedure. We administered the compounds using a within-subject, Latin square design (0, 10, 20 and 40mg/kg, *i.p.*). Compounds 12.0 and 12.3 dose-dependently reduced voluntary ethanol consumption. Other parameters such as water intake and food intake were not affected suggesting that 12.0 and 12.3 are well tolerated. Studies of conditioned place preference, taste preference and locomotor activity are ongoing.

Title: Combined use of acamprosate and escitalopram reduces ethanol consumption in chronically stressed mice

Authors: *M. HO[1], D. J. HINTON[1], J. R. AYERS-RINGLER[1], A. OLIVEROS[1], V. M. KARPYAK[2], D.-S. CHOI[1];
[1]Mol. Pharmacol. and Exptl. Therapeut., [2]Pyshicatry, Mayo Clin., Rochester, MN

Abstract: Depression is a common psychiatric comorbidity of alcoholism which poses major risk to relapse even under treatment. Acamprosate and escitalopram are FDA-approved antidipsotropic agent and antidepressant respectively, but their combined effect on drinking and depression symptoms had not been thoroughly studied. This study aims at investigating whether the combined use of these medications will reduce ethanol consumption and improve depressive-like symptoms in chronically stressed mice. 8-week-old C56BL/6 mice (n = 20) were individually housed and subjected to chronic unpredictable stress paradigm. The stress paradigm consisted of daily exposure to one of the three stresses (forced swim, social defeat and restrain stress) in random order and time. Another group of mice (n = 20; non-stress controls) remained group-housed and were subjected only to normal handling. After 3 weeks of stress, stressed mice demonstrated significantly longer immobility time in forced swim test compared to non-stressed mice (t test $p < 0.05$), indicating a higher degree of hopelessness. All mice were trained for a week to consume 15% ethanol in a two-bottle choice drinking (tap water vs ethanol in tap water) in dark with 2-hour limited access starting from the third hour into the dark phase. In the following week, each stress group were further divided into 4 drug subgroups (n = 5): saline, 200mg/kg acamprosate, 5mg/kg escitalopram and the combination of both were administrated i.p. twice daily (12 hours apart), with one of the injection just preceded the two-bottle choice drinking test under the same setting as training. In stressed mice, only the subgroup administered with the combination of acamprosate and escitalopram showed significantly lower ethanol consumption compared to control; while in non-stressed mice, all drug groups showed significantly lower ethanol consumption (one-way ANOVA $p < 0.05$). At the end of the drug administration week, forced swim test was performed. Stressed mice continued to display longer immobility time than non-stressed mice, but no significant difference was observed among drug subgroups. These results suggest that while both sole and combined administration of acamprosate and escitalopram can reduce binge ethanol consumption in non-stressed mice, only the combined administration is effective in chronically stressed mice, indicating that targeting both glutamatergic and serotoninergic systems simultaneously may be needed for suppressing alcohol consumption in depressed alcoholic individuals.

Title: Ceftriaxone attenuates ethanol drinking and restores extracellular glutamate level through normalization of GLT-1 in nucleus accumbens of male alcohol-preferring rats

Authors: *S. DAS;
Medicinal and Biol. Chem., The Univ. of Toledo, Toledo, OH

Abstract: Alteration of glutamatergic-neurotransmission is a hallmark of alcohol dependence. We have previously reported that chronic ethanol-drinking downregulated glutamate transporter 1 (GLT-1) in nucleus accumbens (NAc) in male P rats in a manner that was reversed by ceftriaxone treatment. However, the effect of ceftriaxone on extracellular glutamate concentrations in NAc after chronic ethanol-drinking has not yet been studied. In the present study, male P rats were treated with ceftriaxone (100 mg/kg/day, i.p.) for five consecutive days following five-weeks of free choice ethanol (15% and 30%) drinking. *In vivo* microdialysis was performed to measure the extracellular glutamate concentrations in NAc and the effect of blockade of GLT-1 with dihydrokainic acid (DHK) on extracellular glutamate in NAc of ceftriaxone-treated rats was determined. Ceftriaxone treatment attenuated ethanol intake as well as ethanol preference. Extracellular glutamate was significantly higher in NAc after five-weeks of ethanol drinking in saline-treated compared to water control rats. Ceftriaxone treatment blocked the increase extracellular glutamate produced by ethanol intake. Blockade of GLT-1 by DHK reversed the effects of ceftriaxone on glutamate and implicated the role of GLT-1 in the normalization of extracellular glutamate by ceftriaxone. In addition, GLT-1 protein was decreased in ethanol exposed animals and ceftriaxone treatment reversed this deficit. Ceftriaxone treatment also increased glutamine synthetase activity in NAc as compared to ethanol drinking saline-treated rats. Our present study demonstrates that ceftriaxone treatment prevents ethanol drinking in part through normalization of extracellular glutamate concentrations in NAc of male P rats via GLT-1. **Keywords:** Alcohol abuse; GLT-1; no-net-flux microdialysis; ceftriaxone; dihydrokainic acid.

Title: Effect of acute injection of methylphenidate (Ritalin) and its combination with morphine on behavior of male rats prenatally exposed to methamphetamine

Authors: *K. NOHEJLOVA, A. YAMAMOTOVA, R. SLAMBEROVA;
Charles Univ. in Prague/ Third Fac. of Med., Prague, Czech Republic

Abstract: Psychostimulant methylphenidate hydrochloride (Ritalin) is used for treatment of attention deficit hyperactivity disorder. It has a chemical structure closely related to the structure of methamphetamine. In the brain it blocks the reuptake of the catecholamines, including dopamine, via binding to its transporter. As a result, amount of available dopamine increases. Dopamine thereafter modulates activity of neuronal system in prefrontal cortex, affecting regulation of cognitive performance and also motor function. The first aim of our study was to compare effect of two doses of Ritalin (1 and 5 mg/kg) on spontaneous behavior in adult male rats prenatally exposed to methamphetamine (MA). The second aim was to analyze further possible changes in behavior when Ritalin is applied in combination with same doses of morphine (MOR). Spontaneous behavior was analyzed using LABORAS system (Metris, The Netherlands). Following parameters were evaluated: locomotion, rearing, average speed of movement and distance moved. Adult male Wistar rats prenatally exposes either to MA or, as control, to saline (Sa) were used in experiment. In the first set of experiments animals received Ritalin in the dose of 1 and 5 mg/kg prior to introduction to LABORAS, where they spent one hour. In the second set, animals received Ritalin with same dose of morphine (Ritalin + MOR at the doses 1 mg/kg; and Ritalin + MOR at the doses 5 mg/kg). Results: (1) higher dose of Ritalin (5 mg/kg) increased animals performance in all of the followed parameters, except of distance moved, regardless prenatal treatment. Bothe doses of Ritalin had more prominent effect in prenatally Sa exposed animals compared to MA exposed ones. Animals prenatally exposed to MA, which received low dose of Ritalin (1 mg/kg) had lowest activity expressed by all parameters. (2) Animals prenatally exposed to Sa, which received higher dose of Ritalin and MOR (5 mg/kg) combination had the highest activity expressed by increase in all parameters. Contrary, animals that were treated with higher doses of Ritalin and MOR, which were prenatally exposed to MA, had the lowest activity. Summarizing, the study suggests that low doses of Ritalin decrease activity in subjects with prenatal to another psychostimulant, while higher dose have opposite effect regardless of prenatal exposure. In addition, it seems that prenatal exposure to Sa in control group had sensitizing effect to psychostimulant, while prenatal exposure to MA had sensitizing effect to morphine. Title: Acute treatment with methylphenidate (Ritalin) modulates morphine antinociception in rats depending on the dose and tested body site

Authors: *A. YAMAMOTOVA, K. NOHEJLOVA, R. SLAMBEROVA;
Charles Univ, 3rd Fac Med., Prague, Czech Republic

Abstract: Methylphenidate hydrochloride (MPH) is a stimulant drug used for attention deficit hyperactivity disorder treatment and less frequently for management of cancer-related fatigue and sedation. MPH blocks the reuptake of the catecholamines dopamine and noradrenalin by binding to the transporters, thereby increasing catecholamine availability. Noradrenalin acting on noradrenergic receptors can either facilitate or inhibit pain depending on the supraspinal site of release and the type of adrenoceptor activated. The aim of our study was to compare antinociceptive effect of MPH and its combination with morphine (MOR). Antinociceptive effects of MPH and MOR in adult male Wistar rats were investigated by means of withdrawal latency in the plantar test (Ugo Basile, Italy) after single administration of MPH (1 mg/kg or 5 mg/kg s.c.), MOR (1 mg/kg or 5 mg/kg s.c) or their combination. Latencies of withdrawal reflexes of hind limbs and the tail were repeatedly measured before injection of drugs and then three additional times with 15-min intertrial intervals. The percent of the maximal analgesic response defined as (test latency−baseline latency)/(cut-off time−baseline latency)×100% was calculated for each rat on both nociception tasks. On the tail, both doses of MPH were without any antinociceptive effect, whereas 5 mg/kg MPH was effective on the hind limbs. Lower dose of MPH+MOR (1 mg/kg) enhanced antinociception both in the plantar and the tail flick tests in comparison with single doses of MPH or MOR. On the other hand, higher dose of MPH+MOR (5 mg/kg) increased antinociception in the plantar test in comparison with MOR and decreased antinociception in the tail flick test in comparison with MOR. Our research supports the evidence that MPH in lower doses has the ability to enhance the analgesic properties of morphine when both types of drugs are used in combination; however in higher doses it can weaken antinociceptive potency of morphine especially at the spinal site.

Title: Morphine decreases social interaction of adult male rats, while THC does not affect it

Authors: *R. SLAMBEROVA[1], A. MIKULECKA[2], E. MACUCHOVA[1], I. HREBICKOVA[1], M. SEVCIKOVA[1], K. NOHEJLOVA[1], M. POMETLOVA[1];
[1]Charles Univ., Third Fac. Med., Prague, Czech Republic; [2]Dept. of Developmental Epileptology, Acad. of Sci. of the Czech Republic, Inst. of Physiol., Prague, Czech Republic

Abstract: Psychotropic drugs of abuse are known to have serious influence on humans' as well as animals' behavior. Both, opioids and cannabinoids were shown to affect social behavior in rodents. The aim of the present study was to compare effect of three low doses of morphine (MOR) and delta9-tetrahydrocannabinol (THC) on behavior tested by social interaction test (SIT) in adult male rats. Wistar rats were tested in low stress variant of SIT. 45 minutes prior to testing experimental animals received one of the drugs and doses: MOR (1; 2.5; 5 mg/kg) or THC (0.5; 1; 2 mg/kg). Control rats were injected with solvent (saline for MOR and ethanol for THC). Occurrence and time spent in specific patterns of social interactions (SI) and non-social activities (locomotion and rearing) was video-recorded for 5 minutes and then analyzed by ODLog software (Macropod Software). Morphine in doses of 1 and 2.5 mg/kg displayed decreased SI in total. Detailed analysis of specific patterns of SI revealed decrease in sniffing and allo-grooming after all doses of MOR, and the highest dose (5 mg/kg) of MOR decreased following and increased genital investigation. Climbing was not affected by MOR at all. Regarding to non-social activities: only lower doses of MOR (1 and 2.5 mg/kg) increased rearing activity, although walking was not affected by any of the doses of MOR. THC, in either of the tested doses, did not induce any specific changes in SI or non-social activities, which could be revealed by detailed analysis of behavior, when compared to matching control group (ethanol). However, post-analysis of behavior of the animals showed differences between all THC groups and their ethanol control group when compared to saline controls. It was lower SI in total, lower rearing, but higher sniffing and allo-grooming in THC and ethanol groups than in saline control group. Thus, it seems that this effect is more due to the ethanol than the THC per se. Based on the present results we can assume that opioids affect SI more than cannabinoid. The low tested doses of cannabinoid did not affect evaluated parameters from SIT. This outcome could be the result of ethanol masking an effect of THC.

Title: Sex differences in morphine tolerance and reward in "humanized" A118G mice

Authors: *A. HENDERSON REDMOND[1], M. B. YUILL[2], T. E. LOWE[1], M. L. ZEE[1], J. GUINDON[3], D. J. MORGAN[2];
[1]Dept. of Anesthesiol., [2]Departments of Anesthesiol. and Pharmacol., Pennsylvania State Univ. Col. of Med., Hershey, PA; [3]Dept. of Pharmacol. and Neurosci., Texas Tech. Univ. Hlth. Sci. Ctr., Lubbock, TX

Abstract: The rewarding and analgesic effects of opiates are mediated primarily by the mu-opioid receptor, of which the A118G single-nucleotide polymorphism (SNP) has the greatest link to addiction potential. Clinical and preclinical studies find the G allele associated with increases in heroin reward and self-administration. Clinically, heterozygous individuals expressing one copy of 118G allele report greater pain and reduced responsiveness to opioid drugs after surgery. Taken together, these results suggest that the G allele may confer a genetic vulnerability to opiate addiction and reward. Given the rise in the use of prescription opiates, it is important to understand how the A118G SNP may alter reward, sensitivity, and tolerance to opiates to better treat patients and to also identify those vulnerable to opiate abuse. The purpose of this study was to assess whether the A118G SNP differentially mediates responsiveness to morphine and whether these responses vary as a function of sex. Male and female mice homozygous for the "humanized" 118AA or 118GG alleles were used to test the hypothesis that 118GG mutant mice are less sensitive to the acute and rewarding effects of morphine and developed tolerance to its antinociceptive effects at a faster rate than 118AA wild-type mice. The rewarding effects of morphine were assessed using a conditioned place preference test (CPP). Sensitivity and chronic tolerance to the antinociceptive effects of morphine were examined using the tail-flick, hotplate, and formalin tests. We find that 118AA (but not 118GG) females developed CPP to morphine. While morphine tolerance was not different between 118AA and 118GG mice there was a main effect of sex driven by differences in initial sensitivity to morphine. Interestingly, a challenge dose of morphine two weeks post testing found the effects of tolerance continued to persist in female, but not in male mice. In addition, many of the sex effects observed were driven by differences between the 118AA males and 118GG females, suggesting a genotype interaction

related to sex differences. These results provide further evidence of gender-specific differences between males and females in regards to their sensitivity and tolerance responses to morphine with females exhibiting lower sensitivity to the antinociceptive effects of morphine. In particular, the 118GG females seem to show the least responsiveness to both the antinociceptive and rewarding effects of morphine. Taken together, these data suggest that female 118GG mice may need more morphine to achieve the same degree of antinociception, which could lead to increased susceptibility to opiate abuse.

Abstract: Galantamine, an acetylcholinesterase (AChE) inhibitor and positive allosteric modulator of nicotinic acetylcholine receptors (nAChRs) that has been approved for use as a cognitive enhancer in humans, has recently demonstrated potential as a smoking cessation aid in pre-clinical assays. One way galantamine might serve as an effective therapy for smoking cessation would be by producing nicotine-like effects. In the current study, a nonhuman primate model of subjective effects was used to examine the extent to which galantamine shares effects with nicotine; moreover, the relative contribution of AChE inhibition and positive allosteric modulation of nAChR to the effects of galantamine was examined. Galantamine was studied in addition to donepezil, another AChE inhibitor which has been approved for attenuation of the cognitive deficits associated with Alzheimer's disease, and PNU-120596, a positive allosteric modulator of nAChRs that produces cognitive enhancement in monkeys. Rhesus monkeys (n=5) discriminating nicotine (1.78 mg/kg calculated as the base weight) responded under a fixed ratio 5 schedule of stimulus-shock termination. Nicotine, galantamine, and donepezil dose-dependently increased nicotine-lever responding; the percentage of nicotine-lever responses was a mean of 98% at 1.78 mg/kg of nicotine, 98% at 1.78 mg/kg of galantamine, and 89% at 0.56 mg/kg of donepezil. The ED50 values (95% confidence limits) were 0.41 (0.1-1.74) mg/kg for

nicotine, 0.77 (0.46-1.28) mg/kg for galantamine, and 0.20 (0.14-0.29) mg/kg for donepezil. PNU-120596, up to a dose of 10 mg/kg, produced a maximum of 1% nicotine-lever responding. Collectively, these results suggest that AChE inhibition and direct nAChR stimulation result in overlapping subjective effects, whereas positive nAChR modulation does not appear to be sufficient to mimic the subjective effects of nicotine. Supported by USPHS Grant DA25267.

Title: Reward-based network plasticity as Bayesian inference

Authors: ***W. MAASS**, D. KAPPEL, S. HABENSCHUSS, R. LEGENSTEIN;
Graz Univ. of Technol., Graz, Austria

Abstract: Experimental data show that synaptic connections, synaptic efficacy, and tuning curves of neurons in are subject to permanently ongoing more-or-less stochastic changes, even in the absence of overt learning tasks. These data raise the question, how stable reward-based learning is possible. We show that these data can be understood from the perspective of a Bayesian learning theory, which posits that networks learn a posterior distribution of network configurations, rather than a single „optimal“ network configuration. In this theoretical framework, the experimentally observed ongoing changes in network configurations (including synaptic connections and synaptic weights) assume an important functional role: They enable the network to sample over time from a low-dimensional manifold of network configurations that have high probability under a posterior distribution of network states, thereby enabling Bayesian inference of network configurations. This posterior results from a prior that enforces structural rules of cortical networks (such as sparse connectivity, specific connection probabilities between specific types of neurons, heavy-tailed distributions of synaptic weights). The other factor of the posterior is a term that reflects the likelihood of a network configuration to lead to rewards (e.g., in the context of some motor learning task). We present a new mathematical framework (employing stochastic differential equations and Fokker-Plack equations) that creates links between local stochastic learning rules and the probability of network configurations under the posterior distribution. In particular, we show that previously proposed rules for reward-gated STDP can be derived from the more general principles of reward-based Bayesian inference of

network configurations. This new model for reward-based network plasticity is not only consistent with experimental data on ongoing stochastic changes in network configurations (in fact: requires such ongoing stochastic changes), but also offers several functional advantages over previously considered learning frameworks based on convergence of the network configuration to an optimal one: --better generalization capability (since the prior works against overfitting of network configurations to a small set of training examples) --automatic compensation for network disturbances or changes in the environment (e.g., reward distributions) --a more more goal-oriented exploration of new network configurations in reward-based learning.

Title: Modelling methamphetamine psychosis in mice: role of BDNF and reelin

Authors: *M. VAN DEN BUUSE[1], E. E. MANNING[2];
[1]La Trobe Univ., Bundoora, Melbourne, Australia; [2]Florey Inst. of Neurosci. and Mental Hlth., University of Melbourne, Australia

Abstract: The abuse of methamphetamine (METH a.k.a. ice or crystal meth) has reached near-epidemic proportions worldwide. Abuse is particularly prevalent among young adults. METH abuse is associated with a heavy burden on the health care and criminal justice system. Among regular METH users, the prevalence of psychosis is 11 times higher than in the general population. This psychosis closely resembles paranoid schizophrenia with persecution delusions, auditory and visual hallucinations, and social withdrawal. Late adolescence may be a period of particular developmental vulnerability. However, the brain mechanisms involved in vulnerability to methamphetamine psychosis and their overlap with those involved in schizophrenia, remain unresolved. We developed an animal model of methamphetamine abuse and psychosis where mice are treated chronically during late adolescence/young adulthood. The animals receive escalating doses of methamphetamine when they are 6, 7 and 8 weeks of age and the behavioural effects of this chronic 'binge'-like protocol are assessed in adulthood in a range of tests relevant for psychosis-like behaviour, sensorimotor gating, learning and memory, and social behaviour. Because several studies have shown that levels of brain-derived neurotrophic factor (BDNF) and

reelin are reduced by about 50% in post-mortem brain samples from patients with schizophrenia, we used BDNF- and reelin heterozygous mice. BDNF heterozygous mice showed significantly greater sensitization to METH than wildtype control mice and showed selected deficits in social behaviour and spatial memory (Manning & van den Buuse, in preparation). In contrast, after a METH challenge dose, METH-pretreated reelin heterozygous mice tended to show less hyperactivity than similarly pretreated wildtype controls, suggesting a protective effect of partial reelin depletion although male METH-treated reelin heterozygous mice displayed reduced short-term spatial memory. Anxiety was increased in both METH-treated mice controls and reelin heterozygous mice but no differences were found for prepulse inhibition, a measure of sensorimotor gating. These preliminary results reveal involvement of BDNF and reelin in selected behavioural changes in a mouse model of METH abuse and psychosis.

Title: Modelling the consequences of recreational use of MDMA or 5-MeO-DIPT in humans using a weekend 'rave' exposures

Authors: *F. LUETZENBERG, E. WATKINS, D. M. COMPTON;
Psychology, Palm Beach Atlantic Univ., West Palm Beach, FL

Abstract: Previous research has supported the position that the hallucinogenic "club drugs" 3,4-methylenedioxymethamphetamine (MDMA) and 5-methoxy-N,N-diisopropyltryptamine hydrochloride (Foxy), albeit to different degrees, remain popular as recreational drugs. Much is known about MDMA including observations that in comparison to female rodents, males appear to be more sensitive to the toxic effects associated with abuse. Conversely, less is known about the possible sex differences associated with the abuse of Foxy, especially when the consequences of its use are examined during the neuropsychological development period of adolescence. In the present study, beginning at 35 days of age male and female rats were given multiple doses of MDMA, Foxy (5 mg/kg), or saline across a 48 hour "weekend" under conditions approximating that of a rave. Behavioral testing occurred in adulthood when the rats were 131 days old and had been drug free for 66 days. Assessments included general activity, stepdown passive avoidance, and a series of Morris water maze spatial and nonspatial memory tasks. Depending on task demands, the performance of MDMA-treated rats was inferior to that of the Foxy-treated rats

and saline controls. The performance of both drug groups was comparable and inferior to that of control rats on a spatial learning set task. Generally, greater impairments were observed in MDMA-treated rats than the Foxy-treated rats. Last, sex differences were observed on some but not all spatial tasks with MDMA-treated males performing significantly worse than similarly treated female rats. The results will be discussed in the context of putative sex-mediated differences in sensitivity to MDMA or Foxy. In addition, the disruptive effects of these drugs to central serotonergic systems during adolescence that may contribute to cognitive deficits and maladaptive behavior will be explored.

Abstract: Methoxetamine (MXE) is a new ketamine derivative synthetic drug, acting as an N-methyl-D-aspartate receptor antagonist. Recently, there have been many reports regarding its misuse in humans that have led to serious or even fatal consequences. Despite these reports, MXE is not regulated in many countries, which may be partly due to the lack of scientific evidence regarding its abuse potential. In the present study, we aimed to evaluate the abuse potential (rewarding and reinforcing effects) of MXE through the conditioned place preference (CPP) and self-administration (SA) tests in Sprague-Dawley rats. In addition, locomotor activity during the conditioning phase of the CPP was also analyzed. Ketamine was used as a reference drug. MXE (2.5 and 5 mg/kg) induced significant CPP in rats, an effect comparable to that of ketamine (5 mg/kg). Interestingly, MXE did not produce any locomotor alterations whereas ketamine decreased the locomotor activity of the rats. In the SA test, the rats showed modest self-administration of MXE (0.25, 0.5, 1.0 mg/kg/infusion), while ketamine (0.5 mg/kg/infusion) was robustly self-administered. These results demonstrate that MXE, similar to ketamine, has rewarding and reinforcing effects in rats, suggesting that the drug has a potential for human

abuse. Furthermore, the discrepant effects of MXE and ketamine in locomotor activity and self-administration rates propose that the psychopharmacological effects of these drugs may diverge in some aspects. More importantly, this study advocates the careful monitoring and prompt regulation of MXE and its related substances.

Title: Opposing effects of group I mGluRs on dendritic spine density in the rat nucleus accumbens

Authors: *K. GROSS, R. L. MEISEL, P. G. MERMELSTEIN;
Univ. of Minnesota, Minneapolis, MN

Abstract: The group I mGluRs, mGluR1a and mGluR5, are involved in the development and expression of drug addiction. Manipulation of group I mGluR activity can attenuate behavioral sensitization to drugs of abuse, drug seeking behaviors in models of self-administration, and conditioned place preference, suggesting that modulation of these receptors is a possible avenue for therapeutic treatment. Group I mGluR activity affects both neuronal structure and function in the nucleus accumbens (NAc), which likely plays a role in their effect on addictive behavior. In particular, mGluR5 activity has been associated with synapse elimination in the NAc; however, the role of mGluR1a in structural plasticity in this region is less clear. We sought to compare the effects of mGluR1a versus mGluR5 activation on structural plasticity in the NAc. Rats were given a systemic injection of an mGluR5 positive allosteric modulator (PAM), CDPPB, an mGluR1 PAM, SYN119, or vehicle and were then sacrificed 24 hours later. Neurons in the NAc were ballistically labeled with DiI, and spine densities were determined. Our data revealed an interesting bidirectional effect on spine density, with activation of mGluR5 by CDPPB resulting in decreased dendritic spine density in both the core and shell of the NAc, but mGluR1a activation by SYN119 increasing dendritic spine density in both of these subregions. While changes in spine density were measured 24 hours after drug administration, changes in actin binding proteins and their regulators were observed on a more rapid timescale. These data suggest that positive modulation of different group I mGluRs results in activation of opposing

signaling pathways in the NAc that lead to bidirectional effects on cytoskeletal regulation and dendritic spine density.

Title: Estradiol facilitation of extended access cocaine self administration in female rats requires activation of mGluR5

Authors: *L. A. MARTINEZ, B. M. PETERSON, P. G. MERMELSTEIN;
Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Females exhibit enhanced responsiveness to the addictive properties of cocaine and several other drugs of abuse. The underlying neural mechanisms that produce this heightened response are not well understood. We have recently found that estradiol decreases dendritic spine density in the core of the female nucleus accumbens, with subsequent enhancement of behavioral sensitization to cocaine, through activation of the metabotropic glutamate receptor mGluR5. The present experiment sought to determine whether mGluR5 activation is also required for the facilitative effects of estradiol on cocaine self administration. To test this hypothesis, ovariectomized female rats treated with estradiol on a 2 days on, 2 days off schedule were initially trained to self administer sucrose pellets (FR1 schedule). Females were then removed from estradiol treatment, implanted with IV catheters, and trained to self administer cocaine (1.5 mg/kg/inf; FR1 schedule). At the completion of cocaine training, females were again restarted on the 2 days on, 2 days off schedule with either oil or estradiol, but with the additional injection of either the mGluR5 antagonist MPEP or vehicle 30 minutes prior to hormone injections. Extended access to cocaine self administration was for 10 days (1.5 mg/kg/inf; 6 hrs per day, FR1 schedule). Females treated with estradiol had significantly higher average daily infusions of cocaine across the 10 days of extended access compared to oil- treated females. This effect of estradiol was completely blocked by MPEP treatment. Furthermore, MPEP treatment alone had no effect on self administration. These data indicate that mGluR5 signaling may be a critical mechanism linking estradiol to enhanced addictive responses in females.

Title: In female rat nucleus accumbens, the endocannabinoid system mediates the effects of estradiol on psychostimulant responses and structural plasticity

Authors: *B. PETERSON[1], L. A. MARTINEZ[1], E. LEISHMAN[2], H. B. BRADSHAW[2], R. L. MEISEL[1], P. G. MERMELSTEIN[1];
[1]Neurosci. Dept, Univ. of Minnesota, Minneapolis, MN; [2]Physiological and Brain Sci., Indiana Univ., Bloomington, IN

Abstract: Estradiol potentiates psychostimulant responses in females, yet the underlying neurobiological mechanisms remain a mystery. Recently our lab has demonstrated that in female rats, the facilitatory effect of estradiol on cocaine-induced locomotor sensitization required activation the metabotropic glutamate receptor mGluR5, and the cannabinoid receptor CB1R. To search for neurobiological underpinnings to these behavioral effects of estradiol, we investigated structural plasticity within the nucleus accumbens (NAc) core. Similar to the observations regarding locomotor sensitization, pretreatment with the mGluR5 antagonist, MPEP (1mg/kg), blocked estradiol-mediated decreases in nucleus accumbens (NAc) core dendritic spine density. In addition, we demonstrate that the estradiol-mediated decrease in dendritic spine density is attenuated by pretreatment with the CB1R inverse agonist, AM251 (1mg/kg). Collectively our data suggest that the effects of estradiol on psychostimulant behavioral responses and NAc core structure require activation of both mGluR5 and CB1R. These data support our model wherein estradiol binds membrane-localized ERα to transactivate mGluR5 in the female rat striatum, leading to CB1R activation. Experiments are currently underway to definitively determine whether estradiol activation of mGluR5 directly mobilizes endogenous cannabinoids (endoCBs) within the NAc.

Title: VTA kappa opioid receptor modulation of aversion-induced reductions in dopamine and punishment

Authors: *M. A. ROBBLE, D. S. WHEELER, R. A. WHEELER;
Marquette Univ., Milwaukee, WI

Abstract: Adaptive responses to rewarding and aversive environmental events are critical to survival. Rewarding stimuli and their predictors reliably increase nucleus accumbens (NAc) dopamine signaling which promotes reward based learning. However, less is understood about the involvement of NAc dopamine in aversion learning, and the neural systems that modulate it. Studies monitoring subsecond dopamine release in the NAc have shown that aversive stimuli and their predictors decrease dopamine signaling, and it has been proposed that such reductions are a critical modulator of action selection that promotes avoidance learning. Kappa opioid receptors are expressed on the cell bodies of midbrain dopamine neurons in the ventral tegmental area (VTA), and their activation mediates the anhedonic and dysphoric component of drug withdrawal and other aversion states. Correspondingly, kappa opioid receptor activation has been shown to reduce electrically evoked dopamine release in a NAc slice preparation. Here we examined the neurochemical and behavioral relevance of VTA kappa opioid receptor activation by an aversive stimulus. First, we used fast scan cyclic voltammetry in awake and behaving rats to monitor terminal dopamine release in the nucleus accumbens shell. Following recovery from surgery, rats received intra-VTA infusions of Nor-binaltorphimine (Nor-BNI), a kappa opioid receptor antagonist, or vehicle 24 hours prior to a recording session. During the recording session, carbon fiber microelectrode position in the NAc shell was determined by the observation of spontaneous dopamine transients. Once a suitable recording environment was found, 20 consecutive one minute recordings were taken and served as a baseline. Rats then received 30 intraoral infusions of quinine (0.2ml/infusion, 1inf/min), an aversive tastant, over a 30 minute period. All quinine infusions were recorded with a video camera for subsequent taste reactivity scoring. Passive intraoral infusions of quinine reliably decreased nucleus accumbens dopamine release, and this effect was attenuated by bilateral intra-VTA administration of Nor-BNI. Further analyses of taste reactivity will determine whether Nor-BNI alters the hedonic value of quinine. These results indicate that aversive stimuli decrease nucleus accumbens dopamine signaling, in part, through activation of VTA kappa opioid receptors. Current studies are underway to examine whether VTA kappa opioid receptors mediate the ability of quinine to serve as a punisher in an operant sucrose seeking task.

Title: Extended Amygdala PACAP in the behavioral stress response

Authors: ***M. SEIGLIE**, A. IEMOLO, P. COTTONE, V. SABINO;
Dept. of Pharmacol. and Psychiatry, Boston Univ. Sch. of Med., Boston, MA

Abstract: Anxiety-related disorders are the most common forms of mental disorders; characterized by feelings of excessive worry in the absence of specific external stimuli, they are accompanied by physical, affective and behavioral symptoms. Pituitary adenylate cyclase-activating polypeptide (PACAP) is a 38-amino acid peptide expressed not only in the hypothalamus but also in various extra-hypothalamic regions including the extended amygdala. PACAP and PAC1 receptor (PAC1R) have been proposed to play a key role in mediating the behavioral and endocrine responses to stress; however, few studies have examined the involvement of the extrahypothalamic PACAP system in the modulation of stress. Our aim was to elucidate the role of the PACAP/PAC1R system of the central nucleus of the amygdala (CeA) and the bed nucleus of the stria terminalis (BNST) in the context of anxiety-like behaviors. The effects of PACAP microinfusion into either the CeA or the BNST of male rats was assessed in the acoustic startle response (ASR), a behavioral test sensitive to states of anxiety and fear. To test the functional relevance of the endogenous system, the effects of intra-CeA and intra-BNST PACAP antagonist PACAP(6-38) on ASR were assessed, as well as on footshock-induced sensitization of ASR. Infusion of PACAP into both the CeA and BNST increased ASR. Importantly, doses of the antagonist PACAP(6-38) which per se did not affect ASR, were able to prevent the sensitization of ASR by footshock, when infused into both the CeA and BNST. The effects of acute stressors on the expression of PACAP and PAC1R in these brain areas is currently being investigated using immunohistochemistry and real-time PCR. These data prove an anxiogenic role for the PACAP/PAC1 system of the extended amygdala and suggest that hyperactivity of this system may underlie the anxiogenic effects of stress.

Title: Enhanced motor learning by injecting corticotrophin releasing factor to the cerebellum

Authors: *E. TAKEUCHI[1], M. HIRAISHI[2], A. KATOH[1];
[1]Inst. of Innovative Science, Tokai Univ., Hiratsuka, Kanagawa, Japan; [2]Applied Biochemistry, Sch. of Engin., Tokai Univ., Kanagawa, Japan

Abstract: Corticotropin releasing factor (CRF) is a 41-amino acid peptide. It is secreted from the hypothalamic paraventricular nuclei and regulates the release of adrenocorticotropic hormone. CRF is known to play crucial roles in stress related responses through the hypothalamic-pituitary-adrenal axis and recent studies reported that CRF acts as a neurotransmitter throughout the central nervous system as well. For example, CRF is essential for the induction of long-term depression (LTD) at the parallel fiber - Purkinje cell synapses in the cerebellum. Since the LTD has been thought to be one of the fundamental mechanisms for motor learning, CRF may contribute to motor learning. However, the role of CRF on motor learning *in vivo* still remains unclear. Here, we conducted behavioral studies to examine the effects of CRF on motor learning. We performed rotarod test using Wister rats. The animals injected CRF in the cerebellar cortex were able to stay longer duration on the rotating rod compared to animals injected phosphate buffered saline. The effect was more profound when the rotating speed became faster from 12 rpm to 20 rpm. Interestingly, such enhancement of motor coordination was mainly observed during the early trials. Our results suggest that CRF has a role to acquire the motor learning *in vivo*, especially during the early phase of training.

Title: Dose-dependent reduction of palatable food consumption in binge prone versus binge resistant rats after orexin receptor-1 antagonism

Authors: *K. A. RICHARDSON[1,2], S. UTHAYATHAS[1];
[1]Dept of Pharmacol., Howard Univ. Col. of Med., Washington, DC; [2]Behavioral Neurosci. Branch, Neurobio. of Relapse Section, Natl. Inst. on Drug Abuse, IRP, Baltimore, MD

Abstract: Orexin (or hypocretin) hypothalamic peptides are involved in the regulation of food intake. The purpose of the study was to determine whether there were dose-dependent differences in the consumption of palatable food (PF, high fat, high sugar pellets) in binge-eating prone (BEP) and binge-eating resistant (BER) rats after SB-334867 administration (SB, orexin-1 receptor antagonist). Female Sprague-Dawley rats (freely cycling, 200-300g, n= 6/group) were individually housed and underwent intermittent feeding tests to identify BEP and BER phenotypes. Vaginal lavages were taken for each rat every day and smears were stained to determine the estrous cycle. The BEP and BER phenotypes were based on the consumption of PF pellets. BER rats were those that consistently (> 50% of the time) consumed within the bottom tertile of PF across a minimum of 6 testing days. BEP rats were those that consistently (> 50% of the time) consumed within the top tertile of PF across a minimum of 6 testing days. After phenotypes were identified, animals received either vehicle, 5, 10 or 20mg/kg SB (i.p.). Preliminary analyses show that all three doses of SB reduce PF consumption in BEP and BER rats versus vehicle ($p<0.05$). Dose-dependent reduction in PF consumption is significant in BEP rats and not BER rats when comparing 5mg/kg versus 20mg/kg SB ($p<0.05$). Studies are underway to determine if there are estrous cycle-dependent differences in PF consumption for BEP and BER rats. These data show that antagonism of the orexin system is more effective in reducing consumption of PF in animals that demonstrate binge eating prone behavior.

Title: Pituitary adenylate cyclase-activating polypeptide (PACAP) dysregulates social interaction behavior in rats

Authors: *R. J. DONAHUE, A. VENKATARAMAN, E. G. MELONI, W. A. CARLEZON, Jr.;
Dept. of Psychiatry, Harvard Med. School, McLean Hosp., Belmont, MA

Abstract: Severe or prolonged stress can trigger psychiatric illnesses including mood and anxiety disorders. Social withdrawal, defined as diminished interest or participation in social activities, is a core feature of these disorders. Preclinical studies have shown that exposure to a stressful or aversive stimulus (e.g., exposure to predator odor) can disrupt normal social interaction (SI) behaviors in rats, but the mechanisms of this effect are unknown. Pituitary adenylate cyclase-activating polypeptide (PACAP) is a highly conserved neuropeptide that has recently been identified as an important regulator of stress effects and is implicated in the pathophysiology of mood disorders. We recently demonstrated that PACAP administration produces acute increases in anxiety-like behaviors and anhedonia (reduced sensitivity to reward), as well as disruptions in attention and social behavior. In addition, mutant mice lacking the cognate PACAP receptor, PAC1, show reduced aggression and an increase in affiliative behaviors, implicating endogenous PACAP systems in regulating social behavior. Here, we investigated how PACAP (0, 0.25, 0.5, 1.0 μg, administered intracerebroventicularly [ICV]) affects social interaction behaviors. One week after ICV cannula implantation, rats were infused with PACAP and placed in a 60 x 60 x 40 cm Plexiglas chamber with a weight-matched partner rat 1 hr later. Acute PACAP administration produced dose-dependent decreases in active SI (i.e. approach and reciprocal behaviors). Surprisingly, the dose-effect pattern observed at the acute test was reversed when the rats were re-tested without additional treatment 1 week later: rats that had received the highest dose of PACAP (1.0 μg) showed increases in direct SI whereas rats that received the lowest dose of PACAP (0.25 μg) showed nominal decreases in SI and increases in anxiety-like behaviors. This same general pattern (but with more variability) was observed in rats infused with PACAP and tested only at the 1 week time point suggesting that the acute SI exposure is not critical for the development of long-term effects. Preliminary studies suggest that administration of the stress peptide corticotrophin-releasing factor (CRF; 0.5 μg, ICV) also produces acute decreases in active SI, but these effects normalize by the 1 week time point. We are currently examining the role of the transcription factor cAMP response element binding protein (CREB) in mediating the effects of PACAP within the NAc shell and CeA, brain areas involved in encoding reward and aversion. This work may help to devise therapeutics that mitigate specific signs of these disorders by affecting the actions of stress peptides.

Title: An neuropeptide Y Y2 receptor antagonist reverses Corticosterone-induced anxiogenic-related behavior and neuronal hypertrophy

Authors: *J. C. MORALES-MEDINA[1,2], I. JUAREZ[5], S. DOMINGUEZ-LOPEZ[3,4], R. KANDIMALLA[2], G. GOBBI[4], G. FLORES[6], R. QUIRION[2];

Abstract: Neuropeptide Y (NPY) has been proposed as a potential target for anxiety treatment by modulating its actions through Y1 and Y2 receptors. Indeed, cumulative evidence has shown that NPY modulates corticosterone (CORT) secretion, a key component of anxiety and stress. However, the mechanism of action of NPY on CORT is not completely understood. In particular, acute CORT administration induces an increase in anxiogenic-related behavior in the elevated plus maze (EPM) that parallels with neuronal hypertrophy in the basolateral amygdala (BLA). Whether these CORT effects can be prevented by modulation of NPY receptors has not been studied yet. In the present study, we aimed to investigate the behavioral and neuro-protective effects of the Y1-like receptor agonist, [Leu31Pro34] PYY, the Y1 receptor antagonist, BIBO3304, the Y2 receptor agonist PYY3-36, and the Y2 receptor antagonist, BIIE0246 in CORT-treated rats. While BIIE0246 increased the number of entries in the open arm of the EPM in CORT-treated rats, PYY3-36 decreased the number of entries in control animals. [Leu31Pro34] PYY or BIBO3304 does not produce behavioral modifications in CORT or control rats. Furthermore, BIIE0246 reduced the neuronal hypertrophy in the BLA in CORT-treated rats without inducing neuronal modifications in control rats. Thus, these results showed that BIIE0246 reverses the behavioral and neuronal deleterious effects of CORT treatment and suggest that selective antagonism of the Y2 receptor subtype have a potential use in the treatment of anxiety-related disorders.

Title: Developmental fluoxetine exposure alters affiliative and anxiety-like behavior and oxytocin receptor binding in the prairie vole (Microtus ochrogaster)

Authors: *R. H. LARKE[1,2], M. C. PALUMBO[1,2], S. M. FREEMAN[2], K. L. BALES[1,2];
[1]Psychology, [2]California Natl. Primate Res. Ctr., Univ. of California, Davis, Davis, CA

Abstract: Developmental selective serotonin reuptake inhibitor (SSRI) exposure constitutes a significant risk factor for Autism Spectrum Disorder (ASD). Early manipulation of the serotonin system leads to lasting changes in oxytocin signaling, and the oxytocin system has been linked to ASD. We used the socially monogamous prairie vole as a translational model of developmental SSRI exposure. Twenty female prairie voles were treated with 5mg/kg subcutaneous fluoxetine or saline daily throughout gestation until weaning, so that offspring were exposed to fluoxetine (FLX) or saline (SAL) throughout prenatal and postnatal development. Post-weaning, subjects underwent behavioral testing to detect changes in anxiety-like behavior, sociality, and pair-bond formation; 24 hours later, they were euthanized and brains flash frozen. Quantitative autoradiography was used to measure oxytocin receptor (OTR) density. Preliminary analyses (adult males, N=10) indicate that OTR density in the lateral septum is reduced in FLX animals ($F=5.04$, $p<.05$), and that FLX animals spend more time alone in the partner preference test compared to SAL animals ($F=3.47$, $p<=.05$). FLX increased autogrooming in the open field test ($F=4.46$, $p<.05$), and anxiety-like behavior in the elevated plus maze ($t=2.16$, $p<.05$). Developmental SSRI exposure alters social behavior in the prairie vole in a manner relevant to ASD by increasing anxiety-like behavior and decreasing social interaction. These changes are mediated by alterations to neural OTR density, making the prairie vole a useful translational model for examining serotonin-oxytocin interactions in relation to ASD.

Title: Rats with antipsychotic-induced dopamine supersensitivity have blunted neurotensin function in the nucleus accumbens

Authors: *A. SERVONNET[1], A.-M. BÉDARD[2], D. LÉVESQUE[3], P.-P. ROMPRÉ[1], A.-N. SAMAHA[2];
[1]Neurosciences, [2]Pharmacol., [3]Pharm., Univ. De Montréal, Montreal, QC, Canada

Abstract: Some of the symptoms of schizophrenia can be treated effectively with antipsychotic drugs. Antipsychotics exert their therapeutic efficacy by occupying striatal dopaminergic (DA) D2 receptors. Although antipsychotics are given to attenuate striatal DA neurotransmission, their chronic use can induce supersensitivity to DA receptor stimulation. This DA supersensitivity can undermine the efficacy of ongoing antipsychotic treatment, alter reward function, and increase the risk of psychosis relapse upon interruption of antipsychotic treatment. The neuropeptide neurotensin is a key dopamine modulator. Within the nucleus accumbens, activation of NTS1 receptors suppresses DA-mediated responses in part by decreasing the agonist binding affinity of D2 receptors. Furthermore, chronic antipsychotic treatment upregulates neurotensin levels in the nucleus accumbens. Here we tested the hypothesis that the expression of antipsychotic-induced DA supersensitivity is linked to altered neurotensin function in the nucleus accumbens. To test this hypothesis, rats were treated with haloperidol for 2 weeks, using a regimen that is clinically representative and that induces sensitization to the behavioural effects of DA agonists (i.e., DA supersensitivity). Three to nine days following treatment cessation, we injected neurotensin into the nucleus accumbens core (0 and 10 μg/0.5 μl/hemisphere) and assessed its ability to suppress amphetamine-induced locomotion. Nine days following antipsychotic treatment cessation, we also assessed the levels of proneurotensin mRNA and NTS1 receptors in striatal subregions. Antipsychotic-pretreated rats showed augmented amphetamine-induced locomotion, indicating that they had developed DA supersensitivity. As shown previously, intra-accumbens injections of neurotensin suppressed amphetamine-induced locomotion in control rats. However, this effect was lost in antipsychotic-pretreated rats. Haloperidol pretreatment elevated proneurotensin mRNA in the caudate-putamen and in the core, but not the shell, of the nucleus accumbens. There were no changes in striatal NTS1 density. Thus, the expression of antipsychotic-induced DA supersensitivity is accompanied by blunted neurotensin function in the nucleus accumbens core and increased proneurotensin transcription in this region. The challenge now is to determine whether normalizing striatal neurotensin function attenuates the behavioural symptoms of antipsychotic-induced DA supersensitivity. These results will lead to a better understanding of the mechanisms underlying DA supersensitivity evoked by antipsychotic treatment.

Title: Signaling at Orexin 1 receptors in prelimbic cortex is necessary for Conditioned Saccharin Seeking

Authors: *K. ROACH[1], A. M. CASON[2], G. ASTON-JONES[3];
[1]Allegheny Col., Meadville, PA; [2]Neurosci., Med. Univ. of South Carolina, Charleston, SC;
[3]Rutgers Univ., Piscataway, NJ

Abstract: Previous studies in our laboratory have indicated that signaling at the orexin 1 receptor (OxR1) is involved in cue-induced reinstatement of saccharin-seeking (Cason and Aston-Jones, 2013). However, the precise orexin pathway involved in cue-induced saccharin seeking is still underexplored. Here, we examined the role of the OxR1 in cue-induced reinstatement of extinguished saccharin seeking by examining the effects of local microinfusions of the OxR1 antagonist, SB-334867 (SB), or vehicle into two orexin terminal regions prelimbic cortices (PL) and paraventricular nucleus of the thalamus (PVT). These regions have been previously implicated in hedonic feeding and cue-driven feeding. In the current study, rats were trained to self-administer saccharin (paired with a tone+light cue) and then extinguished as described previously (Cason and Aston-Jones, 2013). Reinstatement of extinguished saccharin seeking was prompted by the appearance of the previously paired tone+light cues. Prior to reinstatement testing, rats were given a bilateral microinfusion (0.3ul) of SB (1mM) or vehicle (artificial cerebrospinal fluid) into PL or PVT. Microinfusions of SB into the PL decreased saccharin seeking behavior during the cue-induced reinstatement sessions compared to vehicle microinfusions. SB was less effective when microinfused into the PVT. The PL result was confirmed by comparing Fos analysis of the PL versus infralimbic (IL) cortices. Systemic SB decreased Fos expression in PL, but not IL, cortex, during cue-induced saccharin seeking. Together these findings indicate that signaling at the OxR1 in the pre-limbic cortex is necessary for cue-induced saccharin seeking.

Title: The effect of orexin receptor blockade on open field behaviors are both sex and age dependent

Authors: *S. R. BLUME[1], S. LUZ[1], D. M. EACRET[1], N. SOTUYO[1], R. J. VALENTINO[1,2], S. BHATNAGAR[1,2];
[1]Abramson Res. Ctr., Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Adolescence is a sensitive and critical period in brain development where psychiatric disorders such as anxiety, depression and post-traumatic stress disorder are more likely to emerge following a stressful life event. Between females and males, females are two times more likely to suffer from psychiatric disorders and show different symptomatology compared to males. Patients suffering from these disorders show alterations in orexins (also called hypocretins), an important neuropeptide synthesized in the lateral hypothalamus that regulates arousal, wakefulness and the hypothalamic-pituitary-adrenal axis. Activation of orexin receptors increases arousal and wakefulness whereas orexin receptor antagonists decrease arousal and wakefulness. However, the role of orexins in mediating behaviors related to arousal in males compared to females and in adolescence compared to adulthood is not known. Here, we examine the influence of orexin receptor blockade (SB334867) in open field behavior in adolescent (PD 31-33) and adult (PD 75-77) female and male rats. Animals were injected with either 10mg/Kg SB334867 (orexin receptor antagonist) or vehicle (i.p.) and placed in the open field 30 minutes post-injection. Behavior was analyzed using the automated behavioral analysis software EthoVision. During the 30 minutes in the open field, orexin receptor blockade significantly reduced the total distance traveled in adolescent females compared to control and drug treated adult females. In contrast, orexin receptor blockade in males showed no differences in distance traveled between age and treatment groups. Preliminary experiments show similar prepro-orexin mRNA levels in control adolescent and adult females, indicating that orexin levels do not explain the differences observed in adolescent and adult females. These results suggest the effect of orexin receptor blockade on open field behavior is both age and sex dependent. Our results also suggest that orexin receptor expression and/or function likely have a developmental maturation that is sex-specific. Current studies are underway to examine additional doses of SB334867 and to determine whether there are differences in orexin receptor expression in adolescent and adult females and males.

Title: Reduction of vasopressinergic system following amphetamine sensitization in male and female rats

Authors: *G. M. RENARD, C. AHUMADA, C. BAHAMONDES, R. A. SILVA, G. CRUZ, R. SOTOMAYOR-ZÁRATE;
Univ. de Valparaíso, Valparaiso, Chile

Abstract: Sex differences in the reward circuit response to drugs of abuse are a trending topic in the neurobiology of addiction research. The role of vasopressin (AVP) projections from medial amygdala (MeA) to lateral septum (LS) is well known in different behaviors like anxiety and social behavior that could be altered by drugs. The purpose of this study was to investigate whether amphetamine (AMPH) sensitization affects MeA-LS vasopressinergic system in male and female rats. Male and female Sprague Dawley rats (55-60 days old) were divided in 2 groups: Control rats (0.9% saline solution ml/Kg i.p.) and AMPH-treated rats (AMPH 1.5 mg/Kg i.p.). The stage of the oestrus cycle was determined daily by vaginal smears examination. At the induction phase of sensitization, animals received a daily injection during 5 consecutive days and locomotor activity was measured. The criterion for sensitization was a 20% increase in locomotor activity over 5-day injection period. Five days after the last injection, all rats were injected with AMPH and locomotor activity was measured. AVP mRNA expression in MeA were studied by RT-qPCR and LS AVP levels were also studied by ELISA. Our results showed that approximately 80% of males and females were sensitized. Animals that did not show sensitization to AMPH showed higher locomotor activity at first AMPH injection than sensitized animals. Female rats were sensitized independent of the stage of the oestrus cycle. At the challenge day, the locomotor activity in control rats was higher in females than males. Regarding vasopressinergic system, sensitized rats showed lower levels of AVP mRNA expression in MeA and lower SL AVP than control rats. Thus, our results suggest that AMPH sensitization could alter anxiety and social behavior by reducing the activity of the extrahypothalamic vasopressinergic system.

Title: Peripheral vasopressin type 1a receptors mediate locomotor inhibition following systemic oxytocin administration in rats

Authors: M. WOLFE, H. WISNIEWSKI, G. IBANEZ, H. TARIGA, D. HARGROVE, *B. F. LINDSTROM;
Ferring Res. Inst., San Diego, CA

Abstract: The neuropeptide oxytocin (OT) has been implicated in a wide range of behaviors in rodents, including pro-social behaviors, analgesia/antinociception, erections, and grooming. OT is not selective for the OT receptor and is known to act at vasopressin type 1a (V1a) and type 2 (V2) receptors. The goals of this study were to (i) evaluate behavioral effects induced by OT in an open-field locomotor assay and (ii) identify receptor subtypes (OT or V1a) mediating these behavioral effects in rats. Behaviors were recorded and analyzed by an automated open-field system designed to sense motion using a grid of perpendicularly placed infrared beams. Both ambulatory (forward movement and rearing) and non-ambulatory (stereotypy) behaviors were measured during 1 hour following administration of OT. Measures of locomotor activity included: distance (cumulative distance traveled by the subject), rearing (number of breaks in the vertical plane), and stereotypic behavior (e.g., scratching, grooming, or digging). Subcutaneous (sc) dosing of OT (0.2 and 1 mg/kg) resulted in a dose-dependent decrease in all locomotor activities measured, however, this effect was absent following intracerebroventricular (icv) administration of OT (30 ng, 5 µl) suggesting that the decreased locomotion was a result of peripheral receptor activation. Interestingly, pre-treatment with the V1a receptor antagonist [Pmp1,Tyr(Me)2]AVP (0.002 and 0.2 mg/kg, sc) dose-dependently blocked the locomotor deficits caused by OT, while pre-treatment with the selective OT receptor antagonist barusiban (0.1 mg/kg, sc) did not. Furthermore, neither barusiban (100 ng, 5µl) nor [Pmp1,Tyr(Me)2]AVP (125 ng, 5µl) given ICV blocked the locomotor inhibition caused by sc administration of OT, further suggesting a peripheral mechanism of action not mediated by the OT receptors, but instead by peripheral V1a receptors. These findings highlight the importance of considering potential off-target effects when using OT in pharmacodynamic studies. We conclude that the exploration of OT pharmacology in the brain and in the periphery is further complicated by the use of non-selective ligands, and that peripheral V1a receptors may underlie many behavioral effects seen following OT dosing.

Title: Defense against social isolation: the study of hormones in an animal model

Authors: T. WISNIEWSKI, N. MCNEAL, W. COLBURN, A. DAGNER, A. TOGHRAEE, M. L. SCOTTI, *A. J. GRIPPO;
Dept of Psychology, Northern Illinois Univ., Dekalb, IL

Abstract: Social stressors, such as social isolation, increase behaviors associated with anxiety and depression and negatively influence physical health in humans. One possible reason for these negative effects might be the result of dysregulation of central oxytocin, which facilitates stress-coping and positive social interactions. To investigate the influence of oxytocin, an animal model that is socially similar to humans is necessary. The prairie vole is a useful model, displaying strong bonds with mates and family members, and exhibiting several negative effects on behavior and health following disruption of social bonds. We investigated the hypothesis that oxytocin antagonism would facilitate depressive and anxiety-like behaviors. 38 female prairie voles were assigned to one of two conditions: socially isolated (separated from a sibling), or a non-isolated, control condition (paired with a sibling) for four weeks. The voles in each group were then treated with either an oxytocin antagonist or saline 1 hour prior to an operational behavioral test. The oxytocin antagonist significantly ($P<.05$) increased anxiety-like behaviors in paired but not isolated animals; whereas it significantly increased depressive behaviors in isolated but not paired animals. These change observed in anxiety behaviors are inconsistent with our previous research. The present research suggests that oxytocin might have varied interactions within the brain as a function of different social environments. Future studies should isolate the specific influence of oxytocin in mediating emotional as well as physiological dysfunction during social stress. Further research involving animal models, such as this, can provide insight into the negative consequences of social stress in humans.

Title: Investigation of Nogo-A neutralizing antibody treatment and neurogenesis after cortical stroke in adult rats

Authors: D. SHEPHERD[1], S.-Y. TSAI[2], S. P. CAPPUCCI[1], I. VAAGENES[2], V. HUSAK[2], A. MARINOPOULOS[2], R. FARRER[2], *G. KARTJE[2];

Abstract: Stroke is a leading cause of adult disability with no approved pharmacological treatments beyond the acute phase. Experimental approaches to improving functional recovery include treatments that enhance plasticity of existing neural circuits or the inherent regenerative capacity of the brain. One such treatment, neutralizing antibodies to the neurite outgrowth inhibitor Nogo-A ("anti-Nogo-A immunotherapy"), has been shown by our laboratory to enhance structural plasticity and functional recovery after stroke in adult and aged rats. However, the exact cellular targets of this novel treatment are not fully understood. A recent study proposed a role for Nogo-A in the maintenance of the subventricular zone (SVZ), one of the adult brain's main neurogenic niches (Rolando et al., J Neurosci, 2012). Endogenous neural precursor cells may contribute to injury mitigation and behavioral recovery after stroke, raising the intriguing question of whether neural precursor cells are a therapeutic target of anti-Nogo-A immunotherapy. To investigate this possibility, we induced cortical ischemia in rats via middle cerebral artery occlusion, followed by anti-Nogo-A antibody treatment delivered by osmotic minipump into the ipsilesional lateral ventricle. At three time points, cellular proliferation in the SVZ was measured by bromodeoxyuridine injection and stereological cell counting, and the neuroblast response was assessed using quantitative immunohistochemistry. We confirmed Nogo-A expression by doublecortin-positive neuroblasts in the SVZ of both sham and ischemic brains. However, we found no evidence of changes in proliferation after either 3, 7, or 14 days of anti-Nogo-A treatment, and no evidence of a treatment effect on neuroblast density. We are currently investigating whether Nogo-A neutralization affects longer-term parameters of post-stroke neurogenesis, including the differentiation, integration, and survival of newborn neurons.

Title: Acute effects of ß-hydroxybutyrate (BHB) in CD-1 mice after experimental stroke

Authors: ***K. A. KOCH**[1], A. THINNES[2], D. BERRESSEM[3], J. BARNSTORF-BRANDES[2], G. ECKERT[3], J. KLEIN[3];
[1]Goethe Univ. Frankfurt Am Main, Frankfurt Am Main, Germany; [2]Pharmacol., [3]Goethe Univ., Frankfurt am Main, Germany

Abstract: (R)-3-Hydroxybutyrate (BHB) is the most important ketone body. In the present study, we have used an experimental stroke model, middle cerebral artery occlusion (MCAO), in mice to investigate the levels of metabolites linked to BHB after brain ischemia. In female CD-1 mice, we used a transient model (90min). Immediately afterwards, mice were injected with 10, 30 or 100 mg/kg BHB. After 22h of reperfusion, mice underwent several motoric and cognitive tests. Two hours later, mice were sacrificed, and tissue were harvested. Sample preparation included extraction of metabolites and derivatisation prior to GC-MS analysis. We found that mice who had received 30 mg/kg BHB performed significantly better than the control group in behavioral tests (neurological score NSS 5.0 ± 1.2 for BHB; 13.1 ± 0,6 for saline) (all data given as means ± S.E., N=11). Both 10 and 100 mg/kg BHB doses gave worse results than the intermediate dose of 30 mg/kg. BHB plasma levels were increased in stroked mice (sham group 181±24µM; stroked group 5.56±1.61mM) but was reduced by 30 mg/kg BHB application (2.31±0.51 mM). With respect to energy metabolites, plasma lactate levels were increased after stroke (sham group 3.41 ±0.34mM; stroked group 9.47±0.73mM) but BHB (30mg/kg) application kept lactate levels at low values (1.98±0.42mM). In contrast, plasma pyruvate levels were decreased in stroked mice (sham group 116.7±17.6µM; stroked group 17.5±3.9µM). Glucose levels were increased 24h after stroke (sham group 10.0±1.4mM; stroked group 20.0±3.8mM) but attenuated by BHB to 13.3±2.7mM. In brain homogenates, BHB levels were 118 24.8 µM in sham-operated mice (calculated with 70% intracellular water). BHB levels were higher in the brains of stroked mice (321±97µM) and even higher after additional BHB administration (459±79µM) Furthermore, 24 h after stroke, lactate levels in brain homogenate were unchanged by stroke (sham group 19.8±1.65mM; stroked group 20.0±4.33mM) but increased after 30 mg/kg BHB (30.0±1.96mM. Finally, glucose levels (43.0±8.3µM in sham-operated mice) were increased after stroke (435±189µM) and further increased after BHB

treatment (771±203 μM). In conclusion, brain ischemia causes an increase of all energy metabolites in blood plasma, with a particularly strong effect on BHB levels. In the brain, stroke causes an increase of glucose and BHB concentrations, two nutrients that may be used alternatively by brain cells. Additional BHB application causes a further rise of BHB in the brain which causes a accumulation of glucose, possibly by a preference of the brain for BHB oxidation. The high lactate levels may be a consequence of brain hypermetabolism 24 h after transient ischemia.

Title: Mechanisms of dopaminergic drug treatment on motor recovery in ischemic stroke injury

Authors: *L. YAN, L. H. XU, Y. H. LIU, Q. LI, W. H. YUNG, Y. KE;
Sch. of Biomed. Sci., The Chinese Univ. of Hong Kong, Hong Kong, China

Abstract: The development of effective treatment for ischemic stroke is a vexing challenge for centuries, especially for chronic patients where neuroprotective and thrombolytic agents available do not promote functional recovery. Recent clinical studies have shown that administration of dopamine agonists or restoring central dopamine level via levodopa, can substantially improve motor performance in stroke patients. However, the mechanisms of dopaminergic treatment on motor recovery have not been thoroughly explored. In our study, we tested the hypothesis that levodopa acts by enhancing cortical neuroplasticity to promote functional recovery. In rodent model of focal ischemic stroke induced by photothrombosis, we assessed the integrity of cortical dopaminergic system and found that it is significantly disrupted by focal stroke. Through a 3-week daily treatment of levodopa, we recapitulated its beneficial effects on sensorimotor function by subjecting the animals to various motor tasks, including open-field test, rotarod performance test, forelimb food retrieval task, limb-use asymmetry test and horizontal ladder test. Further examination of neuronal connectivity and synaptic protein

expression revealed that perilesional tissue remodeling occurs following stroke and is modulated by dopamine. With tantalizing evidence that dopamine replacement can enhance functional recovery by coalescing connections across the cortex, we demonstrated that the modulating dopaminergic transmission is a promising therapeutic strategy for stroke rehabilitation.

Title: Aleglitazar therapy decreases microglia activation and leads to neuroprotective effects after focal brain ischemia in mice

Authors: V. BOUJON, G. KRONENBERG, R. UHLEMANN, M. ENDRES, *U. K. DIRNAGL, K. GERTZ;
Charite Universitätsmedizin Berlin, Berlin, Germany

Abstract: Cerebral ischemia leads to neuroinflammation by triggering multiple inflammatory pathways affecting the entire neurovascular unit. Microglia are a key component of the brain's inflammatory response. In this project, we studied the effects of aleglitazar, a new dual PPARα and PPARγ agonist, on the properties of microglia and on post-stroke outcome. 129/SV mice were subjected to filamentous middle cerebral artery occlusion (MCAo)/reperfusion. Animals were treated with aleglitazar or vehicle once per day, starting from reperfusion. Acute lesion sizes were measured on day 7 after 30 min MCAo. Additionally, the effects of aleglitazar on microglia phenotypes were tested in well established *in vitro* assays. Lipopolysaccharide (LPS)-challenged primary and BV-2 microglia were treated with aleglitazar. Nitric oxide (NO) production was quantified as nitrite accumulation using the Griess reagent for nitrite. Transcription and release of pro-inflammatory cytokines were assessed by quantitative RT-PCR and enzyme-linked immunosorbent assays (ELISAs). Proliferation, migration and phagocytosis of microglia were assessed by Fluorescence Activated Cell Sorting (FACS) analysis, Boyden-Chamber assay and phagocytosis of E. coli bioparticles, respectively. Aleglitazar reduced the mRNA expression of inducible nitric oxide synthase (iNOS), Nuclear Factor kappa B (NfκB) and of tumor necrosis factor (TNF)α, as well as the release of interleukin 6 (IL-6) and TNFα into the culture medium of LPS-challenged microglia. Furthermore, treatment with aleglitazar significantly decreased the proliferative, migratory and phagocytic properties of microglia, as

well as their level of NO secretion. At the concentrations used, aleglitazar did not affect viability of microglia. In addition, aleglitazar efficiently reduced the mRNA transcription of pro-inflammatory marker genes including iNOS and interleukin-1 (IL-1)β after brain ischemia. Moreover, aleglitazar treatment significantly reduced the infarct volume at 7 days after MCAo/reperfusion. Our results provide first evidence that treatment with the new dual PPARα and PPARγ agonist aleglitazar decreases LPS-induced microglia activation, reduces the expression of pro-inflammatory molecules and protects from brain ischemia *in vivo*. Therefore, pharmacological treatment with aleglitazar represents a promising approach to reduce neuroinflammation, thereby affording neuroprotection after ischemic stroke.

Title: The multi-herbal mixture HT047 promotes motor recovery in a rat model of chronic stroke

Authors: *J. SONG, D. LEE, Y.-S. KIM, S. LEE, H. KIM, H. LEE, H. GUO, H. KIM; Kyunghee Univ., Soeul, Korea, Republic of

Abstract: HT047 is a multi-herbal mixture consisting of Pueraria lobata root and Scutellaria baicalensis root which have been used together to treat stroke in traditional Asian medicine. In the present study, the effects of HT047 on motor recovery in chronic stroke were investigated. Sprague-Dawley rats subjected to 60 min of middle cerebral artery occlusion (MCAO) were randomly divided into two groups, control and HT047 group. Twenty-four hours after MCAO, HT047 was orally administered to rats for 14 days at a dose of 300 mg/kg and then rats were received chow diet containing 1.35 % HT047 up to 6 months. Rats were weighed daily over 6

months after MCAO. Functional recovery was assessed during subacute (weekly intervals for one month) and recovery (monthly intervals up to 6 months) phases using rotarod test and limb placement test. In rotarod test, rats were trained for 7 days prior to MCAO. The latency to fall on the accelerating rotarod was recorded for 5 min. Rotarod performances were expressed as a percentage of the performance of the day before ischemia. In limb placement test, rats were held by the examiner and forelimb placing was noted when approaching a table or table edge from various directions with and without allowing visual, tactile, and proprioceptive support as earlier described by De Ryck et al. (1989). The maximum score was 14 for each body side. After MCAO, the mean weight loss of rats in control group peaked at Day 4, with a maximum loss of 14.8% of the original body weight recorded on the day of surgery. The mean weight of HT047 group was significantly higher than that of control group at 4 days post-surgery (274.3 ± 4.2 vs. 258.0 ± 6.0 g, $p<0.05$). Treatment with HT047 markedly enhanced the recovery on body weight loss after MCAO surgery. In rotarod test, HT047 accelerated recovery of motor function during a subacute period and protected age-related decline during a chronic recovery phase. Rats treated with HT047 showed significant improvement of rotarod performance at 1, 2, 3 and 4 weeks post-surgery compared to control group. At week 4, rotarod performance for each group was 63.2 ± 7.8 % for control group and 88.6 ± 5.7 % for HT047 group. In limb placement test, scores of HT047 group were significantly higher than that of control group during subacute period. At week 4, score for each group was 4.6 ± 0.6 points for control group and 8.7 ± 0.8 points for HT047 group. These results suggests that HT047 treatment prevents weight loss and improves functional recovery after cerebral ischemia.

Title: Effectiveness of targeting P2X7 receptor for the treatment of central post-stroke pain in rat model

Authors: *Y.-H. KUAN[1], H.-C. SHIH[1], S.-C. TANG[2], J.-S. JENG[2], B.-C. SHYU[1]; [1]Neurosciences, IBMS, Taipei, Taiwan; [2]Dept. of Neurol. and Stroke Ctr., Natl. Taiwan Univ. Hosp. and Natl. Taiwan Univ. Col. of Med., Taipei, Taiwan

Abstract: Stroke is a leading cause of death and disability in industrialized countries. Approximately 8-14% of stroke survivors suffer from central post-stroke pain (CPSP) when hemorrhagic stroke occurs in lateral thalamic regions, which severely affects their quality of life. Because the mechanisms of CPSP are not well understood, effective treatments have not been developed. In the present study, we tested the hypothesis that persistent CPSP is caused by P2X7 receptor activation after brain tissue damage and subsequent elevations in inflammatory cytokines. A thalamic hemorrhagic rat model was used, characterized by thermal and mechanical allodynia that develops in the subacute to chronic phases upon CPSP onset. We found a significant increase in P2X7 expression in reactive microglia/monocyte-drived macrophages in thalamic peri-lesion tissues at 5 weeks post-hemorrhage. Thalamic P2X7 receptors were directly involved in pain transmission and hypersensitivity. The systemic targeting of P2X7 receptors during the acute stage of hemorrhage rescued abnormal pain behaviors and neuronal activity in the thalamocingulate pathway by reducing reactive microglia/monocyte-drived macrophages aggregation and associated inflammatory cytokines. After CPSP onset, the targeting of interleukin-1β reversed abnormal pain sensitivity. The aberrant spontaneous thalamocortical oscillations in rats with CPSP were modulated by blocking P2X7 receptors. Taken together, our results suggest that targeting P2X7 may be bi-effective in the treatment of CPSP, as both a pain blocker and immunosuppressant that inhibits inflammatory damage to brain tissue. P2X7 receptors may serve as a potential target to prevent the occurrence of CPSP and may be beneficial for the recovery of patients from stroke.

Title: The arginine-vasopressin receptor blocker Conivaptan reduces stroke-evoked brain edema and blood-brain-barrier disruption

Authors: *S. M. JONES[1], E. ZEYNALOV[1], J. SEO[1], L. SNELL[2], J. ELLIOTT[3];
[1]Neurotrauma Res., Swedish Med. Ctr., Englewood, CO; [2]Colorado Neurolog. Inst., Englewood, CO; [3]Colorado Brain and Spine Inst., Englewood, CO

Abstract: Stroke is the fourth leading cause of death and the number one leading cause of disability in the US. Stroke is often associated with the syndrome of inappropriate release of antidiuretic hormone (SIADH). SIADH is the result of uncontrolled arginine-vasopressin (AVP) secretion which causes water retention in the body, hyponatremia, and low plasma osmolality. These events can quickly exacerbate post-ischemic brain edema and increase mortality rate if plasma sodium levels and osmolality are not corrected Conivaptan (Vaprisol) is an antagonist of both AVPR1a and AVPR2 receptors, available for clinical use to correct hyponatremia, blood volume and osmolality. As an AVPR1a receptor blocker, Conivaptan may prevent vasoconstriction and platelet aggregation, effects which can directly benefit regional cerebral blood flow (rCBF) after stroke. Recent literature suggests that selective AVPR1a receptor blockers can reduce post-ischemic brain edema formation, provide neuroprotection, and decrease BBB disruption. The AVPR2 blocking effect of Conivaptan is responsible for excretion of excess water by the kidney and elevation of blood osmolality, which could also alleviate brain edema. Therefore, we conducted a study to investigate whether Conivaptan can prevent brain edema and BBB disruption in mice after stroke. **Methods:** C57/BL6 mice underwent the filament model of middle cerebral artery occlusion (MCAO) with reperfusion. Continuous IV infusion with Conivaptan or normal saline (NS) was initiated immediately at reperfusion and administered via a catheter in the jugular vein for 48 hours. For comparison, the AVPR2 antagonist Tolvaptan was administered p.o. immediately and again 6 hours after reperfusion. Physiological variables including neurological deficit scores, serum and urine osmolality and sodium levels were recorded during the experiment. Brain water content (BWC) and Evans Blue (EB) extravasation index were evaluated at the end point. **Results:** BWC was increased in the ipsilateral hemisphere of vehicle treated mice (81.66 ± 0.43%). Treatment with Conivaptan reduced BWC to 80.84 ± 0.56% (Conivaptan, 0.02 mg), and 78.28 ± 0.48% (Conivaptan, 0.2 mg, $p < 0.05$ vs NS). Conivaptan also reduced the EB extravasation index from 1.22 ± 0.08 (NS) to 1.01 ± 0.02 (Conivaptan, 0.2 mg, $p < 0.05$). **Conclusion:** Continuous IV infusion with Conivaptan for 48 hours after experimental stroke reduces brain edema, and BBB disruption. Conivaptan may potentially be used in patients to alleviate brain edema after stroke.

Title: Changed profile of glutamate receptors by constraint-induced movement therapy links to functional recovery of the forelimb in capsular hemorrhage rats

Authors: *A. ISHIDA, Y. UEDA, C.-G. JUNG, K. ISHIDA, H. HIDA;
Nagoya City Univ. Grad. Sch. of Med. Sci., Nagoya, Aichi, Japan

Abstract: Constraint-induced movement therapy (CIMT), a method for intensive use of an impaired forelimb, is an effective poststroke rehabilitation to promote functional recovery, although an immediate focused training could induce excitotoxicity deteriorating brain injury after stroke. To investigate the relationship between CIMT and excitatory glutamate receptor profile, male Wistar rats (200-250 g) were given to collagenase (type IV, 15 U/ml, 1.4 μl) to make small hemorrhage near the internal capsule (ICH), and allowed to CIMT for a week with a one-sleeve cast forcing the use of only impaired forelimb in all daily activities. Four groups were prepared: ICH with no CIMT (ICH), ICH with CIMT in early phase (1-8 days post ICH, E-CIMT) or in late phase (17-24 days, L-CIMT), and ICH with forced-nonuse of an impaired forelimb (1-8 days post ICH, E-FNU). It was revealed that protein expressions of NMDA-type receptor subunits, especially NR2A and 2B, were significantly increased in affected motor cortex in E-CIMT compared to ICH group, while those were decreased in the same area in E-FNU group. On the other hand, expressions of AMPA receptors were not changed among groups. More αFosB-positive cells in the motor cortex of ipsi-lesional side indicated enhanced neuronal activity after ICH in E-CIMT group. To investigate the involvement of NMDA receptor signaling in E-CIMT group, NMDA receptor antagonist MK-801 (10 pmol/ml/h, 7 days) was administrated to the motor cortex of ipsi-lesional side using osmotic mini-pump. Although E-CIMT group showed better functional recovery in the reaching and ladder stepping test, the recovery was apparently blocked by MK-801 injection during CIMT. These data suggest that CIMT from early phase after ICH changes the profile of NMDA-type receptor signaling in the motor cortex of ipsi-lesional side, probably affecting the functional recovery by CIMT

Title: Effect of sensorimotor intervention on norepinephrine levels in the hippocampal dentate gyrus and in the pons in adult rats with cortical ablation induced damage

Authors: G. A. GARCÍA-DÍAZ[1], L. E. RAMOS-LANGUREN[2], A. GONZÁLEZ-MACIEL[3], A. BUENO-NAVA[4], A. ÁVILA-LUNA[4], N. CHAVEZ-GARCÍA[5], *S. MONTES[5], R. GONZALEZ-PIÑA[4];

Nacional de Reabilitación. Mexico, Mexico City, Mexico; [5]Natl. Inst. Neurol. Neurosurg, Mexico City, Mexico

Abstract: Nowadays, a consensus has been reached that designates the functional and structural reorganization of synapses as the primary mechanisms underlying the process of recovery from brain injury. We have reported that pontine norepinephrine (NE) is increased in animals after cortical ablation (CA). Anatomical relationships between the dorsal pontine locus coeruleus (LC) and the dentate gyrus (DG) have been described. To find out whether the increase of pontine NE during recovery is accompanied by changes on NE content in the DG, we measured the NE levels from both structures. Additionally, we analyzed structural modifications in the LC and in the DG in adult rats 20 days after CA. Rats were introduced to 15 sessions of sensorimotor intervention (SMI) as an enhancing recovery procedure. The animals were randomly divided into 4 groups: sham-operated (Sh group) motor cortex injured (Inj group), sham-operated with SMI (Sh+SMI group), and motor cortex injured with SMI (Inj+SMI group). The injured groups underwent cortical damage by means of the aspiration of the tissue of the right motor cortex. In the Inj+SMI group, animals were introduced to SMI one day after CA. All groups underwent histological analysis. Injured rats showed reduction in the number of granule cells in the DG and decreased dentate granule cell layer thickness. Importantly, after SMI, the loss of granule cells was prevented. No differences in the number of cells in the LC were observed among the test groups. On the one hand, NE content in the DG diminished in the Inj group versus controls, on the other hand Inj+SMI group statistically increased NE content as compared to Inj group. Pontine NE levels were not different among groups, suggesting NE pontine recovery. Our results suggest that rehabilitory intervention in the form of sensory motor stimulation elicits structural modifications in the hippocampus that could reorganize the system and lead the recovery process, modulating structural and functional plasticity.

Abstract: Occlusion of the middle cerebral artery (MCAo) is the most common cause of ischemic stroke in human. Cerebral ischemia leads to brain lesions existing of an irreversibly injured core and ischemic boundary zone, the penumbra, containing damaged but potentially salvageable tissue. Using a transient MCAo mouse model we investigated the effect of a specific multi-nutrient intervention as a therapeutic approach to counteract impairments of cerebral connectivity, cerebral blood flow (CBF), cognition, motor function and neurodegeneration. This specific experimental diet was developed to support neuronal membrane synthesis and maintenance of vascular health. Male C57BL/6j mice (3 months) were subjected to transient (30 min) right MCAo using the intraluminal filament model. Success of surgery was verified intraoperatively. Before tMCAo, baseline measurements of motor parameters (open field, rotarod, grip test, pole test) and spatial learning/memory (Water Maze) were performed and repeated after tMCAo. Starting directly after tMCAo, animals were fed the control diet or the experimental diet. At 14 and 35 days after tMCAo, MRI scanning was conducted to identify stroke location and size (RARE+DWI), and functional and neuronal connectivity and CBF measures (rsfMRI, DTI, MRS, FAIR-ASL) on the 11.7T magnet (Bruker BioSpec). Directly following the MR measurements, brains were collected and immunohistochemical analyses were performed. Data processing is ongoing and final results will be presented. First results show that at 7 days after tMCAo, all mice showed a decreased CBF in the occluded cerebral hemisphere compared to the control hemisphere. Mice fed experimental diet had a higher cortical CBF in the ischemic hemisphere than control fed mice. 35 days post tMCAo, experimental diet fed animals had a restored cortical and hippocampal CBF in the ischemic hemisphere. On control diet, cortical and hippocampal CBF remained decreased in the occluded cerebral hemisphere compared to the control hemisphere. The first functional benefits of the experimental diet were noted in the open field, where locomotor activity was improved at 16 days after tMCAo as compared to animals on the control diet. No therapeutic intervention is available for stroke yet. Our present data show that a specific dietary intervention has beneficial effects on the cerebral hemodynamics after tMCAo. In addition, the diet may reduce some of the functional consequences of tMCAo. Together our data indicate that specific multi-nutrient interventions

may be able to counteract harmful effects of ischemic stroke, protecting against neuronal and connectivity loss and accompanying functional deficits.

Title: Shiatsu improves functional motor capacity in post-stroke patients

Authors: ***H. C. MARCUSSO**[1], S. M. TAGAMI[3], D. PARIZOTTO[2], D. M. DOS SANTOS[2], R. N. ISAYAMA[3];
[2]Human Morphophysiology, [1]UNICASTELO, Fernandopolis, Brazil; [3]Physiotherapy, UNASP-SP, Sao Paulo, Brazil

Abstract: Stroke is an important cerebrovascular disease to cause morbidity and mortality in Brazil and worldwide. Motor function and cognition are mostly impaired in post-stroke patients, resulting in reduced functional capacity that compromises their quality of life. Functional and emotional recovery is variable and depends on the severity of the injury, socio-cultural factors and therapeutic strategies. Shiatsu is an ancient technique of complimentary therapy based on non-invasive points of pressure that are usually at the anatomical sites of muscle-tendon transition or close to motor points where muscles are effectively stimulated by electrodes. Finger pressure using as a shiatsu technique employed on spastic muscles could ameliorate spasticity by stimulating Golgi tendo organs. Such structures, specially regulate muscular tone of rigid muscles. Preview studies suggest that shiatsu mitigates sequel of stroke. Although cerebrovascular injuries cause primary lesion of the upper motor neuron, interventions in peripheral neuromuscular structures may also benefit muscle tone and performance, by increasing the functionality and quality of life of these patients. The aim of this study was evaluating the beneficial effects of shiatsu on functional capacity and quality of life in post-stroke chronic patients. This study was approved by the ethics committee. Six (n=6) post-stroke patients were assigned for shiatsu-kinesiotherapy group (SHI) with pressure points in upper and lower limbs. A control kinesiotherapy group (CRT, n=6) received conventional kinesiotherapy and both groups were treated twice a week for four months. Patients responded to SF-36

questionnaire and Barthel index prior and after all therapeutic procedures. The results showed that shiatsu and/or kinesiotherapy did not change blood pressure, mood, consciousness or caused discomfort in post-stroke patients. SF-36 revealed that SHI group had improved their pain management, vitality, social and the mental health state ($p < 0.05$) comparing to its control. Barthel index showed a recovery in SHI group from severe to moderate dependence (index ≥ 60 and < 80), which did not occur in CRT. This study revealed a significant improvement for management of pain, vitality, social functioning and mental health domains in SHI as compared to its control. Barthel index demonstrated that SHI is functionally more independent than the CRT. It may be concluded that shiatsu associated with conventional kinesiotherapy in post-stroke patients promotes recovery of functional capacity as well as their quality of life.

Title: *In vivo* inhibition of mir-155 recovery following experimental mouse stroke

Authors: *E. CABALLERO-GARRIDO[1], J. PENA-PHILIPPIDES[1], T. LORDKIPANIDZE[2], D. BRAGIN[1], Y. YANG[3], T. ROITBAK[1];
[1]Neurosurg., Univ. of New Mexico, Albuquerque, NM; [2]Ilia State Univ., Tbilisi, Georgia; [3]BRaIN Imaging Ctr. and Col. of Pharm., , Univ. of New Mexico,, Albuquerque, NM

Abstract: A multi-functional microRNA miR-155 has been recognized as an important modulator of numerous biological and pathological processes such as hematopoietic lineage differentiation, immunity, inflammation, cancer, and cardiovascular diseases. The goal of the present study is to explore the role of miR-155 in regulating cerebral vasculature after stroke. Specifically, we investigated the effect of *in vivo* inhibition of miR-155 on brain microvasculature, as well as infarct size and overall recovery following experimental cerebral ischemia. The intravenous injections of a specific miR-155 inhibitor were initiated at 48 hours after mouse distal middle cerebral artery occlusion (dMCAO), and resulted in 50% inhibition of miR-155 in the brain tissue. The efficiency of *in vivo* miR-155 inihibition was evaluated using

confocal microscopy, PCR and western blot analyses. Microvasculature in peri-infarct area, infarct size and animal functional recovery were assessed at 1, 2 and 3 weeks after dMCAO. Using *in vivo* two-photon microscopy, we detected improved blood flow and microvascular integrity in the peri-infarct area of miR-155 inhibitor-injected mice. Electron microscopy revealed that, in contrast with the control group, these animals had well-preserved capillary tight junctions (TJ). Western blot analysis showed that among all TJ proteins, ZO-1 was consistently affected by miR-155 inhibition. We propose that stabilization of this scaffolding and signaling protein could strengthen TJ barrier function in the inhibitor-injected animals. The improved vascular integrity in these animals was associated with reduced brain damage: MRI analysis showed significant (34%) reduction of infarct size in miR-155 inhibitor-injected mice at 21 days after dMCAO. Reduced brain injury was confirmed by electron microscopy, demonstrating decreased neuronal damage in the peri-infarct area of stroke. Preservation of the brain tissue was reflected in efficient functional recovery of inhibitor-injected animals. Our studies include recovery and behavioral assessment using the "Adhesive Removal," and "CatWalk" test. Based on our findings, we propose that *in vivo* miR-155 inhibition following ischemia supports brain microvasculature, reduces brain tissue damage, and improves the animal functional recovery. This approach could be further explored as a potential treatment for stroke.

Title: Lifting brakes on stroke recovery: motor plasticity in Lynx1 knockout mice

Authors: *N. W. HODGSON[1,2], E. NEWPORT[3], A. DROMERICK[3], T. K. HENSCH[1,2]; [1]Boston Children's Hosp., Boston, MA; [2]Harvard Med. Sch., Boston, MA; [3]Georgetown Univ. Ctr. for Brain Plasticity & Recovery, Washington, DC

Abstract: Motor function recovery following stroke is associated with increased plasticity in peri- and contralesional cortex, however this is limited in the adult CNS. Here, we test whether removal of a molecular "brake" on plasticity holds therapeutic value to improve recovery from

stroke. Lynx1 is an endogenous prototoxin similar to the snake venom α-bungarotoxin. It acts to limit cortical rewiring in adulthood by dampening nicotinic acetylcholine receptor function, and mice lacking Lynx1 recover from amblyopia ('lazy eye') long after corresponding wild-type animals have stabilized (Morishita et al., 2010). Using a photothrombotic ischemic cortical injury model in C57BL/6J (WT) and Lynx1 knockout (KO) mice, we compared their respective post-stroke recovery trajectory. Mature male WT and Lynx1 KO mice at both postnatal day 60 (P60) and P300 were trained to proficiency on a skilled capellini handling task, then received ischemic unilateral sensorimotor cortex lesions contralateral to their dominant forepaw. Motor function was assessed by capellini handling as well as DigiGait analysis, and sensorimotor function was measured by an adhesive tape removal task, for 21 days following cortical lesion. Behaviorally, Lynx1 KO mice showed less initial impairment on all tasks and a greater recovery on those associated with motor function. At P60, the amount of time to manipulate and consume a segment of capellini improved faster in Lynx1 KO versus WT controls (τ = 4.942 and 37.87 days, respectively). Recovery rates for other metrics measured in the capellini handling task, tape removal task and gait analysis were similar between groups. Over the same time period, biochemical markers of oxidative stress (GSH/GSSG) were compared across hemispheres. Prior to stroke, P60 Lynx1 KO mice showed a 23% baseline reduction in GSH/GSSG ratio, but were able to recover faster post-stroke than in WT controls (τ = 5.838 and 75.06 days, respectively). Similarly, P300 Lynx1 KO mice showed a 45% baseline reduction in GSH/GSSG ratio and again recovered faster than WT (τ = 8.17 and 34.55 days, respectively). The pre-stroke oxidative shift in GSH/GSSG ratio observed in Lynx1 KO animals may prime antioxidant systems to increase the rate of recovery. Lifting other molecular brakes based on developmental mechanisms, such as axonal growth inhibitors (NgR/PirB signaling; Fang et al 2010, Adelson et al 2012) or extra-cellular matrix components (CSPGs; Gherardini et al 2015) may be similarly beneficial for stroke recovery in adulthood, yet Lynx1 offers a non-invasive strategy via nicotinic receptor signaling.

Title: Training of the non-paretic arm in unilateral stroke improves arm function and performance

Authors: *C. CHOPICK[1,2], D. C. GOOD[1], C. WINSTEIN[3], R. L. SAINBURG[1,2];
[1]Neurol., Penn State Col. of Med., Hershey, PA; [2]Dept. of Kinesiology, Penn State Univ., University Park, PA; [3]Div. of Biokinesiology and Physical Therapy, USC, Los Angeles, CA

Abstract: We previously elaborated hemisphere specific motor deficits in the non-paretic, ipsilesional arm of chronic unilateral stroke patients. We now show that these deficits can be associated with substantial limitations in functional performance, especially in patients with moderate to severe contralesional paresis. In this pilot feasibility study, we ask whether intense training of the ipsilesional arm can lead to substantial and durable improvements in functional performance. Non-paretic arm training employed both virtual reality (VR) tasks and challenging real-life activities involving rapid and accurate object placement, object manipulation, tracing, and targeted throwing tasks. Three patients with moderate to severe paresis engaged in a 4 week intervention, involving 3 sessions per week, which lasted for 2 hours each. For 30 minutes, patients focused on VR activities involving rapid accurate motions of the arm, followed by real-life activities for the remaining 1.5 hours. Dependent measures included: 1) Jebsen-Taylor Hand Function Test (JTHFT), 2) Slotted Pegboard test, 3) Kinematics during a center out reaching task, and 4) a modified version of the Functional Independence Measure (FIM). These tests were given twice prior to training, separated by a 1 week interval, immediately following training, and 1 month after training. Improvements were made on measures of unilateral function, activities of daily living, and functional independence, including greater than 15% improvement on the JTHFT, a test of unimanual functional performance, and in reaching kinematics, including improved speed, accuracy, and smoothness. All patients also reported improved functional independence, including one patient reporting that he became completely independent in dressing and undressing and another stating that he now can independently dispense his own toothpaste, and brush his teeth. Our findings provide preliminary support to the idea that short term training of the non-paretic arm can lead to substantial and durable improvements in functional performance.

Title: Reactive and voluntary stepping in individuals with stroke: a comparison between paretic and nonparetic leg responses

Authors: C.-L. YANG[1], V. GRAY[1], M. FUJIMOTO[2], *S. MCCOMBE WALLER[1], M. W. ROGERS[1];
[1]Dept. of Physical Therapy and Rehabil. Sci., Univ. of Maryland, Sch. of Med., Baltimore, MD;
[2]Dept. of Sport and Hlth. Sci., Ritsumeikan Univ., Kusatsu, Japan

Abstract: Background: Fall risk after stroke is a major healthcare concern. Impaired lateral weight transfer between paretic (P) and nonparetic (NP) legs during reactive and voluntary stepping may disrupt balance stability and increase fall risk after stroke. Objective: We compared the stepping responses of the P and NP leg during unexpected waist-pulls to the P and NP side versus cued voluntary stepping of the P and NP leg in individuals with chronic stroke. Methods: Fourteen community dwelling individuals >6 months post stroke completed reactive and voluntary lateral step testing. For reactive lateral stepping, 24 trials of randomly-ordered unexpected waist-pull perturbations were applied to the subject (2 directions × 3 repetitions × 4 magnitudes). For voluntary lateral stepping, subjects were instructed to perform 10 trials of a single lateral step as fast as possible according to the direction of a light cue (2 directions × 5 repetitions). The main outcome measures were first step characteristics including step onset, step duration, normalized step clearance, normalized step length in the mediolateral (ML) and anteroposterior (AP) direction, normalized global step length, and normalized center of pressure (COP) velocity. Nonparametric tests were used for comparison of significance between the P and NP leg responses during reactive and voluntary stepping. Results: During reactive stepping, subjects initiated steps with the NP leg 61 % of the time regardless of the pull direction. Compared to the lateral steps initiated with the NP leg, the P leg steps had a marginally lower clearance (P=0.068), longer ML step length (P=0.068), and shorter global step length (P=0.068). In contrast, during voluntary stepping, all subjects could generate a P voluntary lateral step, however step clearance (P=0.056), ML step length (P=0.026), and global step length were smaller (P=0.056). The AP step length was larger compared to NP stepping (P=0.011). Across the four conditions (reactive lateral steps initiated with P/NP leg and voluntary lateral steps initiated with P/NP leg), a significant difference was found in the first step duration (P=0.031). Post hoc analysis showed a significantly longer step duration in voluntary NP leg stepping compared to reactive NP leg stepping (P=0.046). Conclusion: We have identified differences between P and NP leg responses during reactive and voluntary stepping in individuals post-stroke. This has implications for the development of rehabilitation interventions to prevent falls in this high risk group.

Title: Asymmetrical corticomotor input to the plantarflexors influences the biomechanical strategy of speed modulation in individuals post-stroke

Authors: *J. A. PALMER[1], H. HSIAO[2], L. N. AWAD[4], S. A. BINDER-MACLEOD[3]; [2]Biomechanics and Movement Sci., [3]Physical Therapy, [1]Univ. of Delaware, Newark, DE; [4]Sch. of Engin. and Applied Sci., Harvard Univ., Boston, MA

Abstract: In the presence of lost function following brain injury, one of the most common and consistent observations is that individuals develop compensation strategies and demonstrate heavy reliance on the nonparetic limb during gait. Such compensations have been shown to be related to major neuronal reconstruction and growth in the cerebral cortex, which can translate to cortical imbalances between the lesioned and nonlesioned hemisphere related to poor motor recovery. Impaired ankle moment generation of the paretic limb has been identified as a significant contributor to walking-related disability after stroke and is related to walking speed. However, when individuals post-stroke are asked to increase walking speed (i.e. modulate gait speed), different biomechanical strategies are used that are independent of their level of walking function. We hypothesized that balance of contralateral corticomotor input to the paretic and nonparetic plantarflexor muscles (i.e. corticomotor asymmetry) will moderate the relationship between change in paretic ankle moment and change in gait speed. To test this hypothesis, we measured corticomotor input to the paretic and nonparetic soleus muscles and the paretic ankle moments at self-selected and fast walking conditions in 19 persons with hemiparesis following stroke. Preliminary results indicated that no relationship exists between magnitude of gait speed modulation versus changes in paretic ankle moment during speed modulation ($r=0.035$) ($p=0.44$) or corticomotor asymmetry ($r=0.122$) ($p=0.30$). However, there was a strong relationship between change in paretic ankle moment with speed modulation and corticomotor asymmetry ($r=0.629$) ($p<0.01$). This provides novel evidence that asymmetrical corticomotor input to the lower extremity may underlie biomechanical compensation strategies used for gait speed modulation post-stroke. These findings have significant implications for approaches used in post-stroke rehabilitation.

Title: Astrocyte-derived exosomes reduce infract volume and reduce neurological alterations in a rat model of ischemic stroke

Authors: B. BERNAL-VICENTE, E. HERNÁNDEZ-PONCE, A. RAMOS-MORALES, *L. B. TOVAR Y ROMO;
Univ. Nacional Autonoma de Mexico, Mexico City, Mexico

Abstract: Stroke is the third cause of death and permanent disabilities worldwide. Given the lack of effective therapies for this type of acute insults to the CNS, it is important to understand how endogenous mechanisms for brain repair activated upon ischemia modulate the outcome and promote tissue recovery. One of the main mediators of the endogenous response elicited after stroke is vascular endothelial growth factor (VEGF), which is secreted by astrocytes and has been shown to reduce infarct volume in experimental models *in vivo* when administered exogenously. Here, we explored how astrocytes contribute to protect neurons after ischemia by releasing exosomes containing signaling mediators of survival and whether this effect is dependent on VEGF-mediated signaling. For this, we cultured rat primary cortical astrocytes that were subjected to hypoxia for 2 hours. Then, exosomes released over a period of 24 hours were collected and administered by stereotaxic intraventricular injection to rats subjected to transient middle cerebral artery occlusion (MCAO) 30 min after reperfusion. We found that astrocyte-derived exosomes reduced the infarct volume, as assessed by tretazolium chloride staining, and reduced the neurological symptoms manifested 24 hours after stroke. We then investigated whether the protection was driven by the activation of VEGF receptor 2 and found that this receptor was partially involved in the neuroprotection. We also studied the effect of astrocyte-derived exosomes on the modulation of blood brain barrier permeability, which is known to play an important role in the development of the neuroinflammatory process that occurs after stroke. We found that exosomes reduced the amount of protein extravasation induced by stroke, which might also constitute a mechanism for astrocyte-mediated neuroprotection. These results are important clues to understand the mechanisms of intercellular communication that participate in the concerted response that takes place in the brain after an acute insult and may point to new therapeutic targets that could be potentiated by clinical interventions.

Title: Virtual reality based upper limb neurorehabilitation in acute stroke: a single-case study

Authors: H. KINZNER[1], *G. GARIPELLI[2], D. PEREZ-MARCOS[2], T. TADI[2], K. DISERENS[1];
[1]Dept. of Clin. Neurosciences, Ctr. Hospitalier Universitaire Vaudois, Lausanne, Switzerland; [2]MindMaze SA, Ecublens, Switzerland

Abstract: A 60-year-old right-handed (Edinburgh Test > 95) male subject was treated at the acute Neurorehabilitation unit at the Centre Hospitalier Universitaire Vaudois (Lausanne, Switzerland) with a Virtual Reality (VR) based upper limb motor rehabilitation system (MindMotionPRO, MindMaze SA), starting 9 days post stroke. Pre-intervention medical evaluation revealed ischemic stroke (left paramedian pontine), resulting in hemiparesis on the right side (on day 8, NIHSS = 6; Frenchay Arm Test score = 3/5; Fugl-Meyer Assessment Upper Extremity (FMA-UE): synergy & reflex of shoulder, elbow and forearm score = 26/66, joint pain score = 21/24, sensation score = 8/12 and passive joint motion score = 22/24). The patient carried out VR reaching exercises implying active shoulder and arm movements for approximately 1 hour per day, using two visual feedback mechanisms: (i) direct mode (patient arm movements are translated to the ipsilateral avatar arm); and (ii) mirror mode (patient arm movements are translated to the contralateral avatar arm), resulting in a “virtual mirror illusion”. The mirror mode is similar to mirror therapy and aims at activating the neural pathways ipsilateral to stroke lesion. It was applied when the patient reported fatigue of the paretic arm. The patient completed 3 sessions in 3 consecutive days, comprising a total of ~400 reach movements. Exercises were undertaken in a game-like scenario that enhanced patient motivation. During his stay in the acute care, the patient also undertook thrombolysis treatment and nearly 1 hour of physical therapy per day. On the day of discharge (day 13; NIHSS = 3) there was an improvement in arm synergy (FMA-UE synergy & reflex of shoulder, elbow and forearm score = 32/66) and a reduction in the joint pain (joint pain score = 24/24). There were no pre-post changes in the wrist and hand movement score, sensation score or functional skills (as indicated by the Frenchay Arm Test). Overall, the subject was highly motivated and immersed in the VR tasks provided. From the results of this study, we surmise that the administration of VR based upper limb motor rehabilitation in the acute care is feasible and well accepted by the patient. Emerging evidence suggests that such training in the early phases of acute stroke recovery results in significant improvements in brain activation and functional outcomes. We believe that the

virtual mirror training can activate the neural mechanisms underlying motor recovery even when the patients have a very low motor function of the paretic arm.

Title: Impact of a Conductive Education intervention on supraspinal structures in adults with chronic stroke

Authors: *R. D. THEISS[1], T. B. PARRISH[2], R. K. O'SHEA[1];
[1]Physical Therapy, Governors State Univ., University Park, IL; [2]Radiology, Northwestern Univ., Chicago, IL

Abstract: The location and severity of damage to the brain after a stroke influences the extent of functional limitations experienced by the stroke survivor. After injury, measurable physiological changes continue that can be correlated with functional clinical measures. With physical rehabilitation interventions, functional impairments can be lessened, presumably through mechanisms of neuroplasticity. Though interventions are often effective for restoring at least partial function for individuals with stroke, little is known about what underlies the positive results for specific interventions. The purpose of this study was to examine the connections within the brain of stroke survivors who have undergone physical rehabilitation but still have persisting physical impairments and assess changes in neurological functional and structural connectivity after participating in a novel cognitive-physical rehabilitation intervention program known as Conductive Education (CE). CE is a multidisciplinary, motor-learning based intervention. This study expanded the use to adults with chronic stroke and added imaging. Four adults with chronic (>6mo) stroke were enrolled into the study. All subjects had completed outpatient rehabilitation at least 5yrs prior. Two subjects had pontine-level lesions; two had subcortical lesions. Prior to CE participation, baseline measures of function (via clinical assessment) and supraspinal neurological structures (via imaging) were obtained. A licensed physical therapist evaluated each subject for measures of physical impairment and social and community participation. Additionally, Magnetic Resonance Imaging (MRI) data were collected to assess functional and structural connectivity, myelin concentration, and cerebral perfusion.

This imaging included resting fMRI, diffusion tensor imaging, and an arterial spin labeling method. Subjects then participated in weekly, 2-hour CE program sessions for 10 weeks. At the end of the CE program, clinical assessment measures and imaging data were again collected and analyzed for pre/post intervention changes. Preliminary results showed that participants improved physical function and performance as well as community participation at or above the levels of minimal clinical important difference (MCID). The improvements in hand function were statistically significant within the group, but other improvements were individual and varied. Likewise, varied imaging results are expected. From this pilot study, we conclude that a CE intervention could be effective for adults with chronic stroke by inducing supraspinal changes measurable with emerging imaging techniques.

Title: Changes in motor unit firing behavior following maximal efforts post stroke

Authors: *K. BATHON[1], T. ONUSHKO[2], J. NGUYEN[3], E. MCGONIGLE[4], N. GEOFFROY[3], N. KETCHUM[4], F. NEGRO[5], D. FARINA[5], S. HUNTER[3], B. SCHMIT[2], A. HYNGSTROM[3]; [1]Clin. and Translational Rehabil., [2]Biomed. Engin., [3]Physical Therapy, Marquette Univ., Milwaukee, WI; [4]Physical Med. and Rehabil., Med. Col. of Wisconsin, Milwaukee, WI; [5]Neurorehabilitation Engin., Goettingen Georg-Augst Univ., Goettingen, Germany

Abstract: Motor unit firing behavior is altered post stroke and may contribute to force generating impairments. In particular, there is saturation in firing rates as compared to firing rates in healthy controls. It is not known if paretic motor unit firing behaviors can modulate in response to excitatory inputs. The purpose of this study was to quantify the effects of maximal efforts on knee extensor motor unit discharge rates in chronic stroke. Twelve chronic stroke subjects (63 ± 6 years old) and ten control subjects (62 ± 5 years old) participated in this study. Knee extension torque was recorded using a Biodex dynamometer equipped with a JR3 load cell. Vastus lateralis motor unit discharge rates were extracted from surface motor unit potentials recorded using a high-density surface array (stroke n = 33 units, control = 47 units). Baseline maximal voluntary contractions (MVCs) of the knee extensors were recorded for the paretic leg of stroke subjects (PL) and the dominant leg of control subjects (CL). Following the MVCs, subjects practiced producing 30% knee extension MVC torques while they were provided with

visual feedback of their performance. Then, visual feedback was removed and subjects performed sub-maximal contractions under two different conditions (randomized): (A) a set of three 5 s contractions each followed by 10 s rest at 30% MVC (repeated three times with 30 s rest between each set) and (B) the same as protocol A, but with the addition of an MVC between each of the 5 s contractions. Finally, subjects were asked to produce what they believed to be 30% of their knee extension MVC. There was a significant increase in knee extension torque in the PL during the sub-maximal portion of Protocol B compared with Protocol A (% MVC ± SE: 31% ± 3% vs. 23% ± 3%, t-test, $p < 0.05$), while there was no significant change in torque production observed for the CL (34% ± 1% vs. 31% ± 2%, t-test, $p > 0.05$). Stroke and control had increased firing rates at recruitment during sub-maximal contractions for Protocol B (stroke = 9.8pps ± 1.1; control 12.4pps ± 1.7) as compared to Protocol A (stroke = 6.5pps ± 0.7, control = 9.1pps ± 0.7). In addition, for the stroke group, peak firing rates during Protocol B (7.6pps ± 0.8) were greater as compared to Protocol A (5.9pps ± 0.5). On average, the mean firing rates during contractions for Protocol B (stroke = 9.6 ± 0.7; control = 12.8 ± 0.8) were greater for both groups as compared to Protocol A (stroke = 8.5 ± 0.5; control = 11.8 ± 0.7). These data suggest that immediately following a maximal effort, paretic motor units can modulate firing rates. The change in firing rates is likely due to additional neural drive to the motorneuron pools from the brief maximal contraction.

Title: Brain reorganisation following robot-assisted therapy in stroke patients

Authors: ***N. ESTÉVEZ**[1], V. KLAMROTH-MARGANSKA[2,3], B. HARTOG-KEISKER[1], L. MICHELS[1], M.-C. HEPP-REYMOND[4], R. RIENER[2,3], S. KOLLIAS[1];

Abstract: Stroke often leads to chronic motor disability of the upper limb, which can severely affect patients' activities of daily living. Recovery of function following a stroke is related to brain reorganisation, which can be promoted by movement therapy. Additionally, previous evidence indicates that robot-assisted therapies providing intensive and task-specific training of the affected limb may be particularly effective at restoring motor function. In the present study, we investigated brain reorganisation induced by robotic therapy in patients with chronic stroke. Patients suffering from moderate and severe upper limb impairments were trained with ARMin - an exoskeleton robot, which supports movements of the entire limb and allows task-specific training in the three dimensional spaces. To assess therapy-induced changes in brain activation, functional magnetic resonance imaging (fMRI) was performed during repetitive active and passive elbow flexion/extension movements at three time points: before therapy, after eight weeks of movement therapy, and at two-month follow-up. To provide constant and accurate performance of the tasks across sessions, an MRI-compatible robot guided and monitored movements during recordings. Additionally, data from several behavioural measures, assessed at each time point, were included to evaluate motor performance over time. This study includes data from eight patients with moderate and severe motor impairment. After therapy with ARMin gains in motor performance were observed in all trained patients. At two-month follow-up, performance remained stable and even slightly improved in patients with moderate deficits, whereas the outcome of the severely impaired patients was more variable. Training led to reduced activation volume in the sensorimotor cortex for passive and active movements in almost all moderately impaired patients. Most patients suffering from severe impairment showed an increase in activation in the sensorimotor cortex during active tasks. For passive movements, no activation was found for half of the severely impaired patients during all three assessments. The remaining patients also showed a tendency for increased activation. Changes observed after therapy often persisted at two-month follow-up, especially in moderately impaired during both tasks and severely impaired during active ones, though they were less pronounced. Our results demonstrated that robot-assisted therapy promotes brain reorganisation and functional arm recovery in patients with chronic stroke. However, the induced reorganisation patterns and long-term effects of the therapy depend on the degree of impairment.

Title: Assessing cognitive function following medial prefrontal stroke in the rat

Authors: *J. LIVINGSTON-THOMAS[1,2], M. JEFFERS[1,2], C. NGUEMENI[1,2], M. SHOICHET[3], C. MORSHEAD[3], D. CORBETT[1,2,4];
[1]Univ. of Ottawa, Ottawa, ON, Canada; [2]Canadian Partnership for Stroke Recovery, Ottawa, ON, Canada; [3]Univ. of Toronto, Toronto, ON, Canada; [4]Mem. Univ., St. John's, NL, Canada

Abstract: Cognitive impairments are prevalent following clinical stroke. However, to date, preclinical research has focused almost exclusively on motor deficits. In order to conduct systematic evaluations into the nature of post-stroke cognitive dysfunction and recovery, it is crucial to develop focal stroke models that affect cognition while leaving motor function intact. Furthermore, in order to investigate potential cognitive post-stroke treatments, it is important that deficits are persistent in the chronic phase. This experiment was performed to evaluate a focal medial prefrontal cortex (mPFC) stroke model using a battery of tests that examined a range of cognitive functions 1-4 months following stroke. Male Sprague-Dawley rats weighing 250-300 g underwent focal ischemia induced in the mPFC using bilateral intracerebral injections of endothelin-1, or sham surgery. Beginning at 1 month post-stroke, cognitive function was assessed using open field, temporal object recognition, object-context recognition, object-placement recognition, attentional set-shifting, light-dark box, spontaneous alternation, Barnes maze, and win-shift/win-stay tests. Prefrontal cortex injury resulted in bilateral damage to the prelimbic and cingulate cortices, extending typically between 4.22 to 1.34 mm anterior to bregma. Animals that underwent stroke surgery exhibited significant changes in all object recognition functions compared to Sham animals ($p<0.05$). Stroke animals also exhibited impaired performance on the Barnes maze ($p=0.012$), and took significantly more trials to learn the second rule in the win-shift/win-stay test ($p=0.013$). Further, they exhibited reduced anxiety-like behaviour in the open field ($p=0.049$). Spontaneous alternation behaviour and locomotion in the open field were not affected. The deficits observed are consistent with some of the key characteristics of prefrontal stroke in humans. Our results show that this model produces persistent deficits in multiple prefrontal cognitive functions, and therefore may be useful for identifying and developing potential therapies for improving cognitive dysfunction in the chronic phase following stroke.

Title: Electrically preconditioned neural progenitor cells on a conductive polymer scaffold enhance stroke recovery

Authors: *P. GEORGE, T. M. BLISS, T. HUA, A. LEE, S. MEHTA, G. SUN, G. K. STEINBERG;
Neurol., Stanford Univ., Stanford, CA

Abstract: Background: Human neural progenitor cells (hNPCs) improve functional recovery after stroke in pre-clinical models. However, the optimal conditions for delivery and exact pathways of recovery remain elusive. Tissue engineered scaffolds offer a unique method to manipulate the environment for hNPC transplantation. We have developed a novel hNPC delivery system utilizing an electrically conductive polymer scaffold to improve recovery and further elucidate repair mechanisms. Methods: Human hNPCs were seeded onto an electrically conductive polymer scaffold. Electrical fields were applied to the hNPCs to electrically "precondition" the cells. One day after *in vitro* stimulation, the polymer scaffold was implanted into a distal MCA occlusion rat model 1 week post-stroke. Subsequently, functional recovery was assessed using the vibrissae-paw test and neurological scores. Control groups consisted of unstimulated hNPCs on the polymer and polymer alone without cells. To assess how electrical stimulation altered the cells, we performed qPCR analysis of genes of interest in stimulated and unstimulated cells on the polymer, and in hNPCs on a plastic petri dish. To further elucidate mechanisms, VEGF-A was blocked with bevacizumab during the *in vitro* preconditioning period. Results: Alternating current (AC) preconditioned hNPCs improved the rate of neurologic functional recovery compared to unstimulated hNPCs on the polymer ($p<0.05$) and significantly improved recovery compared to direct current (DC) preconditioned cells and polymer alone ($p<0.01$). VEGF-A was upregulated in AC preconditioned cells compared to other groups ($p<0.05$). If VEGF-A was inhibited during electrical preconditioning, no improvement in behavior was observed compared to the unstimulated hNPCs. Blood vessel density also increases with electrically preconditioned hNPCs ($p<0.05$) and returns to baseline if VEGF-A is blocked. Conclusions: Our results show that a conductive polymer scaffold can be used to enhance stroke recovery and manipulate hNPCs to elucidate mechanisms of stroke recovery. VEGF-A (a protein critical to angiogenesis and other plasticity processes) was found to be modified by electrical preconditioning of hNPCs, suggesting one possible mechanisms for enhanced functional recovery.

Title: Whisker stimulation enhances oligodendrogenesis and axonal/dendritic repair in the barrel cortex following focal ischemia in mice

Authors: *J. SUN[1,2,3], J. LEE[2], X. GU[2], Z. Z. WEI[3], Y. ZHANG[3], J. LI[3], S. YU[2], L. WEI[2]; [1]Labs of Stem Cell Biol and Regenerative Med., Beijing, China; [2]Anesthesiol. and Neurol., Emory Univ. Sch. of Med., Atlanta, GA; [3]Neurol., Beijing Friendship Hosp. Capital Med. Univ., Beijing, GA

Abstract: Peripheral stimulation and activity have significant 'use-dependent' impacts on morphological and functional alterations in the central nervous system (CNS) and on the outcome of CNS disorders. Our previous studies showed that stimulating corresponding whiskers after focal cerebral ischemia in the whisker-barrel cortex promoted neurogenic and angiogenic activities and functional recovery. In the present study, we tested the hypothesis that enhancing peripheral activity and sensory input to the ischemic barrel cortex by whisker stimulation might promote oligodendrogenic activity and axonal/dendritic repair in the ischemic barrel cortex of mice. We used a nestin-CreER/YFP transgenic mouse for neural cell lineage tracing. Three days after focal barrel cortex ischemia in mice, whisker stimulations were manually performed (15 min × 2 times/day) to enhance afferent signals to the ischemic barrel cortex. By 14 days after stroke, significantly more nestin-CreER/YFP+ cells in whisker stimulation group were evident in the subventricular zone (SVZ), corpus callosum, and penumbra regions. Whisker stimulation group exhibited significant increases of YFP+/DCX+ and YFP+/Oligo2+ cells while there was no change of YFP+/GFAP+ cells, indicating enhanced neurogenesis and oligodendrogenesis, but not astrocytogenesis. Immunostaining and Western blot analyses revealed that the ischemica-induced reductions of neurofilament and myelin basic protein were significantly recovered by whisker stimulation. In addition, whisker stimulation fully prevented the reduction in the expression of synapsin-1, synaptophysin, and growth-associated protein-43 (GAP-43). Whisker stimulation also improved functional recovery tested using adhesive removal test and HomeCage monitoring system. Our data suggest that peripheral stimulation can increase regenerative activities including oligodendrogenesis, enhance axonal/dendritic repair, and prevent synaptic damages in the post-ischemic brain, which may contribute to long-term functional recovery from ischemic stroke.

Title: CREB/DREADD system: switching on/off recovery of motor function after stroke

Authors: *L. CARACCIOLO[1], A. HAMADE[2], T. BULFONE[2], A. GUZNER[2], Y. SANO[3], A. J. SILVA[3], S. T. CARMICHAEL[2];
[1]Neurol., David Geffen Sch. of Med. At UCLA, Los Angeles, CA; [2]Neurol., [3]Neurobio., David Geffen Sch. of Med. at UCLA, Los Angeles, CA

Abstract: CREB plays a major role in learning, neuronal plasticity and memory formation. We investigated the role of CREB in promoting neuronal recovery after focal stroke. This was done by promoting a gain and/or a selective loss of function in delivery of CREB in the peri-lesion motor cortex using inhibitory hM4Di DREADD lentivirus(Designer Receptors Exclusively Activated by Designer Drugs) which is coupled to Gi signaling and activates the inward rectifying potassium channel that inhibits neuronal excitability. Mice received an injection of lentivirus that over-express CREB+hM4Di or hM4Di alone at the time of stroke. Mice were tested behaviorally over 12 weeks after stroke. Saline or Clozapine-N-Oxide (CNO, an inert molecule), that stimulates DREADD receptors (selective loss of function) was delivered 30 minutes before each behavioral test. CREB/hM4Di over-expression shows enhanced motor recovery. Mice transfected with CREB/hM4Di + saline have faster speed in eating pasta, reduction in the number of foot faults in grid-walking, and preference for right paw rearing in cylinder task 4 weeks after stroke. Mice transfected with the control virus hM4Di + CNO showed a greater deficit in recovery after stroke for all the behavioral tasks performed during the entire treatment. Unexpectedly, the administration of CNO to CREB/hM4Di transfected mice showed reduced motor performance after stroke, even worse than the control virus in stroke (hM4Di + stroke + CNO). Moreover, we observed motor deficit in non-stroke mice with CREB/hM4Di + CNO was comparable to the stroked mice with the control virus (hM4Di + stroke + CNO). In conclusion, CREB induction in a small pool of cells of forelimb motor cortex promotes recovery. Inhibition of neuronal activity in this small pool of cells (hM4Di + CNO) doesn't have any effect on motor performance (control mice). Surprisingly, inhibition of neuronal activity in CREB-transfected neurons causes degraded motor control, worse than the effects observed in stroked mice transfected with the control virus (hM4Di + stroke + CNO). This is also seen in CREB/hM4Di + CNO (non-stroke). Thus inducing CREB in motor cortex promotes a network for recovery after stroke. When this network is acutely inhibited, not only the recovered function in stroke is lost, but overall motor control is degraded. This is seen to a statistically lesser degree even when CREB is induced in normal (non-stroke) motor cortex. The plasticity induced by CREB and stroke enable a local network of neurons to control a large

region of functional motor circuitry. Supported by: The Richard Merkin Foundation for Neural Regeneration at UCLA, Dr. Miriam & Sheldon G. Adelson Medical Research Foundation

Title: Investigating vagus nerve stimulation paired with motor rehabilitation to enhance recovery on a novel task measuring supination and the generalization of recovery across different motor tasks in a rat model of ischemic stroke

Authors: *E. MEYERS[1], S. HAYS[1], R. SOLORZANO[2], R. CHOI[2], M. KILGARD[2], R. RENNAKER[1];
[1]Erik Jonsson Sch. of Engin. and Computer Sci., [2]Sch. of Behavioral and Brain Sci., Univ. of Texas At Dallas, Richardson, TX

Abstract: Stroke affects millions each year, frequently resulting in loss of motor control in the upper extremities. Precise arm and hand function including supination and force generation are commonly affected. Patients often undergo extensive physical rehabilitation but most fail to achieve substantial recovery of function, highlighting the need for improved rehabilitative interventions. Reorganization of neural circuitry throughout the central nervous system is believed to be responsible for recovery and the degree of reorganization is associated with the benefits of rehabilitation. Therapies capable of enhancing reorganization during rehabilitation may enhance functional recovery and improve the quality of life for these patients. By pairing stimulation of the left cervical vagus with motor training, we are able to enhance reorganization in motor circuitry. Consistent with this enhancement of plasticity, we find that vagus nerve stimulation (VNS) paired with rehabilitative training significantly improves recovery of forelimb function in rat models of ischemic and hemorrhagic stroke, traumatic brain injury, and spinal cord injury. In this study we will test if VNS can enhance functional recovery after stroke on a novel task measuring supination, and if this recovery generalizes to a different task measuring forelimb strength. Animals are trained to reach through a small aperture in a clear acrylic cage, grasp a spherical knob, and then supinate to receive a reward pellet. Once the animal trained to the specified degree threshold, a unilateral primary motor cortex ischemic lesion (Endothelin-1) is administered and a vagus nerve cuff implanted. Animals are divided in to two groups: one group receiving VNS paired with rehabilitation on the supination task for 6 weeks, and the other group receiving no stimulation but an identical amount of rehabilitation on the same supination

task. Following the conclusion of rehabilitation, animals are then tested on a separate task measuring volitional forelimb force generation to observe any generalization of recovery across dissimilar tasks. We are currently in the process of evaluating the ability of VNS to improve supination function after stroke. Adult female Sprague-Dawley rats are used and all handling, housing, surgical procedures, and behavioral training of the rats are approved by the University of Texas Institutional Animal Care and Use Committee. The results from this study will shape the design of upcoming stroke clinical trials and provide valuable insight in VNS mediated recovery seen in previous studies.

Title: Enhancement of motor recovery using dual-mode noninvasive brain stimulation over the bilateral primary motor cortices in stroke patients

Authors: ***E. PARK**, J. CHO, W. CHANG, A. LEE, Y.-H. KIM;
Samsung Med. Ctr., Seoul, Korea, Republic of

Abstract: Introduction: Noninvasive brain stimulation (NBS) using the repetitive transcranial magnetic stimulation (rTMS) or the transcranial direct current stimulation (tDCS) was recently adopted for modulating motor function of stroke patients. We investigated the effect of simultaneous dual-mode stimulation using rTMS and tDCS over bilateral primary motor cortices (M1) whether it is more effective than single stimulation using rTMS for recovery of motor functions and properties of corticospinal tract (CST) in subacute stroke patients. Methods: Thirty subacute stroke patients whose total Fugl-Meyer Assessment (FMA) score marked under 84 were recruited in this double-blind study. In the dual-mode stimulation group, the 10 Hz rTMS (90% of resting motor threshold, 1,000 pulses) were applied over the ipsilesional M1 for 20 minutes with simultaneous application of the cathodal tDCS (2mA) on the contralesional M1. Single stimulation group underwent 10 Hz rTMS alone without tDCS. Ten daily sessions were conducted for two consecutive weeks. The upper, lower and total FMA scores were measured before, after, and two months after the intervention. To analyze the structural integrity of CST, all patients underwent MRI including diffusion tensor imaging (DTI) at the same time. The

integrity of CST was measured by the ratio of fractional anisotropy (rFA, ipsilesional FA/ contralesional FA). Results: The scores of upper and total FMA scores were significantly improved over time in both the dual-mode and the single stimulation group ($p<0.05$). However, there were significant group and time interaction effects in both upper and total FMA scores ($p<0.05$). Post-hoc analysis showed that the mean changes in upper ($p=0.034$) and total ($p=0.024$) FMA scores were significantly better in the dual-mode stimulation group than the single stimulation group over time. Furthermore, the rFA of CST showed positive correlations with the upper ($r=0539$, $p=0.038$) and total ($r=0548$, $p=0.043$) FMA score at two months after intervention only in the dual-mode stimulation group. Conclusion: The dual-mode NBS with simultaneous application of 10 Hz rTMS and the cathodal tDCS over the bilateral M1s was safe and superior to 10 Hz rTMS alone for enhancing motor recovery and plastic change of CST integrity in subacute stroke patients.

Title: Vagus nerve stimulation paired with rehabilitative training improves recovery of forelimb function in an aged model of ischemic stroke

Authors: *A. D. RUIZ[1], S. A. HAYS[2], D. R. HULSEY[3], N. KHODAPARAST[4], R. L. RENNAKER, II[2], M. P. KILGARD[3];

Abstract: Stroke is a debilitating neurological event affecting nearly 7 million people in the U.S. Advanced age is a leading risk factor for stroke and is associated with worse recovery. Following a stroke, many patients are left with some degree of impairment in upper extremity function, even after intensive rehabilitation therapy. Recent studies indicate that vagus nerve stimulation (VNS) paired with rehabilitative training significantly enhances recovery of multiple measures of forelimb strength and movement speed in models of ischemic stroke, intracerebral hemorrhage, and traumatic brain injury. However, all of these studies have been performed in young rats. It is possible that advanced age, which limits neuroplasticity and post-stroke recovery, may occlude the beneficial effect of VNS therapy. To further the translational potential of VNS therapy, we

evaluated the ability of VNS paired rehabilitative training to drive neuroplasticity and improve forelimb recovery in a model of ischemic stroke in aged rats. A cohort of rats, aged 16 months, was trained to perform the isometric force task, an automated and quantitative measure of forelimb function, to proficiency. Following a cortical ischemic lesion, rats underwent rehabilitative training for 6 weeks with or without VNS paired with forelimb movement. Motor maps were derived using intracortical microstimulation (ICMS). Our results indicate that VNS paired with rehabilitative training improves recovery of forelimb strength compared to equivalent rehabilitative training without VNS motor cortex compared to rehab alone. To whether reorganization in circuitry within the motor cortex is enhanced by VNS to support recovery, we are evaluating morphological changes in the perilesional and homotopic contralesionsal motor cortex. Our results indicate that VNS paired with rehabilitative training may effectively enhance recovery in elderly stroke patients.

Title: Overexpression of soluble hemopexin as a therapeutic tool for intracerebral hemorrhage

Authors: ***A. LAMPERT**[1,2], J. L. LECLERC[1,2,3], J. SANTIAGO-MORENO[1,2], A. DANG[1,2], S. DORE[1,2,3,4];
[1]Anesthesiol., [2]Ctr. for Translational Res. in Neurodegenerative Dis., [3]Neurosci., [4]Neurology, Psychiatry, Psychology, and Pharmaceutics, Univ. of Florida, Gainesville, FL

Abstract: Intracerebral hemorrhage (ICH) has the highest morbidity, disability, and mortality rates of any stroke subtype, including ischemic stroke. When a hemorrhagic stroke occurs, the

blood-brain barrier is broken and blood components enter the brain. A major cause of morbidity and mortality following ICH is the direct toxicity of blood metabolites, namely free heme, on adjacent brain tissue. Hemopexin (Hpx) is the endogenous protein responsible for scavenging free heme; thereby, modulating its proxidant and proinflammatory properties. Given the low relative level of Hpx expression in the brain, we hypothesized that overexpression of Hpx would improve anatomical and functional outcomes after ICH. Unique adeno-associated viral vectors (and control vectors) were designed to specifically overexpress Hpx-(tags) locally within the brain of C57BL/6 mice. After inducing an ICH with the autologous whole blood model, Hpx-overexpressing mice were found to have smaller lesion volumes ($p<0.05$) and reduced blood accumulation (red positive pixel count, $p<0.05$) at 72h post-ICH, as identified by quantification of cresyl violet stained brain sections (n=12-13/group). Furthermore, this reduced ICH-induced brain injury was associated with improved neurologic functional recovery as measured by a 24-point neurological deficit scale at 48h and 72h post-ICH ($p<0.05$). To begin identifying the mechanisms involved in Hpx-mediated neuroprotection, histological staining for ferric iron, 4-hydroxynonenal, GFAP, Iba1, heme oxygenase-1, and myeloperoxidase was performed and the distribution of Hpx-tag proteins was evaluated by Western blotting with anti-tag probing of brain homogenates, cerebrospinal fluid, and serum. Hpx-overexpressing mice were found to have significantly increased cortical microgliosis and astrogliosis and peripheral neutrophil infiltration, but no changes in striatal microgliosis and astrogliosis, ferric iron content, heme oxygenase-1 expression, or lipid peroxidation. Additionally, Hpx-tag proteins were found to be highly expressed in all three types of biological specimens evaluated. The increased levels of Hpx in the serum of overexpressing mice were confirmed to be approximately 62% higher by ELISA. These results indicate that overexpression of Hpx in the brain results in the capacity to facilitate the clearance of heme by central and peripheral mechanisms. Specific modulation of local Hpx levels may represent a clinically relevant strategy for the treatment of secondary brain injury following ICH.

Title: Haptoglobin improves intracerebral hemorrhage outcomes by modulating angiogenesis

Authors: *J. L. LECLERC[1,2,3], T. ESFANDIARY[1,3], S. DORE[1,2,3,4];
[1]Anesthesiol., [2]Neurosci., [3]Ctr. for Translational Res. in Neurodegenerative Dis., [4]Neurology, Psychiatry, Psychology, and Pharmaceutics, Univ. of Florida, Gainesville, FL

Abstract: Intracerebral hemorrhage (ICH) most often occurs spontaneously and is one of the most devastating stroke subtypes. Following ICH, toxic blood components must be cleared from the brain as part of the tissue repair/scar formation healing process. Angiogenesis is a key physiologic mechanism that facilitates tissue repair following acute injury, but must be tightly regulated to prevent excessive activity and deleterious consequences. After ICH, regulation of angiogenesis within the appropriate range in injured brain regions would allow for delivery of glucose and oxygen to support the energy-requiring reparative processes and facilitate the necessary entry of peripheral cells involved. Haptoglobin (Hp) is an acute phase protein that binds extracorpuscular hemoglobin, thereby directly reducing its oxidative potential, and has also been shown to have potent angiogenic, vasculogenic, and wound healing properties. Using the autologous blood model of ICH, we have shown that Hp overexpression significantly improves anatomical and functional outcomes and reduces oxidative processes. Here, we aimed to confirm our previous results and further characterize the mechanisms by which Hp exerts these neuroprotective effects. Similar to our previous study, Hp was overexpressed in the brain using adeno-associated viral vectors and we used the collagenase-induced spontaneous bleeding model of ICH, which is accompanied by clinically relevant intraventricular hemorrhage. Functional outcomes were assessed by a 24-point neurological deficit score and automated open field locomotor ability, and mice were euthanized at 72h post-hemorrhage to evaluate various ICH outcomes and mechanisms of Hp neuroprotection by histological staining. In line with our previous study, Hp-overexpressing mice demonstrated significantly smaller lesion volumes ($p<0.01$) and less residual blood ($p<0.05$). This reduced ICH-induced brain injury was accompanied by trends towards improved ambulatory ability and less focal neurological deficits at 72h post-hemorrhage ($p<0.07$). Hp-overexpressing mice had significantly reduced PECAM-1 immunoreactivity and tended to have less VEGF immunoreactivity. After correcting for lesion volume, Hp-overexpressing mice retained the significantly reduced PECAM-1 expression, but VEGF expression was increased, collectively suggesting a direct role of Hp in positively modulating angiogenesis after ICH. Hp therapy could represent a new treatment strategy for ICH through a multifactorial mechanism that includes the modulation of important angiogenic processes.

Title: Asymmetrical transport of food volatiles during retronasal smell

Authors: R. NI[1], M. H. MICHALSKI[3], E. BROWN[3], N. T. T. DOAN[2], J. P. ZINTER, III[2], N. T. OUELLETTE[1], *G. M. SHEPHERD[4];

Abstract: The ability of humans to distinguish the delicate differences in flavor between many kinds of cuisines depends mostly on retronasal smell, in which the food volatiles entrained into the airway at the back of the oral cavity are transported in the exhaled air to pass through the nasal cavity and stimulate the olfactory receptor neurons. Nothing is known about the fluid dynamics of this retronasal airflow, particularly how the food volatiles are preferentially carried by retronasal flow toward the nasal cavity rather than by orthonasal flow into the lung. To analyze this mechanism, we obtained CT images of the oronasal airway from a healthy human subject, printed it out using a 3D printer, and analyzed the flow field inside the airway using a particle tracking approach. The results show that, during inhalation, the specific local detailed anatomical structure of the oropharynx creates an air curtain outside a virtual cavity connecting the oropharynx and the back of the mouth, which prevents the food volatiles from being transported into the main stream toward the lung. In contrast, during exhalation, the airflow preferentially sweeps by this virtual cavity and effectively enhances the entrainment of the food volatiles into the main retronasal flow. This asymmetrical transport efficiency is also found to have a nontrivial Reynolds number dependence: it peaks at a range of an intermediate Reynolds number close to 800 because the air curtain effect during inhalation becomes strongest in this range. In summary, this study provides the first experimental evidence to connect the evolutionary geometry of our airway near the oropharynx with the transport efficiency of the food volatiles. It will shed new light on our understanding of retronasal smell and its critical contribution to food flavor.

Title: Chemosensory cilia of olfactory sensory neurons may use glucose from surrounding mucus to satisfy energy demands of odor transduction

Authors: *J. BACIGALUPO[1], P. VILLAR[2], K. BLANCHARD[2], D. VILLALOBOS[2], R. DELGADO[2], C. VERGARA[2], J. G. REYES[3];
[2]Biology, Fac. of Sci., [1]Univ. of Chile, Santiago, Chile; [3]Inst. de Química, P. Univ. Católica de Valparaiso, Valparaiso, Chile

Abstract: About ten olfactory cilia (~60 μm long, 0.2 μm), devoid of inner membranes, project from the apical knob of the single dendrite of an olfactory sensory neuron (OSN). Odorants bind to G-protein coupled receptors triggering the opening of Ca2+-permeable cyclic nucleotide-gated channels (CNGs), mediated by a cAMP-cascade. Ca2+ then activates Cl- channels. Both channels underlie a depolarizing receptor potential. ATP is highly demanded in cilia physiology by a cyclase, ATPases and kinases. The closest mitochondria (2-4) are in the knob. Slow ATP diffusion and limited basal ATP levels suggest the requirement of another ATP source beside mitochondria for sustaining transduction under intense stimulation. Immunohistochemistry revealed glucose transporters in supporting cells (SCs) and ciliary layer of the olfactory epithelium, which contains OSNs cilia and SCs microvilli (Nuñez-Parra et al, PlosOne, 2012). This suggests that glucose could be released to the mucus by SCs and incorporated by the cilia for producing ATP by glycolysis. We confirmed by immunocytochemistry the presence of GLU-3 glucose transporter in OSN cilia and SC microvilli and found that the cilia incorporate a fluorescent glucose analog from the mucus. Glycolytic enzymes were detected by immunoblotting of ciliary membranes. Glycolysis and oxidative phosphorylation inhibitors diminished odor responses in field epithelial and suction pipette recordings. OSNs exhibited fatigue upon removal of glucose (0.2 mM) from extracellular solution. Glucose measurements detected its presence in the epithelial surface. These results suggest that olfactory cilia use two complementary ATP sources, oxidative phosphorylation in the knob and glycolysis in the cilia.

Title: Epigenetic regulation of olfactory receptor expression during differentiation of single sensory neurons

Authors: *L. TAN, X. S. XIE;
Harvard Univ., Cambridge, MA

Abstract: Mammals sense odors through the massive gene family of olfactory receptors (ORs). Despite the enormous number of OR genes (more than 1,000 in mouse), each olfactory sensory neuron randomly chooses one, and only one, OR for expression. In neurobiology, this "one-neuron-one-receptor" rule has been a longstanding mystery. Recent experiments showed an epigenetic mechanism for maintaining the "one-neuron-one-receptor" rule: Once any ORs are activated during neuronal differentiation, their expression inhibits further OR activation by down-regulating a histone demethylase Kdm1a (also known as Lsd1), an enzyme required for the removal of the repressive histone marker H3K9me3 on OR genes. However, it remains unclear at a quantitative level how a single OR is initiated in the first place. In particular, does a simple scheme of activation and feedback suffice to guarantee the "one-neuron-one-receptor" rule? Here we show theoretically that a simple kinetic model can indeed produce robust OR choices if, and only if, two timescales--slow OR activation by stepwise H3K9me3 demethylation, and fast feedback to turn off Kdm1a--are well separated. In contrast to recent studies, which emphasized the dichotomy between activation and maintenance of OR expression, we suggest that these two phases should not be viewed separately. In fact, it is the ratio between the two timescales that determines to which extent the "one-neuron-one-receptor" rule holds. To achieve the published accuracy (only 2% of neurons express more than one ORs), we predict that OR activation must be as slow as 5-10 days and the feedback as fast as 1-2 hours. Our model further suggests H3K9me3-to-H3K9me2 demethylation as an additional rate-limiting step responsible for the choice of a single OR. We also tested our results via single-cell transcriptomic sequencing of olfactory sensory neurons. Our work provides the theoretical underpinning behind the choice of ORs, and demonstrates how the nervous system utilizes the slow kinetics of epigenetic changes to direct a dramatic outcome neurogenesis. Our conclusions may be generally applicable to other systems where monoallelic expression is desired, and provide guidelines for the design of a synthetic system of singular expression.

Title: Odor discrimination and detection threshold in mousensor transgenics

Authors: *R. MINA, P. FEINSTEIN, C. D'HULST;
CUNY Grad. Center/Hunter Col., New York, NY

Abstract: Research in understanding the functional properties of odorant receptors that mediate olfaction has been deterred by the difficulty in expressing them in heterologous cells. Our lab has therefore created a reliable method of functionally expressing odorant receptors using transgenic mice, called MouSensors. This enables a dramatic increase of the number of native olfactory sensory neurons expressing a defined odorant receptor. We also designed an *in vivo* imaging protocol to assess the activation of the overexpressed receptors. To determine whether overexpressing a specific odorant receptor changes the odor detection threshold we will perform a proof of principle behavioral experiment using our existing mouse M71 and human OR MouSensors. Genotyped animals will be subjected to a discrimination behavior test using known ligands such as acetophenone and a chosen human odorant. We will compare the threshold of odor detection in drinking water after mice develop an aversion to the odor through lithium chloride injection between transgenes and their wild-type littermates. Preference for odorized water versus non-odorized water will be calculated.

Abstract: The ability to detect and discriminate a broad range of environmental chemicals and to translate that information into meaningful cellular responses is essential for the survival of all

individuals. This challenge is met by different chemosensory systems. Among those, the main olfactory system is indispensable for the perception of volatile odorants. While the peripheral odor detection mechanisms have been extensively investigated, little is known about how sensitivity of individual olfactory sensory neurons (OSNs) relates to the detection threshold in behaving animals. Furthermore, there has been a long-standing disparity between the sensitivity of physiological responses of olfactory neurons and behavioral thresholds measured in intact animals. Using a combined approach of gene targeting, electrophysiology, *in vivo* imaging, and behavior, we examined odor detection thresholds of single OSNs in the olfactory epithelium, glomeruli in the olfactory bulb, and behaving mice. We focused on a class of main olfactory receptors - the Trace Amine-Associated Receptors (TAARs). Our results indicate that TAARs contribute significantly to setting behavioral thresholds to specific odors (amines). Perforated patch-clamp recordings from knobs of TAAR-expressing OSNs and *in vivo* imaging of the corresponding glomeruli in awake mice exhibited similarly low detection thresholds. In comparison, *in vivo* imaging of the same glomeruli in anesthetized mice showed a pronounced decrease in sensitivity. Behavioral detection thresholds reported by a go-no go assay were slightly higher than those observed in glomerular responses of awake animals. Together, our results show that behavioral thresholds can closely follow the sensitivity of one or a few populations of genetically defined OSNs. In addition, active processes in awake animals, such as sniffing, make an important contribution to odor sensitivity. More generally, our combinatorial approach allows us to characterize for the first time how chemical detection at the level of OSNs relates to olfactory perception in the behaving animal.

Title: Switching of pup-directed behaviors by vomeronasal receptor inputs

Authors: *Y. ISOGAI[1], H.-Y. AHN[1], M. I. LOVE[2], Z. WU[1], V. HUA[1], D. BAMBAH-MUKKU[1], R. IRIZARRY[2], C. DULAC[3];

Abstract: One of the fundamental problems in neuroscience is to elucidate the neural circuits underlying the sociality of animals. Especially in mice, which heavily rely on chemosensory signals to guide their behaviors, the vomeronasal organ (VNO) plays a vital role in social and defensive behaviors. The vomeronasal circuits therefore serve as an attractive entry point to study social behavior circuits in detail. Our previous study linked approximately 90 vomeronasal receptors to socially and physiologically relevant stimuli. This study led us to conclude that VRs encode highly specific identity (e.g., gender, species) or physiologically relevant information (e.g., stress and reproductive information). We therefore hypothesized that the VNO functions similarly to a switchboard, by which individual receptors signal specific information to the brain, critical for animals' behavioral decisions. To test this hypothesis, we investigated pup-directed behaviors, in which the VNO has been previously demonstrated to play a critical role. Importantly, wild type virgin males display pup-directed aggression whereas males lacking the VNO function, TrpC2 knockout mice for example, strikingly display parental behaviors. We screened specific vomeronasal receptors activated by pups by a combination of RNA-seq and high-throughput RNA *in situ* hybridization and successfully identified specific vomeronasal receptors tuned to pup-associated cues. We found that male mice lacking a subset of these receptors displayed dramatically reduced pup-directed aggression and increased parental behaviors. Taken together, these specific VNO "switches" controlling pup-directed behaviors will serve as a powerful platform to dissect the neural circuits underlying one of the most important aspects of social life – nurturing the offspring.

Title: Functional clustering of mouse vomeronasal sensory neurons through exhaustive calcium imaging

Authors: *D. LEE, T. E. HOLY;
Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Examining neuronal activity can provide insight into a neuron's molecular features and upstream/downstream neural circuits. Here, we recorded neuronal activity from approximately 10,000 highly heterogeneous sensory neurons in the mouse vomeronasal organ,

and categorized them by comparing their ligand-evoked responses. To examine neuronal activity from such a large number of pheromone-sensing neurons, we imaged transgenic mice expressing a genetically encoded calcium indicator (GCaMP3) with a variant of light sheet microscopy called objective-coupled planar illumination (OCPI) microscopy. Among the entire population recorded, we performed an in-depth analysis on ~1500 neurons responsive to previously known ligands. Neurons showing similar responsiveness across the entire panel of ligands, all presented at 10 μM, were categorized into the same cluster, resulting in 30 different clusters. By examining responses at multiple ligands concentrations, it was possible to further subdivide the neurons based on their sensitivity. The existence of distinct subtypes - rather than a continuum of sensitivities - is consistent with the presence of two or more receptor genes with very similar tuning profiles but differing in terms of sensitivity. We asked whether these types and sub-types might correspond to distinct receptor genes by analyzing two other properties of these neurons. First, because spontaneous activity has been shown, in other olfactory systems, to depend upon the specific receptor gene, we measured the standard deviation of fluorescence intensity in the absence of ligands. The mean standard deviation of the neurons in each cluster varied among clusters, suggesting that sensory neurons in different clusters exhibit distinct levels of spontaneous activity. Second, we measured the duration of neuronal response upon ligand treatment. Interestingly, neurons in the same cluster exhibited dichotomous response durations to the same ligands, but subclusters exhibited temporally-uniform responses. This indicates that response duration could further subdivide the functional clusters defined by ligand selectivity. Together, our exhaustive calcium imaging and analysis of ligand selectivity, sensitivity, spontaneous activity, and response duration provided functional categorization of heterogeneous neurons to a resolution consistent with single receptor genes.

Title: Identification of new ligands and analysis of the signal processing in the mouse olfactory Grueneberg ganglion

Authors: *F. MOINE, J. BRECHBÜHL, V. FRANZEN, M. NENNIGER TOSATO, M.-C. BROILLET;
Dept. of Pharmacol. and Toxicology, Univ. of Lausanne, Lausanne, Switzerland

Abstract: Organisms take advantage of their olfactory system to detect and analyze the odorants and pheromones present in their chemical environment. The mouse olfactory system is

composed of olfactory subsystems which are the main olfactory epithelium, the vomeronasal organ, the septal organ and the Grueneberg ganglion (GG). We have previously shown that, in rodents, the GG mediates the detection of volatile cues encoding for impending danger, such as alarm pheromones and predator-derived kairomones. The kairomones are molecules emitted by mice predators and implicated in interspecies danger communication. Several kairomones share a similar chemical signature with the mouse alarm pheromone (AP) that we characterized by SPME/GC-MS, the 2-sec-butyl-thiazoline (SBT). They possess a heterocyclic sulfur- or nitrogen-containing motif. The SBT alarm pheromone is indeed chemically related to kairomones emitted by mice predators, such as the 2,4,5-trimethylthiazoline (TMT) from the red fox or the 2-propylthietane (2-PT) from the stoat. We have shown that these chemical danger cues induce specifically calcium transients in mouse GG neurons. We are now tracking the circuitry triggered by SBT after this activation of mouse GG neurons, using the expression of immediate-early genes. These experiments are performed in control versus GG-axotomized mice focusing on the brain areas involved in fear detection. In parallel experiments, we have also detected by HS-SPME/GC-MS new GG ligands among which new families of chemical molecules emitted by mice predators. We then verified the activation of the GG neurons generated by these new ligands via calcium imaging experiments and their fear-inducing properties in mice by behavioral analysis. We could thus determine further the molecular receptive range of mouse GG neurons. Moreover, immunohistochemical and molecular techniques help us identify multiple signaling elements present in mouse GG neurons. In summary, these results confirm that the Grueneberg ganglion plays a dual role in detecting both intra- and interspecific chemical molecules. Title: Spatial patterns of receptor neuron input to the olfactory bulb are correlated with odor-evoked fMRI maps of glomerular activity

Authors: *B. G. SANGANAHALLI[1], M. R. REBELLO[2], P. HERMAN[1], G. M. SHEPHERD[3], J. V. VERHAGEN[2], F. HYDER[1];

Abstract: Functional imaging signals arise from distinct metabolic and hemodynamic events at the neuropil, but how these processes are influenced by pre- and post-synaptic activities is needed for quantitative interpretation of stimulus-evoked mapping data. The olfactory bulb (OB) glomeruli, spherical neuropil regions with well-defined neuronal circuitry, can provide insights into this issue. Optical calcium-sensitive fluorescent dye imaging (OICa2+) reflects dynamics of pre-synaptic input to glomeruli, whereas high-resolution functional magnetic resonance imaging (fMRI) using deoxyhemoglobin contrast reveals neuropil function within the glomerular layer where both pre- and post-synaptic activities contribute. We imaged odor-specific activity patterns of the dorsal OB in the same anesthetized rats with fMRI and OICa2+ and then co-registered the respective maps to compare patterns in the same space. Maps by each modality were highly reproducible as trial-to-trial patterns for a given odor, overlapping by ~80%. Maps evoked by ethyl butyrate and methyl valerate for a given modality overlapped by ~80%, suggesting activation of similar dorsal glomerular networks by these odors. Comparison of maps generated by both methods for a given odor showed ~70% overlap, indicating similar odor-specific maps by each method. These results suggest that odor-specific glomerular patterns by high-resolution fMRI primarily tracks pre-synaptic input to the OB. Thus combining OICa2+ and fMRI lays the framework for studies of OB processing over a range of spatiotemporal scales, where OICa2+ can feature the fast dynamics of dorsal glomerular clusters and fMRI can map the entire glomerular sheet in the OB.

Title: Use of the medicinal chemistry rules in olfactory detection as a new point of view in odorant classification

Authors: *E. POIVET, N. TAHIROVA, L. XU, S. FIRESTEIN;
Biol. sciences, Columbia Univ., New York, NY

Abstract: Since the first identification of mammalian olfactory receptors (ORs) in 1991, the deorphanization of the ORs appears to be laborious. Each olfactory sensory neuron (OSN) expresses a single OR, and all axons from OSNs expressing that particular OR project to the same glomeruli in the olfactory bulbs, suggesting an “odor-map” in the brain. While some ORs can accept multiple chemically distinct odorants, others may be more specific. Furthermore, two different ORs can have overlapping panels of odorant ligands. These properties make the “odor-map” complicated. In addition, the classification system of odorants offered by organic chemistry does not always recapitulate a biologically relevant function. Associating an odorant's chemical structure to its perception is a long-standing challenge. Since medicinal chemistry emphasizes biological function over chemical form, we are testing whether odorants related by medicinal chemistry rules are treated by ORs as being similar, using calcium imaging on mouse dissociated OSNs. Starting from the acetophenone, we have built a panel of six odorants using medicinal chemistry rules to test the hypothesis that, among odorants, heteroaromatic rings can substitute for benzene rings, with ORs exhibiting a predictable preference between them. The ORs response patterns to our odorants panel lead to an odorant classification totally different to the one expected if based on organic chemistry. We then applied our panel of six odorants on mice in a habituation-dishabituation behavior test. The results from this behavioral test confirmed our observations in calcium imaging in the dissociated OSNs. Together, our results suggest that electronegativity inside the ring is more important for odorant specification than the nature of the ring itself, and that the organic chemistry classification of molecules may not be relevant when applied to olfaction.

Title: Role of sensory neurons in intensity dependent behavioral response switch in *Drosophila*

Authors: H. RONG[1], P. DAS[3], A. LUBE[3], Y. BEN-SHAHAR[2], *B. RAMAN[3];
[1]Biomed. Engin., [2]Biol., Washington Univ., St. Louis, MO; [3]Biomed. Engin., Washington Univ. In St. Louis, Saint Louis, MO

Abstract: To survive and propagate, animals must be able to decode complex chemosensory signals and respond with appropriate behaviors. Thus, many animals evolved highly sensitive, dedicated chemosensory systems that are finely tuned to the qualitative and quantitative aspects

of their chemical environments. The molecular identification of diverse chemosensory receptors in different animal species has greatly advanced our understanding of how the nervous system perceives and decodes odor identities. However, how the nervous system decodes odor intensities remains poorly understood, especially considering that some odors can elicit contrasting behavioral responses (e.g., attraction versus repulsion) at different odor intensities. Consequently, to address this fundamental question in sensory neurobiology we propose to take advantage of the relatively simple, and well-studied olfactory system of the fruit fly *Drosophila* melanogaster. Using T-maze assay, we found that some odorants (not all) that were highly attractive to flies at low concentrations, became repulsive above an odor-specific intensity threshold. Preliminary data revealed that when the intensity of such odorants increases, the activity of sensory neurons that were highly sensitive to those odorants switched from a regular spiking (< 100 Hz) to a high firing bursting regime (>>100 Hz). This transition in low-threshold neurons was correlated with the recruitment of neural activity of independent high-threshold olfactory neurons that were not sensitive to that odorant. While neither class of neurons by themselves were sufficient to fully explain the behavioral response preference and its switch, we found that a linear model integrating the information from the two response types was sufficient to explain the fly behavior in the T-maze assay to small repertoire of odorants presented at varying intensities. In sum, our results indicates that the fly's olfactory system may employ a simple and efficient mechanism to encode odor intensity by integrating information from a relatively small subset of olfactory response types.

Title: Differential effects of adaptation on odor discrimination

Authors: *S. HANEY[1], D. SAHA[2], B. RAMAN[2], M. BAZHENOV[1];
[1]Univ. of California, Riverside, Los Angeles, CA; [2]Dept. of Biomed. Engin., Washington Univ., St. Louis, MO

Abstract: Animals are exposed to a complex and dynamic olfactory environment. To represent and respond to this environment, the olfactory system utilizes combination of spatial (across population of neurons) and temporal (rate of firing and/or synchrony of firing) coding strategies.

If, however, the olfactory stimulus changes over time, as it commonly does in the natural environment, the ability of the olfactory system to use time as a coding variable can be jeopardized. In many other sensory systems, including vision and audition, adaptation plays a critical role in resetting neural systems to its baseline state to allow for a robust representation of temporally structured stimuli. We show this strategy is also employed successfully in the insect olfactory system. Responses of the olfactory receptor neurons (ORNs), the primary sensory neurons in olfaction, adapt with odor-dependent properties that adds complexity to the temporal component of odor encoding. We quantify the spectrum of the ORN adaptation *in vivo* and use these data to construct a detailed kinetic model in silico. We then use our network model, including populations of ORNs and antennal lobe projections neurons and local inhibitory interneurons, to investigate the role of the ORN adaptation in coding. Particularly we asked the question how adaptation affects reliability of the odor representation when several odors are presented simultaneously, mimicking a complex olfactory environment. We found that strong adaptation allows for a foreground odor to be represented faithfully even in the presence of another different background odor. When background and foreground odors were very similar, however, the adaptation increased the likelihood of misclassification. We employed, these findings to propose a novel behavioral experiment where adaptation can be exploited to produce 'olfactory illusions' that may result in misclassification of odorants. Our results provide a novel insight into the strengths and vulnerabilities of a ubiquitous coding strategy, adaptation, in the specific case of insect olfaction.

Title: A functional role for off-transients in olfactory coding

Authors: ***D. SAHA**, C. LI, W. PADOVANO, B. RAMAN;
Biomed. Engin., Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Sensory stimuli often evoke temporal patterns of spiking activity across a population of neurons at each level of the neural processing hierarchy. A fundamental problem in sensory neuroscience is determining what stimulus-specific information is encoded during distinct dynamical phases of ensemble neural activity and determines the behavioral relevance of the

information that is encoded in these epochs. In the insect olfactory system, odorants are detected by olfactory receptor neurons (ORNs) in the antenna, which transduce chemical stimuli into trains of action potentials. The ORN signals are relayed downstream to the antennal lobe, where spatiotemporal patterns of activity across ensembles of projection neurons represent odors. The odor-evoked projection neuron responses are elaborate and change most rapidly after stimulus onset and offset (referred to as on-transient and off-transient responses, respectively). For lengthy odor presentations, the antennal lobe activity converges to a steady state within ~1.5 s of stimulus onset. These dynamic neural activity patterns are repeatable across trials and contain information about odor identity and intensity. In this study, we examined what information is encoded in the neural activity that follows stimulus termination. We found that these OFF responses also contain information about stimulus identity and intensity. We reveal a striking relationship between the ON and OFF responses and an important behavioral role for OFF responses. Finally, we discuss how the signal processing and representation approach our data suggests may be a conserved approach to actively indicate the absence of a stimulus.

Title: Spontaneous firing of sensory neurons modulates the gain in the downstream circuit of a simple olfactory system

Authors: ***N. KATTA**, M. O'NEILL, D. SAHA, B. RAMAN;
Biomed. Engin., Washington Univ. In St. Louis, Saint Louis, MO

Abstract: In locusts and other insects, odorants are transduced into electrical signal by the olfactory receptor neurons and transmitted to central circuits for further processing. The initial encounter with an odorant can occur under diverse ambient conditions. For example, environmental variables important to chemical sensing such as flow rate, temperature, humidity etc. can change independently or in combination with one another, yet the odor detection and recognition has to remain invariant. Previous studies have shown that these exogenous variables do influence the responses of the sensory (first-order) neurons and therefore modulate the central circuits. However, how the sensory neuron activity is manipulated to engage or disengage adaptive gain control mechanisms in the following circuits is yet to be understood. It is possible

that the magnitude of the stimulus-evoked response in the receptor neurons, their spontaneous activity, or a combination of these factors can change how information about a chemical cue is processed downstream. To this end, we studied the effects of ambient conditions on olfactory sensing and downstream processing by modulating flow rate of odorant delivery and relative humidity. We examined activity at four levels of the olfactory system: individual olfactory receptor neurons, population receptor neuron activity as assayed by electroantennograms, individual projection neurons in the antennal lobe of the brain, and population antennal lobe activity as assayed by local field potential recordings obtained from the mushroom body. Our results reveal that flow rate modulation primarily changed the overall response magnitudes evoked by different odorants without altering the baseline sensory neuron activity. These changes in sensory input appeared to have had little effect on the downstream neural activity. Increases in the relative humidity, however, caused a decrease in both response magnitude and spontaneous activity of the receptor neurons, which brought about a significant compensatory change in the spontaneous and odor-evoked activity of the second-order neurons in the antennal lobe. Further, our preliminary data suggests that these manipulations did not induce any significant change in response time constants or other finer temporal features of processing in these early circuits. Taken together, our data suggests that these changes in the downstream circuit of the brain were primarily due to changes in spontaneous baseline activity of the first-order neurons.

Title: Food deprivation inhibits mitral cell firing in the mouse main olfactory bulb

Authors: ***K. O'CONNELL**, J. W. GAMMONS, W. WEI;
Physiol., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: There is increasing evidence from both rodent and human behavioral studies that nutritional status and body weight influence olfactory behaviors. Since the main olfactory bulb (MOB) receives extensive inputs from other brain regions via centrifugal fibers, it is likely that these inputs contribute significantly to the modulation of olfactory processing in response to changes in an organism's metabolic state. However, presently there is a significant gap in our understanding of how these centrifugal inputs influence olfactory processing and behavior as a

function of the intrinsic homeostatic needs of the animal. It is well established that CNS control of body weight homeostasis and energy balance occurs initially in the hypothalamus, which subsequently projects to a plethora of other brain regions, including the olfactory bulb. In this study, we found that overnight food deprivation is associated with a ~6-fold decrease in the spontaneous action potential firing rate of mitral/tufted (M/T) cells compared to ad libitum-fed controls (Ad lib: 22.8 ± 7.1 Hz; Fast: 3.6 ± 1.0 Hz, $p = 0.01$). This change in M/T cell firing rate was also associated in a change in the rheobase of M/T cells. In the presence of synaptic blockers, more somatic current injection was required to evoke an AP in M/T cells from fasted mice compared to that required for neurons from ad libitum-fed animals. This suggests that food deprivation alters the intrinsic excitability of M/T cells, possibly by modulating ion channel expression in response to nutrient deprivation. However, we also found evidence that food deprivation alters inhibitory synaptic input to M/T cells. We observed an increase in the immediate-early gene cFos in the granule cell (GC) layer of the MOB following overnight fasting in mice. Since GC cells are key GABAergic interneurons that shape M/T cell output and are primary postsynaptic targets of centrifugal fiber (CFF) inputs from the rest of the brain (including the hypothalamus), CFF activation of GCs may contribute to the decrease in M/T cell firing via increased inhibitory GABAergic or peptidergic input to M/T cells. Consistent with this, we observed a change in the IPSC frequency in M/T cells from fasted mice compared to ad libitum fed animals. Taken together, these results suggest that hypothalamic signals of metabolic status may influence the activity of M/T cells and thus, olfactory function, with implications for food preference and palatability.

Title: Odor processing dynamics in the olfactory system: what is the impact of obesity?

Authors: ***C. MARTIN**[1,2], Y. CHELMINSKI[2], H. GURDEN[2], N. MEUNIER[3];
[1]CNRS, Orsay, France; [2]IMNC, Univ. Paris-Sud, Orsay, France; [3]INRA Univ. Versailles St-Quentin, Jouy-en-Josas, France

Abstract: Over the past three decades, obesity rates have expanded and have become a serious public health issue. This pathology is defined as the condition in which an excess in body fat is harmful for health, and characterized by a deregulation of food intake. The bidirectional

relationship between the olfactory system and food intake regulation and motivation for food is still unclear and needs further insights. The objective of this study is to test whether the nutritional status modulates odor representations at the first levels of odor processing. Our model is a strain of genetically obese mice (ob/ob mice), deficient in leptin hormone. We investigated odor-evoked electrical response of the olfactory epithelium recorded by electro-olfactogram (EOG) and oscillations of the local field potential in the main olfactory bulb in both obese and control mice. Mice were challenged for an operant test of odor discrimination in a go/no-go task and odor evoked responses compared between trained and untrained animals. In this context, ob/ob mice did not show deficits for odor learning. However, examining the EOG characteristics and beta (15-40 Hz) and gamma (60-100 Hz) frequency oscillations characteristics of odor processing and plasticity, we found a reorganization of electrical activities in the olfactory bulb and epithelium.

Title: Optogenetic activation of olfactory sensory neurons in the nose drives rhythmic activity in widespread brain areas

Authors: ***A. H. MOBERLY**, M. MA;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Respiration is not only influenced by autonomic demands, but also by emotional states (fear, anxiety, anger, etc.). On the other hand, conscious control of respiration rate (in the form of rhythmic, nasal breathing) can affect physiology, mood, and cognition. In rodents, nasal respiration entrains rhythmic neural activity in many brain regions including olfactory centers (olfactory bulb, olfactory tubercle, and pirifom cortex) somatosensory cortex, and limbic structures (amygdala and hippocampus). Thus, respiratory input is well positioned to serve as a reference for the synchronization of brain activity across widespread regions. However, the source of respiration-locked neural activity remains unclear. Because these low-frequency rhythms are decoupled from the breathing cycle when inspired air bypasses the olfactory epithelium, primary olfactory sensory neurons (OSNs) may be the source of respiration-locked input to the brain. Since OSNs not only respond to odorants but also to mechanical stimulation

they may provide an early representation of airflow that propagates to olfactory and other brain regions. We confirmed that OSN activation can influence widespread field potential oscillations by stimulating OSNs in the nasal epithelium of OMP-ChR2 mice in combination with multisite local field potential (LFP) recordings. Light stimulation evoked strong oscillatory activity at stimulation frequencies higher than the animal's baseline respiration rate. We observed this result in the barrel cortex and hippocampus - two areas recently discovered to express respiratory-locked rhythms. These results suggest that peripheral information provided by OSNs is able to drive widespread neural activity.

Title: Plasticity in Arc-transcribing accessory olfactory bulb internal granule cells following intermale aggression

Authors: *H. L. CANSLER, J. P. MEEKS;
UT Southwestern, Dallas, TX

Abstract: The mechanisms underlying the brain's ability to rapidly process sensory information and produce appropriate behaviors is an area of much recent interest. The accessory olfactory system (AOS) is well suited for approaching these questions because it is a relatively simple and compact system that regulates innate, sex-typical behaviors, such as reproductive behavior and territorial aggression. The accessory olfactory bulb (AOB) is the first neural circuit to process chemosignals from the sensory periphery, making it a critical link between sensation and downstream circuits known to guide behavior. Despite decades of research, specific plastic changes that occur in the AOB in response to salient behavioral events remain poorly understood on a cellular and molecular level. We investigated the AOB circuit response to intermale territorial aggression using the immediate early gene Arc, which indicates recent activity and is implicated in diverse forms of plasticity throughout the brain. We found that adult resident C57BL6/J males significantly upregulated Arc protein expression in posterior internal granule cells (IGCs) compared to controls following a 10-minute exposure to a novel Balb/cJ male intruder. Arc protein expression peaks 1-2 hours after behavior and returns to baseline by 4 hours. Exposure to soiled bedding is sufficient to produce this effect, and vomeronasal input is

required, as indicated by experiments with Trpc2-/- mice. We have also found that the Arc gene is necessary for the normal expression of aggressive behavior in the resident-intruder paradigm. One week of solo housing is required for robust aggression from residents, and one-day residents as well as Arc-/- one-week residents exhibit significantly decreased aggressive behavior. This finding implicates Arc in an AOS-mediated behavior for the first time. We used transgenic mice that express GFP in Arc-transcribing cells (Arc-d4EGFP-BAC mice) to investigate the physiological effects of Arc transcription. We targeted patch-clamp recordings to GFP+ and GFP- IGCs during the 4-8 hours after behavior. We found that Arc-expressing IGCs exhibit a fast-spiking phenotype when depolarized with a current injection. The same group also exhibits decreased Ih depolarization when hyperpolarized with a current injection. This suggests that these IGCs either undergo a plastic change following the resident-intruder paradigm, or that Arc expression is specific to a subpopulation of IGCs with these intrinsic properties. These data represent a step towards understanding sensory-mediated plasticity in circuits that guide innate, sex-typical behaviors.

Title: Synaptic plasticity in the olfactory bulb underlying aversive olfactory learning is inhibited by ER stress

Authors: *F. OKUTANI[1], J. TONG[2], H. KABA[2];
[1]Kochi Med. Sch,, Kochi, Japan; [2]Physiol., Kochi Med. Sch., Nankoku, Japan

Abstract: The endoplasmic reticulum (ER) is an organelle in which secretory and transmembrane proteins are folded or processed, and is susceptible to various irritants, such as tunicamycin (TM), that provoke the accumulation of unfolded protein response and induce ER stress in the lumen, which is linked to neuronal death in various neurodegenerative diseases, including Parkinson's disease, Alzheimer's disease, and many others. It is well known that patients suffer from olfactory dysfunction in these diseases. Therefore we examined the inhibitory effect of ER stress on synaptic plasticity in the rat olfactory bulb (OB) as a model of aversive olfactory learning. Before eye opening young rats depend on somatosensory and olfactory function for survival, as they can learn their dam's odor and approach her without visual information. They do this in part by learning their mother's odor as a conditioned stimulus

that is paired with an unconditioned somatosensory stimulus given by maternal care. We have shown that synaptic plasticity in the OB underlies aversive olfactory learning. In order to establish aversive olfactory learning, pairing of an artificial odor and foot-shock during training on postnatal day (PND) 11 is required. Rats show aversion to the odor on the next day. Infusion of TM into the OB during odor exposure on PND 11 impaired olfactory learning tested on PND 12 in a dose-dependent manner. Short-term memory, however, was maintained even after TM infusion because rats show aversion to the odor at the testing one hour after the training. Electrophysiology using OB slices of PND 11 rats enables us to observe long-term potentiation (LTP) induced in field excitatory postsynaptic potentials slope in the granule cell layer, which is evoked by antidromic stimulation of the lateral olfactory tract. TM administration has an inhibitory effect on the late phase of LTP without affecting the early phase of LTP. These results are consistent each other to suggest that ER stress impaired aversive olfactory learning by inhibiting synaptic plasticity in the OB.

Title: Impact of olfactory fear conditioning on olfactory tuning in cortical and medial amygdaloid nuclei

Authors: V. SAVAGE, G. MINOGUE, T. REDMOND, A. ROCHA-CARTAGENA, *G. A. COUSENS;
Drew Univ., Madison, NJ

Abstract: Remarkable progress has been made in recent years in characterizing features of odor representation in piriform cortex. Less is known about odor representation in other primary olfactory regions, including cortical and medial amygdaloid nuclei. Here we show that neurons within cortical and medial amygdaloid nuclei of urethane-anesthetized rats exhibited odor-selective alterations in firing rate often in phase with the ongoing respiratory cycle. Cells exhibited a range of tuning breadths to molecularly distinct odorants, and adjacent cells were often similarly tuned. Preliminary data suggests that prior olfactory fear conditioning enhanced recruitment of cells responsive to the conditioned odor. Current work is examining regional differences odor responsivity and selectivity across amygdaloid nuclei with differing patterns of innervation by main and accessory olfactory bulbs. These findings suggest that cortical and medial amygdaloid nuclei contribute to odor representation and that prior learning can alter olfactory tuning.

Title: Dynamics of activity in main olfactory bulb granule cells during associative odor learning

Authors: ***B. N. CAZAKOFF**, S. D. SHEA;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Odors are critical to the survival and reproductive success of many organisms. In order to guide appropriate behaviour, the brain must not only form accurate representations of these odor identities, but also flexibly encode their association with positive or negative outcomes. Several brain regions display activity that reflects odor valence, including the main olfactory bulb (MOB). For example, mitral/tufted cells (MTs), which receive input from peripheral receptor neurons and constitute MOB output, exhibit differences in their activity depending on whether or not the odor is rewarded (Kay and Laurent 1999, Doucette and Restrepo 2008). How such divergent activity arises is not known, but several lines of evidence implicate intrinsic MOB inhibitory neurons known as granule cells (GCs). GCs are the primary target of cortical and other centrifugal feedback to the MOB, and they make reciprocal dendrodendritic synapses that inhibit MTs. Therefore, they are well placed to modulate MT activity according to changes in stimulus value. Recent technical advances have enabled examination of GC activity in awake animals using neurophysiology and imaging methods (Cazakoff et al 2014, Kato et al 2013). Nevertheless, whether GC activity reflects odor valence is unknown. We are using 'loose patch' electrophysiology to monitor GC spiking activity in awake, head-fixed mice actively learning to associate odors with positive (delivery of sucrose solution) or negative (delivery of quinine solution) outcomes. We first trained mice to reliably lick for sucrose reward upon detection of any of a set of 8 odors. Subsequently, when an arbitrarily chosen odor becomes associated with delivery of an aversive quinine solution, the mice learn to withhold licking to that odor to avoid the tastant. Consistently, mice rapidly achieve reliable and accurate performance of this behavior. Following the training period they are able to quickly (within ~20-60 trials) form associations of novel odors with sucrose and quinine and can also learn reversals of a previous association. Having established this rapid odor association behavior, we are now recording from MOB neurons, including GCs, during ongoing learning of this task. These results will provide important insight into the role of GCs in olfactory processing and the greater role of inhibition in shaping sensory responses in context.

Title: Noradrenergic blockage in the olfactory bulb during similar odor discrimination learning leads to impaired odor discrimination and pattern separation in rats

Authors: ***A. M. SHAKHAWAT**, A. GHEIDI, I. T. K. MACINTYRE, Q. YUAN;
Fac. of Med., Mem. Univ., St John's, NL, Canada

Abstract: Norepinephrine (NE) is critical for olfactory learning and odor discrimination in both neonatal and adult rodents. In adult rats and mice, blockage of the olfactory bulb adrenoreceptors impairs fine odor discrimination and reduces synchronized firing of mitral cells in the olfactory bulb in response to the rewarded odor. How NE manipulation in the olfactory bulb influences the odor coding in cortical structures such as the piriform cortex is not well understood. Here, using cellular compartment analysis of temporal activity by fluorescence *in situ* hybridization (catFISH) of an immediate early gene Arc, we studied how blockage of adrenoceptors in the olfactory bulb during odor discrimination training affects odor representations in the piriform cortex. CatFISH enables visualization of Arc at two time points in the same animals. Two ensembles activated by the same odor (rewarded) were used to index the stability of Arc activation, while two ensembles activated by two different odors (rewarded and unrewarded) were used to study pattern separation in the piriform cortex. Consistent with previous reports, local bulbar infusion of both α and β-adrenoreceptors antagonists (α-receptor antagonist Phentolamine, 10 mM and β-receptor antagonist Alprenolol, 120 mM) impaired difficult similar odor discrimination learning. Rats given these antagonists needed significantly more trials than the saline infused group to reach the same level of successful odor discrimination. The neural representations of the rewarded odor in the anterior piriform cortex, revealed by the visualization of Arc+ cells, were similar in the two groups when learning took place. The number of Arc+ cells and the reliability of activated cells when the animals were exposed to the same odor twice during the catFISH procedure, were not different in the two groups. However, at an earlier time point when the saline infused group learned but the drug group did not, we observed an increase in the reliability of activated neural ensembles to the rewarded odor in the saline group compared to the drug group. Furthermore, successful odor discrimination learning also promoted ensemble separation in the piriform cortex when both rewarded and unrewarded odors were tested.

Together, NE blockage in the olfactory bulb impaired similar odor discrimination by reducing the stability of pyramidal cell activation and pattern separation in the piriform cortex.

Title: Transient asymmetry in primary and higher order olfactory cortex during odor learning

Authors: ***Y. COHEN**[1], D. PUTRINO[2], D. A. WILSON[1];
[1]EBI, Nathan Kline Institue, Orangeburg, NY; [2]Dept. of Rehabil. Med., Weill Med. Col. of Cornell Univ., NYC, NY

Abstract: A fundamental question in neuroscience is the significance of asymmetry, or cerebral lateralization, which allows functional specialization of bilateral brain regions. Lateralization is a multifaceted phenomenon occurring at both the structural and functional levels, and can be expressed as either a stable lifelong trait, or as a dynamic feature during behavior and development. Importantly, abnormal lateralization has been linked to neurological and psychiatric disorders. There is increasing evidence of cerebral lateralization in rodents related to synaptic plasticity and memory (olfaction: Cohen et al., 2015; audition: Marlin et al., 2015; hippocampus: Shipton et al., 2014). For example, in piriform cortex (PCX) of rats performing a two-alternative forced choice odor discrimination task, we demonstrated local field potential (LFP) beta frequency oscillations in the left PCX are more robust during initial learning than the right PCX. In contrast, the right PCX shows beta band enhancement at the late stages of learning while the left PCX changes return to baseline. The extent of this asymmetry in plasticity through the olfactory system, and its underlying mechanisms are unknown. Here using telemetry LFP recordings of rats performing odor discrimination task as before (Cohen et al., 2015), we demonstrate that the orbitofrontal cortex, a region receiving both direct and indirect input from the PCX, is also lateralized during the learning. However, as opposed to PCX where the left hemisphere changes most dramatically during early learning, trial-related beta oscillations in right OFC are most pronounced during initial and reversal learning, with only limited change in left OFC.We are currently screening PCX and OFC for lateralization in molecular markers related to plasticity to begin to understand the mechanisms of this widespread cortical asymmetry related to odor learning.

Title: Investigating attentional modulation of odor coding in the olfactory tubercle

Authors: ***K. S. CARLSON**, E. S. DAUSTER, M. A. GADZIOLA, D. W. WESSON; Neurosciences, Case Western Reserve Univ., Cleveland, OH

Abstract: Depending on the internal state of an individual, the same sensory stimulus may be perceived differently at different times. Attentional processes are especially well known to allow an individual to filter out irrelevant stimuli to focus on aspects of the environment that are relevant for survival. What are the underlying neural processes that contribute to this difference in perception? While this question has been investigated at the cellular level in sensory systems such as vision and audition, very few studies have explored attentional modulation of olfaction at this level. Human functional imaging research has, however, uncovered evidence that odor-directed attention modulates the representation of odors in the olfactory tubercle. While the rodent olfactory system lends itself well as an ideal model to explore the influences of attention at the cellular level, behavioral tasks involving manipulations of selective odor-directed attention in rodents are unavailable. To overcome this, we designed a novel two-alternative choice behavioral task that yields precise and systematic manipulations of odor-directed selective attention. Our results to date 1) show the development and implementation of this novel task in Long-Evans rats, 2) provide fundamental insights into the role of attention in modulating olfactory acuity, and 3) demonstrate the feasibility of utilizing this task, paired with extracellular recordings, to investigate the effects of attentional modulation on odor coding in the olfactory tubercle. Together, these results enhance our understanding of how attention shapes sensory processing and perception, which is impaired in a variety of neurological disorders, including Alzheimer's disease.

Title: Role of basal forebrain cholinergic neurons in olfactory learning

Authors: *A. F. NUNEZ-PARRA, D. RESTREPO;
Cell and Developmental Biol., Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: The ability of the olfactory system to represent sensory cues is strongly influenced by neuromodulators released in response to a challenging and constantly changing external environment. Of particular interest is the neuromodulator acetylcholine (ACh), which has been linked in several brain regions with attention, cue detection and learning. The olfactory bulb and piriform cortex receive abundant cholinergic innervation from the basal forebrain and it has been suggested that in these regions ACh promotes contrast enhancement among similar odorants and network synchronization to generate a more efficient olfactory coding, ultimately affecting olfactory learning and memory. Substantial efforts have been made to study the cellular effects of ACh in the olfactory system, yet the time course of activation of basal forebrain neurons during active olfactory learning remains unknown. Here, we performed multielectrode recordings from the basal forebrain of awake freely moving animals exposed to the associative learning paradigm go-no go. This task studies learning of a water-deprived rodent to actively discriminate between two odorants (a rewarded and a non-rewarded odor). We found that more that 50% of the basal forebrain neurons activity diverges (either increase or decrease their firing rate) when the animal started the behavioral trial. Importantly, when the stimulus was presented, between 18 and 32% of the basal forebrain neurons exhibited a change in firing rate. During HIT trials the increase/decrease in activity was long lasting (4s), extending after the end of stimulus delivery (delivery time=2.5s). In contrast, when the animal rejected a trial correctly, the modulation in firing rate was transient and lasted only 1.5s. This condition was not maintained in a relatively easy task when the stimulus consisted of an odor vs. mineral oil or in a go-go task, where both stimuli are rewarded and no discrimination between stimuli is required. In addition, we used selective optogenetic stimulation to identify neurons that were directly or indirectly activated by light in the basal forebrain of animals expressing channelrhodopsin under the control of the choline acetyltransferase promoter, an enzyme that is exclusively expressed in cholinergic neurons. Our preliminary results show that these neurons are recruited at the

beginning of the trial and after the odors are presented. In summary, our data shows for the first time in awake freely moving animals that precise temporal cholinergic release from the basal forebrain plays an important role in information processing required for proper olfactory coding.

Title: Odor-driven oscillations in human olfactory cortex

Authors: *H. JIANG[1], S. LEVINE[1], S. SCHUELE[1], J. ROSENOW[1], J. PARVIZI[2], J. TAO[3], J. GOTTFRIED[1];
[1]Neurol., Northwestern Univ., chicago, IL; [2]Stanford Univ., Palo Alto, CA; [3]Neurol., The Univ. of Chicago, Chicago, IL

Abstract: The mechanisms by which human olfactory cortex processes odor stimuli are poorly understood. Previous studies involving human intracranial EEG have shown that the amygdala produces event-related potentials in response to odorants, but the electrophysiological properties of important olfactory regions such as piriform cortex are not yet known. Five patients with depth electrode coverage in medial temporal lobe (including piriform cortex) performed an odor detection task while undergoing intracranial EEG monitoring. Each patient received between four and eight odors varying across dimensions of valence and edibility, along with odorless air, and on each trial reported whether or not an odor was detectable. In all five patients, results showed that piriform cortex exhibited significantly increased power in the theta-band frequency (4-7 Hz) after the onset of sniff during odor presentation relative to no odor presentation. We then applied a linear binary classifier to trial-wise piriform spectrograms, which reliably predicted the specific odor presented on each trial 55-75% of the time (chance = 50 %). Classification accuracy across odor pairs was also higher among piriform electrodes relative to other electrodes placed within cortical and subcortical regions, ranking within the top 1-10% of recorded electrodes. These results confirm involvement of posterior piriform cortex in early processing of odor identity. Additionally our finding of prominent theta-band odor-evoked

activity accords well with animal models implicating theta rhythms as a fundamental olfactory electrophysiological signature.

Title: Odor source localization in a single sniff

Authors: ***S. HAESLER**, J. ESQUIVELZETA-RABELL, K. MUTLU, J. NOUTEL; Neuroelectronics Res. Flanders, Leuven, Belgium

Abstract: Navigation, finding food sources and avoiding danger critically depend on the identification and spatial localization of airborne chemicals in the environment. When monitoring the olfactory environment, rodents engage in active sampling behaviours, commonly also referred to as exploratory sniffing. Exploratory sniffing is characterized by stereotypical high frequency respirations, which are also reliably evoked by novel odorant stimuli. To resolve the mechanistic principles underlying exploratory sniffing and novelty processing, we have developed a behavioral paradigm in mice, which provides parametric measures of novelty perception. In our task, we present novel and familiar olfactory stimuli to head-restrained mice while measuring respiration. To enable highly reliable, repeated monitoring of respiration in the same animal over long time periods, we developed a novel method for non-contact respiration measurements using infrared thermography. Using video frame analysis, we extract respiration rates from the thermal data, collected at 60Hz. By simultaneously measuring intranasal pressure through implanted cannula, we validate our novel method and confirm faithful detection of inhalation and exhalation onsets. Moreover, we find that the common practice of cannula implantation, distorts odor flow and creates an asymmetric stimulus bias between the two nostrils. One key feature of our novel method is the ability to retrieve positional information about the location and movement of the two nostrils. When introducing novel odorants, we find a remarkable degree of nostril movements, even though mice are head-restrained. Using asymmetric stimulus delivery, we further find that mice direct their nostrils to the odor source within the first sniff after odor onset. This olfactomotor response is highly reliable, as mice orient towards the correct side in >80% of first novel odor presentations. Directional responses

habituate concurrently with subsequent odor presentation, similar to the habituation of the sniffing response. The spatial orienting response provides direct evidence mice can use intranasal stimulus gradients for source localization. In our ongoing work, we investigate the effect of unilateral naris occlusion on the spatial orienting response and explore which brain areas are critical for odour source localization.

Title: Experimental platform for dissecting olfactory system in *C. elegans*

Authors: ***K. ASHIDA**, H. SHIDARA, K. HOTTA, K. OKA;
Keio Univ., Yokohama, Japan

Abstract: The sensory neuron, AWC, responds to removal of odor stimulus in Caenorhabditis elegans. AIY interneurons, which receive inhibitory synaptic inputs from AWC, respond to the onset of odor stimulus. Although these neurons have been known to relate to olfactory learning and adaptation, the relation between AWC and AIY neurons on olfactory information processing and learning is poorly understood. To quantify this relation directly, timing and intensity of neuronal activity are crucial. Therefore, simultaneous Ca2+ imaging of AWC and AIY is a powerful tool. First, we prepared transgenic worms to dissect two neurons. Because Ca2+ responses of AIY interneurons to olfactory stimulus are detected only in neuritis close to axon of AWC, it is difficult to distinguish neural activities in neurites of AIY from that in axon of AWC. Therefore, we expressed the Ca2+ indicator with nuclear localization tag in AWC and the conventional indicator in AIY [Schrodel, et al., 2013], and checked Ca2+ responses to the odor, isoamyl alcohol, in these neurons. The Ca2+ in AWC increased with odor removal and decreased with odor application. On the other hand, AIY responded to odor application with Ca2+ increasing. These responses correspond to the result from the previous research [Chalasani, et al., 2007], and indicate that the simultaneous imaging system works correctly. Then, we identified the relation between Ca2+ responses from AWC and AIY using this system. AIY neurites responded before AWC soma response. In AWC, the onset of Ca2+ increase started axon first, and soma and dendrites follow it. Moreover, we found new characteristics of Ca2+ responses in AWC. AWC has been known to be stationary against odor stimuli [Kato, et al., 2014]. However, Ca2+ responses to periodic stimuli of odor were not stationary. There was a delay from stimulus timing to the outset of Ca2+ responses. The delay time at the onset of stimuli was shorter than

that after a few minutes from the onset of the stimulus. In conclusion, we succeeded to construct simultaneous imaging system of the sensory neuron and interneuron. This system clarified the timing of the Ca2+ response of AWC and AIY. The result showed that the system was useful for elucidating the olfactory information processing, especially adaptation and learning.

Title: Unraveling the dual role of the Dopaminergic system underlying locomotor behavior and the innate value of an aversive olfactory stimulus in *Drosophila*

Authors: N. FUENZALIDA-URIBE, *J. M. CAMPUSANO;
P. Univ. Catolica Chile, Santiago, Chile

Abstract: The Mushroom Body (MB) is a brain integration center key in processing several sensory stimuli and in defining locomotor behavior in insects. Dopamine (DA) systems innervate and modulate the activity of neurons thorughout the entire insect brain including the MB. It has been shown that through the regulation of specific neuronal populations in MB, this biogenic amine becomes relevant in the modulation of different innate behaviors in *Drosophila*. Here we have studied the role of two DArgic clusters (PAM and PPL1) which innervate different zones of MB, on the innate value observed in adult flies in presence of an aversive stimulus (Benzaldehyde, Bz) and the locomotor behavior associated. In order to do this, we manipulated the synaptic transmission of these DA neural clusters through the expression of Tetanus toxin (Tetx), Kir2.1 channel and TrpA1 channels. Our results show that PPL1 and PAM neurons differentially modulate the innate value of Bz in the adult fly. On other hand, blocking the neurotransmission of PAM neurons also decreased the locomotor behavior of flies exposed to Bz, an effect not observed when silencing PPL1. A chronic Nicotine treatment rescued the defect on motor output observed in PAM-silenced neurons while did not rescue the changes in the innate value to Bz. Our results show the differential contribution of specific DArgic pathways innervating MB in the modulation of locomotor behavior and the innate value to an odorant in *Drosophila*. Title: Alterations in brain-derived leptin-homolog lead to obesity phenotypes in *Drosophila* through regulation of food odor value signaling

Authors: *J. BESHEL, Y. ZHONG;
Neurosci., Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Motivated feeding results from the interplay of homeostatic and hedonic drives and dysregulation of either may contribute adversely to conditions of overweight and obesity. Recent work demonstrates domeless receptors in *Drosophila* can be activated by human Leptin, a typically adipose-derived “satiety hormone” with a long-established role in weight regulation. Interestingly, knockdown of endogenous domeless-ligand upd2 in the fat body of flies leads to smaller body size and has no effect on feeding, the opposite behavior of leptin-deficient mammals. While we replicate the lower weight and unchanged food intake in upd2-manipulated flies, we further show manipulations to another endogenous ligand for the domeless receptor, brain-based unpaired 1 (upd1), recapitulate mammalian obesity phenotypes in flies. Flies with reductions in upd1 restricted to neural tissue show increased weights, increased food intake, and increased attraction to food odors. We additionally report domeless receptors likely mediate observed phenotypes. We show behavior-relevant domeless receptors are located on neurons expressing *Drosophila* Neuropeptide F (dNPF), the Neuropeptide Y (NPY) homolog, in the central brain with targeted receptor knockdown specifically to these cells replicating increased weight, attraction and intake phenotypes. We speculate upd1 acts as the homeostatic regulator of our previously reported dNPF food odor value signal, up- or down-regulating this hedonic signal as a function of satiety state. Our findings suggest Leptin-NPY and upd1-dNPF represent functionally homologous circuits across diverse species and imply in mammals adipose- and less understood brain-derived Leptin may play different roles in feeding and weight regulation.

Abstract: To achieve long-term weight loss in obese subjects, reverses enhanced preference and intake of sweet/fatty foods. Although taste preference changes following bariatric surgery have been previously described, potential concomitant odor preference changes remain unexplored. Therefore, the aim of this study was to determine the relationship between taste and odor preference changes and successful weight loss following bariatric surgery in a cohort of patients by means of a questionnaire. The study was performed on 57 human subjects with body mass index (BMI) above 30 (at least class I obesity), who were scheduled to receive or had previously received Roux-en-Y gastric bypass (RYGB) surgery or the gastric sleeve procedure. A Self-Assessment Manikin (SAM) test was used to measure the participant's affective reaction (ranging from pleasure to displeasure) to a variety of food-related and odor-related pictures. An unpaired t test was performed to determine the difference between SAM ratings pre- and post-surgery; Spearman rho was used to describe the relationship between amount of change in BMI since surgery and SAM ratings. Results confirmed earlier reports about changes in sweet/fatty foods preference after surgery and revealed a shift in preference toward less calorie-dense foods. Patients experiencing calorie-dense foods aversion revealed more postoperative weight loss and reduction in BMI compared to their counterparts without these features. Our results also revealed that changes in olfactory preferences that occur following bariatric surgery do have a significant correlation with successful post-surgical change in BMI. Importantly, data showed a clear and consistent association of coffee and banana odor ratings and the change in BMI following surgery. In particular, patients rating a coffee and/or banana odor as more pleasing after surgery had a lower post-surgical BMI. Coffee odor was also shown to become more pleasing as time since surgery increased. In conclusion, results showed that following bariatric surgery both taste and odor preferences are significantly altered and that these changes correlate with more successful changes in BMI. These results may suggest diagnostic criteria to identify people at risk for less than optimal changes in BMI following bariatric surgery.

Title: Mice selected for high and low saccharin intake differ in consumption of appetitive taste solutions regardless of their taste quality

Authors: *R. POOLE[1], M. INOUE[2], N. BOSAK[1], A. BACHMANOV[1];
[1]Monell Chem. Senses Ctr., Philadelphia, PA; [2]Tokyo Univ. of Pharm. and Life Sci., Hachioji, Tokyo, Japan

Abstract: In mice, variation in sweet taste is influenced by polymorphisms of the Tas1r3 gene. However, there are Tas1r3-independent genetic factors that influence variation in sweet taste responses as well. To examine Tas1r3-independent sweet taste mechanisms, we selectively bred two strains of mice that share a common Tas1r3 allele, yet differ in saccharin intake: the Sac-H and Sac-L strains, with high and low saccharin intakes, respectively. Electrophysiological recordings of taste-evoked responses in the chorda tympani nerve showed that these strains had similar peripheral taste responsiveness. These results suggest that strain differences in saccharin intake may be caused by strain differences in central taste processing. To distinguish whether these central mechanisms are specific to sweet taste or are more general and apply to other appetitive taste stimuli, we examined preferences for sweet (saccharin, sucralose, and sucrose) and non-sweet (oil, maltodextrin, MSG, and IMP) palatable solutions using two-bottle choice tests. We found that regardless of taste quality, when preference scores exceeded 80% in both strains, Sac-H mice consumed significantly more taste solution than Sac-L mice. Interestingly, although mice preferred MSG, preference scores did not exceed 80% at any concentration tested, and MSG intakes did not differ between strains either. Given that MSG and IMP have the same taste quality (i.e., umami), these results support the conclusion that differential consumption of taste solutions by Sac-H and Sac-L mice is driven by the hedonic value of a taste solution, not taste quality. Our data suggest that mice selected for saccharin intake are a valuable model for analyzing mechanisms of reward because taste stimuli must evoke a strong appetitive response to trigger differential intake.

Title: Generalization of conditioned taste aversion of dashi to salts is modified by lactic acid in mice

Authors: *E. R. DELAY[1], B. M. WEAVER[2], D. R. LANE[2], T. KONDOH[3];
[1]Dept. of Biol., [2]Neurosci. Undergraduate Program, Univ. of Vermont, Burlington, VT; [3]Inst. for Innovation, Ajinomoto Co., Inc., Kawasaki 210-8681, Japan

Abstract: Dried bonito *dashi*, a Japanese fish stock, is an important component of Japanese cuisine and is a preferred flavor of humans and rodents. It is made of a complex mixture of amino acid, proteins, organic acids and minerals. Previous research (Delay & Kondoh, 2015) reported that in mice *dashi* elicits all 5 of the basic tastes. The purpose of this study was to use conditioned taste aversion (CTA) methods to determine if an aversion to *dashi* generalizes to one or more of 4 salts (NaCl, KCl, CaCl2, MgCl2), and if lactic acid (a large component of *dashi*) to these salts alters the taste and resulting generalized aversion in C57BL/6J mice with compromised olfactory systems. Conditioning and generalization testing were done with 25% solution of *dashi* (conditioned stimulus) presented in a Davis Rig (MS160). Stimulus generalization was measured by counting licks when mice were presented with NaCl (100 and 300 mM), KCl (100 and 300 mM), CaCl2 (15 and 30 mM), and MgCl2 (20 and 40 mM), with or without 0.9% lactic acid added. We found that all 4 salts showed mild naturally aversive qualities at their highest concentration. Additionally, *dashi* CTA generalized more to the divalent salts than the monovalent salts. Interestingly, lactic acid had little effect on CTA generalization to the monovalent salts whereas it decreased generalization to divalent salts. The CTA of *dashi* did not generalize to lactic acid alone. These results indicate that all 4 salts may contribute to the taste of *dashi* and that interactions between lactic acid and divalent salts alter the tastes elicited by these salts. These findings suggest lactic acid may play a complex role on the perception of foods. Further studies will examine whether citric acid, another organic acid, can also modulate CTA generalization in a manner similar to lactic acid.

Title: Multiple glutamate receptors detect L-amino acid taste in mice

Authors: *S. PAL CHOUDHURI, R. J. DELAY, E. R. DELAY;
Biol., The Univ. of Vermont, Burlington, VT

Abstract: G-protein coupled receptors (GPCRs) are thought to be involved in the detection of umami and possibly L-amino acid taste. These include the heterodimer T1R1/T1R3, mGluR4, and mGluR1. While several studies suggest T1R1/T1R3 is a broadly tuned L-amino acid receptor, little is known about the function of mGluRs in L-amino acid taste transduction. Our previous data indicate that other taste receptors may also contribute to the taste of L-amino acids and 5' nucleotides such as inosine 5' monophosphate (IMP). Here we performed calcium imaging of isolated taste sensory cells (TSCs) using the ratiometric dye Fura 2 AM to investigate the role of different mGluRs in detecting various L-amino acids. We harvested TSCs from wild type (C57BL/CJ) and T1R3 knock-out (T1R3 KO) mice. Using selective agonist for various mGluRs such as (RS)-3, 5-dihydroxyphenylglycine (DHPG) (an mGluR1 agonist) and L-(+)-2-amino-4-phosphonobutyric acid (L-AP4) (an mGluR4 agonist), we evaluated the responses of TSCs to determine if each TSCs might respond to IMP and to the L-amino acids, monopotassium L-glutamate, L-serine and L-arginine. Additionally we used selective antagonists against different mGluRs such as (RS)-1-aminoindan-1,5-dicarboxylic acid (AIDA) (an mGluR1 antagonist), (RS)-α-methylserine-O-phosphate (MSOP) and (RS)-α-cyclopropyl-4-phosphonophenylglycine (CPPG) (both mGluR4 antagonists) to determine if the antagonists can block the responses elicited by these L-amino acids and IMP. We found that antagonist for mGluR4 and mGluR1 significantly blocked the responses elicited by IMP and each of these L-amino acids. Additionally the antagonists were able to block L-amino acid elicited responses in TSCs of T1R3 KO mice. Collectively, this study provides evidence for the involvement of several mGluRs in L-amino acid taste responses in mice and supports the hypothesis that multiple receptors contribute to IMP and L-amino acid taste.

Title: Receptive field size, chemical and thermal responses and fiber conduction velocity of rat chorda tympani geniculate ganglion neurons

Authors: Y. YOKOTA, *R. M. BRADLEY;
Univ. Michigan Sch. Dent., Ann Arbor, MI

Abstract: Afferent chorda tympani (CT) fibers innervating anterior tongue taste receptors in fungiform papillae have neuron cell bodies in the geniculate ganglion, that differ in soma size and axon diameter. This structural diversity could relate to functional differences. To investigate these functional differences we recorded extracellular responses from single geniculate ganglion neurons to lingual application of chemical and thermal stimuli and determined receptive field properties. Receptive field size was mapped by electrical stimulation of individual fungiform papillae. Response latency to electrical stimulation was used to determine fiber conduction velocity. To date we have analyzed the responses of 30 neurons to room temperature chemical stimuli (0.5M NaCl, 0.5M NH4Cl, 0.01N HCl, 0.03M citric acid, 0.02M quinine HCl and 1.0M sucrose), and distilled water at 4°C. Based on response to chemical and thermal stimuli, neurons were divided into five categories. Three neurons were classified as SALT, responding only to NaCl and NH4Cl. Average receptive field size of these neurons was 6.3 ± 1.3 papillae. Seven neurons, classified as OTHER, responded to salts and other chemical stimuli (acids, bitter and sweet) and had smaller receptive fields (4.5 ± 1.3 papillae). Six neurons responded to salts and cold, classified as SALT/THERMAL, and 7 neurons responded to salts, other chemical stimuli and cold, classified as OTHER/THERMAL. Average receptive field size of SALT/THERMAL was 6.4 ± 1.7 papillae, and for OTHER/THERMAL was 5.1 ± 1.9 papillae. Seven neurons categorized as THERMAL, responded only to cold. Receptive field size of these neurons was 1.6 ± 0.5 papillae, significantly smaller than average field size of SALT and OTHER, and located at the tongue tip. These data show that neuron response categories have different receptive field sizes. For all 30 neurons, receptive field size ranged from 1 to 8 papillae. Conduction velocity was determined using latency to electrical stimulation (46.8 ± 13.1 msec) and conduction distance (58 ± 3 mm). The conduction velocity of 29 neurons was 0.4-2.0 m/s, classified as C fibers, and one neuron was classified as an Aδ fiber (2.5 m/s). Neurons with large receptive fields had higher conduction velocities than neurons with small receptive fields. We conclude that geniculate ganglion neurons can be distinguished by receptive field size and response properties. Because several papillae and taste buds are connected to a single ganglion neuron, responses from the periphery reflect broad taste responsiveness from multiple taste organs.

Title: Sex differences in rat glossopharyngeal nerve taste responses

Authors: L. J. MARTIN[1], *S. I. SOLLARS[2];
[1]Psychology, [2]Univ. of Nebraska at Omaha, Omaha, NE

Abstract: Sex differences in taste-guided behavior have been well established in several species, but the gustatory processes underlying these behaviors have not been well characterized. While male and female rats display differences in NaCl preference and discrimination, there is contradictory evidence whether the chorda tympani nerve (CT) responds differently to NaCl based on sex. Additionally, it is unclear whether sex differences exist in peripheral processing of sweet and bitter stimuli, though electrophysiological recordings from the parabrachial nucleus of the pons indicate differential activity toward these two stimuli in male versus female rats. To further characterize the role of sex differences in taste processing, whole-nerve electrophysiology was performed on the glossopharyngeal nerve (GL) of adult male and female Sprague-Dawley rats in response to taste stimulation of the posterior tongue. Stimuli included: 0.5 M sucrose, 0.1 M citric acid, 0.01 M quinine, 0.05-1.0 M NaCl, and 0.05-1.0 M sodium acetate (NaAc). Responses to all stimuli were compared to a 0.5M NH_4Cl reference standard, with 15 sec of steady state responses starting 10 seconds after stimulus onset used as the data. Water rinses occurred before and after each stimulus. After these stimuli were administered, a 100 μM solution of the epithelial sodium channel blocker amiloride was applied to the posterior tongue and the NaCl and NaAc series were completed again using the amiloride solution as the rinse. Surprisingly, male but not female responses to NaCl and NaAc were significantly suppressed by amiloride. Results also indicate that GL responses to sucrose were higher in males than in females. This is consistent with previous research indicating that males have a lower discrimination threshold for sucrose. Previous work indicates that glossopharyngeal nerve responses are not sensitive to amiloride, but our results suggest that salt transduction on the posterior tongue may be different between males and females. This result could explain the sex-related differences in behavioral responses to NaCl, as amiloride-sensitive and amiloride-insensitive salt pathways have been shown to have different roles in regulating behavior. There were no significant differences in GL responses for the other solutions tested. Overall, our results suggest that taste input from the posterior tongue is processed differently between male and female rats, and these differences may contribute to taste-guided behavior.

Title: Perinatal undernutrition alters feeding behavior and fat c-Fos expression in the solitary tract neurons of adult male Wistar rats

Authors: L. RUBIO NAVARRO[1], *M. A. SALAS[3], M. REGALADO[2], C. TORRERO[2]; [1]Developmental Neurobio. and Neurophysiol., [2]Natl. Univ. of México, Queretaro, Qro, Mexico; [3]UNAM, Queretaro, Mexico

Abstract: Malnutrition early in life has long lasting effects on brain areas related with food intake. Food selection can be affected by undernutrition, and with self-selection method we can evaluate qualitative changes in nutritional balance. The present study was design to evaluate the alteration on feeding preferences patterns using protein, carbohydrate and fat in adult rats that were exposed to perinatal caloric restriction. Additionally, the estimation of the neuron activated by fat stimuli in the nucleus of the solitary tract (NST) in adult male undernourished rats at present is unknown. We used male control (CG) and undernourished groups (UG) of 9 week old. In the undernourished group (UG) pregnant dams received different percentage of a balance diet during gestation. After birth pups continue the undernutrition by remaining 12h with a foster dam, and 12h with a nipple-ligated mother. At weaning, five pups were house in group until self-selection paradigm. Three days before testing were house individually and body weight and food consumption were evaluated. After that, during three days we recorded the protein, carbohydrate and fat intake and body weight of rats. After the test the male rat were food and water restricted during 12h, thereafter stimulated with fat and sacrificed 90 min post stimulation, controls were isolated until sacrifice and brainstem tissue was processed by c-Fos immunoreactivity and different areas of the NST were considered. We observed that undernourished rats consumed the same amount of carbohydrates than control rats, protein and fat intake tended to increase during the three days of testing compared with control rats. Control group showed little c-Fos like immunoreactivity (FLI) by contrast, fat food induce clear and consistent more FLI in medial and caudal areas of the NTS in undernourished rats compared with control subjects. The present data contribute to define basic neuronal network activated by gustatory cues affected by perinatal restriction that indicate the alteration in associative learning capacities and homeostatic adaptations to the environment, that make prone adult males to the development of abnormal feeding behavior.

Title: Organization inhibitory circuitry connected to projection neuron populations in the mouse rostral nucleus of the solitary tract

Authors: *J. A. CORSON, R. M. BRADLEY;
Univ. of Michigan, Ann Arbor, MI

Abstract: The rostral nucleus of the solitary tract (rNST) is the target of gustatory primary afferents from the oral cavity. Thus, the rNST is in a prime position to control all aspects of gustatory-related behavior, from perception (parabrachial nucleus [PBN] projections) to reflexes (reticular formation [RF] projections). However, the intrinsic circuitry that transforms incoming sensory information into output action potential trains remains relatively unstudied. Using mice expressing channelrhodopsin under the control of the vesicular GABA transporter promoter (VGAT-ChR2), we investigated the organization of local inhibitory connectivity. Fluorescent microbeads were injected into either the PBN or RF to retrogradely label neurons projecting to either of these second-order targets. Local GABAergic circuits were activated with a custom-made laser scanning photostimulation system while recording the resulting inhibitory synaptic currents (IPSCs) in an *in vitro* slice preparation. The laser spot was scanned over a grid (50 μm spacing, encompassing all rNST subdivisions) in a random order to systematically activate spatially discrete populations of inhibitory interneurons. IPSCs were automatically detected using a time-based deconvolution algorithm and the kinetics (amplitude, charge, rising slope, and decay constants) computed. Cells were filled with biocytin during recording and the cell morphology reconstructed following peroxidase visualization. The spatial distributions of inhibitory connectivity were compared using a magnitude-normalized linear distance algorithm. rNST-RF projection neurons received inhibitory connections from rNST regions further from the cell soma than rNST-PBN projection neurons. The total inhibitory charge from all stimulation sites was also greater for rNST-RF projection neurons. This suggests that neurons governing oromotor reflexes receive stronger local inhibitory modulation of firing patterns than those governing hedonics and perception. The dendritic morphology of rNST projection neurons as well as the optically-evoked synaptic amplitude and rising slope were only moderately correlated to the spatial distribution of inhibitory connectivity. Further, the strength (i.e. amplitude and charge) of optically-evoked IPSCs was larger than spontaneous IPSCs. This indicates a specificity of local inhibitory interneuron axon targeting rather than a stochastic connectivity and

that this local inhibition is stronger than extrinsic inhibition. Together, these results suggest the presence of distinct local circuits capable of modulating the diverse rNST output pathways.

Title: Optogenetic manipulation of lateral hypothalamic input to the nucleus of the solitary tract modulates licking behavior in the awake rat

Authors: J. D. SAMMONS[1], C. E. BASS[2], J. D. VICTOR[3], *P. M. DI LORENZO[1]; [1]Psychology, Binghamton Univ., Binghamton, NY; [2]Dept. of Pharmacol. and Toxicology, Univ. of Buffalo SUNY Sch. of Med. and Biomed. Sci., Buffalo, NY; [3]Brain and Mind Inst., Weill Cornell Med. Sch., New York, NY

Abstract: The lateral hypothalamus (LH) sends direct synaptic connections to the nucleus of the solitary tract (NTS, the first synaptic relay in the central gustatory pathway). Through electrical stimulation, the LH has been shown to modulate gustatory neurons within the NTS (Matsuo et al., J. Neurosci. 4:1201-1207, 1984). However, the functional significance of direct synaptic connections from the LH to the NTS remains inconclusive. Here, we used optogenetic tools to selectively manipulate LH-NTS input while the rats were preforming a Go-no-Go (GnG) task to assess the role of the LH in modulating the lick cycle. Initially, we infused adeno-associated viral constructs encoding either Channelrhodopsin-2 (ChR2) or halorhodopsin (eNphR3.0) bilaterally into the LH of male rats. Following 2-4 wks, we implanted an optrode consisting of a fiber optic cable attached to a bundle of 8 tungsten microwires into the taste-responsive portion of the NTS and allowed the rats to recover. Rats were then water deprived and placed in an experimental chamber where they were allowed to freely lick in a GnG paradigm. A single cue stimulus lick (always 0.1 M NaCl) was presented followed by 5 dry licks and then 3 licks of a test stimulus (0.1 M NaCl, 0.1 M MSG/IMP or 0.1 M KCl). After a 1 s timeout, the task was to continue licking for a 3-lick (12µL/lick) 0.5 M sucrose reward if the test and cue stimuli were the same and to withhold licking if they were different. Continued licking when test and cue were different was punished by 3 licks of 1 mM quinine and a 5 s timeout. In a random half of each trial type, LH fibers in the NTS were optically stimulated (25 Hz of 473 nm or 532 nm laser light at 8-10 mW) for a maximum 1 s per test lick. Preliminary results show that optogenetic stimulation of LH-NTS input extended the inter-lick bout duration following a correct rejection. Additionally,

in some cases, the lick frequency was increased after incorrectly accepting the punishment stimulus. No significant differences were observed in reward presentation trials. These data suggest that LH input to the NTS may modulate the initiation and termination of lick bouts through its direct influence on NTS output.

Title: Transfer of chemosensory information between the NTS and PbN in the awake-behaving rats

Authors: *O. D. ESCANILLA, P. M. DI LORENZO;
Binghamton Univ., Binghamton, NY

Abstract: The nucleus of the solitary tract (NTS) is the first central nuclei relay in the gustatory pathway and has major projections to the parabrachial nucleus of the pons (PbN; the second synapse in the central gustatory pathway). Previous studies in anesthetized rats have shown that PbN cells initially follow the temporal pattern of NTS cells, but changes in the later portion of the response (Di Lorenzo and Monroe, Brain Res, 763 (2) 167 - 181, 1997). Here, we simultaneously recorded neurons from the NTS and the PbN to examine how the representation of chemosensory information is transferred between these two structures in awake, behaving rats. To do this, rats were implanted with an 8-tungsten wire electrode in both the NTS (AP: -15.3, ML: 1.8, with a 4 mm head tilt) and the PbN (AP: -12.5, ML: 1.6, with a 4 mm head tilt) and allowed to recover. Rats were then mildly water deprived and placed in the experimental chamber containing a lick spout for fluid delivery. Gustatory stimuli were 0.1M Sucrose, 0.1M NaCl, 0.01M Citric Acid, 0.0001M Quinine, and artificial saliva (AS). Odor and paired odor-taste stimuli were formulated by diluting each odorant, (0.01%) amyl acetate or (0.01%) acetic acid, in either AS (for retronasal odor only presentations) or different tastant solutions. Odor concentrations were below the detectable gustatory or somatosensory range in rats. Each odor, taste or taste-odor stimulus was presented for 5 consecutive licks separated by AS rinses that were on a variable ratio 5 schedule. Analyses of coherence and cross correlation functions of joint firing patterns revealed properties of lick information that could underlie the functional connectivity between the two structures. More specifically, preliminary results show that some

lick coherent cells in the NTS unidirectionally inhibit anti-lick cells in the PbN while others have reciprocal inhibition with PbN cells that were not lick coherent. These findings will help us elucidate the neural circuitry between these two brainstem structures and how they are correlated to ingestive behavior. Supported by NIDCD grant RO1DC006914 to PMD

Title: A lick-related circuit in the parabrachial nucleus of the pons in the awake, freely licking rat

Authors: *M. S. WEISS[1], P. M. DI LORENZO[1], J. D. SAMMONS[1], J. D. VICTOR[2]; [1]Psychology, Binghamton Univ., Binghamton, NY; [2]Neurol. and Neurosci., Weill Cornell Med. Col., New York, NY

Abstract: In the rodent central pathway for gustation, taste quality information from the periphery first synapses in the nucleus of the solitary tract (NTS), which in turn sends the bulk of its projections to the parabrachial nucleus of the pons (PbN). Electrophysiological recordings from both the NTS and PbN have revealed a proportion of cells, recorded alongside taste-responsive neurons, that do not respond to taste stimuli, leaving in question the functional role of these neurons. Many of these non-taste-responsive cells show activity that is strongly lick-related. Here, we examined the activity of small ensembles of neurons that show patterns of activity relating to an animal's licking behavior to reveal the functional microcircuitry that supports these various cell types within the taste-responsive portion of the PbN. In addition to lick-related cells, we also studied taste-responsive neurons, as they often show strong coherence with licking (Weiss et al., J Neurophysiol 111: 1655-1670, 2014). Initially, an 8-channel electrode bundle was surgically implanted into the PbN of male Sprague-Dawley rats. Following recovery and 22hrs of water-deprivation, rats were placed in an operant chamber with free access to a lick spout. Each lick produced 12µl of a taste stimulus for five consecutive licks and artificial saliva (as a rinse) on a variable-ratio 5 schedule in between stimulus presentations. Results from 18 rats identified 2 groups of neurons that fired in phase with licks: a) "Lick+" neurons showed peak firing rates at the lick (n = 99), and b) "Lick-" neurons showed peak firing rates during the inter-lick interval (n = 25). Additionally, some cells were anti-lick cells (n = 24) that fired vigorously during the interbout interval but became quiescent during the lick bout.

Analyses of cross-correlation functions (CCFs) produced evidence of a reciprocal inhibitory circuit between Lick+ and Lick- cells. Analyses of simultaneously recorded taste-responsive cells and Lick+ cells suggested a common input to both cells with additional unidirectional excitation of the lick cell by the taste cell. CCFs of simultaneous recordings of multiple anti-lick cells suggested that they were influenced by a common input. We show evidence of a circuit where anti-lick cells inhibit lick and taste-responsive cells. When a lick bout begins the anti-lick cells release lick and taste-responsive cells from inhibition leading to a lick-phase locked circuit. The most critical remaining question is what neural elements control the activity of the anti-lick cells to initiate the lick cycle.

Title: CCK and calbindin in the primate parabrachial nucleus

Authors: *B. GEHRING[1], S. DE LACALLE[2];
[2]Biomed. Sci., [1]Ohio Univ., Athens, OH

Abstract: As a peptide hormone, cholecystokinin (CCK) mediates satiety by acting on the CCK receptors distributed widely throughout the central nervous system, including the brainstem. Among other actions, CCK's stimulatory effects on the vagus nerve oppose those of ghrelin. Calbindin-D28k, which was also first shown to be present in the intestine, is expressed in a number of neuronal and endocrine cells. For example, CCK/calbindin-containing GABAergic neurons have been identified in the hippocampal formation. Anatomical interactions between calbindin-containing neurons and CCK fibers have been demonstrated in the rat thalamus (Battaglia, 1992). Following earlier work using CGRP as a marker for ascending visceral pathways in the human brain (de Lacalle & Saper, 2000) here we describe the distribution of calbindin- and CCK-immunoreactive elements in the primate parabrachial nucleus (PB), a pontine structure with a crucial role in autonomic control. Our observations were made on horizontal sections through the brainstem from two neurologically normal human individuals and two male Cebus monkeys. Tissue was processed for immunocytochemistry using commercially available antibodies. We found several areas of dense peptide immunoreactivity in fibers, as well as scattered stained cell bodies. The distribution of peptide-stained fibers was strikingly conserved compared with that described in the rat. The Cebus monkey's PB showed calbindin-positive neurons in the rostral sections of both the MPB and LPB, disappearing in the caudal

sections, which contained mostly fibers in the MPB. The human sections showed an abundance of calbindin-positive neurons in the rostral MPB and dense groupings of stained cell bodies in the MPB and LPB at caudal levels. By contrast, CCK-immunoreactive cell bodies were found at all levels throughout the human MPB and LPB but only in the most rostral sections of the Cebus LPB. In the Cebus, the MPB and LPB at the rostral levels contained also a dense network of traversing CCK-immunoreactive fibers. Compared with the literature on the functional anatomy of the PB and its afferent and efferent projections, our results contribute to define the chemical identity of these neuronal groups in the primate brain, thus providing support to the delineation of physiological roles for the distinct subnuclei of this crucial visceral regulatory region.

Title: Representation of multisensory signals in the gustatory cortex of rats before and after associative learning

Authors: *R. VINCIS, A. FONTANINI;
Dept. of Neurobio. and Behavior, SUNY at Stony Brook Univ., Stony Brook, NY

Abstract: Taste experience is inherently multimodal and strongly modulated by expectations. Most research on the effects of expectation on gustatory cortical (GC) activity has relied on using auditory cues. While auditory stimuli prove to be effective for establishing cue-responsiveness in GC, it is likely that in natural settings cues from other sensory modalities would be more ecologically relevant to taste. Indeed, in the context of foraging and eating images, odors, and tactile stimuli are more inherently associated with taste than sounds are. Therefore, GC neural activity may also represent anticipatory cues from these sensory modalities. In order to investigate this hypothesis, we recorded the activity of GC neurons in response to olfactory (O), visual (V), auditory (A), somatosensory (S), and gustatory stimuli before and after cue-taste association in alert rats. Adult rats (n=10) were chronically and bilaterally implanted with movable bundles of electrodes in GC. In a first group of naive subjects (untrained; n=5), orofacial movements and single unit activity (n=135) were recorded while sensory stimuli were randomly delivered. A second group (trained; n=5) was classically conditioned with four sensory stimuli (O, V, A and S) predicting the availability of sucrose.

During the entire training period (14 days) orofacial movements were recorded in order to ascertain the time-course of conditioning. At the end of the training, single unit responses to the conditioned cues were recorded from GC (n=118). Our results show robust multimodality of GC neurons in untrained rats (% neurons responding to O, S, V, and A, respectively: 14, 13, 5, 5). The majority of neurons were responsive to 1-stimulus modalities, with odor and somatosensory stimuli being the most effective. In the conditioning group, rats learned all the cue-taste pairs. Analysis of orofacial movements revealed that rats learned the cue-taste association faster with odor and somatosensory cues compared to visual and auditory ones. Learning led to a 2-fold increase in the proportion of responsive neurons for each cues and to an increase in the percentage of neurons responding to multiple cues. Further analyses showed that learning increase the similarity between responses to olfactory and somatosensory cues relative to visual and auditory ones. Altogether, our results show that GC neurons respond to stimuli from multiple sensory modalities both naively and when they are taste-predictive cues, that the neural representations' strength and similarity change with learning, and sensory modalities more ecologically related to gustation are associated with a taste faster and are similarly represented in GC.

Title: Dynamic modulation of gustatory thalamocortical synaptic inputs by basolateral amygdala

Authors: ***M. E. STONE**, A. MAFFEI, A. FONTANINI;
Neurobio. and Behavior, SUNY Stony Brook, Stony Brook, NY

Abstract: Gustatory cortex (GC) neurons process multiple aspects of a tasting experience, encoding not only the physiochemical identity of tastes but also their anticipation and hedonic value. Information pertaining to these stimulus features reaches GC via the gustatory thalamus (VPMpc) and basolateral amygdala (BLA). However, it is not known if these inputs converge onto the same neurons or if limbic activity can affect evoked thalamocortical responses in GC. We have shown previously using intracellular recordings in GC that BLA stimulation evokes a monosynaptic EPSP followed by longer lasting inhibition. Train stimuli can maximally evoke excitation or inhibition depending on frequency and background state of the cell. The time-varying nature of the response suggests BLA may gate other GC inputs by altering the

excitatory/inhibitory balance. Here, we use *in vivo* intracellular recordings in anesthetized rats to describe the thalamocortical synapse and test our hypothesis that BLA can modulate cortical responses to VPMpc. Electrical stimulation of VPMpc evokes a monosynaptic, glutamatergic EPSP in all GC cells, followed 50/50 by either a multisynaptic, GABAergic inhibition or by a sustained depolarization. This response heterogeneity is consistent with the reported heterogeneity in GC responses to tastes and is enhanced when trains of VPMpc stimuli are delivered. Synaptic inputs from both VPMpc and BLA converge onto a large subpopulation of GC neurons. Comparing the dorsoventral profile of recording electrode sites, VPMpc-responsive cells are more dorsal while BLA-responsive cells are more ventral, with an area of significant overlap across GC. We confirm the presence of this convergence of inputs using anterograde tracing methods. GC cells receiving both monosynaptic inputs were used to examine the influence of BLA on VPMpc responses. Single shocks or 20 Hz BLA bursts preceded single VPMpc stimuli at varying latencies. Both BLA stimulation protocols can modulate the amplitude of the evoked VPMpc PSP at short latencies. The effect is mostly to suppress and less frequently to enhance VPMpc responses, a result consistent with the presence of mixed reversal potentials early in the evoked BLA PSP and also with the heterogeneity of VPMpc responses. The inhibitory tail of the BLA burst significantly decreases the variability of the GC neuron's membrane potential for up to 250 ms, a possible mechanism for BLA to influence GC taste response variability. In summary, our results show that thalamic and limbic inputs converge onto the same GC neurons and suggest BLA may shape cortical taste processing by dynamically gating the excitatory/inhibitory balance of the circuit.

Title: Amygdalo-cortical synaptic plasticity in primary gustatory cortex

Authors: *M. HALEY, A. FONTANINI, A. MAFFEI;
SUNY At Stony Brook, Stony Brook, NY

Abstract: Input from the basolateral amygdala (BLA) to primary gustatory cortex (GC) carries information on the hedonic value of a taste stimulus as well as anticipatory predictive cues. Previous studies have demonstrated that following taste learning, the functional connectivity between these two areas is increased. While this increase in connectivity suggests plastic changes

in the BLA-GC projection, details regarding the capacity for plasticity of this projection at the synaptic level remain unknown. Using whole-cell patch clamp recordings in GC slices combined with optogenetic activation of BLA terminal fields, we investigated how different physiological relevant patterns of activity promote plasticity induction at BLA-GC synapses. We developed two induction paradigms based on Hebbian learning rules, pairing presynaptic and postsynaptic activity, and varied the pattern of presynaptic activity. We found that phasic activation of BLA afferents (5ms pulses at 20 Hz) promotes long-term depression (LTD) of the synapse (% change: -24.6 ± 6.8, $p < 0.0001$, n = 10/14). Tonic activation of BLA afferents (6s ramp) promotes long-term potentiation (LTP) of the synapse (% change: 82.4 ± 19, $p < 0.0001$, n = 12/18). Our results indicate that BLA-GC synapses are capable of both LTD and LTP and that the pattern of presynaptic BLA activity dictates the direction of plasticity.

Title: Sucrose promotes quinine and capsaicin consumption in rats

Authors: *M. A. VILLAVICENCIO CAMARILLO[1], E. G. FONSECA DE LA CRUZ[2,1], S. A. SIMON[3], R. GUTIERREZ[1];
[1]Ctr. De Investigación Y Estudios Avanzados, Mexico, Mexico; [2]Inst. de Fisiología Celular, UNAM, México, Mexico; [3]Dept. of Neurobio., Duke Univ. Med. Ctr., Durham, NC

Abstract: Bitterness and pungency (mediated by the trigeminal system) in the oral cavity evolved to warn animals from consuming potential noxious substances. Nevertheless, learning and social induction, among other mechanisms, promote aversive chemical intake. For example, association between bitterness or burning substances with reinforcing tastes (e.g sweet or fat) are known to promote spicy food intake. We wondered whether a rewarding food (e.g. sucrose) is able to reinforce the consumption of aversive and/or burning stimuli (e.g. quinine hydrochloride [QHCl] or capsaicin, respectively). To address this issue, we trained one group of rats (Q; n=4) in a 30-minutes freely licking task to lick a spout at the central port of a behavioral box to obtain 10 µl drops of QHCl (0.3mM) and another group (CAP, n=4) to obtain 10 µl drops of capsaicin (4 ppm). Then, when a pause in licking greater than 1 s was detected, subjects were required to switch to a lateral port where they had to lick in order to obtain the either same number of drops

of sucrose (20%; 10 µl) or less if the rat made a pause of licking longer than 1 s. Therefore, in each trial, rats were forced to consumed aversive substances to get rewarding sucrose. We found that after 9 sessions of training rats stabilized the volume consumed of either QHCl (7.7 ml) or capsaicin (9.5 ml) to obtain a similar amount of sucrose (Q = 7.6 ml; CAP = 8.8 ml). Interestingly, in this sessions, Q group opted for drink smaller amounts of QHCl per trial compared with CAP group (11.8 vs. 20.6 drops). Nevertheless, sucrose obtained by Q rats was compensated by increasing the number of trials per session in comparison with CAP rats (Q = 68.35; CAP = 48.15). Then, to discard the possibility that rats drunk either QHCl or capsaicin because they were as rewarding as sucrose, we measured how much sucrose volume subjects will drink in the central port to obtain the same (or less) capsaicin or quinine volume in the lateral ports as a reward. We found that rats switched ingested a greater amount of sucrose (25 ml) than aversive stimuli (Q = 3.5 ml; CAP = 3 ml), suggesting that, in the first condition, aversive substances intake was only reinforced by sucrose. Together this preliminary data demonstrated that a rewarding taste promotes aversive or pungent stimuli consumption; as well, it is shown that rats maximize sucrose intake by using different strategies depending on the system that aversive substances are activating (bitter taste or burning sensation). In summary, these results highlight other mechanisms by which unpleasant substances consumption might be promoted.

Title: Orbitofrontal cortex neuron responses during a sweet intensity discrimination task in rats

Authors: *E. G. FONSECA DE LA CRUZ[1,2], A. MATSUMOTO TAKANE[3], M. VILLAVICENCIO[2], R. GUTIERREZ[2];
[1]Inst. De Fisiología Celular, UNAM, Mexico City, Mexico; [2]Pharmacol., CINVESTAV, Mexico City, Mexico; [3]Psychology, UNAM, Mexico City, Mexico

Abstract: Taste perception carries important information of food hedonic properties, thereby it has a key role in determining food consumption. It has been proposed that a distorted taste perception might underlie pathological eating patterns. Thereby it is important to develop

methodological ways to measure taste sensitivity and its underlying neural correlates. Orbitofrontal Cortex (OFC), also known as secondary gustatory cortex, might be involved in processing information about taste identification sensitivity. It has been shown that single neurons in OFC responds in an intensity dependent manner to sweet taste. Nevertheless, to our knowledge, OFC participation in processing sweet taste identification sensitivity has not been addressed. To addresss this issue, we trained rats in a sucrose discrimination paradigm that allows sucrose identification sensitivity measure by using psychophysics, and record single neuron activity in OFC while rats perform the task. Rats were trained to lick in a central spout to receive a single 15µl drop of 3% (low) or 18% (high) sucrose concentration and emit differential responses (left or right) according to the taste cue received. Correct responses were reinforced by three 15µl water drops. Additional Licks (AL's) after cue provides the reaction time to detect the sucrose drop. Once subjects learned the task, generalization sessions with intermixed training and probe trials were introduced. Probe trials (20% trials) consisted in the presentation of training and intermediate sucrose (3, 4.75, 7.5 or 11.75, 18%) that rats were required to classified as "low" or "high" concentration. This trials were unreinforced. High concentration response probability were obtained and fitted to a sigmoid function to obtain psychophysical sensitivity measurements. Preliminary results shows that subject reach ~>85% correct responses after ~20 training sessions. AL´s are significantly higher for high sucrose concentration, which might indicate palatability differences between training concentrations. AL´s for intermediate sucrose concentration were similar, nonetheless rats classified persistently intermediate low concentration (4.75%) as low and 11.75% as high, suggesting that rats were discriminating sucrose intensity per se and not AL's number. Preliminary data from 147 neurons are consistent with literature. We found neurons inhibited or excited by licking or cue, as well as neurons that fire synchronized with licking. Generalization sessions with electrophysiological recordings are about to be performed in order to evaluate OFC participation in sweet intensity perception.

Title: Optogenetic induced inactivation of the lateral orbitofrontal cortex during a sucrose freely licking task

Authors: *D. A. GARCÍA[1,2], L. PRADO[2], R. GUTIERREZ[2];
[1]INSTITUTO DE FISIOLOGIA CELULAR, UNAM, Mexico city, Mexico; [2]Pharmacol., CINVESTAV, Mexico City, Mexico

Abstract: The orbitofrontal cortex (OFC) is a brain structure that contains the secondary gustatory cortex, it is related to taste processing, but it is also involved in licking behavior, since direct infusion of a GABA A agonist (muscimol) into the lateral OFC fragment the microstructure of licking behavior (Gutiérrez, et al. J Neurophysiol, 95(1):119-133, 2006). However, these kind of pharmacological techniques have slow kinetics and poor reversibility. In this contextual frame, we decided to use an optogenetic approach and optrode recordings in the VGAT-ChR2-EYFP transgenic mice, which expresses channelrhodopsin in GABAergic interneurons that constitute approximately 20% of cortical neurons (Taniguchi et al. Neuron, 71: 995-1013, 2011). Briefly, the mouse was allowed to freely lick to obtain sucrose in a spout; each trial has three epochs:1) A baseline epoch, where the mouse had to lick an sipper with sucrose three times and at fourth lick, a LED stimulation was turned on. 2) In the stimulation epoch, mouse was stimulated with a power of 15 mW during 1s (10 ms pulse duration) at different randomly frequencies (4, 7, 14, 21, 30, 50 Hz) or during 1 s of constant stimulation. 3) A time out epoch, laser was turned off during the next second. We recorded activity of 110 neurons at the same time of task. We found a cortical modulation in firing rate during the stimulation epoch, were neuronal inhibition at high frequencies (30 and 50 Hz) and during 1s of continuous stimulation; this effect was reversible when the LED was turned off spiking activity rapidly returned to baseline levels. Behaviorally, we saw a slight alteration in rhythmicity of licking by the presentation of larger pauses (interlick intervals) in some animals (but not in all) at high frequencies and 1s continuous stimulation. Our data propose a viable model for study inhibitory cortical circuits at the subsecond level in sensory and cognitive functions without overtly affecting oromotor responses.

Title: Anandamide-induced network oscillation in the insular cortex implicated in taste-driven feeding

Authors: *Y. KANG;
Osaka Univ. Grad. Sch. Dent., Osaka, Japan

Abstract: Anandamide (AEA) and N-oleoylethanolamine (OEA) are produced or increased in the intestine and brain during fasting and satiety, respectively. Subsequently, the former facilitates food intake via activation of cannabinoid type 1 receptors (CB1Rs) while the latter decreases food intake via activation of peroxisome proliferator-activated receptor-α (PPAR-α) and/or G-protein-coupled receptor 119 (GPR119). Neuronal activity in the gastrointestinal region of the autonomic insula (GI-Au-I) that rostrally adjoins the gustatory insula (Gu-I) increases during fasting, causing appetite sensation while umami and sweet taste sensations in the Gu-I enhances appetite sensation in the GI-Au-I. Given that AEA induces neural coordination between the Gu-I and GI-Au-I, such coordination would be critically involved in inducing the taste-driven feeding. However, these possibilities have not been addressed. Here, we demonstrate with live imaging that application of AEA induces theta-rhythm oscillatory coordination between the Gu-I and GI-Au-I. This neural coordination was modulated by GABAB receptor-mediated feed-forward inhibition and was abolished by AM251, a CB1R antagonist and OEA, a GPR119 agonist and rolipram, a phosphodiesterase 4 inhibitor. We propose a novel brain mechanism in which taste-driven feeding is regulated by the neural coordination between the Gu-I and GI-Au-I through the opposing activities between the CB1R and GPR119. Our results provide a new insight into the higher-order brain mechanism responsible for emotional feeding behavior caused by taste recognition, in contrast to the known involvement of the hypothalamus in the regulation of food intake as nutrients.

Title: Exocytosis and energy metabolism from mitochondria at hair cell ribbon synapses

Authors: *K. LEAL[1,2], H. VON GERSDORFF[1,2];
[1]Oregon Hlth. and Sci. Univ., Portland, OR; [2]Vollum Inst., Portland, OR

Abstract: Hair cell afferent fiber synapses possess highly specialized active zones of glutamate release that enable rapid and faithful transfer on sensory information to neurons that innervate the brain. Hair cells are capable of releasing thousands of synaptic vesicles per second and continue to do so for tens of seconds unlike conventional synapses. However, the factors that contribute to the rapid supply of synaptic vesicles and sustained release at these ribbon-type synapses remain unknown. At presynaptic terminals, ATP consumption and production is highly regulated in response to synaptic activity. Given the high-activity levels of hair cells, mitochondria are strikingly abundant and are often located near to synaptic ribbons, suggesting a need for a large amount of local ATP production. Here, we investigated the contribution of ATP and mitochondrial respiration to synaptic transmission at the auditory hair cell to afferent fiber synapse of the adult bullfrog amphibian papilla. Using whole-cell paired recordings of a hair cell and afferent fiber terminal, we found that hair cell synapses maintain robust exocytosis in the absence of ATP provided by the patch pipette. This surprising result contrasts with results obtained at ribbon synapses in the retina. We examined exocytosis via simultaneous presynaptic capacitance changes and excitatory postsynaptic currents (EPSCs). Exocytosis runs down dramatically in the presence of ATP-γS, a non-hydrolyzable form of ATP. In hair cells, ATP-γS does not reduce calcium current amplitude, but does significantly decrease capacitance jumps with successive depolarizations of 200 ms, which deplete the readily releasable pool of vesicles. This suggests that an abundant supply of ATP is a necessary component for continuous vesicle release at hair cells synapses. To test the contribution of presynaptic mitochondrial ATP production to sustain synaptic transmission, we dialyzed hair cells with oligomycin, an inhibitor of mitochondrial ATP synthase, in the presence of ATP-γS to further out compete endogenous ATP. Inhibition of mitochondrial respiration in hair cells had effects similar to ATP-γS, greatly reducing exocytosis and EPSC amplitude. Our results indicate that hair cells maintain copious exocytosis by producing large amounts of ATP from mitochondria. We conclude that high levels of ATP are required for maintaining the readily releasable pool of synaptic vesicles during repeated stimulation of hair cell synapses.

Title: Latency and efficiency of multivesicular release at hair cell ribbon synapses

Authors: *O. GROSS[1], H. VON GERSDORFF[2];
[2]Vollum Inst., [1]Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Auditory hair cells encode features of acoustic stimuli in patterns of neurotransmitter exocytosis at ribbon-type synapses. This synaptic signal drives an excitatory postsynaptic current (EPSC) in afferent nerve fibers, which carry auditory information to the brain via spikes in the auditory nerve. Both rate and time codes of spikes are used to encode information. Spontaneous EPSCs observed in the afferent fiber when the hair cell is strongly hyperpolarized (V_M = -90 mV) exhibit a uniform time course and mean amplitude of ~60 pA. When hair cells are depolarized beyond the activation threshold of their L-type Ca^{2+} channels (about -65 mV), spontaneous EPSC amplitudes become more heterogeneous, exceeding 250-300 pA in some cases. Remarkably, the time course remains the same for all EPSC events, independent of amplitude. While recent work has shown that large EPSCs reduce the failure rate and improve phase-locking of afferent fiber spikes, the mechanisms and consequences of large EPSC events are not fully understood. To explore the mechanism of large events, we performed simultaneous whole cell recordings from hair cells and afferent fibers in the 400 Hz tonotopic region of the adult bullfrog amphibian papilla. Comparison of the hair cell membrane capacitance jump with the deconvolved EPSC produced by moderate hair cell depolarization suggests that large individual EPSCs arise from the simultaneous fusion of multiple synaptic vesicles at a single ribbon site (multivesicular release or MVR). To characterize MVR on a short time scale, we examined the latency of the first multiquantal event (MQE) during hair cell stimulation. We found that reliable low-latency (1-2 ms) MVR is achieved when ~4 Ca^{2+} channels are open per ribbon. The minimum Ca^{2+} current that reliably triggers low-latency MVR is only ~30% of the maximum Ca^{2+} current. Interestingly, this range of stimulation corresponds to the steepest region of the I-V curve of Ca^{2+} channels. Thus, MVR is maximally efficient over the same range of stimuli for which the Ca^{2+} current is best able to discriminate between stimulus strengths (i.e. the range where voltage sensitivity is maximal). Furthermore, a shift in the overall distribution of event amplitudes toward larger values was observed as the strength of the hair cell depolarization was increased. This result indicates that the mean event amplitude is modulated dynamically by stimulus strength. We suggest that this modulation has the potential to increase the efficiency of information coding at the first auditory synapse by supplementing the event rate code.

Title: Use of an *in vitro* screening platform to identify compounds that regenerate hair cells in the inner ear

Authors: *K. I. LORRAIN, A. DEARIE, M. POON, J. SEIDERS, J. ROPPE, P. PRASIT, D. LORRAIN;
Biol., Inception Sciences, Inc., San Diego, CA

Abstract: Loss of mechanosensory hairs cells in the inner ear is one of the main causes of sensorineural hearing loss. Although hair cell regeneration occurs in birds and amphibians, it does not occur in the adult mammal. Our goal here was to identify small molecule targets capable of inducing hair cell regeneration leading to hearing restoration. To this end we developed a high throughput assay for the detection of inner ear hair cells using the In Cell™ imaging system. Acute dissociation of the organ of Corti (oC) generates mouse otospheres which are capable of division and differentiation. Otospheres comprise a mixed population of cell types, including Sox2+ support and Myo7a+ hair cells. Cells are plated in a 96-well plate format, treated with compound and read on the In Cell™ imaging system. We have developed a series of algorithms using Developer™ software that accurately and quickly quantifies support cell proliferation and hair cell formation. Compounds showing activity were next validated in mouse oC explants. Follow up screens have been implemented to further validate each compound class.

Title: Inhibition of protein nitration attenuates cisplatin-induced modulation of LMO4 and mitigates the ototoxic effects

Authors: *S. JAMESDANIEL[1], R. RATHINAM[1], W. NEUMANN[2];
[1]Inst. of Envrn. Hlth. Sci., Wayne State Univ., Detroit, MI; [2]Pharmaceut. Sci., Southern Illinois Univ. Edwardsville, Edwardsville, IL

Abstract: Ototoxicity is one of the major side-effects of the commonly used chemotherapeutic agent cisplatin. More than 50% of patients treated with this anti-cancer drug develop hearing loss and the incidence of ototoxicity increases significantly in children, particularly, at higher doses

of cisplatin with debilitating consequences. Therefore, it is extremely important to delineate the signaling pathways that facilitate ototoxicity in order to design rational therapeutic strategies to prevent cisplatin-induced hearing loss and preserve the quality of life in cancer survivors. During the past few years, a good deal of progress has been made in elucidating the mechanisms underlying cisplatin-induced ototoxicity. Nevertheless, the attenuation of this side-effect with otoprotective compounds is still inadequate. We reported that cisplatin treatment leads to the nitration of cochlear LMO4 and hypothesized that LMO4 nitration plays a pivotal role in facilitating cisplatin-mediated ototoxicity. In this study we provide evidence that inhibition of protein nitration by SRI110, a peroxynitrite decomposition catalyst, not only attenuates cisplatin-induced modulation of LMO4, but mitigates the ototoxic side-effects of cisplatin, in organ of Corti cell cultures. SRI110 is a selective inhibitor of protein nitration that spares the superoxide radical. Treatment of UBOC1 cells, which has been used as a model in ototoxicity studies, with cisplatin (10 μM) for 24 hours, induced apoptosis, as indicated by an increase in the expression of active caspase 3, and decreased LMO4 levels, as indicated by immunoblotting and immunostaining with anti-LMO4. Co-treatment with SRI110 (50 μM) attenuated the cisplatin-induced decrease in LMO4. Moreover, it significantly reversed the cisplatin-induced cellular apoptosis ($p<0.5$), which was quantified by flow cytometry analysis of active caspase 3 expression. The modulation of LMO4 levels by cisplatin and SRI110 treatment correlated with the changes in the active caspase 3 levels ($r = -0.891$) indicating the functional significance of LMO4 nitration in cisplatin-induced ototoxicity and the otoprotective efficacy of SRI110. Delineation of this key signaling mechanism provides a basis for identifying potential interventional targets, and in addition, provides information vital to the search for better otoprotective compounds. This study was supported by NOHR grant (2013-2014) and NIEHS P30 Grant (P30 ES020957).

Title: Damage to sensory hair cells occurs via excessive activation of ionotropic glutamate receptors that is independent of afferent and efferent innervation

Authors: *L. SHEETS;
Mass Eye & Ear Infirmary/ Harvard Med. Sch., Boston, MA

Abstract: Excessive release of glutamate from sensory hair cells plays a central role in eliciting the pathological events that follow damaging sound exposures. The effects of excess glutamate on afferent fibers innervating hair cells has been well characterized—perfusion of AMPA/kainate type GLUR agonists into mammalian cochlea has been shown to induce pathological dendritic swellings similar to those observed in noise-exposed ears. But less is known about the cellular mechanisms instigating noise-induced hair-cell damage, and whether glutamate excitotoxicity also contributes to pathological changes in hair cells has not been directly examined. To address whether glutamate excitotoxicity damages sensory hair cells, I examined lateral-line neuromasts (NMs) in 5-day-old zebrafish larvae exposed to drugs that mimic glutamate-induced excitotoxic trauma. Exposure to kainic acid (KA) resulted in profound swelling of lateral-line afferent terminals analogous to that observed in KA exposed mammalian cochleae. Unexpectedly, KA exposure also contributed to hair cell damage and significant hair cell loss. To test whether hair-cell damage was a secondary effect from over stimulating innervating afferent neurons, I exposed *neurog1a* morphants—fish that have morphologically mature and electrically active NM hair cells that are devoid of afferent and efferent innervation—to KA. Significant hair-cell loss occurred in KA exposed *neurog1a* morphants, and the loss was comparable to that observed in wild-type siblings. The action of KA is likely specific, as NM hair cell loss occurred in a dose-dependent manner and was prevented when morphants were co-exposed to the competitive AMPA/kainate receptor antagonist CNQX. In addition, transient increases in intracellular calcium were observed in morphant NM hair cells following KA exposure, frequently preceding hair-cell death. Cumulatively, these data indicate that excessive glutamate signaling mediates damage to sensory hair cells independent of damage to postsynaptic terminals, and suggest that excess glutamate resulting from noise exposure directly contributes to noise-induced hair-cell damage and death.

Title: Targeted deletion of oncomodulin leads to changes in auditory thresholds independent of outer hair cell loss

Authors: *D. D. SIMMONS, A. AZGHADI, M. KAZANTSEV, A. J. HORNAK;
Integrative Biol. and Physiol., UCLA, Los Angeles, CA

Abstract: The regulation and control of Ca^{2+} is one of the major challenges of cochlear hair cells. Oncomodulin (Ocm) is an EF-hand Ca^{2+} binding protein, a member of the parvalbumin protein family, and found almost exclusively in the outer hair cells (OHCs). In the cochlea, OHCs use a prestin-based electromotility mechanism to amplify vibrations of the cochlear partition that directly enhance sensitivity and frequency selectivity, and serve as the primary targets of a brainstem efferent pathway that may protect the ear from noise damage. Cochlear OHCs are one of the most prominent targets of noise and aging defects. We hypothesized that deletion of a major Ca^{2+} buffer in OHCs would lead to hearing loss. Using a targeted deletion of Ocm, we investigated the relationship between OHC loss, hearing thresholds, and the presence of efferent terminals. Targeted deletion of Ocm resulted in progressive hearing loss beginning in high frequencies around 3 months with significantly elevated threshold shifts. However at 3 months, there was typically little evidence of OHC loss in Ocm mutants. Around 4 months, Ocm null mutants demonstrated increasing amounts of hair cell loss in basal high frequency regions. We also found significant changes in prestin-immunoreactivity occurred around 4 months. Mutant animals exhibited a basal to apical prestin-immunoreactive intensity gradient. Additionally in mutants, OHCs were shorter especially in apical regions. In 3-month-old mutants, efferent terminals were found on OHCs and appeared normal. However after 4 months, Ocm mutant mice had basal (high frequency) regions where OHCs lacked efferent terminals. Efferent terminals showed significant remodeling in areas of the cochlea where OHCs were absent. The loss of efferent terminals coincided with changes in prestin expression. These data suggest that targeted deletion of Ocm leads to progressive elevation of hearing thresholds that are independent of OHC loss. Changes in prestin expression and efferent innervation seem to occur prior to OHC loss.

Title: The effects of the somatostatin analogue pasireotide and role of NFAT in protection of auditory hair cells after aminoglycoside exposure

Authors: *V. RADOJEVIC, A. PERKOVIC, D. BODMER;
Dept. of Biomedicine, Univ. Hospital, Clin. For Otorhinolaryngolog, Basel, Switzerland

Abstract: Hearing impairment is a global health problem with high socioeconomic impact. Damage to auditory hair cells in the inner ear due to aging, disease, acoustic trauma, or exposure to ototoxins underlies most cases of sensorineural hearing loss. Since the mammalian ear cannot replace damaged hair cells, loss of hearing is irreversible and progresses throughout life. We previously demonstrated that the Ca2+ -sensitive neuropeptide somatostatin and its analogue octreotide can protect hair cells from gentamicin-induced hair cell death *in vitro*, and that SST receptors are expressed in the mammalian inner ear. Aminoglycosides trigger an influx of calcium ions (Ca2+) and rapid rise in intracellular calcium in hair cells which activates intracellular signaling cascades that may terminate in both survival or apoptotic events. Somatostatin (SST), acts via a family of G-protein-coupled receptors (SSTR1-SSTR5) that are differentially distributed throughout the central nervous system. SST receptors provide neuroprotection by direct coupling to voltage-dependent Ca2+ channels which are inhibited by SST binding to its receptors. In the present study, we report that the SST analogue pasireotide (high affinity to SST receptor subtypes SSTR1, 2, 3 & 5 with improved half-life vs. octreotide) also prevents gentamicin-induced hair cell death. We explored whether or not NFAT, a Ca2+ -sensitive transcription factor, may play a role in SST-mediated signaling. We found that activated NFAT translocated to the nuclear fraction of organ of Corti explants exposed to gentamicin, and this was prevented by pasireotide. To determine whether or not NFAT mediated the protection of hair cells by pasireotide, we treated OC's with the direct NFAT inhibitor VIVIT-11. Indeed, VIVIT-11 was able to significantly protect hair cells from gentamicin-induced apoptosis and, similar to the effects of pasireotide, prevented the gentamicin-dependent nuclear translocation of NFAT. Finally, we measured expression of NMDA1 receptor and PI3K, genes previously shown to be related to gentamicin induced HC death. Both pasireotide and VIVIT-11 significantly prevented the gentamicin-induced change in expression of the NMDA receptor and PI3K. These data suggest a model in which somatostatin analogues antagonize aminoglycoside induced alterations in cellular Ca2+ fluxes, leading to preservation of hair cell survival pathways (PI3K, NMDA) in a manner requiring NFAT. Our data suggest that SST analogues and NFAT inhibitors may offer new therapeutic possibilities for treatment of hearing loss.

Title: A stereological investigation of the parvalbumin positive neurons in the adult human spiral ganglion

Authors: C. KAUR[1], T. C. NAG[1], A. THAKAR[2], D. N. BHARDWAJ[3], T. G. JACOB[3], *T. ROY[4];
[1]Anat., [2]Otorhinolaryngology, [3]Forensic Med. and Toxicology, [4]All India Inst. Med. Sci., New Delhi, India

Abstract: It is well established that different Ca binding proteins have distinct buffering properties and are related to neuronal firing rates. Parvalbumin (PV) is associated with highly metabolically active neurons in comparison to other calcium binding proteins. The expression of PV has been used to describe anatomically various sensory pathways, including the spiral ganglion (SG). To complement our previous findings, where the degree of the intensity of immunoreactivity of PV in the SG were 'weakly' and 'strongly' positive, in the present study we attempted to quantify and compare the PV and cresyl violet (CV) positive neurons, separately using unbiased stereology to estimate total number, mean volume of neurons and the volume of SG in the adult human. Estimation of total number of neurons in the SG at various ages and their functional status is important as these neurons are constantly exposed to noise and other environmental factors leading to excess of neurotransmitter release that may result in loss of SG neurons. Five adult human cadaveric heads were obtained from the forensic science mortuary at All India Institute of Medical Sciences, New Delhi, with approval from institute ethics committee. These were accident victims (from the third decade of life) and had no history of inner ear disease or hearing loss before death. The temporal bone containing the SG was dissected, fixed, decalcified, cryoprotected and serially sectioned (30μm) in the coronal plane. Every 7th section was immunostained with PV (Abcam, ab11427, 1:5000) and with CV separately, using standard protocol. PV and CV stained sections were used independently for estimation of the total number of neurons (Optical Fractionator), neuronal volume (Cavalieri) and the volume of its nucleus (Nucleator) with StereoInvestigator software (Microbrightfield Inc. VT, USA). The estimated total number of SG neurons was 27,723 ± 2371.03 and 27,484 ± 3251.3 respectively in the PV and CV stained sections. There was no significant difference in the counts from CV stained sections when compared with PV immunostained sections (Student's t test, $p = 0.911$). This count of neurons is nearly half of what has been previously reported for human SG by other groups. The mean volume of SG neurons and its nucleus was 130.57 um3 ± 37.16 and 131.68 um3 ± 50.68 um3; and 1.8 um3 ± 0.35 and 2.12 um3 ± 0.35. The mean volume of SG was 3569.45 um3 ± 791.22 and 3487.63um3 ± 951.49 in the PV and CV stained sections, respectively. Since both methods to estimate neuronal numbers yielded similar results, therefore we conclude that there is preponderance of PV positive neurons in the human SG, implying its predominant role in Ca buffering.

Title: Effective protection against severe noise-induced hearing loss by a small molecule clinical drug candidate following daily, post-trauma systemic administration

Authors: *J. DYHRFJELD-JOHNSEN, M. PETREMANN, V. BRIEUC, A. BROUSSY; Sensorion, Montpellier, France

Abstract: Sensorineural hearing loss is caused by damage to the sensory hair cells and neurons of the cochlea and is the most common type of permanent hearing loss (American Speech-Language-Hearing Association; ASHA). Among adults, the 2 main causes of sensorineural hearing loss are excessive noise exposure and aging (Hearing Loss Association of America; HLAA). Currently no approved pharmaceutical treatment exists and recent meta-analysis of the standard-of-care, off-label use of corticosteroid therapy have concluded that neither systemic nor intratympanic administration has any significant treatment effect (Crane et al. 2015, Laryngoscope 125(1):209-17). We here demonstrate that the small molecule, clinical drug candidate SENS-90 significantly reduces permanent hearing loss and loss of outer sensory hair cells in a rat model of severe noise induced hearing loss after daily, post-trauma, systemic administration. Following baseline audiometry, 7 week old awake and behaving male Wistar rats were exposed to 120 dB octave band noise (8-16 kHz) for 2 hours on a slowly rotating platform in a sound-attenuating cubicle. SENS-90 (n=7) or placebo (n=7) treatment was initiated after the end of acoustic trauma exposure using intraperitoneal administration and continued daily until day 13. Both SENS-90 and placebo treated animals displayed up to ~60 dB temporary ABR threshold shifts at 24h (8/16/24 kHz) accompanied by strong or complete suppression of DPOAE amplitudes (4/8/16/24/32 kHz). However, on day 14, SENS-90 treated animals displayed up to ~60% lower permanent ABR threshold shifts and up to ~60% higher DPOAE amplitudes. Taking into account potential variability of individual acoustic trauma, both recovery of ABR thresholds and DPOAE amplitudes from 24h to day 14 were also determined to be significantly improved after SENS-90 treatment. The functional audiometry data were supported by significantly reduced mean outer hair cell loss after drug treatment determined from cochleograms constructed from cell counts in fixed cochlea at day 14. Altogether, these results demonstrate that daily, systemic administration of the small molecule clinical candidate drug SENS-90 initiated after severe acoustic overexposure strongly and significantly protects against permanent hearing loss and cochlear cell loss.

Title: The upregulation of Nrf2/HO-1 pathway restores cochlear redox homeostasis after noise exposure

Authors: *D. TROIANI[1], F. PACIELLO[2], R. ROLESI[2], S. L. M. ERAMO[1], A. R. FETONI[2]; [1]Inst. Physiol. Univ. Cattolica Sch. of Med., Rome, Italy; [2]Otolaryngology, Univ. Cattolica Sch. of Med., Rome, Italy

Abstract: The redox-sensitive transcription nuclear erythroid 2-related factor 2 (Nrf2) plays a critical role in the maintenance of cellular homeostasis under stress conditions by regulating endogenous cellular defenses against oxidative stress, including heme-oxygenase 1 (HO-1) activation. The progressive increase of reactive oxygen species (ROS) in conjunction with an imbalance of antioxidant defenses, have been demonstrated to play a significant role in Noise-induced hearing loss (NIHL). Namely, in this study we assessed the efficacy of a polyphenol compound, Rosmarinic Acid (RA), to activate Nrf2/HO-1 pathway, by potentiating the endogenous antioxidant defenses in a model of NIHL. Wistar rats were exposed to a pure tone (120 dB, 10 kHz) for 60 min in an anechoic room. One hour before and for the consequent 3 days, animals were treated with RA (10 mg/kg bw i.p.). Cochlear injury was evaluated by assessing functional (ABR recording) and morphological alterations (OHC survival). Oxidative stress was estimated by immunostaining or Western blot procedures to detect superoxide amount (DHE assay), lipid peroxidation (4-HNE) and the level of endogenous antioxidant responses (superoxide dismutase 1 and 2 and Nrf2-HO-1 pathway). Noise exposure induces oxidative stress in the cochlea, as indicated by superoxide and lipid peroxidation over-expression. To face the oxidative stress, the endogenous defense system is as well activated, as shown by the slight expression of SOD1 and SOD2. In addition, we observed the activation of the Nrf2/HO-1 pathway after noise exposure. However, the endogenous antioxidant system failed to restore the redox homeostasis and its activity was unable to prevent the cochlear damage. On the contrary, Nrf2/HO-1 signaling pathway was potentiated after RA administration, as well as SODs activity. This enhancement of endogenous antioxidant defenses was responsible for the reduction of oxidative stress parameters. In conclusion, the induction/activation of Nrf2-ARE signaling pathway and the up-regulation of endogenous antioxidant responses represent a relevant molecular mechanism to restore the redox imbalance caused by noise overexposure.

Title: Differential influences of visual-task performance on cochlear responses in musicians and non-musicians

Authors: ***S. BOOTHALINGAM**[1], M. HALINSKI[1], C. E. MURRAY[1], J. LEE[2], B. A. WRIGHT[1], S. DHAR[1];
[1]Northwestern Univ., Evanston, IL; [2]Univ. of Wisconsin, Madison, WI

Abstract: Introduction: The corticofugal neural network from the auditory cortex influences the functioning of sub-cortical systems through auditory and cross-modal attention. Activation of this network selectively adjusts gain in the system, improving the signal-to-noise ratio of the incoming sensory stream. The final leg of this network is the medial olivocochlear system (MOC) in the brainstem, which directly inhibits cochlear activity. The strength of this cochlear inhibition appears to be greater in musicians than non-musicians when induced using only auditory stimuli. Here we asked whether cochlear responses were also differentially affected in these two populations during performance of a demanding visual task. Method: Inhibitory activity of the MOC was monitored using distortion product otoacoustic emissions (DPOAEs), sounds generated by the cochlea in response to a pure-tone pair. DPOAE levels were measured in the right ear of participants. Musicians had received formal musical training, and currently practiced music >3 hours/week. Non-musicians had not received formal musical training or played music regularly in the last 4 years. The demanding visual task was Rapid Serial Visual Presentation (RSVP), in which images were presented in rapid succession and participants were required to respond upon detecting a repeated image. DPOAEs were measured in three conditions: with no visual task (baseline), while performing the visual task (RSVP), and immediately after performing the visual task (afterRSVP). DPOAE level differences between the baseline and the RSVP condition provided a metric of visual-task mediated changes in the cochlea, while those between the baseline and the afterRSVP condition quantified the decay of the influence of the prior visual task. Results: In preliminary data, DPOAE levels were significantly lower in musicians (n=4) than non-musicians (n=5) across all three conditions. Performing the RSVP task reduced the DPOAE level for both groups (re: each group's baseline), but the reduction was significantly smaller in musicians compared to non-musicians. The

influence of the visual task did not persist in the afterRSVP condition for either group. Conclusion: The smaller influence of the visual task, combined with the overall lower DPOAE levels, in musicians than non-musicians, raises the possibility that efferent inhibition at the cochlea in musicians may be at a constant maximum. This state could result from the extended auditory-visual training in musicians. In contrast, in non-musicians, the tonic level of cochlear efferent inhibition may be low and increase only as required by task demands.

Title: The use of electrocochleography in the diagnosis endolymphatic hydrops without vertigo

Authors: *M. MAHEU[1,3], S. ALHABIB[2], F. CHAMPOUX[1,3], I. SALIBA[2];
[1]Univ. of Montreal, Montreal, QC, Canada; [2]Dept. of Surgery, Div. of otorhinolaryngology-Head & Neck Surgery, Univ. of Montreal, University of Montreal, QC, Canada; [3]Ctr. for Interdisciplinary Res. in Rehabil. of Greater Montreal, Raymond-Dewar Inst., Montreal, QC, Canada

Abstract: Introduction Electrocochleography has been extensively studied in the diagnosis of Meniere disease (MD). The different categories of MD are well described by the American Academy of Otolaryngology- Head and neck surgery (AAO-HNS). The main criteria are vertigo, ear fullness, tinnitus and fluctuating sensorineural hearing loss. All the categories of MD described by AAO-HNS have a common symptom: vertigo. Although, many patients report ear fullness without vertigo, not caused by external or middle ear pathology, and therefore are often misdiagnosed. Electrocochleography (ECochG), using SP/AP amplitude ratio and SP/AP area ratio, has been demonstrated as a specific and sensible objective tool in the diagnosis of endolymphatic hydrops in MD. Objective and hypothesis The main objective of the study is to use ECochG to differentiate subjects that report ear fullness without vertigo, compared to controls. We believe that the use of SP/AP area ratio will allow differentiating between controls and the ear fullness group. Methodology 40 patients were recruited for the present study (20 controls and 20 with ear fullness). We recorded ECochG using an extra-tympanic electrode in each of these patients and studied the SP/AP amplitude ratio and the SP/AP area ratio. We then

compared the results from the ear fullness group to the results from the control group. Results There was a statistically significant difference (p=0.019) for SP/AP area ratio between the control group (Mean=1.48 SD=0.29) and ear fullness group (Mean=6.03; SD=7.16). However, no significant difference (p=0,063) could be observed for the SP/AP amplitude ratio between the control group (M=19,55; SD=9,74) and ear fullness group (M=30,06; SD=20,31). Conclusion It is shown that SP/AP area ratio can differentiate between patients having endolymphatic hydrops symptoms and controls. This is relevant because we can now identify objectively, using the SP/AP area ratio, the source of the symptoms expressed by the patient and possibly treat the condition more efficiently.

Title: Anatomical similarity is mandatory to provide body ownership toward body-shadow

Authors: *A. KANAZAWA, K. KODAKA;
Grad. Sch. of Design & Archtecture, Nagoya Ci, Nagoya-Shi, Japan

Abstract: Rubber hand illusion (RHI) can provide body ownership (BO) to a fake hand based on spatio-temporal correlation between visual and tactile stimulations. Another type of RHI that has gained increasing interest over the last few years is where we see a rubber hand (on desk) moving in sync with the movement of a hand (under the desk). Researchers have controlled an artificial hand (such as a robot hand) in sync with the hand movement, completing the vision-proprioception correlation (Casper et al., 2014). On second thought, the use of a body-shadow seems a quick and natural way to realize such a correlation; however, no research has directly focused on them, despite there being an increasing number of studies showing that the visualization of the body-shadow can change spatial perception (Kurlen et al., 2014). We aim at verifying an effect of body-shadow on RHI with a proprioceptive drift (PD) distance as an indicator of BO. We set three acrylic plates vertically at a suitable interval, where we can see a shadow of a right hand (on the middle) and a rectangle cloth (on the middle or the bottom) on screen of the top plate via a light source installed on the floor. Three shadow environments are designed in the following: the first is hand shadow (HS), where the top panel shows the right hand's shadow in a straightforward manner, the second is rectangle shadow (RS), showing the shadow of the rectangle cloth (clinging to the right hand) that moves in sync with the hand movement, and the third is unmoved rectangle shadow (URS), showing the shadow of the rectangle cloth (on the bottom) that remains stable regardless of the hand movement. In each

environment, 12 participants looked at the shadow for 1 min while not moving the hand (Unmoved) and moving the hand back and forth (Moved), in order. After each task, they were asked to indicate where they felt their right hand was located by the left hand with eyes closed (PD measurement) and to answer some simple questions. The result showed that RS and URS did not produce PD at all, regardless of whether there is hand movement; while, HS involved a significant PD compared with RS and URS, where PD magnitude was significantly larger in Moved (4.2 cm on average) than in Unmoved (2.0 cm on average). The questionnaire result also showed that the subjective strength of the BO was significantly larger in HS, while there was no main effect of the hand movement in HS. These indicate that anatomical similarity to body-part is mandatory to provide BO toward the body-shadow. Interestingly, shifting from Unmoved to Moved condition improved only the PD's magnitude; it did not improve the subjective strength of BO. The observed discrepancy is discussed considering the effect of time.

Title: Axonal density in the ipsilesional and contralesional corticospinal tracts post stroke and relationship to corpus callosum microstructure

Authors: M. LAZAR[1], A. GEORGE[1], Y. LUI[1], V. ALURU[1], S. BILALOGLU[1], D. GELLER[1], *P. RAGHAVAN[2,1];
[1]New York Univ. Sch. of Med., New York, NY; [2]Rehabil. Med., New York Univ. Langone Med. Ctr., New York, NY

Abstract: A stroke can lead to persistent upper limb impairment on one side of the body. Increased activation of the undamaged contralesional motor areas has been shown to correlate with better motor recovery at a later time. This suggests that contralesional neural substrates can potentially drive motor output on the affected side of the body. The corpus callosum synchronizes large scale networks across the two hemispheres and may play a key role in transfer of function between the two sides. The purpose of this study was to examine the interaction between the ispilesional and contralesional corticospinal tracts (CST) and the corpus callosum (CC) as substrates of impaired hand function and of function transfer between the two hands. Thirteen patients with unilateral hand motor deficits at least 4 months post stroke participated in the study. Diffusion tensor imaging (DTI) was employed to derive Fractional

Anisotropy (*FA*). Microstructural white matter properties were also described using Diffusional Kurtosis Imaging (DKI), which include 1) Axonal Water Fraction (f_{axon}), a metric reflective of axonal density and caliber, 2) Intra-axonal Diffusivity (D_{axon}), which describes the overall organization of the intra-axonal milieu, and 3) Axial (AD_{extra}) and 4) Radial (RD_{extra}) extra-axonal diffusivities, which reflect the organization of the glia and the extracellular space. Mean *FA* and DKI metrics were obtained for the CSTs and for the posterior body of the CC, which connects the motor and somatosensory cortices of the two sides. Extent of arm motor impairment was measured using the Fugl-Meyer Scale (FMS). We found that the *FA* and f_{axon} of the ipsilesional CST were significantly decreased compared to that of the contralesional CST ($p<0.005$). Moreover, both the FA and f_{axon} of the ipsilesional CST were significantly correlated with arm motor impairment as measured by the FMS ($r/FA=0.611^*$; $r/f_{axon}=0.561^*$; $^*p<0.05$). No correlations were found between the FMS and the diffusion metrics of the contralesional CST ($p>0.05$). FA & f_{axon} of the ipsilesional CST correlated with the FA of the contralesional CST and with the FA & f_{axon} of the corpus callosum ($r>0.5$, $p<0.05$). These results indicate that functional hand motor impairment relates to microstructural deficits of the affected CST, with axonal loss due to Wallerian degeneration likely the primary driver of this relationship. CST relationships with CC support the hypothesis of inter-hemispheric transfer of information as a potential remediation strategy.

Title: Neurodynamics of letter perception in blind and sighted readers

Authors: ***S. TENG**[1], R. CICHY[1], D. PANTAZIS[2], V. SOMMER[1,3], A. OLIVA[1]; [1]CSAIL, [2]McGovern Inst. for Brain Res., MIT, Cambridge, MA; [3]Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: A large part of cortex in humans is dedicated to visual processing. However, in blind individuals visual cortex does not fall silent, but rather responds to a wide range of nonvisual tasks. What is the role, then, of so-called visual cortex and representations it mediates in blind persons, and how does it compare to representations in the sighted? To address these questions, here we used magnetoencephalography (MEG), multivariate pattern analysis, and

representational similarity analysis (RSA) to compare letter recognition in visual, auditory, and tactile modalities. We presented blind and sighted volunteers with 10 single letters in random order while recording brain activity. In separate experiments, sighted subjects (N=13) were presented with lowercase Roman visual letters, blind subjects (N=11) were presented with Braille tactile letters, and both groups (N=7 blind and sighted) were presented with spoken auditory letters. We compared the representation of letters across blind and sighted subjects as well as modalities using RSA. We found high representational similarity for tactile letters at ~200 ms and visual letter representations at ~600 ms, indicating a possible common processing mechanism. This result is not likely due to sub voce vocalization: representational similarity between spoken and tactile representations in the blind were more diffuse and peaked at later times. The results suggest that brain regions recruited crossmodally may be performing some common underlying computations for analogous tasks, but that letter reading is overall largely driven by distinct processes across sensory modalities and blind vs. sighted populations. This work was supported by NIH R01-EY020484 to A.O. and conducted at the Athinoula A. Martinos Imaging Center at MIT's McGovern Institute for Brain Research.

Title: Causal inference in self-motion estimation

Authors: ***A. TER HORST**, M. KOPPEN, L. P. J. SELEN, W. P. MEDENDORP; Radboud Univ. Nijmegen, Donders Ctr. For Cognition, Nijmegen, Netherlands

Abstract: While in motion humans face a vast amount of, often ambiguous, sensory cues. An observer might use these cues to infer the amount of self-motion, but only after having inferred whether these cues originate from one or multiple sources. During passive self-motion, the visual and vestibular cues are the most salient cues for estimating self- and object-motion. It is known that if both cues are integrated the brain follows the rules of Bayesian optimal integration, however it is unknown under what circumstances the brain associates both cues as coming from a single source and when the brain segregates both cues for separate processing. In other words,

when will a vestibular based estimate of self-motion be pulled towards a discrepant visual cue [that represents object-motion] and when will the brain decide that the cues have different causes and should be segregated? In this study we assess this causal inference problem on the integration and segregation of visual and vestibular cues during passive self-motion using Bayesian inference of a structural causality model. Participants were seated on a linear sled embedded in a virtual reality environment. They were subjected to linear motion that elicited both vestibular and visual cues. A discrepancy in motion amplitude between the visual and vestibular cues was added during these motions. Participants performed a two-alternative forced-choice task, indicating which of two sequential displacements was largest. Results indicate that observers start to segregate cue information when the discrepancy increases. The point on which segregation starts (occurs) depends on variability and can be modeled using a hierarchical probabilistic mixture of integration and segregation based responses.

Title: Eye-hand coordination for adaptation of hand posture to object shape

Authors: ***A. YOUSEFI**, S. BILALOGLU, P. THAI, V. ALURU, Y. LU, J.-R. RIZZO, P. RAGHAVAN;
Rehabil. Med., New York Univ. Sch. of Med., New York, NY

Abstract: We grasp objects of various shapes during daily activities. Visual information about the perceived shape of the object can inform planning of hand posture for efficient grasp. A clear understanding of the mechanisms of eye-hand coordination and adaptation of hand posture to object shape is necessary to develop appropriate treatment strategies for restoration of coordination and dexterity in patients with impaired hand function such as after a stroke. The purpose of this study was to examine the relationship between gaze location and hand posture during reaching and grasping objects of different shapes in healthy subjects. 10 neurologically intact, right-hand dominant subjects participated in the study. The subjects were asked to sit at a table with the grasping hand on the table in front of them with the fist closed. The subjects were asked to reach and grasp the object positioned at 75% of arm's length in front of them, and repeat the task 7 times for 9 different objects with unique shapes (requiring differential angular

excursions of 5-10 degrees at the PIP/MCP joints). The focal point of binocular gaze was tracked by Eyelink2 eye tracker (SR Research Ltd, Ottawa, Ontario, Canada), and the location of the subject's head, hand, forearm, arm and shoulder were tracked by motion sensors attached to the limb segments and to the object (6DOF Ascension sensors, Ascension Technology Corporation Shelburne, Vermont). Adaptation of hand posture to object shape was measured using Cyberglove. (Cyberglove system, San Jose, USA). We examined the position of the focal point of gaze during the various phases of reach-to-grasp: prior to reach onset, and during reach acceleration, deceleration and grasp. The results suggest that examination of gaze patterns can inform planning strategies for control of hand shape during grasping. We can use this information as a benchmark to assess deficits in eye-hand coordination during reach-to-grasp in patients with stroke.

Title: Haptic feedback of rebound improves predictive gaze tracking

Authors: ***F. SALMEN**[1,2], F. CREVECOEUR[1,2], J.-L. THONNARD[2,3], P. LEFEVRE[1,2]; [1]ICTEAM, Univ. catholique de Louvain, Louvain-la-Neuve, Belgium; [2]Inst. of Neurosci. (IoNS), Univ. catholique de Louvain, Brussels, Belgium; [3]Physical and Rehabil. Med. Dept., Cliniques Universitaires Saint-Luc, Brussels, Belgium

Abstract: Humans and animals rely on internal representation of the trajectories of moving stimuli, allowing predictive tracking despite transient target disappearance, or anticipation of future events. For instance, tennis players must predict the time and location of impact to achieve successful shots. An important question is whether the nervous system can integrate haptic feedback to improve the prediction about future events, such as the future trajectory of the ball following impact. To address this question, we studied predictive eye movements in a semi-static (fixed hand, moving target) collision task. Participants interacted with a robotic device

(KINARM, BKIN Technologies, Kingston) which applies force (i.e. haptic feedback of the collision) onto the participant's hand. Visual targets were projected onto a virtual reality display. Eye movement was recorded with an Eyelink camera (SR Research Ltd., Ottawa, Ontario, Canada). The participants (N=6) were instructed to perform visual tracking of round-shaped targets of different sizes before and after a collision with a bar representing the hand position. We assumed constant mass density, such that for a given velocity, a higher impact force was experienced for objects greater in size. The target was blanked for a constant period of 800ms immediately after the collision to address participants' capabilities to predict where the target would reappear. Two different object sizes and velocities resulted in four different impact forces and four different post-collision velocities due to simulated energy loss during the collision. The different conditions corresponded to a factorial design in which visual cues about target size and haptic feedback were provided or not. We then extracted the gaze position upon target reappearance to address participants' capabilities to integrate information about impact force in their predictive eye movements. Our results indicate that participants adjusted their gaze regarding to the target velocity after the collision. We found significant modulation of gaze position with target position at reappearance when both haptic feedback and visual cues about the target size were provided (linear regressions, $p<0.005$). In contrast, there was no significant correlation between gaze and target position at reappearance when no haptic feedback and no visual cue were available. Providing either haptic feedback or visual cue about target size evoked marginally significant correlation between gaze and target coordinate ($p\approx0.1$). We conclude that haptic feedback about impact force and visual cues are integrated in predictive tracking of a target after collision.

Title: Tool use and near-tool effects: Exploring the influence of training demands

Authors: ***G. E. TRACEY**, L. E. BROWN;
Psychology, Trent Univ., Peterborough, ON, Canada

Abstract: Learning to use a tool may involve the integration of multiple senses. Skilled tool users treat visual targets presented near a tool differently after training - these changes are called near-tool effects. The bimodal cell hypothesis explains this change in visual processing by

appealing to the activity of cells in the brain that respond both to visual and tactile stimuli. Visual receptive fields that respond to stimuli presented near the hand may expand down the length of the tool inducing near-tool effects. These effects may depend on active tool use. In this study we asked, can these effects be modulated by the demands placed on tool use? Eighty-one participants completed an experiment with a motor training task followed by a cross-modal interference task. Participants in tool-training groups were instructed to perform pointing movements with a tool held in their right hand. Five targets were presented along the mid-sagittal plane. Participants trained so that their movements were both quick and accurate to reach a criterion on 10/20 trials (the 50% training group) or 18/20 trials (the 90% training group). The control group received no active tool training. Participants would then complete a cross-modal interference task where tools were held in the left and right hands with index fingers placed on vibrotactile stimuli. Tactile stimuli were paired with seven visual stimuli presented near each tool. Stimulus pairs occurred on the same tool (compatible) or opposite tool (incompatible). Participants were instructed to press with their right foot on a keyboard as quickly as possible when they felt the tactile stimulus and reaction time (RT) was recorded. If near-tool effects are influenced by training demands, the size of the near-tool effect may vary with training demands. Our results indicate that our training manipulation was effective. The 90% group was more accurate and had lower movement times than the 50% group. However, a new group emerged who performed 180 trials of training but never reached criterion. They were less accurate and had slower movement times than the 50% training group and did not improve with practice. Results from the cross-modal interference task show that there were compatibility effects that appeared near the hand and near the tool tip that were not present for targets that were beyond the tool tip. There were no consistent differences between the 50% and 90% training groups. Near-tool effects depend on active tool-use in humans but do not appear to vary with training demands.

Title: Large-scale cortical synchronization promotes multisensory processing

Authors: *F. GÖSCHL[1], P. WANG[1], U. FRIESE[1], P. KÖNIG[2], A. K. ENGEL[1];
[1]Dept. of Neurophysiol. and Pathophysiology, Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [2]Inst. of Cognitive Sci., Univ. of Osnabrück, Osnabrück, Germany

Abstract: The integration of sensory signals from different modalities requires flexible interaction of remote brain areas. One candidate mechanism to establish local and long-range communication in the brain is transient synchronization of neural assemblies. In addition to the analysis of oscillatory power, assessment of the phase dynamics of multiple brain signals is a promising avenue to examine the integration of distributed information in multisensory networks. In the present study, human participants were engaged in a visuotactile pattern matching task while high-density EEG was recorded. To investigate the neural correlates of multisensory integration and assess effects of crossmodal stimulus congruence, we adapted an approach for purely data-driven analysis of neuronal coupling in source space that has recently been developed within our group. This method allows imaging of large-scale cortical networks in space, time and frequency without defining a priori constraints. We identified three clusters of interacting sources that synchronized in the beta-band (~ 20 Hz). The spatial and spectro-temporal profile of the first two clusters suggest an involvement in crossmodal sensory processing, whereas the third cluster appears to reflect decision-related processes. By directly relating coupling features to task performance, we demonstrate that the phase of neural coherence within the observed networks predicts behavior. Our results provide further evidence that neural synchronization is crucial for long-range communication in the brain and suggest a possible role of beta-band activity in multisensory integration.

Title: Structural correlates of visual cortex plasticity in sighted braille learners

Authors: *L. BOLA[1,2], K. SIUDA-KRZYWICKA[1,4], M. PAPLINSKA[5], E. SUMERA[6], K. JEDNOROG[3], A. MARCHEWKA[2], M. ZIMMERMANN[7], M. SZWED[1];

Abstract: Neuroplasticity in the adult brain is thought to operate within the limits of sensory division, where the visual cortex processes visual stimuli and responds to visual training, the tactile cortex processes tactile stimuli and responds to tactile training, and so on. A departure from this rule is presumed possible only in sensory loss or brain injury - for example, the visual cortex of blind subjects can be recruited for braille reading. We recently showed that contrary to this presumption, the visual cortex of sighted braille learners becomes critical for tactile reading (Bola et al., SFN 2014). Here we wanted to test whether cross-modal plasticity during braille learning induces structural reorganization of the visual cortex. 29 subjects - mostly braille teachers and educators, naïve in tactile braille reading - were enrolled in a 9-month braille course. At the beginning of the course and at its end, they underwent a magnetic resonance imaging (MRI) session, during which high-quality T1-weighted images were acquired for voxel-based morphometry (VBM) analysis. Additionally, resting-state functional MRI (rsfMRI) data were collected for functional connectivity analysis. 9 months after the end of the course, 19 subjects participated in a follow-up MRI session. After the training we observed grey matter volume increase in the primary and secondary visual cortex, left premotor cortex and left cerebellum (lobules VII and VIII). Structural changes in the early visual cortex were left-lateralized and restricted to regions that represent peripheral visual field. The grey matter volume increases were preserved in a follow up scan, 9-months after the end of the training. Functional connectivity analysis showed that subparts of early visual cortex in which we observed structural plasticity were preferentially connected with primary somatosensory and motor cortices, even before the onset of the training. In line with our previous study (Bola et al., SFN 2014), we did not find structural changes in the somatosensory cortex. Our results show that tactile training can induce structural reorganization in the visual cortex. It is thus the first evidence that cross-modal, structural plasticity is possible in the healthy, adult brain. Together with our previous findings, our results suggest that this plasticity re-arranges the flow of tactile information in the brain. As its result, complex tactile input such as braille is transferred via corto-cortical connections from somatosensory to early visual cortices. That information is then subsequently processed in the high-level visual areas.

Title: Inducing sense of finger extension or retraction based on self-touch illusion and proprioception-vision correlation

Authors: K. MORI, Y. ISHIHIHARA, *K. KODAKA;
Grad. Sch. of Design & Archtecture, Nagoya City Univ., Nagoya-City / AICHI, Japan

Abstract: We can feel that both hands touch each other by providing a synchronized touch in self-touch illusion (STI, Ehrsson et al., 2005). It is well known that proprioceptive drift (PD) occurs in a manner that involves both hands attracting each other in STI. Although it is generally assumed that PD merely involves a horizontal movement of an entire hand, a thought experiment suggests that a finger extension also can fill a spatial gap between two hands (fingers). To the best of our understanding, though such an impression has been described by some participants in past experiments (Kodaka et al., 2014), no research to date has focused on inducing a finger extension in the body illusion. Our study developed a system inducing a sense of extension or retraction (SER) in a good combination of synchronized vibrations (for STI) and a vision-proprioception correlation. This physically regulates a distance between left and right index finger using two linear actuators (fixed to stands where hands are placed) and displays an animated finger image created by computer graphics (CG) through a head-mount display (HMD) that transforms with the movement of both hands. We performed two experiments with a total of 17 participants to measure the effect of synchronized vibrations and the visual correlation on sense of self-touch and SER in our system. There were eight kinds of conditions, each of which took 20 seconds and were repeated four times. The first factor concerned a specific modality's presentation; half of the presented conditions lacked a visual image in the HMD (Exp. 1) and synchronized vibrations (Exp. 2). In each trial with a visual image, the left index finger on CG was transformed in a manner involving extension for both fingers' separation and retraction for their approach; whereas, the length of the right index finger did not change on CG. The second factor concerned the average physical distance between both fingers. The participants were asked to answer some questions regarding STI and SER after each trial. Results indicated that lack of synchronized vibrations drastically and significantly worsened the subjective strength of STI and SRE (47% and 58% on average, respectively); whereas, the lack of a visual image worsened them slightly (80% each on average). This suggests that SRE is essentially based on an effort of the self-touch body image induced by synchronized vibrations. Another analysis found that the sense of retraction was significantly stronger when both hands were in close proximity; whereas, the sense of extension was significantly stronger when they were separated. Based on these results, the process of how SRE is induced with multiple sensor integration is discussed.

Title: Categorizing individuals by tactile, kinesthetic and visual impairments for individualized treatment for upper limb recovery post stroke

Authors: *D. GELLER[1], V. ALURU[1], S. BILALOGLU[1], Y. LU[2], P. RAGHAVAN[3]; [1]Rehabil., Rusk Rehabil. NYU Langone Med. Ctr., New York, NY; [2]New York Univ., New York, NY; [3]New York Univ. Sch. of Med., New York, NY

Abstract: Despite conventional rehabilitation, even relatively well recovered stroke survivors have persistent deficits in hand function that affects their quality of life. Hand function requires integration of sensory inputs with motor output. However, patients with stroke can have varying degree of impairment in tactile, kinesthetic and visual domains which can affect motor learning and recovery. We administered a battery of tests of impairment in tactile, kinesthetic and visual domains that pertain to grasping and lifting, and examined its effect on learning to adapt fingertip forces according to the texture, weight and shape of objects. Twenty subjects with stroke were categorized as having mild, moderate or severe impairments in the 3 sensory domains tested. Fingertip forces and movements during grasping and lifting were measured using force sensors and an instrumented glove. We found that while some subjects had deficits in all three domains, most subjects were impaired specifically in one domain. The impairment in adaptation of fingertip forces during grasping and lifting was directly correlated with the sensory impairment. For example, subjects with tactile deficits did not adapt their fingertip forces to object texture but could adapt their fingertip forces to object weight. Categorizing patients with stroke according to impairment type and severity may help plan individualized treatment programs for improved motor learning and recovery of upper limb function.

Title: Probing the neuroanatomy of olfactory processing in the human orbitofrontal cortex with electrical brain stimulation

Authors: *S. GATTAS, J. YIH, J. PARVIZI;
Lab. of Behavioral and Cognitive Neurosci., Stanford Univ., Stanford, CA

Abstract: Several functional magnetic resonance imaging (fMRI) studies in humans and electrophysiological studies in non-human primates have shown olfaction-related activity in the orbitofrontal cortex (OFC). To probe the causal role of various anatomical OFC subregions in olfaction, we used electrical brain stimulation (EBS) in patients implanted with unilateral subdural electrodes in the right or left OFC. We hypothesized that EBS in specific subregions of the OFC would elicit olfactory hallucinations, and predicted that the valence of subjective olfaction hallucinations would be altered by varying electrical charge density. We included data from 10 patients (6 right hemisphere) with medically intractable epilepsy. In all subjects, the OFC was identified to be outside the ictal onset zone. Right hemisphere group coverage consisted of 75 OFC electrodes (68 stimulated), whereas the left contained 84 (73 stimulated). The EBS procedure involved the delivery of current to adjacent electrode pairs at varying combinations of amplitudes and frequencies, interspersed with sham trials in which no current was delivered. The patients' post-stimulation subjective experiences were categorized as smell, taste, smell and taste, or other effects. Since smell and taste effects were often reported in conjunction, we ultimately grouped these effects into one category. The valence of each evoked effect was then categorized as positive, negative, or neutral. From a bilateral sample of stimulated electrodes, 17.02% evoked an olfaction-gustation effect. Moreover, 93.33% (14/15) of right and 77.78% (7/9) of left hemisphere electrodes with olfaction-gustation effects were located in central-to-posterior OFC. More specifically, electrodes were positioned within the following anatomical subregions; bilateral gyrus rectus (5/8 subjects), bilateral medial orbital gyri (3/9 subjects), the caudal region of the right posterior orbital gyrus (1/3 subjects), and the right lateral orbital gyrus (1/5 subjects). There was no anatomically consistent pattern observed in elicited valence effects. However, increases in frequency or amplitude of electrical stimulation resulted in a greater intensity of the hallucination experienced. The present study provides causal evidence that OFC subregions involved in olfaction-gustation are within central-to-posterior OFC. Lastly, it provides insight on the effect of stimulation parameters on the intensity of the experienced hallucination.

Med., Yale Sch. of Med., Waterbury, CT; [5]Mount Sinai, New York, NY; [6]Steinhardt Sch. of Culture, Educ. and Human Develop., New York Univ., New York, NY

Abstract: Few options exist for training arm movements in subjects with hemiparesis when they have little active range of motion. An inability to move often leads to non-use, stalled recovery and progressive upper limb deformity. The purpose of this study was to test the safety and feasibility of training individuals with hemiparesis with a non-powered device, the Bimanual Arm Trainer, that facilitates coupled bimanual training of shoulder external rotation and elbow extension. Nine subjects with post-stroke hemiparesis, preserved passive range of motion in shoulder, elbow and wrist joints and minimal spasticity, trained with the device twice a week for six weeks. All subjects tolerated the training and no adverse events were reported. Motor impairment on the upper extremity Fugl-Meyer Scale and active range of motion measured using motion analysis techniques were assessed pre- and post-training. Subjects showed significant improvement in the Fugl-Meyer score, particularly for proximal movements of the shoulder and elbow with changes in the flexor synergy pattern. Changes in active range of motion in the paretic limb for both trained and untrained movements corroborated with the improvement in Fugl-Meyer scores. The results demonstrate the safety and feasibility of using the Bimanual Arm Trainer to facilitate motor recovery in individuals with severe hemiparesis.

Title: Mental transformation of body parts in manipulating the somatotopic representation

Authors: ***T. SUDO**[1], Y. OOUCHIDA[1], S.-I. IZUMI[1], K. MOGI[2];
[1]Tohoku Univ., Sendai, Miyagi, Japan; [2]Sony Computer Sci. Laboratories, Inc., Tokyo, Japan

Abstract: The embodied representations of self and others play an important part in social interaction such as perspective taking, imitation, and theory-of-mind mechanisms. In order to perceive one's own body and their environment, and achieve the intended movements successfully, the brain would require integrating multisensory information consisting of proprioceptive information about the location and the current body position, as well as the external signals from visual information. Perspective taking through the manipulation of own body image is dependent on the comparison between the representations of self and others, involving a transformation of egocentric perspective to the allocentric one. Rotation symmetry, in which the subject navigates egocentric image of the self for the destination (Keehner et al, 2006), is one way of transformation between the representation of self and others. Recent studies have suggested that the rotation symmetry in the mental transformation of one's own body correlates with a similar tendency of object mental rotation (Sekiyama 1982; Parsons 1987; Zacks 2008). During the mental rotation of body parts, subjects might change their perspectives as if in a task of object mental rotation. Such a transformation process would also require integrating multisensory information consisting of visual and proprioceptive information. On the other hand, several studies revealed that, when limbs are crossed, the integration of tactile with proprioceptive information is hindered and tactile localization becomes less accurate (Heed et al, 2014). Here we have conducted some consecutive experiments with hand mental rotation paradigm in which we manipulated the hand posture and location of visual stimuli in order to examine the effect of misalignment of somatotopic and external reference frames. The subjects were instructed to make a few perceptual judgments on spatial configurations in the mental rotation paradigm with various alignments of their own hand and presentation stimuli. Behavioral data from this experiment suggest the robustness of integration of sensory information in the mental imagery of bodily self. Based on the results, we discuss the significance of crossmodal congruency in the fundamental aspects of bodily self-consciousness.

Title: The magnetic touch illusion: a proposed perceptual correlate of peripersonal space

Authors: *A. GUTERSTAM, H. ZEBERG, V. MENDERES OZCIFTCI, H. EHRSSON; Karolinska Institutet, Stockholm, Sweden

Abstract: To accurately localize our limbs and guide movements toward external objects, the brain needs to represent the body and its surrounding (peripersonal) visual space. Although we do not perceive the space near our body as "special", single-unit recordings in monkeys have identified visuo-tactile-proprioceptive neurons in specific multisensory regions that represent peripersonal space in body-part-centered reference frames. In humans, the underlying multisensory integrative process has been implicated in limb self-attribution based on studies on the classical rubber hand illusion. In this study, we show that the application of brushstrokes in mid-air at some distance above a rubber hand - but never actually touching it - in synchrony with brushstrokes on the hidden real hand results in the illusory sensation of a "magnetic force" between the brush and the hand, which is strongly correlated with experienced rubber hand ownership. In eight experiments including a total of 101 healthy volunteers (60 females, mean age 27±5 years), we characterized this "magnetic touch illusion" using motion tracking (Polhemus FASTRAK, Vermont, USA) of the brush moving in mid-air and measuring questionnaire responses, proprioceptive drift, or real-time illusion vividness ratings. We found that the magnetic touch illusion exhibits striking similarities to the visual receptive field properties of peripersonal space neurons, featuring a non-linear decay in illusion strength at 40 cm ($p=0.01$) that is not significantly affected by gaze direction ($p>0.05$) (Experiment 1a, 1b, and 1c) and follows changes in rubber hand position (Experiment 4). Furthermore, we show that the mere expectation of a tactile event on the rubber hand does not contribute to the illusion experience (Experiment 2a and 2b) and that the "magnetic force" does not penetrate physical barriers (Experiment 3a and 3b). These findings provide strong support for the notion that multisensory integration within peripersonal space is an underlying mechanism for bodily self-attribution. Moreover, we propose that the magnetic touch illusion constitutes the first example of a perceptual correlate of peripersonal space in humans. As such, our findings provide a novel prediction for neurophysiological studies of peripersonal space, namely that that the visual receptive field of perihand neurons will remap with the introduction of a physical barrier close to the hand.

Title: A rubber hand experiment using an EMG controlled robotic arm in amputee participants

Authors: *Y. SATO[1], T. KAWASE[1], K. TAKANO[1], K. KANSAKU[1,2];
[1]Sys. Neurosci. Sect., Dept. of Rehab. for Brain Funct., Res. Inst. of Natl. Rehabil. Ctr., Tokorozawa, Japan; [2]Brain Sci. Inspired Life Support Res. Ctr., The Univ. of Electro-Communications, Chofu, Japan

Abstract: Feeling ownership of our limbs represents a fundamental aspect of self-consciousness, and in some circumstances, the feeling is extended out of our own body, as in the rubber hand illusion (Botvinick and Cohen, 1998). In our previous rubber hand experiment in able-bodied participants, we used an in-house electromyography (EMG) controlled robotic arm, and evaluated sense of agency (SA) and sense of ownership (SO) by subjective ratings (-3 to +3) (Kalckert & Ehrsson, 2014). We found that subjective ratings (SA/SO) in able-bodied participants were significantly greater than 0 when the robotic arm was synchronously moved with their arm (Sato et al., 2015). In this study we performed the rubber hand experiment using the EMG controlled robotic arm in amputee participants (n=3). The robotic arm was placed in front of the amputee participants. A cloth was placed to cover the stump of the participant's amputated arm. EMG signals were recorded from the participants' amputated arm to control the robotic arm. The wrist of the robotic arm was flexed/extended when the participant's wrist flexors/extensors were contracted. After the experiment, SA and SO were evaluated by subjective ratings (-3 to +3). The experiment was repeated six times. Average value of the subjective ratings (SA/SO) in the 3 amputee participants were 2.2±0.7/2.1±0.6, 1.4±0.1/0.9±0.1, and 1.8±0.4/2.4±0.4, respectively. The subjective ratings (SA/SO) in the participants were significantly greater than 0 ($p < 0.05$). These results suggest that rubber hand illusion-like experience was induced by using an EMG controlled robotic arm in the amputee participants.

Title: Interactions between agency and ownership by moving virtual hand illusion

Authors: *S. UNENAKA, S. SHIBUYA, Y. OHKI;
Depatment of Integrative Physiol., Kyorin Univ. Sch. of Med., Tokyo, Japan

Abstract: Previous studies on bodily self-consciousness have reported some interactions between senses of agency and ownership of a moving rubber hand. However, these interactions were mainly observed in a subjective measurement (i.e. retrospective self-report), but not in an objective one (i.e. proprioceptive drift). We examined the interactions in both the self-report and the proprioceptive drifts using a moving virtual hand illusion. Normal subjects (n=20) placed their right hand on a 2D manipulandum with a low-friction. The hand was not visible directly, but an image of the life-size virtual right hand was displayed 12 cm in front of the real right hand. To induce the virtual hand illusion, subjects were required to move the virtual hand cyclically by manipulating their real hand. A 2 x 2 factorial design was applied to dissociate the senses of agency and ownership: movement types (active and passive) and virtual hand positions (anatomically congruent and incongruent). Subjects' hands were moved passively in the passive conditions, and the virtual hand was rotated at 180 degrees in the incongruent conditions. As the objective measurement of the ownership, proprioceptive drifts were estimated from three tests before and after illusion induction: bimanual arm position matching (BM), visual positional judgment (VJ), and target-reaching movement (TR). Senses of agency and ownership during illusion induction were subjectively measured using a Likert rating-scale questionnaire. Ratings on the questionnaire showed a double dissociation of agency and ownership. Proprioceptive drifts changed differently between the tests. They were observed only in the congruent conditions in BM, similar to the ownership rating. On the other hand, those in VJ and TR were influenced by both movement type and hand position, and were the greatest in the congruent active condition. Proprioceptive drifts obtained from three tests were weakly correlated ($r>0.24$, $p<0.05$), except for those between TR and BM ($r=0.06$). We further performed multiple regression analyses between proprioceptive drifts from three tests (independent variables) and the questionnaire ratings (dependent variables). Results revealed that only the ownership rating ($r=0.42$, $p<0.05$) could be explained by drifts in BM ($\beta=0.29$, $p<0.05$). These results suggest that agency could affect objective ownership measurements, but in different manners between tests; agency can increase proprioceptive drifts only in VJ and TR. On the other hand, in the current study, the subjective ownership measurement was not influenced by agency, which may be reflected in proprioceptive drifts in BM.

Title: Functional mapping of High-Density Diffuse Optical Tomography using movie viewing

Authors: *A. K. FISHELL[1,2], A. T. EGGEBRECHT[1], S. E. PETERSEN[1,3], J. P. CULVER[1,4]; [1]Radiology, [2]Div. of Biol. and Biomed. Sci., [3]Neurol., Washington Univ. Sch. of Med., Saint Louis, MO; [4]Physics, Washington Univ., Saint Louis, MO

Abstract: fMRI has previously shown that cortical responses to movies are highly reproducible, both within and across viewers. In the present study, we asked two questions related to this observation. First, does an optical neuroimaging technique, High-Density Diffuse Optical Tomography (HD-DOT), have sufficient resolution and field-of-view to replicate this result? Second, can movie-evoked responses be used to functionally map cortical areas? To answer these questions, healthy human participants (N=9; 6 Female; Age range: 22-33) viewed a 10 min clip from The Good, The Bad, and The Ugly) while being scanned with a HD-DOT neuroimaging system. We observed high response reproducibility across broad portions of the cortex, both within and across participants. Using an MR-derived pacellation scheme to identify cortical regions, we found that response reproducibility is particularly elevated in visual and auditory regions, recapitulating results obtained using fMRI. Further, we demonstrate the feasibility of using movie stimuli as a tool for mapping functional areas. Specifically, we observed considerable overlap between movie-evoked responses and responses evoked by more traditional localizer paradigms (e.g. passive word listening, retinotopy), indicating that passive movie viewing is a simple paradigm that maps many of the same areas as multiple functional localizers. Finally, we found that the topography of response reproducibility can be modulated by movie content. Participants also viewed a second movie with extremely strong motion content. In comparison to the first stimulus, this “motion intensive” film generated reproducibility maps with greater response reproducibility in motion sensitive area MT, suggesting that movie content can be tailored to localize specific regions of interest. From these results, we conclude that: (1) HD-DOT has sufficient resolution, field-of-view, and signal-to-noise to detect reproducible movie-evoked responses, and (2) movie-evoked responses can serve as a tool for mapping functional areas related to visual and auditory processing.

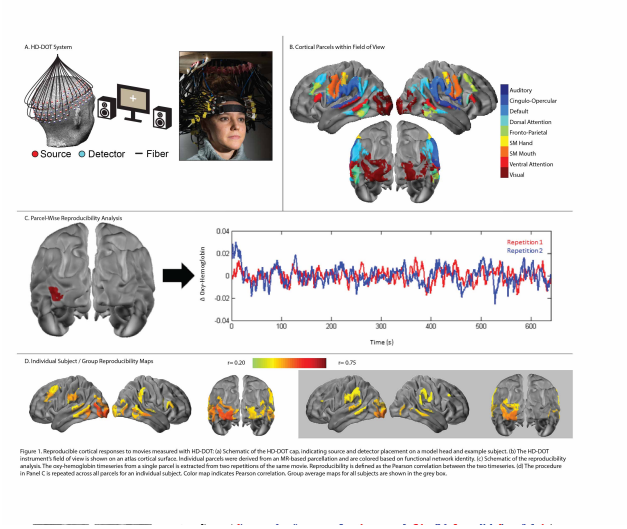

Figure 1. Reproducible cortical responses to movies measured with HD-DOT. (a) Schematic of the HD-DOT cap, indicating source and detector placement on a model head and example subject. (b) The HD-DOT instrument's field of view is shown on an atlas cortical surface. Individual parcels were derived from an MR-based parcellation and are colored based on functional network identity. (c) Schematic of the reproducibility analysis. The oxy-hemoglobin timeseries from a single parcel is extracted from two repetitions of the same movie. Reproducibility is defined as the Pearson correlation between the two timeseries. (d) The procedure in Panel C is repeated across all parcels for an individual subject. Color map indicates Pearson correlation. Group average maps for all subjects are shown in the grey box.

Title: Multisensory integration varies with target and environment complexity in a virtual environment: towards a naturalistic model of multisensory integration

Authors: H. D. BAILEY[1], A. B. MULLANEY[2], K. D. GIBNEY[3], *L. D. KWAKYE[1]; [1]Neurosci., Oberlin Col., Oberlin, OH; [2]Great Sci. Acad., Cleveland, OH; [3]Vanderbilt Univ., Nashville, TN

Abstract: We are continually bombarded by information arriving to each of our senses; however, the brain seems to effortlessly integrate the separate information into a unified percept. Although multisensory integration has been researched extensively using simple computer tasks and stimuli, much less is known about how multisensory integration functions in a real world context. Virtual reality offers the perfect combination of realism and precise control over the environment to investigate this question. We have chosen to begin this area of investigation with a task known as the detection task (redundant target effects). In its computer game version, participants are asked to detect a white circle, white noise burst, or a combination of the two as fast as possible. Participants are faster at detecting multisensory targets than either of the

unisensory targets. In the virtual reality version of this task, participants detected targets varying in complexity within a virtual world that also varied in complexity. The environmental complexity was modulated using the three following virtual worlds: a gray room that contains no depth cues, texture, color, or environmental sounds; a room with textured walls that offers depth cues, soft background white noise, but no color or environmental context; a room that mimics the experimental testing room that offers depth cues, texture, color, and identifiable background noise. The target complexity was modulated using the following three conditions: white circle with no 3D shading and/or white noise burst; white circle with 3D shading thus appearing as a white ball and/or noise which is modulated in amplitude and frequency; tennis ball with 3D shading and color and/or a tennis ball sound. Using the geometric measure of Miller's inequality proposed by Colonius and Diederich (2006), we demonstrated integrative effects in every environment-target pairing and further showed that the degree of integration positively correlates with target complexity but only in our most complex environment. To further investigate this effect of target complexity on integration, we conducted a second experiment to examine the effect of target unpredictability. The effect of target complexity observed in the first experiment did not hold when the target identity or location were unpredictable; however, we were able to observe integrative effects in every condition. Our study is the first to definitively show that minimal and more naturalistic stimuli elicit comparable redundant target effects but that the features of the environment and target modulate the degree of integration.

Title: Adaptation of grip forces to tactile surfaces is based on categorization of frictional surfaces rather than on coefficient of friction

Authors: *S. BILALOGLU[1], Y. LU[2], V. ALURU[3], D. GELLER[3], P. RAGHAVAN[3]; [1]NYU Langone Med. Ctr., New York, NY; [2]Steinhardt Sch. of Culture, Educ. and Human Develop., New York Univ., New York, NY; [3]Dept. of Rehabil. Med., New York Univ. Sch. of Med., New York, NY

Abstract: Adaptation of fingertip forces to the friction at the grip surface is necessary to prevent use of inadequate or excessive grip forces. The purpose of this study was to understand the

interaction between the frictional surfaces and the fingertip grip surface during grasping and lifting. The coefficients of friction (COF) of 18 different frictional surfaces were obtained by dragging the textured surface affixed to a standard mass across a standard surface on a tabletop. The COF ranged from 0.36 to 1.17 (mean=0.73). Ten subjects without neurologic deficits then grasped and lifted an instrumented grip device with the 18 different surfaces 7 times for each surface with bare hands and with a thin layer of tegaderm applied to the fingertip (to control for subject-level variability in fingertip moisture and skin texture). There were no significant differences in 2-point discrimination or pressure sensitivity threshold between barehands and tegaderm, but tegaderm impaired static tactile discrimination. The COF during interaction of the frictional surface with the fingertips was measured as the inverse of the slip ratio (grip force/ load force at the moment of slip). As expected, there was greater between-subject variability in the slip ration with bare hands (ICC=0.67) than with tegaderm (ICC=0.63). However, instead of a monotonic change in the slip ratios with the COF of the textured surfaces (measured against a standard surface), the slip ratios clustered into smooth and rough categories both with bare hands and tegaderm. We therefore collapsed all the smooth and rough surfaces (9 each) and further examined the adaptation of fingertip grip force rates (PGFR) to the frictional surface. We found that the average PGFR was significantly higher for the smooth surfaces compared with the rough surfaces ($b=-5.75$, $p<0.001$) with bare hands but not with tegaderm ($b=-1.26$, $p=0.1932$). The PGFR did not vary with the COF. These results suggest that the tactile surfaces are categorized broadly as smooth and rough, and the adaptation of fingertip forces is based on this broad categorization rather than on the coefficient of friction of the tactile-surfaces per se. Using tegaderm to remove subject-level variability in fingertip moisture and skin texture effectively impairs tactile discrimination and adaptation of grip forces. The receptors on the skin surface necessary for tactile discrimination are also necessary for grip force adaption.

Title: Shared neural representation for visual and tactile material property

Authors: *H. YAMASHIRO[1], H. YAMAMOTO[2], C. ISAMI[3], S. SUKIGARA[3], T. MURASE[4], M. UMEDA[4], T. HIGUCHI[4];
[1]Aino Univ., Ibaraki-Shi, Osaka, Japan; [2]Grad. Sch. of Human and Envrn. Studies, Kyoto Univ., Kyoto-shi, Kyoto, Japan; [3]Kyoto Inst. of Technol., Kyoto-shi, Kyoto, Japan; [4]Meiji Univ. of Integrative Med., Nantan-shi, Kyoto, Japan

Abstract: Humans can perceive tactile property of objects by just seeing them, such that we can see the fluffiness of fur or the smoothness of leather. However, the neural basis of such visuo-tactile information transformation are not fully understood. We hypothesized that such processes involve cooperative action of visual and tactile systems and common neural representations of material properties of objects. To explore such representations, we measured brain activity using functional magnetic resonance imaging (fMRI), while subjects viewed or touched pieces of cloth. Fifteen naïve subjects participated in the experiment. The stimuli were a soft wool cloth or a hard denim cloth, which were presented visually or tactually. In each visual trial, subjects viewed a video presented to their right eye for four seconds, which recorded a rotating piece of cloth stuck onto a sinusoidal wavy surface from an oblique viewpoint, so that the texture of the cloth can be seen clearly. In each tactile trial, subjects repeatedly grasped one of these pieces of cloth for four seconds, which was put onto their right hand and removed by the experimenter. During a three minute run, each stimulus was presented for three times in random order with random inter-stimulus intervals. Each subject was scanned for ten runs. During the scan, subjects performed a one-back task comparing the hardness/softness of the stimulus, in which they reported whether the current stimulus is harder/softer, or same as previous one, by pressing buttons. Surface based searchlight analysis revealed the cross-modal nature of the natural texture perception. On one hand, visual texture representations were found in somatosensory and association cortices as well as visual cortex. On the other hand, tactile texture representations were found in visual cortex and association cortices as well as somatosensory cortex. Furthermore, shared visuo-tactile representations were found in parietal association, somatosensory, and visual cortices. These results suggest that texture information are transferred across functionally segregated sensory and associative brain regions.

Title: Interactions between posterior parietal and primary motor cortices are differentially modulated after the rubber hand illusion with ageing

Authors: *R. ISAYAMA[1,2], M. VESIA[1], G. JEGATHEESWARAN[1,2], B. ELAHI[2], C. GUNRAJ[1], L. CARDINALI[3,4], A. FÁRNE[4], R. CHEN[1];
[1]Div. of Brain, Imaging and Behavior - Systems Neurosci., Toronto Western Res. Inst., Toronto, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada; [3]The Brain and Mind Inst., Univ. of Western Ontario, London, ON, Canada; [4]Lyon Neurosci. Res. Ctr., Lyon, France

Abstract: Background:Ageing affects multiple systems in the brain, including the motor and sensory systems. Several studies have shown that older adults, when compared to younger adults, showed greater shortening of response time to multi-modal than to single-modal sensory cues, suggesting that ageing influences multi-modal sensory integration. However, how ageing affects the neural underpinnings for multi-modal sensory integration, particularly the interaction between posterior parietal cortex (PPC) and primary motor cortex (M1), remains unclear. The objective of this study is to evaluate in older and young adults 1) multi-modal sensory integration at the behavioral level and 2) the changes in the interactions between PPC and M1 with multi-modal sensory integration. We hypothesize that multi-modal sensory integration will be enhanced and will more strongly modify the PPC-M1 interaction in older than young adults. Methods:We tested 10 healthy young (age:24.7±2.6 years) and 9 older adults (age:66.3±5.7 years). Multi-modal sensory integration was examined by the rubber hand illusion (RHI) paradigm. Subjects viewed a rubber hand being stroked by a brush during the application of synchronous (test condition) or asynchronous (control condition) brush strokes on their own unseen hand. The level of RHI was determined with a questionnaire assessing the subject's feeling of ownership of the rubber hand and the drift in the estimation of his/her own hand position. Transcranial magnetic stimulation (TMS) in a paired-pulse paradigm was used to test the interactions between left PPC and left M1. Conditioning stimulus was delivered to the PPC 4, 6, 8, and 10 ms prior to the test stimulus to M1. Motor evoked potentials (MEPs) were recorded from hand muscles at rest before and immediately after RHI induction. PPC-M1 interaction was assessed by comparing the conditioned to the unconditioned (TMS to M1 alone) MEP amplitudes. Results:Both groups exhibited stronger rubber hand ownership in the synchronous than the asynchronous condition, but the difference was greater in younger adults due to stronger ownership in older adults in the asynchronous condition. PPC-M1 interactions were similar between young and older adults at baseline. However, in older but not in younger adults, PPC-M1 interaction was facilitated in the synchronous and inhibited in the asynchronous condition at 6 ms ISI. Conclusions:RHI was easier to be elicited and was associated with greater modulation of the PPC-M1 interaction in older than younger adults. These findings may reflect enhanced multi-modal sensory integration in older adults, leading to faster responses to multi-modal sensory stimuli.

Title: Mechanisms underlying orientation selectivity in the mouse retina

Authors: *A. NATH, G. W. SCHWARTZ;
Northwestern Univ., Chicago, IL

Abstract: Orientation selectivity (OS) is well known in the visual cortex (Hubel and Wiesel 1962) for decades and has recently been found in mouse lateral geniculate nucleus (Marshel et. al. 2012; Zhao et. al. 2013; Piscopo et. al. 2013) and superior colliculus (Feinberg and Meister 2015, Ahmadlou and Heimel 2015). Does this property primarily arise in these regions or is there an orientation selective input from the retina via retinal ganglion cells (RGCs)? Orientation selective RGCs have been reported in the rabbit retina (Levick, 1967; Caldwell et. al. 1978; Amthor, 1989; Bloomfield 1994; Venkataramani and Taylor, 2010) but the underlying neural mechanisms remain unclear. The goal of our research was to find and characterize OS cells in the mouse retina and probe the circuit mechanisms that underlie orientation selectivity. We probed RGCs with flashed and moving bars, and drifting gratings in an *ex vivo* preparation of the intact retina. We characterized light responses in both cell-attached and whole-cell electrophysiological recordings. To correlate physiology with morphology, we imaged cells with two photon and confocal microscopy. We found OS RGCs aligned with the two cardinal axes of the mouse visual system, and we observed OS in both excitatory and inhibitory synaptic inputs to RGCs, in contrast with previous reports (Levick, 1967; Caldwell et. al. 1978; Bloomfield, 1994). Horizontal OS RGCs have horizontally oriented dendritic fields whereas vertical OS RGCs are symmetric in dendritic morphology. Pharmacology revealed that the inhibitory OS pathway is glycinergic. Moreover, this inhibition is oppositely oriented to the excitation in horizontal OS RGCs. However, vertical OS RGCs receive OS inhibition in random orientations. Amacrine cells performing neuritic OS computation might be the source of such inhibition. Additionally, horizontal OS cells might selectively wire with these amacrine cells whereas vertical OS RGCs wire randomly. Computational modeling coupled with pharmacology suggests that OS excitation might arise due to presynaptic inhibition in both kinds of cells. With the power of genetic tools available in mouse, our identification of OS RGCs in this species will lead to future work on the processing of OS circuitry and information throughout the visual system.

Title: Control of excitation-inhibition balance in the directionally selective circuit in mouse retina by nicotinic acetylcholine receptors

Authors: *A. HOGGARTH, S. SETHURAMANUJAM, V. JAIN, A. MCLAUGHLIN, G. B. AWATRAMANI;
Dept. of Biol., Univ. of Victoria, Victoria, BC, Canada

Abstract: Introduction: The precise excitation-inhibition (E/I) balance is a key determining factor of direction selectivity (DS) in the mammalian retina. Acetylcholine (ACh) and GABA released from starburst amacrine cells (SACs) are both thought to act postsynaptically on DS ganglion cells (DSGCs), through the activation of nicotinic ACh receptors (nAChRs) and GABAA ionotropic receptors. Here, we examine the role of presynaptic nAChRs in facilitating GABA release from SACs. Methods: We combined electrophysiology, pharmacology and optogenetic techniques to investigate the role of nAChRs in modulating release of GABA from SACs. DSGCs and SACs were identified in labelled transgenic mouse lines (Hb9::eGFP and ChAT-Cre:Ai9, respectively) for whole-cell and extracellular patch-clamp recordings using 2-photon laser scanning microscopy. Specific expression of channelrhodposin (ChR2) in SACs was attained using the ChAT-Cre promoter and allowed us to selectively examine the output function of these cells. Responses to moving spots of light and moving sine wave grating stimuli were recorded. Results: Consistent with previous studies we found that application of nAChR antagonists (100 μM hexamethonium; Hex) reduced the DSGC's 'preferred' spiking response. Surprisingly, however, we also noted that Hex did not strongly affect the weaker 'null' response. To understand the lack of effect on null direction spiking responses we next performed voltage-clamp experiments. Interestingly, the strength of null direction inhibition mediated by SACs (monitored as inhibitory currents DSGCs voltage clamped at 0 mV) was reversibly reduced by Hex (~ 40 % reduction in peak amplitude). This was likely an effect on SACs, as a similar decrease in the IPSC was observed when SACs were directly stimulated optogenetically (in the presence of agents that occluded photoreceptor responses). In contrast to SAC output, the inputs to SACs were not affected by Hex. Thus, we posit that activation of nAChRs at distal SAC dendrites (output sites) leads to a facilitation of GABAergic release. The reduced null inhibition is consistent with the relative increase in the observed null-direction spiking response in the presence of Hex, a reflection a perturbed E/I balance. Conclusions: ACh release from SACs activates both post- (on DSGCs) as well as presynaptic nAChRs (on SACs) thereby controlling E/I balance. Together, the endogenous activation of pre- and postsynaptic nAChRs serves to sharpen directional tuning in DSGCs.

Title: Spatiotemporal receptive field properties of starburst amacrine cell dendrites

Authors: *H. DING, J. DIAMOND;
NIH, Bethesda, MD

Abstract: Dendritic computation is a fundamental aspect of neuronal information processing, particularly in retinal amacrine cells, in which synaptic inputs and outputs occur in the same dendrites. Separate dendritic branches of starburst amacrine cells (SACs) process visual information independently to generate direction selectivity (DS) in the mammalian retina. Despite a detailed understanding of the connectivity within the DS circuitry, however, the mechanisms underlying DS computation in SACs remains unclear. Recent connectomic findings suggest that spatiotemporal properties of excitatory inputs give rise to direction selectivity in SACs. To examine the functional consequences of this proposed model, we measured the spatiotemporal input-output relationship along individual SAC dendrite by mapping the visual receptive field of presynaptic terminals. Using two-photon fluorescence imaging, we recorded intracellular calcium activity in OFF starburst amacrine cells and mapped the receptive fields of varicosities in the distal region of dendrites where the GABAergic output synapses are located. Anatomical reports indicate that excitatory inputs are located along dendrites proximal to (and possibly overlapping with) inhibitory outputs, suggesting that a spatial offset should exist between the location of a synaptic varicosity and its visual receptive field, a prediction that is confirmed by our experiments. In addition, published connectomic data predict that the temporal characteristics of the receptive field should vary with distance to the soma, with proximal inputs being slower. Our preliminary results indicate temporally heterogeneous responses in SAC varicosities, and further analysis is required to determine whether these differenced correspond to specific regions of the receptive field. We also have measured the response variability within single output synapses and the correlation between multiple synapses along the same dendritic branch to identify factors that limit DS tuning in SACs.

Title: Distinct inhibitory spatial scales improve information transmission in the retina

Authors: *L. T. MCINTOSH[1], M. MANU[3], D. B. KASTNER[4], B. NAECKER[1], S. A. BACCUS[2];
[1]Neurosciences Grad. Program, [2]Neurobio., Stanford Univ., Stanford, CA; [3]Dept. of Neurosurg., Med. Sch. Hannover, Hannover, Germany; [4]Psychiatry, UCSF Sch. of Med., San Francisco, CA

Abstract: All visual information in the brain derives from the responses of retinal ganglion cells, which receive photoreceptor signals that have been pooled and filtered by parallel excitatory and inhibitory pathways. One prominent theory of retinal function, efficient coding theory, states that ganglion cell responses maximize information about the visual environment subject to an energy constraint. As support for this theory, it has been shown that the linear receptive field of retinal ganglion cells has a center-surround structure that closely resembles the filter predicted to maximize information about the visual scene given a constraint on the retinal output variance. Yet despite decades of investigation, the spatiotemporal properties of the linear receptive field surround have not been quantitatively assigned to interneurons. Using simultaneous intracellular and multielectrode recording we directly measured the visual feature conveyed by two parallel interneuron pathways - horizontal cells and narrow-field amacrine cells - and find that they both convey the same temporal feature at different spatial scales, acting synchronously to generate the linear receptive field surround. Moreover, we find that a linear combination of two distinct spatial scales of horizontal and narrow-field amacrine cells generates a linear receptive field that maximizes information transmission better than either horizontal or amacrine cells alone. We show that splitting the linear surround contribution into two parallel interneuron cell types allows for greater flexibility to generate an optimal surround under different environmental conditions where the signal to noise ratio can vary over many orders of magnitude. These results offer an explanation as to how and why the linear receptive field is generated in retinal ganglion cells - multiple interneuron pathways in the retina's parallel and layered circuitry make the retina efficient under a wide range of conditions.

Title: An excitatory amacrine cell detecting object motion provides its feature-selective input to ganglion cells

Authors: *T. KIM, F. SOTO, D. KERSCHENSTEINER;
Washington Univ. In St.Louis, Saint Louis, MO

Abstract: Retinal circuits detect salient features of the visual world and report them to the brain through spike trains of retinal ganglion cells (RGCs). The most abundant RGC type in mice (W3 RGCs) selectively responds to movements of small objects, but is suppressed by global image motion caused by head, body or eye movements. Where and how object motion sensitivity arises in the retina is incompletely understood. Here, we use 2 photon guided patch clamp recordings to characterize responses of VGluT3 expressing amacrine cells (VG3 ACs) to a broad set of visual stimuli. We find that VG3 ACs are object motion sensitive and analyze the synaptic mechanisms underlying this computation. Anatomical circuit reconstructions suggest that VG3 ACs form glutamatergic synapses with W3 RGCs and targeted recordings show that the tuning of W3 RGCs' excitatory input matches that of VG3 ACs' responses. Synaptic excitation of W3 RGCs is diminished and responses to object motion are suppressed in mice lacking VGluT3. Object motion thus is first detected by VG3 ACs, which provide feature selective excitatory input to W3 RGCs. In ongoing work, we are exploring the source of surround inhibition, which suppresses responses of VG3 ACs and W3 RGCs to global image motion.

Title: The development and function of direction selective circuits in the mouse retina

Authors: R. BOS, K. ZHOU, C. GAINER, *M. B. FELLER;
Univ. California, Berkeley, Berkeley, CA

Abstract: In the retina, direction-selective ganglion cells (DSGCs) respond strongly when an image is moving in the preferred direction and weakly when an image is moving in the opposite or “null” direction. Several types of DSGCs have been identified based on morphology, response properties and projections patterns. How these properties arise during development remain to be determined. We performed two-photon calcium imaging to characterize the functional organization of DSGC in developing and adult mice. Specifically, we performed recordings from ventral retina using UV drifting bars to stimulate S-opsin containing cones at different ages (P13-14, adult) and in normal and dark-reared conditions. We were able to reproducibly identify two types of DGSC (ON and ON-OFF DSGCs), verifying their categorization from responses to stationary spots. We confirmed that the directional tuning of these cells was significantly reduced in presence of a GABAA receptor antagonist or after reversibly silencing starburst amacrine cells using a pharmaco-genetic approach (Magnus et al. 2011 ; Vlasits et al, 2014). We characterized two main features of the ON and ON-OFF populations of DSGCs across development. First, we observed that directional tuning of DSGCs was established at eye-opening and remained unchanged with age or after dark-rearing. Second, we verified that in the adult, ON DSGCs clustered along three cardinal axes while ON-OFF DSGCs clustered around four, consistent with previous characterizations, However, at the time around eye opening (P13-14), the cardinal directions of both ON and ON-OFF DSGCs were diffusely distributed. Moreover, early and chronic visual deprivation prevented the maturation of the clustering around the cardinal directions. These results suggest that although the tuning of DSGCs is mature at eye-opening, their clustering along the cardinal axes is influenced by visual experience.

Title: Does the mouse retina contain 'mini-foveas' for region-specific analysis of the visual field?

Authors: *R. N. ELDANAF[1], A. D. HUBERMAN[2,3];
[1]Neurosciences, [2]Neurosciences, Neurobio. Section in the Div. of Biol. Sciences, and Ophthalmology, Univ. of California San Diego, La Jolla, CA; [3]Salk Inst. for Biol. studies, La Jolla, CA

Abstract: In many species, specific types of neurons vary their density across the retina to allow for non-uniform sampling of visual space. For example, in humans and other non-human primates, there is an increased density of certain photoreceptor and retinal ganglion cell (RGC) types in the central retina to permit higher resolution encoding of certain visual signals at that location. In recent years, the mouse has emerged as the model of choice for studying various aspects of visual system development, function and disease. It is known that there are ~30 RGC subtypes, each responsible for relaying specific visual features to the brain for central processing. It was long thought that all mouse RGC subtypes were uniformly distributed across the retina. A recent study from Wong and co-workers (Bleckert et al., Current Biology, 2014), however, showed that a specific subtype of RGCs: On-sustained alpha RGC, exhibit regional variations along the nasal-temporal axis, thereby allowing for an enhanced sampling of the binocular visual field. Motivated by those findings, we asked whether any other RGCs vary their features so as to create specialized sub-topographical maps in the mouse retina. By analyzing the size, branching, stratification and other features of transgenically labeled RGC subtypes (e.g., Huberman et al., Neuron, 2008; 2009; Osterhout et al., Neuron, 2011; Rivlin-Etzion et al., J Neurosci 2011; Dhande et al., J Neurosci, 2013) we obtained detailed analysis of how the features of individual RGC subtypes vary as a function of precise retinal location. The functional relevance of these findings for central visual processing and behavior are discussed.

Title: A novel amacrine cell circuit for signaling steady illumination in the retina

Authors: *J. JACOBY, Y. ZHU, S. H. DEVRIES, G. SCHWARTZ;
Ophthalmology, Northwestern Univ., Chicago, IL

Abstract: At the frontier of systems neuroscience is the pursuit to place identified types of neurons in the context of functional circuits. This circuit-level comprehension of neural networks is paramount in creating new therapies to combat neurodegenerative disease. The neural circuits of the retina offer unique opportunities for circuit-level analysis because of the accessibility of the tissue and our advanced knowledge of cell typology. More than sixty years of research have focused on characterizing the structure and function of most retinal cell types, but have largely left the encoding properties of retinal amacrine cells largely uncharted. Here we (i) present the first physiological recordings of a specific amacrine cell type, (ii) place this cell into a functional microcircuit, and (iii) characterize this cell's impact on the feature detection properties of its postsynaptic retinal ganglion cell. In order to fully comprehend how visual processing takes place within the retina, we must elucidate the role of amacrine cell-driven inhibitory circuits. We report that the CRH-1 amacrine cell, which was recently discovered in a transgenic mouse line, provides inhibitory drive to a new retinal ganglion cell (RGC) in mouse retina, the Suppressed-by-Contrast (SbC) RGC. Generally, retinal amacrine cells are perceived as inhibitory interneurons whose main function is modulation of visual information (through lateral inhibition, feedback control of response kinetics, balancing excitatory drive, and sharpening tuning curves). This novel neural circuit, driven by the CRH-1 amacrine cell, challenges the stereotyped class function of amacrine cells. We provide evidence that CRH-1 amacrine cell-derived feedforward inhibition can, instead, regulate the specific feature selectivity of a postsynaptic ganglion cell. Unlike typical ON, OFF, and ON-OFF cells, SbC RGCs decrease their firing in response to both light increments and decrements (i.e. activity is suppressed by high contrast). Cells with similar contrast suppression profiles have been identified in the retina of other species such as cat and rabbit, and in higher visual areas of the mouse brain. Using molecular genetic techniques, we establish direct anatomical and functional connections to the CRH-1 amacrine cell by recording in dual-cell voltage clamp from synaptically connected CRH-1 amacrine cells and SbC RGCs. This newly identified circuit reveals the mechanism of the SbC computation, in which the CRH-1 amacrine cell plays a central role. We present evidence that this amacrine cell is mediating, not simply modulating, the spiking output and feature detection of the SbC RGC.

Title: Psychophysical measurement of marmoset visual acuity as a function of eccentricity

Authors: *S. U. NUMMELA[1], C. T. MILLER[1], J. F. MITCHELL[1,2];
[1]Psychology, UCSD, LA Jolla, CA; [2]Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY

Abstract: The common marmoset (Callithrix jacchus) is a small bodied New World monkey which offers an interesting point of comparison between mice and macaques in the study of vision (Mitchell and Leopold, 2015). However, many important facets of marmoset vision remain unknown compared to the better studied macaque monkey. Like macaques, marmosets have a specialized fovea with comparably high cone density that drops with retinal eccentricity (Troilo et al, 1993) and also show a similar cortical magnification factor in primary visual cortex (Chaplin et al, 2013). Early studies reported a peak visual acuity of 30 cycles per degree (Ordy and Samorajski, 1968) which is roughly half that of the macaque and consistent with the smaller size of their eye. One interesting feature of the marmoset retina is that beyond eccentricities of 5 degrees the cone density does not drop as rapidly as it does in macaques or humans, maintaining higher ratios of cones than rods in the periphery (Troilo et al, 1993). This could alter how behavioral measures of acuity scale as a function of eccentricity, depending on how signals are pooled from the retina and other visual areas. Therefore, we set out to confirm the initial estimates of acuity behaviorally and additionally measure how it scales as a function of retinal eccentricity. We measured visual acuity in 2 adult male marmosets at eccentricities from 1 to 10 degrees. Head-fixed marmosets were trained to initiate trials by fixating a central spot until a Gabor grating of vertical orientation appeared within one of 6 evenly spaced apertures surrounding central fixation, after which a saccade to the stimulus was rewarded with juice. Spatial frequency of the stimuli was varied using the method of constant stimuli. Like macaques, we find that acuity increases near the fovea, but at eccentricities beyond 5 degrees it remains relatively constant, roughly at 6 cycles per degree. These measurements suggest that acuity scales in proportion to the cone density at the level of the retina.

Title: Summation and division by retinal cholinergic/GABAergic starburst amacrine cells

Authors: *A. J. MCLAUGHLIN, G. AWATRAMANI;
Univ. of Victoria, Victoria, BC, Canada

Abstract: Introduction: Directionally selective ganglion cells (DSGCs) in the retina respond more robustly to moving vs. static stimuli (Barlow and Levick, 1965). GABAergic/cholinergic SACs are suggested to play a pivotal role in motion discrimination. Precisely how GABA and ACh co-modulate the DSGC's input-output function, however, remains unclear. **Methods**: Contrast response functions (CRFs) were measured for static and moving spots from superior coding DSGCs labelled in the Hb9;eGFP retina, identified using a 2-photon microscope. CRFs were quantified using the Naka-Rushton function: $R(C) = Rmax* C/(C+C_{50})$, where C_{50} is the contrast (C) that evoked a half maximal response (R). SAC activity was silenced using a DREAAD approach. **Results:** The CRF for spots moving in the DSGC's preferred direction was shifted to the left (decreased C_{50}) as well as increased in amplitude (R_{max}) compared to the CRF evoked by stationary spots. Thus motion discrimination mechanisms entail an additive (leftward shift in C_{50}) and multiplicative (increase in R_{max}) scaling of the DSGCs' stationary CRF. This effect did not appear to depend on the size of the stimulus (ranging from 50µm to 400µm in diameter). Measurement of the EPSCs and IPSCs to DSGCs suggest that motion discrimination relies on an increase in excitation and a concomitant decrease in inhibition to DSGCs. To test the involvement of GABA and ACh release from SACs in this process, we used a pharmacological approach. Blocking ACh (100 µM curare) greatly reduced motion discrimination (changes in both the C_{50} and R_{max} were reduced), while blocking GABA receptors (10 µM Gabazine, 100 µM TPMPA) enhanced it, suggesting a cross-talk between GABA and ACh signalling pathways. Interestingly, however, in the presence of GABA blockers curare selectively affected motion induced changes in C_{50}, revealing a direct additive role for ACh. Conversely, in the presence of curare, the effects of GABA blockers suggested a divisive role for GABA. Finally, to demonstrate that motion discrimination is mediated by ACh and GABA released from SACs we utilized genetic tools to silence SAC outputs to DSGCs. Preliminary results confirm a role for SACs in mediating motion discrimination. **Conclusion:** Increased ACh excitation and decreased GABA inhibition from SACs underlies the ability of DSGCs to discriminate moving from stationary objects. The results demonstrate how a single neuron perform additive and divisive operations using multiple neurotransmitter systems.

Title: In which the eyes of the beholder are a worm's: Mapping of multiplexed visual cues across the array of cephalic eyes in a leech

Authors: *J. A. JELLIES[1], T. GROVES[2];
[2]Biol. Sci., [1]Western Michigan Univ., Kalamazoo, MI

Abstract: How do visual systems use simple eyes to extract information? Medicinal leeches (Hirudo) can discriminate green and near ultraviolet (UV) light (Jellies. 2014. J.Exp. Biol. 217:974) and use a distributed array of dermal sensilla as a type of "spectral statocyst" to maintain 3-D body position (Jellies. 2014. J. Comp. Physiol. A 200:923). We are extending our studies to examine how the cephalic eyes encode visual cues. Adult leeches were dissected so that the dorsal margin of the anterior sucker could be inverted, exposing the optic nerve heads of all 5 bilateral pairs of cephalic eyes for extracellular recording and light stimulation. We used previously described LEDs (red, green, blue and UV) as stimuli. Complex spiking responses from the population of about 50 photoreceptors in each eye were recorded, rectified, smoothed and integrated for comparisons. A typical response to a 2 s light pulse was a brief transient of high frequency spiking followed by a plateau of spiking. We noticed that the cephalic eyes differed in both size and apparent gaze direction. The first 2 pairs were large, elongated and directed forward, while the posterior 3 pairs were smaller, spherical and directed upward. When we examined responses across light intensity (using a series of neutral density filters), and in combinations with light adaptation, several exceptional features emerged. First, the anterior 2 pairs of eyes responded well to both green and UV light, while the posterior 3 pairs responded best to green light. Second, the anterior 2 pairs of eyes were slowly adapting, whereas the posterior 3 pairs were more rapidly adapting by several measures. The initial phasic transient was larger compared to the plateau in the posterior 3 pairs of eyes. Next, the plateau began smaller and attenuated rapidly in the posterior 3 pairs of eyes whereas the plateau showed little attenuation over 30-60 s of continuous stimulation in the anterior 2 pairs of eyes. Finally, when we stimulated eyes for 15s using a white light and superimposed LED stimuli during the white light, anterior eyes 1 and 2 showed no response. In contrast, the posterior eyes 3,4,5 responded with a strong phasic transient to the superimposed green light (and not at all to red, less so to blue and UV). Our data suggest that spectral, luminal, and temporal cues are differentially mapped across the array of cephalic eyes. The anterior, forward facing eyes might be more selectively responsive to spectral and luminal contrast, as well as shadows whereas the posterior, upward facing eyes might be more responsive to moving edges of green light. It remains to be seen how these multiplexed cues are decoded within the leech CNS to guide behavior.

Title: Quantitative evaluation of perceptual and neuronal brightness vision of retinitis pigmentosa model rat

Authors: *N. SUEMATSU[1,2], A. SATO[3], A. KIMURA[2,4], S. SHIMEGI[2,3], S. SOMA[2,5]; [1]Grad. Sch. of Engin., [2]Grad. Sch. of Med., [3]Grad. Sch. of Frontier Biosci., Osaka Univ., Osaka, Japan; [4]Dept. of Rehabil. Sci., Osaka Hlth. Sci. Univ., Osaka, Japan; [5]Brain Sci. Inst., Tamagawa Univ., Tokyo, Japan

Abstract: Retinitis pigmentosa is a worldwide offering retinal disease, which degenerate photoreceptors and can blind the patients. Nowadays, toward cure of the disease, many studies including cell transplantation, gene therapy, neuroprotection, and retinal prosthesis have been conducted. In such research field, the Royal College of Surgeons (RCS) rat, which has impairment of phagocytic function in retinal pigment epithelium and thus photoreceptors are degenerated with age, has been used as an animal model of the disease. However, the basic perceptual and neuronal visual abilities of the RCS rat are still unclear. We previously reported that the pattern vision of RCS rat was kept until 6 weeks of age, declined gradually at 7-8 weeks of age, and finally lost after 9 weeks of age. In the current study, we focused on the brightness vision from the aspects of psychophysics and neurophysiology. We found that the RCS rats was able to complete the task related to the brightness vision at least until 11 weeks of age, but gradually became slower with weeks of age to complete the task. Moreover, neurons in the superior colliculus, the lateral geniculate nucleus, and the primary visual cortex even of the 11-week-old RCS rats exhibited enough responses to the high-luminance flash stimulus, but also the response latencies were increased with weeks of age. Our findings are sure to provide evaluation standards that are applicable to examine development of the disease and protective or restoration effects achieved by the various treatments for the disease.

Title: Predictive information in the retina depends on stimulus statistics

Authors: *J. M. SALISBURY[1,3], S. DENY[3], T. MORA[4], O. MARRE[3], S. PALMER[2]; [1]Univ. of Chicago, Rockton, IL; [2]Univ. of Chicago, Chicago, IL; [3]Inst. de la Vision, Paris, France; [4]École Normale Supérieure, Paris, France

Abstract: Predicting the future state of the environment is a central challenge for neural systems, both for overcoming delays due to signal transduction and for guiding future behavior. The task is so crucial that we find evidence for prediction at the sensory periphery, in the form of motion anticipation in the spiking activity of retinal ganglion cells (Berry et al., 1999; Leonardo & Meister, 2013). To quantify the retina's capacity for prediction, we use information theory to analyze ganglion cell responses in a highly simplified visual environment, consisting of a single moving bar of light. The trajectory contains both predictable and random components which set a bound on the information that the history of the stimulus contains about its future. We have previously shown that the mutual information between the present neural response and the future of the stimulus saturates this bound for one particular parametrization of the stimulus (Palmer et al., in press). Here we explore the limits of this seemingly optimal capacity for prediction by adjusting the parameters of the stimulus trajectory, making it more or less predictable. We find that adding long-range temporal correlations to the stimulus results in dramatic changes in the retina's ability to predict. When presented with a short-range correlated stimulus, the mutual information between the retinal response and the time-shifted stimulus peaks around 80 ms in the past (due to lags in signal transduction) but extends significantly into the present and near future. When we increase the range of correlations, this information extends further into the future and at higher rates because the stimulus is more predictable. Yet the retina also carries less information at its peak in the past, suggesting that it employs a different coding strategy in this statistical environment. In addition, the location of the peak shifts closer to the present, indicating that the retina is better able to compensate for sensory lags. References Berry, II, M. J., Brivanlou, I. H., Jordan, T. Title: What the mouse´s eye tells the mouse´s brain: Novel retinal ganglion cell types

Authors: *K. FRANKE[1,2,3], T. BADEN[1,2,4], P. BERENS[1,2,4], M. ROMÁN ROSÓN[1,2,3], M. BETHGE[1,4], T. EULER[1,2,4];
[1]Werner Reichardt Ctr. For Integrative Neuroscien, Tuebingen, Germany; [2]Inst. for Ophthalmic Res., Tuebingen, Germany; [3]Grad. Sch. for Neural & Behavioural Sci., Tuebingen, Germany; [4]Bernstein Ctr. for Computat. Neurosci., Tuebingen, Germany

Abstract: In the vertebrate visual system, all output of the retina is carried by retinal ganglion cells (RGCs). Each type encodes distinct visual features in parallel for transmission to the brain. Understanding how the visual scenery is encoded by the outputs of the different RGC types will yield a complete picture of the representation of the visual scene available to the brain. Here we present a functional characterization of the retinal output channels. We show that the number of RGC types is much higher than previously thought, including many novel types of RGC. To record from every cell in the ganglion cell layer we used bulk-electroporation (Briggman & Euler, 2011) and two-photon Ca2+ imaging. A standardized stimulus set, including temporal full-field stimulation, local motion, and dense noise for receptive field mapping, was presented to the retina. Also, electrical single-cell recordings were performed to relate RGC spiking to somatic Ca2+ signals, to retrieve RGC morphologies and to characterize single cell types in more detail. We implemented a probabilistic clustering framework for separating our sample of ~9,000 cells (42 retinas) into functional clusters solely based on features extracted from their light responses using sparse PCA and mixture of Gaussians clustering. Then, the 70+ functional

clusters were post-processed into “RGC groups” based on meta data, such as immunolabels and morphological features. We found that RGCs can be divided into at least 30 functional types. These include many known cell types (OFF and ON alpha, W3, ON-OFF direction-selective), as verified using genetic label and single cell data (e.g. alpha RGCs) and additional information available (e.g. soma size/shape and retinal tiling). In addition, they include new functional types. For example, we identified an OFF DS RGC that does not co-stratify with starburst amacrine cells and an ON transient DS RGC with a single cardinal direction. Also, we found a contrast-suppressed type and a colour-opponent RGC that have not been identified in mouse before. To test if these functionally defined RGC groups correspond to single RGC types, we measured how well the dendritic fields of each type covered the retinal surface. Most RGC groups had a coverage factor (CF) of approx. 1, suggesting that they represent single types. Some groups had a CF much greater than 1, suggesting that they consist of multiple subtypes and that there may be substantially more than 30 types of RGCs in the mouse.

Title: Specificity and intermixing in the retinogeniculate pathway of the adult mouse: a connectomic study

Authors: *J. L. MORGAN[1], A. WETZEL[3], J. W. LICHTMAN[2];
[1]MCB, [2]Mol. and cellular biology, Harvard Univ., Cambridge, MA; [3]Pittsburg Supercomputing Ctr., Pittsburgh, PA

Abstract: Serial section electron microscopy provides data for graphs of synaptic neural networks. The nodes and edges of these graphs can be mined not only for insights into the organization of neural circuits but also for histological features of individual elements. We used this dual approach on a large volume of mouse visual thalamus (400 um x 400 um x 280 um), a 100TB image dataset, to analyze the connectivity between retinal ganglion cells (RGCs) and thalamocortical neurons. The thalamocortical neurons in the dLGN of the thalamus are often

considered to be simple relays for the parallel channels of visual information generated in the retina. Consistent with this view, we found distinct types of retinal ganglion cells by their synaptic structure and found that each type tended to innervate a different subset of thalamocortical cells. However, these subsets of thalamocortical cells were intermixed both in location and connectivity. When we looked at 140 nearby thalamocortical cells we discovered many instances of convergence of different types of RGCs on the same thalamocortical cell. Moreover, anatomical markers, such as dendritic morphology, that previously had been used to identify thalamocortical cell type, were not reliable predictors of which RGCs would innervate a particular thalamocortical cell. Even though the subnetworks of neurons were not sharply delineated, we found examples of strong specificity on a more local level because individual dendrites from different neurons were innervated by the same cohort of RGC axons that hopped form one dendrite to another. Conclusion: The anatomy and network structure of RGC-to-thalamocortical cell connectivity is consistent with multiple channels of visual information passing through the same region of dLGN. The pattern of thalamocortical cell innervation by these parallel channels of retinal input is more complex than expected and at a minimum allows for considerable cross talk between retinal pathways. Furthermore, because neuronal location and shape was a poor proxy for synaptic connectivity, the standard approach, of inferring connectivity based on the appearance of a neuron, needs reexamination.

Title: Pharmacologic dissection of neurovascular coupling pathways underlying functional retinal imaging

Authors: ***M. BEGUM**, D. TSO;
Neurosurg., SUNY Upstate Med. Univ., Syracuse, NY

Abstract: Light-evoked reflectance decreases in the retina, seen using intrinsic signal optical imaging, are likely to be of an outer retinal origin. Other studies have shown that such reflectance changes are dominated by hemodynamics. The specific pathways linking this stimulus-driven outer retinal activity and the resulting neurovascular response (and imaged signals) are unknown. Most previous studies of retinal neurovascular coupling have been *in vitro* and presume an inner retinal origin. In this present study, we sought to dissect the role of several prospective signaling pathways in the observed stimulus-evoked neurovascular responses *in vivo* through intravitreal injections of selected agonists, antagonists and blockers. Adult cats were

anesthetized and positioned in a stereotaxic. Using a modified fundus camera, the retina was stimulated with visible (550nm) patterned stimuli and illuminated in the near-infrared (700-900nm), while intrinsic optical signals were recorded with a CCD camera. Previous retinal imaging studies using intravitreal injections of blockers of inner retinal function (e.g. TTX, PDA, APB) yielded little impact on the retinal imaging signals. In the present study, several drugs selected to interfere with a particular neurovascular coupling pathway had profound impact on the observed light-evoked retinal imaging signals. In some cases, the sign of the observed retinal imaging signal changed from negative (vasodilation) to positive (vasoconstriction). Suramin, a purinergic antagonist, initially abolished the hemodynamic response although the signal subsequently returned with a higher amplitude. With the injection of NECA, an adenosine agonist, the negative reflectance signal inverted to a positive signal. We also used inhibitors of the arachidonic acid pathway to see how its metabolites modulate the imaged response. With indomethacin, an inhibitor of prostaglandin synthase, the hemodynamic response was temporarily abolished. With PPOH, an EET synthesis inhibitor, the response disappeared for the duration of the experiment. These results indicate that arachidonic acid metabolites, and ATP metabolites play crucial roles in the light-evoked hemodynamic response. Preliminary studies of the contribution of the NO pathways via blockade of NOS with L-NAME revealed little effect on the stimulus-driven signals. These studies help establish the chain of retinal events from light absorption to observed changes in retinal reflectance *in vivo*.

Title: Differential transmission of GABA and ACh underlies directional selectivity in the mouse retina

Authors: *S. SETHURAMANUJAM, G. AWATRAMANI;
biology, Univ. of Victoria, Victoria, BC, Canada

Abstract: Introduction: In the mammalian retina, GABA/cholinergic starburst amacrine cells (SACs) play a pivotal role in specifying the response properties of directional selective ganglion cells (DSGCs). SACs provide a strong ‘null-direction’ inhibition to DSGCs, mediated through asymmetric SAC-DSGCs wiring patterns. The extent to which ACh released from SACs contributes to the DSGCs cells response and whether it stimulates the DSGC in a directional

manner is not clear. Here we sought to determine the relative contribution of nicotinic ACh receptors (nAChRs) to the DSGC's response. Methods: DSGCs were identified in a whole-mount mouse retina by their directional spiking responses measured extracellularly. Subsequently, responses to moving stimuli were measured in DSGCs voltage-clamped at a variety of different holding potentials (-70 to +40 mV). In some experiments, photoreceptor signaling was blocked (AP4 and CNQX) and responses were driven by channelrhodopsin (ChR2) expressed selectively in SACs (ChATcre-Ai32) using intense blue light (473 nm). Results:To understand the temporal dynamics of synaptic inputs to DSGCs in the physiologically intact circuit, we developed a deconvolution technique to parse out the fractional light-evoked synaptic conductances mediated by nACh, GABAA, AMPA and NMDA receptors. This was based on the assumption that the total synaptic conductance is a linear sum of the individual receptor components. We measured the voltage-dependent characteristic of each receptor type measured in pharmacological isolation, thus defining its 'basis function'. The total light-evoked synaptic conductance was then fit by the weighted sum of the individual basis functions of the different receptors. By reiterating the fitting procedure over 1 ms intervals, we extracted the temporal evolution of the different receptor mediated conductances. Our preliminary data suggests that while GABA receptor mediated conductances are large in the null direction, the nAChR component appears symmetrical. Conclusions: The results from these experiments provide for the first time an estimate of dynamic ACh signals in the DS circuit. They indicate that a differential transmission of ACh and GABA strongly contributes to the formation of directional selectivity.

Title: Contributions of multiple synaptic mechanisms underlying direction selectivity in the retina

Authors: *W. WEI[1], Z. PEI[1], Q. CHEN[1], D. KOREN[1], B. GIAMMARINARO[2];
[1]Dept. of Neurobio., [2]Univ. of Chicago, Chicago, IL

Abstract: Direction selectivity of direction selective ganglion cells (DSGCs) in the retina results from patterned excitatory and inhibitory inputs onto DSGCs during motion stimuli. The inhibitory inputs onto DSGCs are directionally tuned to the anti-preferred (null) direction, and therefore potently suppress spiking during motion in the null direction. However, whether direction-selective inhibition is indispensable for direction selectivity is unclear. Here we selectively eliminated the directional tuning of inhibitory inputs onto DSGCs by disrupting GABA release from the presynaptic interneuron starburst amacrine cell (SAC) in the mouse retina. We found that even without directionally tuned inhibition, direction selectivity can still be implemented in a subset of On-Off DSGCs by direction selective excitation and a temporal offset between excitation and isotropic inhibition. Thus our results demonstrate the concerted action of multiple synaptic mechanisms for robust direction selectivity in the retina.

Title: Characterization of medullary neuron properties in response to on and off stimuli in a locust looming detection circuit

Authors: *H. WANG[1], R. B. DEWELL[1], M. U. EHRENGRUBER[2], F. GABBIANI[1,3];
[1]Neurosci., Baylor Col. of Med., Houston, TX; [2]Biol., Kantonsschule Hohe Promenade, Zurich, Switzerland; [3]Computat. and Applied Mathematics, Rice Univ., Houston, TX

Abstract: In the locust visual system, the lobula giant movement detector (LGMD) and its postsynaptic target, the descending contralateral movement detector (DCMD) in the protocerebrum, are a pair of looming sensitive interneurons responding strongly to objects approaching on a collision course (looming stimuli). To this date, the neurons presynaptic to the LGMD in the medulla remain to be identified. Here, we stimulated medullary neurons expressing channelrhodopsin with laser light pulses, and recorded their spiking activities with extracellular metal electrodes and the postsynaptic response of the LGMD in the lobula with intracellular recordings. Spike sorting and correlation analysis helped to identify spontaneous medullary spike-triggered IPSPs in the LGMD. Next, moving bars and moving edges (including

both ON and OFF moving edges) were used to stimulate the same medullary neurons. Both medullary neurons and the LGMD exhibited a burst of spikes when a bar just started its motion at the border of the screen, whereas their activity was relatively weaker during the actual motion of the bar on the screen. In contrast to their response to bar movement, medullary neurons exhibited robust spiking during the movement of an OFF edge on the screen. However, the movement of an ON edge evoked relatively less spikes in the same medullary neurons. Similarly, more spikes were observed in response to OFF local visual flashes than to ON local visual flashes. Electrical stimulation close to the recording site during a looming stimulus produced IPSPs in inhibitory branch C of the LGMD, suggesting the recorded units belong to the dorsal uncrossed bundle (DUB), which is thought to mediate OFF inhibition to the LGMD. During a looming stimulus, the recorded medullary neurons exhibited an instantaneous firing rate (IFR) similar to that of the LGMD. Thus, our results indicate that these medullary neurons respond preferentially to OFF edge movement and are possibly involved in looming detection. Our results open the way for an investigation of the coding properties of OFF visual pathway medullary neurons in the context of looming detection.

Title: Morphology and function of three VIP expressing amacrine cell types in the mouse retina

Authors: ***A. AKROUH**, D. KERSCHENSTEINER;
Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Amacrine cells (ACs) are the most diverse class of neurons in the retina. The variety of signals provided by ACs allows the retina to encode a wide range of visual features. Of the 30 50 AC types in mammalian species, few have been studied in detail. Here, we combine genetic and viral strategies to identify and morphologically characterize three VIP expressing GABAergic AC types (VIP1 , VIP2 and VIP3 ACs) in mice. Somata of VIP1 and VIP2 ACs

reside in the inner nuclear layer, somata of VIP3 ACs in the ganglion cell layer. Neurite arbors of VIP ACs differ in size (VIP1 ACs ≈ VIP3 ACs > VIP2 ACs) and stratify in overlapping but distinct sublaminae of the inner plexiform layer. To analyze light responses and underlying synaptic inputs, we target VIP ACs under 2 photon guidance for patch clamp recordings. VIP1 ACs depolarize strongly to light increments (ON) over a wide range of stimulus sizes, but show size selective responses to light decrements (OFF), depolarizing to small and hyperpolarizing to large stimuli. The switch in polarity of OFF responses is caused by pre and postsynaptic surround inhibition. VIP2 and VIP3 ACs both show small depolarizations to ON stimuli and large hyperpolarizations to OFF stimuli, but differ in their spatial response profiles. Depolarizations are caused by ON excitation outweighing ON inhibition, whereas hyperpolarizations result from pre and postsynaptic ON OFF crossover inhibition. Currently, we are working to map downstream circuit connections and to elucidate how VIP ACs contribute to retinal ganglion cell spike output.

Title: GPR55 is involved in scotopic vision in primates

Authors: ***J. M. BOUSKILA**, V. HARRAR, C. CASANOVA, J.-F. BOUCHARD, M. PTITO; Sch. of Optometry, Univ. of Montreal, Montreal, QC, Canada

Abstract: The cannabinoid receptors CB1 (CB1R) and CB2 (CB2R) are present in the retina of many species, including mice and monkeys. We have previously reported that the G protein-coupled receptor 55 (GPR55), a putative cannabinoid receptor, is exclusively expressed in rod photoreceptors in the monkey retina, suggesting it might have a role in scotopic vision. To test

this hypothesis, we recorded full-field electroretinograms (ERGs) after the intravitreal injection of the potent and selective GPR55 antagonist, CID16020046 (CID), under light- and dark-adapted conditions. Nine vervet monkeys (Chlorocebus sabaeus) were used for this study, four controls (injected with the vehicle dimethyl sulfoxide, DMSO) and five injected with CID. We analyzed amplitudes and latencies of the a-wave and the b-wave under scotopic and photopic conditions. Our results showed that CID caused a significant reduction in the amplitude of the b-wave only in scotopic conditions (a rod-driven response). In contrast, the amplitude of the a-wave, and the latency of the a- and b-waves were not significantly different from controls following injection of CID, neither in scotopic nor in photopic conditions. These results support our anatomical findings that GPR55 is only expressed in rod photoreceptors. They also confirm the hypothesis that GPR55 plays an instrumental role in primate scotopic vision, from which we suggest clinical applications in conditions of night-blindness.

Title: Functional recovery in retinas of mice rescued from rod photoreceptor degeneration

Authors: ***J. P. CAFARO**[1], T. WANG[2], J. PAHLBERG[3], A. P. SAMPATH[3], J. CHEN[2], G. D. FIELD[1];
[1]Neurobio., Duke Univ., Durham, NC; [2]Zilkha Neurogenetic Institute, Univ. of Southern California, Los Angeles, CA; [3]Jules Stein Eye Inst., Los Angeles, CA

Abstract: Degeneration of rod photoreceptors, such as occurs in retinitis pigmentosa, prevents transduction of low intensity light stimuli leading to night blindness in humans. Rod degeneration also triggers degeneration of cone photoreceptors and changes downstream in the retinal circuit, eventually leading to complete blindness. Progress has been made towards

rescuing rods from cell death, but secondary changes triggered by rod degeneration may limit recovery of retinal function. Here we assess functional recovery of the retina in a novel mouse model in which photoreceptor degeneration was halted and rod functionality recovered. The mouse mutant lacks expression of the β-subunit of the cyclic nucleotide-gated channel ($CNG\beta1^{-/-}$), which can be corrected via tamoxifen-inducible Cre-mediated recombination at the endogenous locus. Rods in $CNG\beta1^{-/-}$ mice display substantially limited photoresponses and rod degeneration begins ~1 month (postnatal), with near complete loss of rods ~6 months. Tamoxifen (TM) administration restores rod photoresponses and prevents further rod cell death; thus restoring transduction, near optimally, within the limits of the degenerated retina. We assess functional recovery of the retina by measuring responses from distinct populations of retinal ganglion cells (RGCs), the retina's sole neural output, using a large-scale multi-unit electrode array. We compare RGC responses between: 1) wild type mice, 2) $CNG\beta1^{/-}$ mice without TM-induced rescue, and 3) $CNG\beta1^{-/-}$ mice with TM-induced rescue initiated at several time points during degeneration. We use dim flash responses from darkness to assess RGC threshold responses and a white noise stimulus and reverse-correlation to examine recovery of spatial and temporal receptive field properties at both rod- and cone-mediated light levels. Preliminary results show significant recovery of dim flash responses in $CNG\beta1^{-/-}$ mice when rod rescue is initiated ~1 month compared with mice without TM-induced rescue. This work provides needed insight into the limits of functional recovery in retinas that have begun photoreceptor degeneration.

Title: Synaptic signaling to rod bipolar cells in mouse retina with channelrhodopsin2-expressing horizontal cells

Authors: ***S. A. BARNES**[1], X. LIU[2], A. A. HIRANO[3], N. C. BRECHA[3];
[1]Dalhousie Univ., Halifax, NS, Canada; [2]Chongqing Univ. of Sci. and Technol., Chongqing, China; [3]UCLA, Los Angeles, CA

Abstract: Voltage-gated Ca channels in rod photoreceptors mediate the release of glutamate onto second order rod bipolar cells (BRCs) and horizontal cells (HCs). HCs send inhibitory feedback back to rods that modulates those Ca channels and may signal to rod bipolar cells (RBCs) via direct GABAergic inhibition. Inhibitory feedback has been assessed with calcium imaging in rod synaptic terminals but the response of RBCs to HC depolarization has been more challenging to detect. We expressed channelrhodopsin2 (ChR2) in Cx57-iCre HCs to investigate the effects of HC depolarization in patch clamped RBCs under light adapted conditions. Patch clamp of ChR2-expressing HCs revealed rapidly activating (τ < 1 ms) and deactivating inward currents (τ = ~23 ms) when stimulated with 10 ms steps of 480 nm light. Peak amplitude of the inward currents at saturating light intensity was 200-300 pA at -60 mV. Under current clamp, HCs depolarized rapidly in response to 50 ms, 480 nm stimulation with an overshoot, and then settled to a sustained membrane potential close to -25 mV for ~100 ms followed by a slow decay. Voltage-clamped responses of identified, Lucifer yellow-filled RBCs in retinal slices held at -80 mV during 50 ms, 480 nm stimulation showed a biphasic response having a sustained inward current (5-10 pA) lasting 200 ms followed by a transient outward rebound current (ca. 20 pA) of 200 ms time course. The inward and outward currents were both blocked by L(+)-2-amino-4-phosphonobutyrate (L-AP4). Picrotoxin blocked the rebound currents in RBCs, but since APB eliminated this current during ChR2 stimulation, this action of GABA appears to be indirect. External solutions included nipecotic acid added to reduce GABA uptake, 5 µM GABA for the degradation-synthesis cycle, pyridoxal 5'-phosphate, a GAD cofactor, and glutamine, a GABA precursor. Loss of the RBC response to 480 nm stimulation during L-AP4 block of the mGluR6-initiated cascade suggests signal transmission from rods to RBCs. If part of this signal originates in HCs and is conveyed in a picrotoxin-sensitive manner to rods, it may do so via the proposed GABAergic regulation of rod Ca channels in which the HCO_3^- permeability of HC GABARs changes synaptic cleft pH. Rod Ca channel inhibition, occurring as the result of HC GABA release and autaptic HC GABAR mediated HCO_3^- flux and cleft acidification, would reduce glutamate release during the first stage of the biphasic response, while Ca channel disinhibition could follow with a rebound release of glutamate after cleft pH recovery to a homeostatic level.

Title: Class-specific coupling patterns among ON cone bipolar cells in the mammalian retina

Authors: *C. L. SIGULINSKY, J. S. LAURITZEN, D. P. EMRICH, C. N. RAPP, A. M. SESSIONS, R. L. PFEIFFER, K. D. RAPP, J. R. ANDERSON, R. E. MARC; Ophthalmology, Moran Eye Center, Univ. of Utah, Salt Lake City, UT

Abstract: Purpose: Gap junctions between retinal bipolar cells have been reported or predicted, but their roles, partners, and patterns remain largely unknown. Using connectomics strategies, we reconstructed the axonal arbors of 30 ON cone bipolar cells (ON CBCs) and their synaptic contacts in Retinal Connectome 1 (RC1) to map coupling topologies. Methods: RC1 is a 2 nm resolution volume of a light-adapted adult female Dutch Belted rabbit retina, built by automated transmission electron microscopy and computational assembly. ON CBCs and their coupling partners were annotated using the Viking application and explored with 3D rendering and graph visualization of connectivity. Gap junctions were validated by 0.25 nm resolution recapture with goniometric tilt as necessary. Results: Over 100 gap junctions were identified between the axonal arbors of ON CBC pairs. Three classes of ON CBCs (CBb3m, CBb4w, CBb5w) showed coupling with members of their own class (in-class coupling), producing stratified sheets of coupled cells. CBb4w and CBb5w cells formed gap junctions at each of their 7-11 (CBb5w) or 8-15 (CBb4w) contacts with neighboring class members, but their processes never overlapped, creating near perfect tiling. In contrast, CBb3m cells only made 2-4 contacts. Neighboring CBb3m arbors never overlapped, but gaps existed. Six classes of ON CBCs exhibited cross-class coupling with subsets of other ON CBC classes. Co-stratification is required for this cross-class coupling, but is not sufficient, as CBb3-4i cells coupled with CBb3m and CBb4w cells, but not with other co-stratifying CBb3 and CBb4 classes. Only CBb3m and CBb4w cells exhibited both in- and cross-class coupling, while others only cross-class coupled. CBb5w cells only in-class coupled. In contrast, CBb7 cells did not couple with any ON CBCs, but did show heterocellular coupling with AII amacrine cells. Interestingly, classes that lacked in-class coupling did not tile. Rather, they exhibited packing: suboptimal organization that lacks overlap, but results in gaps between arbors of neighboring class members. Conclusions: Gap junctions between ON CBCs are sparsely distributed, but pervasive. ON CBCs form class-specific patterns of homocellular coupling, which represent novel synaptic architectures in retinal circuitry. In- and cross-class motifs have implications in signal-to-noise control and smoothing transitions across operating ranges, respectively. The spatial correlation of in-class coupling suggests a role in defining arbor boundaries. Incorporating such coupling topologies and weights into future network models will provide more powerful predictions of network function and development.

Title: Information transmission at the mammalian cone to Off bipolar cell synapse

Authors: *S. DENIZ[1], C. P. RATLIFF[2], S. H. DEVRIES[1];
[1]Ophthalmology, Northwestern Univ., Chicago, IL; [2]Stein Eye Institute, UCLA, Los Angeles, CA

Abstract: In the visual system, parallel processing starts at the cone synapse when an individual cone signals to 12 or more anatomical bipolar cell types. These different bipolar cell types are distinguished by making characteristic numbers of contacts with a cone at either basal or invaginating locations. To determine how contact number and location impact the statistical properties of signaling, we recorded in voltage clamp from a presynaptic cone and a postsynaptic cone bipolar cell (cb) and measured the reproducibility of the synaptic response. Paired recordings were obtained from slices of the cone dominant ground squirrel retina. The input voltage clamp command to the cone was a 16 s white noise stimulus consistent of four 4 s repeats. The stimulus contained frequencies at equal power between 0-100 Hz with a mean of -42 to -51 mV and a standard deviation of 2.5 mV. We used the frequency-dependent bipolar cell response mean and variance to calculate the SNR and information rate for each synapse. Cone to bipolar cell pairs intracellularly labeled during recording were processed for immunohistochemistry and contact counting. We found that information rate differed between the OFF-bipolar cell types as shown in the first three columns of the table. Contacts between the recorded cells were imaged and counted using a confocal microscope. The average number of contacts for each type is listed in the next three columns.

Bipolar type	Information rate (bits.s^{-1})	± SEM	n	Contacts/cone	± SEM	n	Information rate/ cone contact (bits.s^{-1})
cb1a	181	16.5	12	1.1	0.1	10	164.5

cb1b	163.3	21.2	3	3.5	2.5	2	46.7
cb2	306.6	29.1	10	7.1	0.3	10	43.2
cb3a	249.8	24.2	17	7.2	1.2	6	34.7
cb3b	235.2	21.6	13	4.1	0.5	11	57.4

Overall, the bipolar cells that make the largest number of contacts with a cone have the highest information rates. Specifically, cb2 and cb3a cells make an average of ~7.1 contacts with a cone and have information rates of 306.6 and 249.8 bits/s^{-1}, respectively. This is in line with the general idea that more contacts enable the bipolar cell to sample release from more ribbons, which in turn provides a better estimate of the cone signal. Surprisingly, although making the fewest contacts overall, the cb1a cell had almost a 3-fold higher information rate on a per contact basis. The reasons for this increase are unknown. The results show that the cone signal undergoes a different resampling at the cone synapse in the different types of Off cone bipolar cells, and suggest a specialized function for cb1a cell contacts that remains to be determined.

Abstract: Two types of photoreceptors - rods and cones - are specialized sensory cells that convert light into neural signals in the retina. Their unique ribbon synapses form triad synapses at a narrow band known as the outer plexiform layer (OPL) with bipolar and horizontal cells. Deletion of Bassoon and CAST, proteins of the presynaptic active zone cytomatrix, disrupts

these ribbon synapses, impairs visual function and leads to the formation of ectopic synapses of photoreceptors with bipolar and horizontal cells in the outer nuclear layer (ONL) in mutant mice. Here we explored the effect of the deletion of ELKS, a family member of CAST, and the deletion of both, CAST and ELKS, on the structure and localization of ribbon synapses as well as visual processing in retina. The ELKS gene was conditionally deleted using Cre recombinase under the control of the Crx promoter, which expresses mostly in photoreceptors. The ELKS conditional knock out (KO) mouse showed normal development, while CAST and ELKS double KO (dKO) showed serious body weight reduction. Morphological analysis of the retina indicated a drastic increase of ectopic synapses in the ONL of dKO but little synapse mislocalization in ELKS KO. Visualizing the synaptic ultrastructure by electron microscopy indicated a reduction of ribbon length by ~50% and impaired triad structure in CAST KO and dKO. Moreover, in preliminary experiments, visual function tested by scotopic electroretinogram (ERG) showed a reduction of oscillatory potentials and b-waves, suggesting visual dysfunction due to impaired transmission at ribbon synapses of dKO, while ELKS KO showed largely unaltered ERGs. From these results, we conclude that CAST and ELKS contribute to normal structure and function of retinal photoreceptor ribbon synapses.

Title: Characterization of a voltage-gated conductance and its modulation by extracellular signaling molecules in Müller cells acutely isolated from the tiger salamander retina

Authors: *B. K. TCHERNOOKOVA[1], R. P. MALCHOW[2];
[1]Biol. Sci., Univ. Of Illinois At Chicago, Chicago, IL; [2]Biol. Sci., Univ. of Illinois at Chicago, Chicago, IL

Abstract: The radial glia, or Müller cells, of the vertebrate retina regulate a number of key aspects of retinal function, including providing trophic support to neurons, synthesizing neurotransmitter precursors, regulating synaptic activity through uptake of neurotransmitters, and maintaining water and ion homeostasis. In the present experiments, we examined voltage-activated currents in Müller cells acutely isolated from tiger salamander (Ambystoma tigrinum)

retinae using whole-cell voltage-clamp techniques. In the presence of 20 mM barium, we observed a voltage-dependent transient inward current that was activated by depolarization and was blocked by the addition of 200 μM cadmium. The transient inward current persisted when extracellular sodium was replaced with choline. The block by cadmium coupled with the lack of effect upon removal of extracellular sodium suggests that these currents are mediated by barium entry through voltage-dependent calcium channels. In addition, the amplitude of the inward current was significantly reduced upon superfusion of 100μM ATP. Much evidence now suggests that ATP can act as an intercellular signaling molecule in the retina and can activate purine/pyrimidine receptors on the membranes of Müller cells. Our present experiments suggest that one key effect of extracellular ATP on Müller cells is to reduce potential calcium influx through voltage-gated conductances present on these cells. We are currently using multiple techniques to investigate the ways retinal Müller cells respond to ATP and other compounds and the roles these responses may play in retinal physiology.

Title: Regulation of extracellular pH by isolated Muller cells of the tiger salamander: HCO3-dependent and HCO3-independent mechanisms

Authors: *M. A. KREITZER[1], D. SWYGART[1], C. HEER[1], R. KAUFMAN[1], B. WILLIAMS[1], B. K. TCHERNOOKOVA[2], R. P. MALCHOW[2,3];

Abstract: There is growing interest in the retina and the broader CNS regarding the role glial cells play in shaping synaptic transmission. In the retina, synaptic transmission is highly sensitive to small changes in extracellular pH. This has led to suggestions that extracellular pH dynamics might play an important role in shaping visual signals, including the establishment of lateral inhibition, a key feature of neuronal processing that increases perceived visual contrast. However, few studies have directly measured proton fluxes from individual identified cells. Self-

referencing H^+ selective microelectrodes have proven to be ideally suited for sensing extracellular pH changes from isolated cells. The present report builds on an ongoing characterization of regulation of retinal extracellular pH to include characterization of changes in extracellular pH mediated by Müller glial cells. We report that extracellular pH adjacent to Müller cells isolated from tiger salamander is regulated by multiple mechanisms that are Na^+ sensitive and likely contain both HCO_3^- dependent and independent components. Removal of extracellular Na^+ abolished the standing proton flux normally detected from isolated Müller cells. Amiloride, an antagonist of Na^+ dependent transport mechanisms, also significantly reduced the standing proton flux. These data support a Na^+ contribution to the regulation of extracellular pH. HCO_3^- also contributes significantly to regulation of extracellular pH. DIDS, an antagonist of HCO_3^- transport, reduced the magnitude of the standing proton extrusion from Müller cells. Surprisingly a reduction in proton flux by DIDS persisted even when HCO_3^- was not presented in the solution. This raises the possibility that DIDS may antagonize additional HCO_3^- independent processes that regulate extracellular pH, although it could also indicate contributions from endogenously produced intracellular HCO_3^-. The ability of benzolamide, an extracellular carbonic anhydrase antagonist, to enhance the magnitude of the standing proton flux lends further support for a role of HCO_3^- dependent processes in the regulation of extracellular pH by Müller cells. These findings extend previous work implicating HCO_3^- in shaping extracellular pH levels by Müller cells and suggests additional roles for HCO_3^- independent mechanisms as well. These results also warrant studies to characterize how these glial-mediated mechanisms regulating extracellular pH contribute to the processing of visual signals in the intact retina.

Title: Scaling of information in large sensory neuronal populations

Authors: *R. J. COTTON[1], A. S. ECKER[2], E. FROUDARAKIS[1], P. BERENS[2], M. BETHGE[2], P. SAGGAU[3], A. S. TOLIAS[1];

Abstract: Individual neurons are noisy. Therefore, it seems necessary to pool the activity of many neurons to obtain an accurate representation of the environment. However, it is widely believed that shared noise in the activity of nearby neurons renders such pooling ineffective, limiting the accuracy of the population code and, ultimately, behavior. However, these predictions are based on extrapolating models fit to small numbers of neurons and have not been tested experimentally. Using a novel high-speed 3D-microscope we densely recorded from hundreds of neurons in the mouse visual cortex and measured the amount of information encoded. We find that the information in this sensory population increases approximately linearly with population size and does not saturate, even for several hundred neurons. This information growth is facilitated by a correlation structure that is not aligned with the tuning, making it less harmful than would be predicted from pairwise measurements. Accordingly, a decoder that accounts for the correlation structure outperforms one that does not. Our findings suggest that sensory representations may be more accurate than previously thought and therefore that psychophysical limitations may arise from downstream neural processes rather than limitations in the sensory encoding.

Title: Characteristic temporal scales of v1 horizontal interactions

Authors: *G. BLAND[1], W. SINGER[1,2,3];
[1]Ernst Strüngmann Inst. (ESI), Frankfurt, Germany; [2]Max Planck Inst. for Brain Res., Frankfurt, Germany; [3]Frankfurt Inst. for Advanced Studies, Frankfurt, Germany

Abstract: A central tenet of our understanding of processing in V1 is the presence of feature selective neurons. Horizontal projections connect these neurons, thereby integrating visual information (review Gilbert 1992). Responses to a static bar are modulated by a flanking bar and the degree of interference depends on distance and orientation of the flanker (Kapadia et al. 1995). Activity has been observed to propagate horizontally across the visual cortex in travelling waves (review Sato et al 2012). However, our understanding of these horizontal interactions is far from complete. In this study, we measure neural responses to two visual events to assess the temporal characteristics of these interactions. To assess spatio-temporal integration in V1, we designed a modified moving bar task. Two awake monkeys passively viewed a full contrast bar moving with a particular orientation and constant orthogonal velocity while fixating. At a specific time the bar and background change to red-green isoluminance, thereby attenuating feed-forward magnocellular input. We ran this paradigm with two bar speeds (1s and 2s traversal time) and recorded unit activity and local field potentials (LFPs) using a 32 channel semi-chronic micro-drive (Grey Matter Research). As expected, the bar induced rate-increase is attenuated under isoluminant conditions relative to full contrast. The responses to the bar underwent a marked modulation when the interval between the luminance change and the passage of the bar across the receptive field was varied. With offsets between the two events >250ms the respective responses were independent. Between 250ms and 100ms, the two responses are locked at a fixed inter-response interval, dependent on the speed of the bar. When the predicted inter-response interval is <100ms, the bar induced response is completely abolished. These results demonstrate highly specific temporal interactions in V1. Visual evoked responses are independent at macro-temporal scales, stereotypic at meso-temporal scales, and strongly interfering at micro-temporal scales. At meso-temporal scales receptive field responses are shifted, with offsets that correspond to the characteristic speed of wave propagation. At micro-temporal scales the slow parvocellular input arrives in the later phase of the wave and is abolished. Thus, we support the role of a horizontal travelling wave for the purposes of predictive coding in V1.

Title: The psychophysicist's microelectrode: weak visual stimuli reveal neuron-like response properties

Authors: *A. W. FREEMAN[1], G. LUO-LI[1], D. ALAIS[2];
[1]Univ. of Sydney, Lidcombe, Australia; [2]Univ. of Sydney, Sydney, Australia

Abstract: AIMS. 1. The visual contrast-response function in human subjects typically has low gradient at low contrast. This is inconsistent with signal detection theory, and we therefore aimed to measure in detail the contrast-response function for contrasts close to zero. 2. Recently published work shows that light decrements are detected sooner than increments. We aimed to see whether this observation held at low contrast. METHODS. Visually normal adult humans were briefly presented with horizontal grating patches. The spatial form of the gratings was a raised cosine so that each presentation provided either an increment or decrement in contrast. Either the left or right half of the grating patch was shown and subjects indicated which half had been shown. Stimuli were randomly timed, and response correctness and reaction time were recorded. RESULTS. 1. There was a small range of contrasts, centred on zero, at which contrast sensitivity was very low. The circles in the figure show mean probabilities over seven subjects. Neurons in primary visual cortex have a resting membrane potential well below threshold (Tan et al., Nature, 509, 226): we propose that the probability plateau indicates the minimum contrast required to depolarise these neurons to threshold. Indeed, incorporating an action potential threshold into standard signal detection theory fits the data well, as shown by the line in the figure. 2. Reaction times at low contrast were less for contrast decrements than for increments. This corresponds well with recently published work showing that off-dominated cortical neurons have shorter latencies to decrements than do on-dominated neurons to increments (Komban et al., Neuron, 82, 224). CONCLUSION. Low-contrast measurements reveal human behaviour that appears to reflect the properties of single neurons in primary visual cortex.

Title: Spatio-temporal synergy requirements for binding feedforward and horizontal waves in V1

Authors: *X. G. TRONCOSO, M. PANANCEAU, B. LE BEC, C. DESBOIS, F. GERARD-MERCIER, Y. FREGNAC;
Unit of Neuroscience, Information and Complexity, UNIC-CNRS, Gif sur Yvette, France

Abstract: Long distance horizontal connections, intrinsic to primary visual cortex (V1), have been hypothesized to play a role in binding cells with identical functional preferences across the visual field, irrespective of their receptive field (RF) location. Combined intracellular and imaging techniques have shown that this binding requires stimulus-induced cooperativity to enhance the long-range orientation-selective spread beyond the feedforward imprint (Chavane et al, 2011). Using test stimuli allowing spatial summation within the aggregate RF of the cortical hypercolumn, we have recently reexamined the spatio-temporal features of the synaptic subthreshold receptive field of V1 cells (Gerard-Mercier et al, SfN2014). Our results showed that synaptic responses to flashed 3-4° Gabor patches can be elicited from the far periphery (up to 15°) and, most remarkably, exhibit a coherent organization, reflecting the grouping bias of the "perceptual association field" for collinear contours (Field et al, 1993). Our new cat V1 intracellular experiments are designed to test issues critical to understand the spatial synergy and temporal coherence requirements. We used 2- and 6-stroke apparent motion (AM) concentric sequences of Gabor patches at saccadic speeds (~200°/s), centered on the subthreshold RF (with the distance between strokes scaled to the diameter of the RF) extending the motion path up to 25° into the periphery. The response to stimulation of the RF center alone was compared to the response to the AM, which was either centripetal or centrifugal with the orientation of the individual elements either collinear or cross-oriented to the motion path. Control conditions included randomized order in the AM, change in speed or contrast, ... We also included sequences restricted to the silent surround to infer filling-in responses induced by the periphery alone. Our results show a supra-linear subthreshold input from the far periphery, and a non-linear boosting of the neuronal discharge resulting in a significant phase advance (5-20 ms) in the spiking response. Summation processes during the AM sequence show de novo emergence of significant responses for stimuli flashed as far as 10-15° away from the classical RF. The boosting effect is specific to centripetal AM at saccadic speeds and could not be induced by centrifugal or random AM, or by AM at lower speeds. Collinear movement was also more effective than cross-oriented movement. All these results are consistent with our hypothesis that

cooperative “Gestalt-like” interactions are triggered when the visual input carries a sufficient level of spatial and temporal coherence matching the underlying V1 connectivity.

Title: The Helmholtz size illusion is processed by extrastriate visual cortex, evidence from TMS

Authors: ***B. D. KEEFE**[1], K. MIKELLIDOU[3], H. CLAWSON[2], A. D. GOUWS[1], P. G. THOMPSON[2], A. B. MORLAND[1];
[1]York Neuorimaging Ctr., [2]Dept. of Psychology, Univ. of York, York, United Kingdom; [3]Univ. of Pisa, Pisa, Italy

Abstract: Neuroimaging research has indicated that for some illusions of size, there are commensurate distortions of retinotopy in V1 which reduce when attention is manipulated off stimulus. It remains unclear, therefore, whether these distortions in retinotopy arise from processing within V1 or feedback from higher visual areas. To test between these possibilities we used the Helmholtz size illusion, in which physically square, horizontally lined stimuli, are perceived as taller than their physically square, vertically lined counterparts. This illusory percept can be neutralised by extending the lines to make the stimuli appear square. To explore the role of striate and extrastriate visual cortex, we performed a TMS experiment in which participants made judgements about the aspect ratio of rectangular Helmholtz stimuli that were perceptually square. We stimulated V1 and two extrastriate areas, LO1 and LO2. Only stimulation of LO1 resulted in a significant release from the illusion. Importantly, with attention maintained on stimulus during TMS, there was no significant release from the illusion during V1 stimulation. Thus we show that extrastriate, rather than primary visual cortex, plays a causal role in our perception of illusory size. Our data appear consistent with the idea that illusion related activity in V1 reflects feedback from extrastriate regions and that V1 does not necessarily play a causal role in illusory percepts.

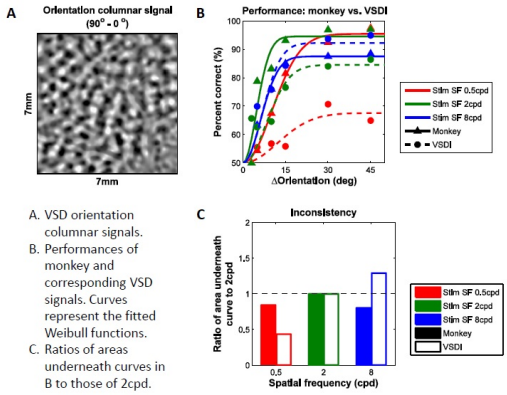
Title: Neural sensitivity in primate V1 is inconsistent with behavioral sensitivity in a fine orientation discrimination task

Authors: *Y. Y. CHEN, Y. BAI, W. S. GEISLER, E. SEIDEMANN;
Univ. of Texas at Austin, Austin, TX

Abstract: Neurons in the primate primary visual cortex (V1) are organized into columns based on their orientation preference. Although this columnar organization has been studied for decades, it is still unclear how neural activity in these columns contributes to orientation perception. As a first step towards addressing this question, we used voltage sensitive dye imaging (VSDI) to measure the columnar signals in V1 of a monkey while it performed a fine orientation discrimination task. To assess neural sensitivity, we developed a linear decoder that pools the single-trial VSDI signals over space using weights proportional to the orientation response map at the columnar scale. The decoder then uses the pooled signals to perform the same task as the monkey. If columnar signals provide the main source of information in the orientation discrimination task, the monkey's performance should be consistent with the measured neural sensitivity. To test this hypothesis, we varied the spatial frequency of the stimulus. Under the hypothesis, spatial frequency should have a similar effect on neural and behavioral sensitivities. However, we found systematic differences in the neural and behavioral effects of spatial frequency. The monkey was most sensitive at the middle frequency (2cpd), and performed worse at both low (0.5cpd) and high (8cpd) frequencies. In contrast, neural sensitivity was best at 8cpd, intermediate at 2cpd, and much worse at 0.5cpd. There are at least two possible sources that could contribute to these discrepancies between the neural and behavioral effects. First, additional sources of information beyond the columnar signals may contribute to behavioral performance at intermediate and low spatial frequencies. Second, the efficiency with which V1 signals at the columnar scale are decoded by subsequent processing stages may decrease with increasing spatial frequency. By studying trial-by-trial covariations between V1 signals and behavioral choices we may be able to distinguish between these possibilities.



A. VSD orientation columnar signals.
B. Performances of monkey and corresponding VSD signals. Curves represent the fitted Weibull functions.
C. Ratios of areas underneath curves in B to those of 2cpd.

Title: Characterizing population-level interactions between v1 and v2

Authors: ***J. D. SEMEDO**[1], B. R. COWLEY[1], A. ZANDVAKILI[2], C. K. MACHENS[3], B. M. YU[1], A. KOHN[2];
[1]Carnegie Mellon Univ., Pittsburgh, PA; [2]Albert Einstein Col. of Med., New York City, NY; [3]Champalimaud Ctr. for the Unknown, Lisbon, Portugal

Abstract: Recording technology now allows us to record populations of neurons in multiple brain areas simultaneously. Traditionally, such recordings have been analyzed by identifying direct interactions between pairs of neurons, which provides a limited view of how distributed activity patterns in one area interact with those in another. We sought instead to use dimensionality reduction approaches to identify a small number of latent variables which summarize population activity patterns, and then to study the interaction of these latent variables. Specifically, we applied probabilistic canonical correlation analysis (pCCA) to populations of neurons recorded simultaneously in visual areas V1 and V2 of anesthetized macaque monkeys,

while the animals were shown sinusoidal gratings of different orientations. We used pCCA to identify response subspaces of high correlation between the populations, termed “communication subspaces”. pCCA revealed that stimulus presentation produced a robust decorrelation of V1-V2 activity, compared to the spontaneous state. To understand the basis of this effect, we examined the relationship between trial-to-trial fluctuations in V1 activity and the V1-V2 communication subspace. We found that the average angle between V1 activity and the communication subspace increases during stimulus presentation, suggesting that V1 variability is ‘filtered out’ when V2 reads out V1 activity. To account for possible delays in the communication between the two areas, we applied pCCA to time-shifted data, obtaining a multivariate cross-correlogram (mCCG) which shows the maximum correlation between the populations as a function of the time delay between them. Shortly after stimulus onset the mCCG included a clear feedforward component, with correlation being maximal for V2 responses that followed those in V1 by 2ms. Later in the evoked response, the mCCG revealed stronger correlation for V2 activity preceding V1. This suggests that the initial feedforward interaction is replaced later in the trial by a feedback interaction. Our results suggest that representing distributed activity patterns with a small number of latent variables can be revealing for understanding the interactions between distinct neuronal populations. In particular, our analysis revealed novel dynamic interactions between V1 and V2, and suggests a sophisticated communication subspace which may mitigate the detrimental effects of V1 variability on V2.

Title: Long-term widefield imaging of genetically encoded calcium indicator signals in the primate visual cortex

Authors: *E. SEIDEMANN[1], Y. CHEN[2], Y. BAI[2], W. S. GEISLER[2], B. V. ZEMELMAN[2];
[1]Univ. Texas At Austin, Austin, TX; [2]Univ. of Texas at Austin, Austin, TX

Abstract: Genetically encoded calcium indicators (GECIs) can be used to measure responses from cell-type specific neural populations over large cortical regions, but until now this technique has not been adapted to awake, behaving macaque monkeys, an important model system for studying human perception, cognition and action. We used viral vectors to infect the primary visual cortex of two macaque monkeys with a transgene for a calcium indicator (GCaMP6). A few weeks after viral injection, high levels of expression of the transgene could be observed over an area of ~10mm^2 per injection site. While the monkeys performed a fixation task, calcium signals provided a robust readout of visual responses with high temporal resolution and sufficient spatial resolution to measure reliable and stable orientation maps over a period of several months. To characterize the nature of the calcium signal, we compared its tuning properties with those of a synthetic voltage sensitive dye (VSD; RH1838) across several fundamental stimulus dimensions. We found that calcium signals are more selective to stimulus orientation, less sensitive to contrast and have smaller population receptive fields than VSD signals. We then used a simple computational model to interpret these results. Our model has two components. (1) A spatial weighting function that captures the region over which neural responses are pooled to obtained the measured local imaging signal. (2) A nonlinear transfer function that describes the quantitative relation between the magnitudes of the different signals (VSD, calcium, spikes) at the single neuron level. Using this model, we find that (1) the local calcium and VSD signals reflect pooled neural activity in a Gaussian shaped region with a space constant of ~0.23 mm. (2) While VSD signals reflect membrane potentials, calcium signals are dominated by spiking activity, but also contain a small contribution from subthreshold activity. Overall our results demonstrate that chronic imaging of GECIs in behaving primates is an exciting new technique for studying the neural basis of behavior.

Title: Neural consequences of transcranial direct current stimulation in the primary visual cortex of awake, behaving macaques

Authors: *K. KAR[1,2], B. KREKELBERG[1];
[1]Ctr. For Mol. and Behav. Neuroscience, Rutgers Univ., Newark, NJ; [2]Behavioral and Neural Sci., Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstract: Transcranial direct current stimulation (tDCS) has been used successfully as a noninvasive neuromodulation tool to affect behavior in both the clinic and in the cognitive neurosciences. The most commonly accepted neuromodulatory effect of tDCS is a subthreshold membrane polarization. Even though some studies support the view that anodal tDCS increases cortical excitability while cathodal tDCS decreases it, reports in the literature are contradictory. To shed light on the neural consequences of tDCS, we investigated the tDCS-induced changes in neural activity in the macaque primary visual cortex. We recorded neural activity from area V1, with chronically implanted floating microelectrode arrays before and after applying tDCS. During each experimental session, we first mapped visual responses and orientation, spatial frequency, and contrast tuning using full field grating stimuli. Second, we applied tDCS for 20 minutes; either cathodal (-1 mA), anodal (+1 mA), or sham (0 mA). One (active) tDCS electrode was placed on the occipital pole of the monkey while the other (reference) was placed near the vertex. Third, we mapped the visual responses and tuning properties again, using the same stimuli. . We compared the multiunit activity (MUA) before and after stimulation. We found that 20 minutes of anodal stimulation significantly increased the multi-unit activity across multiple electrodes. This supports the view that anodal tDCS increases excitability. We did not find any specific contrast or spatial frequency dependence of this anodal tDCS-induced enhancement. Sham or cathodal tDCS did not have any consistent effect on the MUA. To our knowledge, this is the first study demonstrating the efficacy of tDCS to induce electrophysiological changes in the non-human primate. Given the significant structural and functional similarities between the macaque and human brain, and our ability to measure both behavioral and neural consequences

of transcranial stimulation, this animal model has the potential to provide unique insight into the neural mechanisms underlying tDCS and its (clinical) use in humans.

Title: Response properties and rate code of information about stimulus orientation in cat's primary visual cortex

Authors: *S. A. KOZHUKHOV, N. A. LAZAREVA;
The Inst. For Higher Nervous Activity, Moscow, Russian Federation

Abstract: It is evident that orientation tuning of neurons in primary visual cortex (V1) doesn't remain permanent during the response time course: their preferred orientation may undergo large systematic shifts. Such a phenomenon allows a single V1 cell to transmit more information about stimulus orientation that actually contains in total number of spikes by means of temporal-dependent firing rate. However the mechanism of such a process remains largely unexplored. We recorded extracellular single-unit responses of V1 cells in anesthetized and immobilized cats. The stimuli were single thin bars of different orientations. For each response we estimated spike density function to which principle component analysis was applied followed by frequency analysis based on digital filtration. We have found that each response consists of different kinds of transient and sustained components and different types of theta/alpha/beta-range oscillations. These components have different “optimal orientations” and different waveforms. The next step was to confirm that the components don't result from residuals of “neural noise”. In order do that we replaced some of them by Poisson distributed random deflections of the firing rate. As a result “surrogate responses” were built; they don't reproduce the original ones. So, we concluded that the most of components don't result from “neural noise”. Based on these data we propose the following hypothesis about how preferred orientation dynamics originates: 1. Neural response of V1 cell contains several components; each of them contains its own “optimal orientation”, unique waveform and probably its own origin. 2. Due to differences in components’ waveform different constituents may prevail in consecutive intervals of the response. 3. Change of components’ prevalence corresponds to change of preferred orientation of a stimulus during the response time course.

Title: Effects of contrast polarity on flicker perception and primary visual cortex (V1) activity in the tree shrew

Authors: *A. KHANI, M. MOHAMED MUSTAFAR, G. RAINER;
Visual Cognition Laboratory, Inst. of Physiol., Univ. of Fribourg, Fribourg, Switzerland

Abstract: The entrainment of V1 neural activity in macaque and tree shrew exhibits marked black dominance at visual stimulation frequencies of 60Hz and above, such that light decrements elicit considerably stronger neural response transients than light increments. Here our aim is to explore the relationship between the perception of temporally modulated visual stimulation and the activity of V1 neurons. We used impulses of transient increases or decreases in luminance from a gray background at different contrasts and frequencies to generate flickering stimuli (range tested: 7.5 to 60Hz), which enabled us to study frequency-dependent sensitivity to contrast and polarity at the behavioral and neuronal level. For the behavioral study, tree shrews (Tupaia belangeri) were trained to discriminate a flickering stimulus from two other iso-luminant non-flickering stimuli in a 3 alternative forced choice (3AFC) task. We estimated the threshold contrast sensitivity from separate fits for every frequency and polarity. We observed main effects of polarity (2-way ANOVA; $F_{1, 5} = 7.02$; $p < 0.05$) and frequency ($F_{5, 25} = 4.52$; $p < 0.01$). Thus, light decrements were more easily perceived than light increments. For both polarities, performance depended on frequency, with best performance at 24Hz and 60Hz for light and dark stimuli respectively. We analyzed data from 92 V1 single neurons while flickering stimuli, identical to those used in behavioral experiments, were presented within the minimum response field of respective neurons. Preliminary analyses show that neurons exhibit a variety of response patterns, with responses depending on both frequency and polarity. Repeated measures two way ANOVAs on the firing rate of individual neurons revealed a main effect of frequency in more than half of the neurons ($n = 54$; $p < 0.05$), with peak responses typically observed at frequencies of 24 Hz ($n = 3$) and 40 Hz ($n = 51$). These analyses also showed a main effect of polarity ($n= 19$; $p < 0.05$) as well as a significant interaction ($n = 16$; $p < 0.05$). Of the 19 neurons with the main effect of polarity, only were light dominant and the overwhelming majority of those neurons were black dominant. Our findings suggest a general correspondence between black

dominance observed at the behavioral and V1 neuronal level for temporally modulated stimuli, in a frequency range from 7.5 up to 40Hz. The findings are discussed in the context of related studies in other mammalian species.

Title: Two-photon imaging of neuronal avalanches during visual stimulation in awake mice

Authors: ***T. L. RIBEIRO**[1], S. SESHADRI[1], D. WINKOWSKI[2], P. KANOLD[2], D. PLENZ[1]; [1]Section on Critical Brain Dynamics LSN/NIMH, NIH, Bethesda, MD; [2]Dept. of Biol., Univ. of Maryland, College Park, MD

Abstract: Neuronal avalanches, measured as consecutive bouts of thresholded field potentials, are conceived to be a statistical signature that the brain operates near a critical point. In theory, criticality optimizes stimulus sensitivity, information transmission, computational capability, and mnemonic repertoires size. Recently, the cellular origin of those avalanches was demonstrated through the use of imaging techniques, revealing a power-law organization of activity in the rat brain, as the animals wake from anesthesia. It remains unclear whether the same statistical properties are present during stimulation, since the avalanche analysis is mostly restricted to ongoing activity. Moreover, the role of functionally different sub populations (e.g. barrel cortex, orientation map) in the avalanche dynamics is still unknown. In order to answer those questions we employed two-photon imaging to measure spiking activity in pyramidal cells from the primary visual cortex of mice, while they were subject to passive viewing of drifting bars of different orientation. We identified sub populations of different preferred orientation and analyzed neuronal avalanche statistics in those populations with and without visual stimulus present. Power law statistics can be identified during the periods without stimulus and deviations during stimulation were studied. The presence of a critical regime in a population of cells responsible for processing of different characteristics of a visual stimulus is an important feature for those networks.

Title: Distinct resting-state dynamics revealed by local inhibition of primary visual cortex and frontal eye fields in humans

Authors: *L. COCCHI[1], M. V. SALE[1], P. T. BELL[1], A. ZALESKY[2], L. L. GOLLO[3], M. BREAKSPEAR[3], J. B. MATTINGLEY[1];

Abstract: Single-neuron recordings and brain imaging studies suggest that the primate cortical visual system is organized hierarchically. The primary visual cortex (area V1) mediates the flow of bottom-up visual inputs, whereas the frontal eye fields (FEF) modulate activity in V1 via top-down feedback. Interestingly, the nature of these bottom-up and top-down interactions seem to differ as a function of behavioural state. During active task performance, V1 and FEF interact dynamically in support of visual perception and selective attention. By contrast, functional magnetic resonance imaging (fMRI) studies in humans suggest that V1 and FEF are functionally segregated at rest. Here we asked whether local changes in excitability induced via transcranial magnetic stimulation (TMS) of areas V1 and FEF can alter the functional coupling between them at rest. In separate sessions, inhibitory theta-burst stimulation was applied over V1 or FEF in 21 human participants. Resting state fMRI data were obtained immediately before and after stimulation. Local frequency and whole-brain seed-to-voxel analyses revealed that larger reductions in neural activity in V1 were related to increased integration between this region and other visual areas, including FEF. Conversely, focal inhibition of FEF caused increased decoupling between this region and V1. These results suggest opposing influences of local inhibition of V1 and FEF on patterns of integration between these regions at rest. More broadly, our findings highlight the dynamic nature of hierarchical interactions in the human visual system, and provide important clues to understanding the effects of focal lesions on neural activity and behavior.

Title: Decoding behavioral state from local field potential recordings in basal forebrain and visual cortex

Authors: *J. NAIR[1], A.-L. KLAASSEN[2], J. POIROT[1], A. VYSSOTSKI[3], B. RASCH[2], G. RAINER[1];
[1]Visual Cognition Laboratory, Dept. of Medicine., [2]Dept. of Psychology, Univ. of Fribourg, Fribourg, Switzerland; [3]Inst. of Neuroinformatics, Univ. of Zurich, Zurich, Switzerland

Abstract: The basal forebrain (BF) contains cholinergic and non-cholinergic neurons that project to the visual cortex (V1) where they play an important role in modulating neural network state, for example by enhancing responsivity or contrast sensitivity as well as contributing to wake/sleep regulation. Here, our aim is to explore similarities and differences between local field potential (LFP) recordings from BF and V1, in order to better understand how these brain areas function and interact during different brain states. Bilateral tungsten electrodes were implanted in the BF and V1 of rats, and LFP recordings were acquired during six hour periods from animals in their home cage using a wireless recording device. BF electrode placement was verified by BF electrical microstimulation, which could wake up animals at short latency. Based on video recordings and cortical LFP signals, the brain state was scored for 15s segments into wakefulness (W), slow-wave-sleep (SWS) and rapid-eye-movement (REM) sleep. We analyzed three LFP frequency bands: delta (1-5Hz), theta (5-10Hz) and gamma (30-80Hz). We observed considerably stronger gamma activity in BF than V1. BF gamma power was elevated during W over both SWS and REM sleep by 60% or more (paired t-tests: $p<<0.001$), whereas peak BF gamma frequency was significantly lower for W (53Hz) than both REM and SWS (60 and 58Hz respectively, $p<0.01$). We next examined how well the behavioral state could be determined using only the spectral power in pairs of frequency bands for the 15s LFP segments for each brain area. The best behavioral state classification was obtained using the delta and gamma bands in the BF (82%, vs. 77% in V1, paired t-test: $p<0.01$), whereas the other band combinations allowed performance of 76% or less with no apparent difference between V1 and BF (paired t-tests, $p>0.1$). For the theta-gamma band pair, we found that BF signals were more accurate than V1 signals in distinguishing REM from W states (7% vs. 26% errors, paired t-test:

$p<0.01$), whereas the reverse was true for distinguishing REM from SWS (25% vs. 11% errors, paired t-test: $p<0.01$). Our findings reveal substantial differences in the brain-state dependence of local neural activation patterns in basal forebrain and visual cortex. We discuss the functional implications of these findings that form the basis for functional interactions of these brain structures during sleep and wakefulness.

Title: Spike and gamma band responses in macaque V1 and V4 to contrast modulated gratings and natural images

Authors: *M. J. ROBERTS[1,2], E. LOWET[3,2], P. DE WEERD[3,2];
[1]Univ. of Maastricht, Maastricht, Netherlands; [2]The Donders Inst. for Brain, Cognition and Behaviour, Radboud University Nijmegen, Netherlands; [3]Dept. of Neurocognition, Fac. of Psychology and Neurosci., University Maastricht, Maastricht, Netherlands

Abstract: Gamma band activity in visual cortex has been implicated in a number of cognitive and computational operations. The large majority of experiments investigating the functional significance of gamma however have used only artificial stimuli. This has led to controversy over whether findings obtained with artificial stimuli such as gratings can be extended to natural vision. This discussion is rendered difficult as studies using natural images have typically not used the same viewing conditions as for artificial stimuli, making direct comparisons impossible. We recorded multi-unit spiking and local field potentials in areas V1 and V4 of two macaque monkeys fixating centrally. We presented both gratings and natural images. Gratings of limited size with contrasts ranging between 2% and 100% were presented at or near RF locations, while natural stimuli were presented both as full screen images and as patches of a size and position comparable to the gratings. The LFP response to gratings was characterized by a strong gamma band in V1 with peak frequency dependent on stimulus contrast [1]. Gamma power was highest for intermediate contrasts. We found that responses in the gamma band to natural images on average were much weaker in both V1 and V4. This could be consistent with natural images often being poor stimuli to drive robust, synchronized neuronal responses in sufficiently large

ensembles. A recent simulation study [2] demonstrated that the magnitude of local contrast variation between stimulated cortical sites and hence local gamma frequency differences determine whether an ensemble will develop synchrony. We are currently testing whether this and other factors can predict gamma frequency and power in response to natural images. Notably, whereas gamma power on average was lower for natural images than for gratings, we found the opposite for spike rate. We also found that high contrast gratings yielded strong spiking responses and weak gamma. Ongoing analysis is anticipated to shed light on contributions of gamma to natural vision (and limits thereof), on mechanisms underlying local gamma synchronization, and on the dissociation between gamma and spiking.

Title: Amplitude and frequency of visually-induced gamma-band activity are determined by age, gender and stimulus properties across a cohort of 160 human subjects

Authors: *S. VAN PELT[1,2], P. FRIES[1,3];
[1]Radboud Univ. Nijmegen, Nijmegen, Netherlands; [2]Ernst Strüngmann Inst. (ESI) for Neurosci. in Cooperation with Max Planck Society, Frankfurt, Germany; [3]Ernst Strüngmann Inst. for Neurosci. in coop. with Max Planck Society, Frankfurt, Germany

Abstract: Gamma-band synchronization has been implicated in many cortical functions, ranging from low-level visual perception to memory and attention. In recent years, visually-induced gamma-band activity has been shown to be modulated by properties of the stimulus and the task, and also by subject-dependent factors such as age and genetic make-up. In the current study, we set out to quantify the relative contributions of these elements. 160 subjects (mean age 23.2) viewed an inward moving circular sinusoidal grating while their brain activity was recorded using MEG. They had to press a button when the stimulus increased velocity. We manipulated stimulus contrast (50% and 100%), as well as stimulus velocity (0.0, 0.33, and 0.66 deg/s). We quantified the modulatory effects of stimulus properties, subject age, handedness, and gender on the peak frequency and amplitude of the induced gamma-band activity, both in isolation and combined. We also took regressors of non-interest into account such as recording date. We found that gamma-band peak frequency (for the stimulus inducing the highest signal change: 100% contrast at 0.66 deg/s) was normally distributed across the subject population, with a mean value

(+/- SD) of 56.3 +/- 5.8 Hz. Female participants had a significantly higher gamma peak frequency than men (57.0 vs 54.9 Hz). Across the entire population, peak frequency was on average 1.2 Hz lower for the 50% vs. the 100% contrast stimulus. Peak frequency decreased with 1.8 Hz per decrease in stimulus velocity of 1 deg/s. Peak frequency also decreased with increasing age, and with decreasing (age-correlated) occipital gray matter volume. Gamma amplitude showed results qualitatively similar to gamma frequency, except for an absence of gender differences. Quantitatively, amplitude effects were stronger, e.g. a 50% contrast stimulus resulted in a 60% decrease in power change relative to the 100% contrast stimulus. Multivariate, canonical correlation analysis revealed that together, stimulus contrast, stimulus velocity, subject gender and subject age explained 31% of the variance of a weighted combination of gamma peak frequency and stimulus-induced amplitude. The results indicate that there are large inter-individual differences in human gamma-band activity with frequencies spanning from 40 to 75Hz. A substantial part of variance in gamma frequency and amplitude can be accounted for by stimulus properties, and by age and gender. Studies involving gamma-band activity should take these differences into account e.g. when averaging over subjects. Future studies such as genetic association studies might further explain the remainder of the variance in gamma-band activity.

Title: Neural synchrony and the relationship between the BOLD response and the Local Field Potential

Authors: *D. HERMES[1], M. L. NGUYEN[2], J. WINAWER[3];
[1]Stanford Univ., Stanford, CA; [2]Princeton Univ., Princeton, NJ; [3]New York Univ., New York, NY

Abstract: Purpose: Elucidating the neural circuits underlying the BOLD signal measured with fMRI is an important goal in human neuroscience. The BOLD signal has often been correlated with the local field potential (LFP), with many groups finding that BOLD correlates positively with LFP power in the gamma / high gamma band (30-150 Hz), and negatively with power in the alpha band (8-15 Hz). Individual frequency bands, however, do not correspond to distinct neural circuit responses. For example, the gamma band contains at least two distinct signals: an

oscillatory (narrowband) component and an asynchronous (broadband) component. These responses overlap in temporal frequency but differ in biological origin. We propose a model to relate BOLD and LFP in which the LFP is split into components that reflect different hypothesized neural responses rather than distinct frequency bands. Methods: Electrocorticography (ECoG) and fMRI responses to gratings and noise patterns were measured in human subjects in V1-V3. The ECoG spectral response was modeled as the sum of three components in log power/log frequency: an asynchronous broadband component (a straight line) and two narrowband oscillatory components (one Gaussian centered in the alpha band and one in the gamma band). Results: In V1, the BOLD response correlated positively and strongly with the ECoG broadband amplitude. In contrast, the BOLD response did not correlate with the ECoG gamma amplitude, even though the gamma amplitude was large and varied systematically across stimuli. In V2/V3, BOLD was again positively correlated with broadband ECoG and not with narrowband gamma. In all areas, the alpha response correlated negatively with BOLD. Next we simulated responses to a variety of stimuli in a neural population. From these synthetic neural responses, we extracted measures of BOLD and LFP based on assumptions of energetics and field summation. In the simulations, like the data, asynchronous broadband responses were highly correlated with the BOLD response, whereas the amplitude of narrowband gamma oscillations was not. Conclusion: The BOLD signal depends on the metabolic demands of a neural response, whereas LFP power depends on the level of neural synchrony and activity. The simulation provides a novel way to relate neural responses to LFP and BOLD. The amplitude of narrowband gamma oscillations does not correlate systematically with the BOLD signal because this response reflects the degree of synchrony rather than the level of neural response. Alpha oscillations negatively correlate with BOLD. Finally, broadband field potentials correlate positively with the BOLD signal, and best index the global level of neural response.

Title: Stimulus selectivity of gamma oscillations in human visual cortex measured with magnetoencephalography

Authors: ***J. WINAWER**[1], E. R. KUPERS[1], N. CHUA[2], D. HERMES[3], K. AMANO[4];
[1]Psychology, [2]Dept. of Psychology and Ctr. for Neural Sci., New York Univ., New York, NY;

[3]Psychology, Stanford Univ., Stanford, CA; [4]Ctr. for Information and Neural Networks (CiNet), Osaka, Japan

Abstract: Background: Certain visual stimuli elicit large oscillatory cortical responses in the gamma band (30 – 80 Hz). It has been proposed that this signal plays an essential role in cortical communication and visual perception. Recent work using intracranial EEG in human showed that robust gamma oscillations can be measured for some visual stimuli (high contrast gratings) but not many other stimuli, such as noise patterns containing contrast at many orientations, constraining the possible functional role these oscillations play in vision. Here we asked (a) whether the stimulus dependence of gamma oscillations is evident in magnetoencephalography (MEG), a non-invasive measure of brain activity in healthy human subjects, and (b) whether the stimulus dependence of gamma oscillations arises from a stimulus-specific pattern of eye movements. **Methods**: During MEG recordings, subjects viewed static visual stimuli while performing a fixation color change detection task. Stimuli were viewed for either 0.5 seconds (3 subjects) or 1 s (2 subjects), with 0.5 s inter-stimulus interval (blank screen, mean luminance). Stimulus classes consisted of high contrast square wave vertical gratings spanning 0.35 to 2.90 cycles per degree, square wave plaids, or noise patterns with amplitude spectra proportional to $1/f^n$ (n=0,1,2), windowed within circular apertures subtending 24º of visual angle (diameter). Stimuli were shown in random order, with 150 repeats per class. Eye position was recorded at 1 kHz with an EyeLink 1000 eye tracker throughout the experiment. **Results**: Responses were summarized in each channel as the sum of two components, a spectrally broadband elevation over baseline (power law), and a narrowband gamma oscillation (Gaussian in log power/ log frequency, centered between 35 and 80 Hz). In all subjects, grating stimuli spanning all spatial frequencies tested elicited robust gamma oscillations (~0.5 log units above baseline), largely confined to sensors over occipital cortex. No class of noise stimuli elicited spatially specific gamma oscillations consistently across subjects. The frequency, amplitude, and direction of microsaccades did not differ systematically between viewing grating stimuli and noise stimuli. **Conclusions**: These results provide further demonstration of the strong dependence of narrowband gamma oscillations on stimulus pattern. The results also argue against the possibility that the stimulus selectivity stems from the pattern of eye movements associated with particular stimulus classes.

Title: Probing communication through coherence via phase-dependent analysis

Authors: D. LISITSYN, D. HARNACK, *U. A. ERNST;
Univ. Bremen, Bremen, Germany

Abstract: Depending on behavioral context, information is selectively routed throughout the brain. Particularly in the framework of selective visual attention, neurons in V4 with multiple stimuli in their receptive fields respond as if just the attended stimulus was present [Moran, Desimone 1985]. While the mechanisms behind this effect are widely debated, communication through coherence (CTC) has emerged as a promising candidate [Fries 2005]. CTC postulates that stimulus information transmission is enhanced between oscillating populations in a favorable phase relationship, and suppressed when the oscillations are in an unfavorable or random phase relationship. Specifically, spikes from V1 arriving during peaks of V4 oscillatory activity (favorable relationship) should be much more likely to elicit further spikes in V4, resulting in effective communication; spikes arriving during troughs of V4 activity (unfavorable relationship) should fail or at least be less effective in evoking further activity. Multiple modeling and experimental studies provide support for the CTC hypothesis by showing ample evidence of attention-modulated gamma phase-locking. However, there has been no explicit research focusing on the particular temporal structure imposed on information transmission by the CTC hypothesis. In an ideal setting, the peaks in V4 should carry information from the attended stimuli (processed by V1 neurons oscillating in-phase with V4), while the unattended stimuli (processed by V1 neurons in anti-phase with V4) should only modulate activity in the troughs. In the present study, we utilize a simple, biophysically inspired model with two V1 populations having feedforward connections to a V4 population. Each V1 population is driven by a unique temporally varying stimulus, allowing us to trace the stimulus-specific information content of the activity propagated to V4 and to higher areas by utilizing spectral coherence analysis (SCA). In particular, we implement a novel form of phase-dependent SCA and quantify the contribution of the attended/non-attended signal to peaks/troughs in V4 LFPs/spikes during Gamma activity. By investigating multiple possible regimes of population activity, we find that it is possible for LFP troughs to carry information from either just the non-attended or both V1 populations. However, for information routing to succeed, the LFP peaks have to be exclusively modulated by the attended V1 population, showing the necessity of disparate phase-dependent (peak vs trough) information content. Our findings demonstrate that phase-dependent SCA can be used to directly test the CTC hypothesis in physiological recordings.

Title: Multiscale study of reliability and correlation of evoked cortical dynamics during natural scene processing in cat primary visual cortex

Authors: *Y. PASSARELLI, L. FOUBERT, Y. FRÉGNAC, C. MONIER;
Unit of Neuroscience, Information and Complexity, UNIC-CNRS, Gif Sur Yvette, France

Abstract: The principle of efficient coding suggests that visual processing in early sensory systems should be adapted to the statistical properties of the stimulus. By comparing intracellular responses to stimulus statistics of different complexity, we have shown (Baudot *et al.,* 2013) that the temporal reliability of the neural code is optimized for natural statistics and that the stimulus-locked trial to trial variability of the subthreshold membrane potential waveforms is modulated by the statistics of the full field stimulus context. Using the exact same stimulus seed, we present here a multiscale analysis based on more mesoscopic measures including multiple unit recordings (SUA and MUA) and local field potentials (LFP). Our aim is to explore if the single-cell observations can be related (or not) to specific behavior and stimulus dependency shared by local ensemble of neurons and if a laminar dependency of the observed effects can be detected by these mesoscopic methods and what is the global impact of input statistics changes on the correlation between neurons. In the area 17 of the anesthetized and paralyzed cat, we used Michigan silicon probes with different designs to realize laminar and lateral recordings across and within layers. To study the stimuli dependency of the reliability and correlation, we used the same stimuli as in the intracellular study, i.e, different types of visual stimuli with various statistic of increasing complexity: Drifting gratings, gratings and natural Image animated with virtual eye-movements and dense noise stimuli. To ascertain the feedforward and local vs lateral nature of the field potentials, we partitioned the full field stimulation in a central mask large enough to cover the LFP RF (equivalent to the aggregate RF of the hypercolumn) and stimuli were presented in the three center/surround partitions (center only; surround only ; center + surround). For the LFP signal, the frequency content and its reliability (measured with coherence and wavelet analysis) were highly dependent of the type of stimuli and of the layer of the recordings. Similar conclusions were obtained for spiking activity with mean rate, sparseness, Fano-factor and noise correlation measures. In particular large synchronizations of activity were found with natural image animated with saccade movement when the surround was stimulated (surround-only & center + surround).

Title: Visual features driving electrophysiological responses to naturalistic movies in the marmoset ventral pathway

Authors: *J. DAY-COONEY[1], C. HUNG[2,1], B. E. RUSS[1], L. NOTARDONATO[2], A. C. SILVA[2], D. A. LEOPOLD[1];
[1]Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Natl. Inst. of Neurolog. Disorders and Stroke, Bethesda, MD

Abstract: The visual system of the common marmoset closely resembles that of humans and Old World monkeys, including the electrophysiological responses and cytoarchitecture of the visual cortex. The marmoset's lissencephalic cortex allows for a broad sampling of neural activity across the brain's surface without interruption from gyrification. Hence, electrocorticography (ECoG) applied to the marmoset can be used to investigate spatial and temporal patterns of information simultaneously across a large portion of the visual processing hierarchy. To this end, we recorded neural responses across multiple areas in awake marmosets using subdural ECoG electrodes spaced evenly throughout the surface of the occipitotemporal cortical pathway, from primary visual cortex to rostral TE. We measured local field potential (LFP) activity as the subjects freely viewed naturalistic videos. Data from 15-minute periods of free viewing were filtered and rectified to produce a set of stimulus-driven band-limited power fluctuations at each recording site. We compared these fluctuations with the evolving features of the movie, creating a family of functional maps across the cortical surface. The strongest correlations concerned low-level movie features. Power in the beta frequency band (15 to 32 Hz) was anti-correlated to the motion content of the movies in channels spanning from early visual areas to the inferotemporal cortex, whereas power in the high-gamma band (50 to 150 Hz) was positively correlated to the contrast content with a decreasing posterior-to-anterior gradient. To further investigate the nature of the neural activity, the autocorrelation width (ACW) was calculated for each frequency band in each channel. The high-gamma band displayed an increasing posterior-to-anterior gradient for ACW sizes, whereas all other frequency bands were homogenous in ACW sizes across channels. This suggests that the temporal scale of driven high-gamma power fluctuation increased at higher stages of the visual hierarchy. To reconcile this finding with the correlational patterns calculated from the features of the movie, we used a leave-one-out method to assess the contribution of distinct time points to the observed correlations. The analysis revealed that in

early visual cortical areas, time points driving positive correlations in the gamma band coincided with those driving negative correlations in the beta band. We are currently investigating this relationship further to better understand how the beta and gamma bands of the LFP signal are driven by the content of naturalistic stimuli.

Title: Putting the pieces together - the role of parieto-occipital cortex in perceptual grouping

Authors: *K. KUTSCHEIDT[1,2,3], E. HEIN[4], M. ROTH[2,3], A. LINDNER[2];
[1]Dept. of Psychiatry and Psychotherapy, Univ. Hosp. Tübingen, Tuebingen, Germany; [2]Dept. of Cognitive Neurol., Hertie Inst. for Clin. Brain Res., Tübingen, Germany; [3]Intl. Max Planck Res. Sch., Grad. Sch. of Neural & Behavioural Sci., Tübingen, Germany; [4]Evolutionary Cognition, Univ. Tübingen/ Dept. of Psychology, Tübingen, Germany

Abstract: Our holistic perception of the environment is a result of processes, which group the fragments of information arriving at the retina in order to form entities or objects. Studies on simultanagnosia patients, who lost the ability to perceive a visual scene holistically, emphasize the importance of parieto-occipital cortex (POC) as substrate for perceptual grouping. Our aim was to further clarify the role of POC in grouping. To this end we performed an fMRI study using the Ternus display, an ambiguous apparent motion stimulus consisting of three disks presented next to each other. While two of the disks are always presented at the same position, a third disk is presented alternating between a position left and right of the two central disks. This stimulus can elicit two apparent motion percepts: element motion (EM; the outermost disk jumps back and forth across the two central stationary disks) or group motion (GM; all three disks move together as one group). It was suggested that the actual percept depends on whether and how much the Ternus elements are grouped together. The Ternus display was presented in six 5min blocks. Due to the ambiguity of the stimulus, the perceptual interpretation constantly switched between EM and GM within blocks. Participants (n=14) indicated each perceptual switch by pressing a respective button. Functional (TR=2s) and anatomical images were acquired on a 3T Siemens TRIO scanner and processed using SPM8. In participant-specific analyses we computed general linear models including three regressors: onset of GM percept, onset of EM

percept and overall stimulus presentation. For each participant, we identified task-related regions of interest (ROIs) by contrasting stimulus presentation vs. an initial 30 sec baseline. Task-related ROIs were the lingual gyrus, V3a, V5, the anterior insula, supplementary motor area, frontal eye field and the posterior intraparietal sulcus (IPS). For each individual and ROI we next extracted the time course of fMRI-activity in order to perform time-resolved group analyses identifying activity differences between EM and GM precepts. Perceptual switches were always accompanied by significant peaks in fMRI-activity in all ROIs. While the peak-amplitude did not differ between both percepts, we observed a significant shift in the temporal onset of switch-related fMRI-responses in the IPS. Specifically, there was a significantly earlier rise (about 3sec) of switch-related fMRI-activity during perceptual switches from EM to GM. This finding is consistent with the idea of a top-down influence of POC (IPS) on other areas to mediate the perception of GM by spatially grouping all individual elements to a global Gestalt.

Title: Visual cortical representation of word identity, font... and gender?

Authors: ***L. STROTHER**[1,2], A. M. COROS[2], Z. ZHOU[1], T. VILIS[2];
[1]Dept. of Psychology, Univ. of Nevada, Reno, Reno, NV; [2]Brain and Mind Inst., Univ. of Western Ontario, London, ON, Canada

Abstract: We routinely encounter words in different fonts. We used fMRI to delineate neural responses to the same word viewed in different fonts from those to different words presented in the same font. Observers in our experiment viewed words under the following conditions: (a) a single word was repeated over several seconds, in the same font each time; (b) the word was repeated but the font changed for each repetition; (c) different words were presented in different fonts; (d) the font of letters in one half of a word changed; or (e) the font of a word remained constant but letters in one half of the word changed, thus changing the identity of the word each time. We observed differential lateralization in occipitotemporal cortex, including a "visual word form area" (VWFA) reported in other studies, as well as more posterior regions of occipital cortex. As expected, changes in word identity were associated with left-lateralized fMRI responses, especially in the VWFA. In contrast, changes in the font of a word while identity was preserved did not elicit strongly lateralized fMRI responses, and overlapped considerably with

left-lateralized fMRI responses to word identity changes. Our findings highlight involvement of various visual cortical areas in reading, some of which may also play a role in the rapid recognition of other types of highly familiar stimuli, such as faces. We propose to use our method to study other identity-related aspects of words, such as gender, which is relevant to both words (e.g. a person's name) and faces.

Title: Variability of spiking responses varies with perceptual visibility in V4, but not in pulvinar

Authors: E. POLAND[1], T. DONNER[2], D. A. LEOPOLD[3], K.-M. MÜLLER[4], *M. WILKE[5]; [1]Dept. of Cognitive Neurol., Univ. Med. Goettingen (UMG), Goettingen, Germany; [2]Dept. of Psychology, Univ. of Amsterdam, Amsterdam, Netherlands; [3]Section on Cognitive Neurophysiol. and Imaging, Natl. Inst. of Mental Health/Laboratory of Neuropsychology, Bethesda, MD; [4]The Neuromarketing Labs, Siemensstr. 3, Germany; [5]Univ. Med. Goettingen, Goettingen, Germany

Abstract: A fruitful approach to investigate the neural mechanisms of conscious perception is the employment of visual illusions that render salient visual stimuli intermittently perceptually invisible. Previous electrophysiological studies in monkeys have revealed that neuronal spiking in a wide range of brain areas correlates with subjective visibility, with a gradual increase of spike rate modulation from early to higher stages of thalamic and cortical visual processing. However, neuronal spike counts might represent only one possible mechanism how perceptual visibility is encoded by the brain. We here examined whether changes in the reported subjective visibility are associated with changes in neuronal trial-to-trial variability as assessed by the Fano factor (FF). We recorded single and multiunit spiking activity in cortical area V4 and the thalamic pulvinar in two monkeys reporting the perceptual visibility of bright luminance patches in the context of a flash suppression paradigm. Trials were sorted on the basis of reported perceptual suppression, and spiking variability was estimated using a 100 ms sliding window. To evaluate changes in Fano factor following target onset, analysis was performed on all sites independent of their visual responsiveness (V4: N = 116, Pulvinar: N = 374). For perceptual modulation analysis, we considered 33 V4 and 142 pulvinar sites that changed their firing rates

upon physical stimulus removal and evaluated significance with Wilcoxon signed-rank tests (criterion $p<0.05$). We report two main findings: 1) As expected from previous studies, the onset of the visual stimulus significantly decreased the Fano factor in area V4 (FF pre: 2.26, FF post: 1.86). Surprisingly, stimulus onset had only modest effects on variability in the pulvinar (FF pre: 1.56, FF post: 1.52). Similar results were obtained with computation of the mean-matched Fano factor. 2) Although mean firing rates in both V4 and pulvinar correlated with subjective visibility, perceptual suppression was associated with significantly reduced Fano factor only in V4. Variability of pulvinar responses was largely unmodulated by either the physical stimulus or the perceptual state. Our results suggest that sensory input or perceptual states do not stabilize neuronal responses in the pulvinar as in visual cortex. These differences in patterns of neuronal variability may support different computational roles of V4 and pulvinar in visual perception.

Title: Neuronal signals supporting naturalistic texture discrimination

Authors: ***C. M. ZIEMBA**[1], R. L. T. GORIS[1,2], E. P. SIMONCELLI[1,2], J. A. MOVSHON[1]; [1]Ctr. for Neural Sci., [2]Howard Hughes Med. Inst., New York Univ., New York, NY

Abstract: The visual world is richly decorated with texture, which often serves to delineate important elements of natural scenes. In anesthetized macaque monkeys, selectivity for the key statistical features of natural texture is weak in V1, but substantial in V2, suggesting that neuronal activity in the second visual area might directly support texture perception. To test this hypothesis, we investigated the relation between single cell activity in macaque V1 and V2 and simultaneously measured psychophysical judgments of texture. We generated stimuli along a continuum between naturalistic texture (synthesized using a well-known model_Portilla & Simoncelli, 2000) and phase-randomized noise. We trained two macaque monkeys to judge whether a sample texture (presented for 500 ms in the near periphery) more closely resembled a fully naturalistic or phase-randomized texture. To enable a direct comparison of neuronal and behavioral sensitivity, we asked the monkey to discriminate the texture type (chosen from a set of five) for which a concurrently recorded neuron showed maximal selectivity. Both animals

performed the task well, with discrimination thresholds rivaling those of human observers. Under these conditions, some V1 neurons (20/72) and many V2 neurons (44/87) were tuned for naturalness. Selectivity for naturalness evolved with a time course that differed across areas. In V2, selectivity emerged early and peaked 50 ms after the initial transient. In V1, selectivity was initially absent, but increased gradually over 400 ms. Ideal observer analysis of neuronal responses revealed that single V1 and V2 neurons carried much less information about texture naturalness than the animals' behavioral reports. On average, psychophysical sensitivity exceeded neuronal sensitivity by a factor of 12 in V1 and a factor of 8 in V2. Moreover, fluctuations in the activity of single V2 neurons across repeated presentations of the same stimulus did not predict fluctuations in behavioral choice. Together these results thus suggest that texture perception arises from the combined activity of many V2 neurons.

Title: Interaction between macaque face patches and border-ownership cells in response to natural face stimuli and ambiguous contours

Authors: *J. K. HESSE, P. BAO, D. Y. TSAO;
Biol., Caltech, Pasadena, CA

Abstract: Segmentation and recognition of objects in a visual scene are two interdependent problems that are hard to solve separately from each other. When trying to segment an ambiguous scene, it is helpful to already know the present objects and their shapes. However, for recognizing an object in clutter, one would like to consider its isolated segment alone to not get confounded by features of other objects. The border-ownership cells found by von der Heydt and colleagues [1] appear to play an important role in segmentation, as they are consistently selective to the side-of-figure of artificial stimuli. The present work aims to understand the interaction of border-ownership cells in retinotopic cortex and face-selective neurons in inferotemporal cortex in response to natural face stimuli. Using fMRI we first mapped retinotopy and selectivity for border-rich vs border-less stimuli to target border-ownership cells in macaque dorsal V2 and dorsal V3. Guided by this mapping we recorded simultaneously from border-ownership cells and fMRI-identified face patch MF while the monkeys passively fixated on stimuli containing faces

in isolation, overlapping faces and faces with locally ambiguous/illusory contour. We found that cells which responded consistently to the side-of-figure of artificial stimuli used by von der Heydt and others also tended to respond consistently to faces in isolation and overlapping faces. The response amplitude to faces with locally ambiguous/illusory contours was much weaker but still consistent. We are exploring the time course of information about object category in face patches and border-ownership in V2/V3 to test the hypothesis that feedback from IT might aid the formation of a surface representation of objects in retinotopic cortex, which would allow selection of that object for detailed identity recognition. 1. Title: Combinatorial shape logic in ventral pathway visual cortex

Authors: *S. H. SOKOL, C. E. CONNOR;
Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD

Abstract: Categorical object recognition is remarkably robust to wide shape variations. This implies highly effective neural algorithms for abstracting consistently diagnostic combinations of shape properties. Here, we observed operations of this kind in anterior ventral pathway visual cortex of monkeys trained to discriminate letter-like shape categories in a matching task. Each category was defined by its medial axis topology (in the sense that the letter “F” is defined by a rightward L-junction at the top and a rightward T-junction near the middle). Otherwise, shapes varied widely in the lengths and widths of medial axis components, similar to variations in letter-shape across fonts. The shape categories were also mutually confusable, because they shared partial local structures. Learning a new shape category to a criterion of 85% correct performance required approximately a month of training. Following training, we analyzed neural shape coding in anterior inferotemporal cortex (AIT). A sub-fraction (70/528; 13%) of neurons in the +8-20 anterior-posterior range were significantly responsive to one or more task stimuli. To characterize shape coding precisely, we used a genetic algorithm to guide sampling of neural responses to stimuli spanning a huge domain of complex medial axis structures, varying in medial axis topology and in length, width, and orientation of medial axis components. The goal

of this procedure was to sample the response range of the neuron densely enough (with 400-1000 stimuli) to constrain a quantitative model of how shape parameters produce spike rate responses. Medial axis structures characteristic of trained stimuli emerged spontaneously from this evolutionary procedure, reflecting the effects of category discrimination learning on neural tuning in AIT. More specifically, many neurons signaled task-diagnostic logical combinations of shape fragments, representing both “and” and “not” operations. That is, their response functions combined excitatory and inhibitory tuning components that together defined consistent distinctions between trained categories. To verify the specificity of these tuning changes, we compared diagnostic value between trained stimuli and novel, untrained stimuli formed by recombining partial structures from the trained stimuli. This comparison showed that the diagnostic value of AIT response functions was specific to the trained stimuli. Our results suggest that robust object recognition depends in part on explicit, logical analysis of shape property combinations in ventral pathway visual cortex.

Title: Information-facilitating noise correlation in area V4 for natural images

Authors: ***S. GUAN**, R. XIA, D. SHEINBERG;
Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: The population code serves as the essential link between individual neuron’s properties and the functionality of a brain region. A fundamental question about the population code is whether and how the population differs from just a collection of independently functioning neurons. The pairwise shared noise variability of spike counts, or noise correlation, is an easily accessible and potentially powerful measure of non-independent component of population activity. Assessing the role of noise correlation in a population code is not trivial, and the literature includes multiple, often conflicting, perspectives. This is partly due to how noise correlation is experimentally quantified (Cohen & Kohn, 2011), and partly to how its impact is evaluated. In the present study, we attempted to address these discrepancies and to more objectively assess noise correlation and its role in visual coding. We used a 32-channel semi-chronic microdrive array to record spiking activity from area V4 of a macaque monkey in a

passive viewing task. Our study differed from previous investigations in four primary respects: 1) We used complex natural images as visual stimuli, instead of artificial patterns with limited variability, to better approximate signal correlation of natural vision, which may affect the role of noise correlation theoretically (Averbeck, Latham, & Pouget, 2006); 2) for every neuron pair, we quantified noise correlation independently for each stimulus rather than using the mean correlation, so as to preserve the stimulus-dependent modulation of correlation, which can be beneficial for coding (Ponce-Alvarez, Thiele, Albright, Stoner, & Deco, 2013); 3). The estimation of noise correlation was regularized with limited number of hidden factors and cross-validated, to prevent over-fitting that could lead to spurious results when evaluating the impact of noise correlation. 4) We evaluated the coding performance using the likelihood ratio and Shannon information based on a multi-variant Gaussian model, a maximum-entropy and minimal-assumption modal taking noise correlation in to account. Results from our recordings suggest that the stimulus-dependent noise correlation improves discrimination of natural stimuli in V4 population, while stimulus-averaged noise correlation does not. This provides direct evidence of an information-facilitating role of noise correlation in a naturalistic viewing situation.

Title: Contrasting 3D shape coding strategies for objects and environments

Authors: *C. E. CONNOR[1], S. VAZIRI[2];
[1]Krieger Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD; [2]Krieger Mind/Brain Inst., Johns Hopkins Univ., Baltimore, MD

Abstract: We recently reported that the ventral, object-processing pathway of macaque monkey visual cortex contains some neurons that respond more strongly to large-scale, scene-like environmental stimuli (Vaziri et al. 2014, *Neuron* 84: 55-62). Here, we compared 3D shape coding of objects and environments in anterior ventral pathway. We studied individual neurons in the ventral bank of the superior temporal sulcus and the lateral convexity of the inferotemporal gyrus. We used a genetic algorithm to guide sampling of responses to abstract 3D shapes that ranged continuously from small objects to large environments extending beyond the 77º X 61º display screen. The first generation of shape stimuli was random. Successive stimulus

generations were populated by partially morphed descendants of ancestor stimuli from preceding generations. Ancestor fitness (probability of producing descendants) was a function of average neural response rate. The overall goal was comprehensive sampling of the neuron's response domain with 400-600 stimuli. To analyze neural coding, we parameterized stimulus shape in terms of 3D position, 3D surface orientation, maximum and minimum (principal) surface curvatures, and 3D orientation of minimum curvature (which captures orientation of extended edges and corners). Most neurons exhibited a strong, significant difference in responsiveness to objects vs. environments. Consistent with previous results, the shape coding range for a typical object-responsive neuron was defined by a specific configuration of mainly convex surface fragments in object-centered coordinates. In contrast, the shape coding range for a typical environment-responsive neuron comprised diverse rectilinear shape elements, linked by their orientation relationships: large planar surfaces, long exterior edges, and long interior corners, at parallel, orthogonal, and antipodal 3D orientations. Thus, these neurons integrated disparate shape cues consistent with a common 3D reference frame, typically oriented within about 30º of eye/head-centered vertical. This eclectic coding strategy could support robust perception of object/observer relationships to rooms, buildings, ground planes, and the direction of gravity.

Title: Hierarchical sparse coding model and shape representation in V4

Authors: *H. HOSOYA[1], A. HYVÄRINEN[2];
[1]ATR Inst., Kyoto, Japan; [2]Dept. of Computer Sci. and HIIT, Helsinki Univ., Helsinki, Finland

Abstract: Although sparse coding theory has been successful in explaining various receptive field properties in V1, its relevance to higher visual areas has not been well studied. Previously, we investigated such relevance in V2, where we trained a three-layer sparse coding model that took outputs of standard V1 complex cell models, which in turn received natural image patches as inputs. In the resulting model, the third-layer units had excitatory fields combining local orientations that were either similar (iso-oriented excitation) or converging to a single spatial

point (convergent excitation), together with various types of inhibitory fields. We further showed that those units seemed to be related to contour, texture, or corner features in natural images and that the model reproduced three tuning properties specific to macaque V2, in a manner qualitative, quantitative, and stable across model variations. Here, we extend the previous model by adding another layer performing a similar sparse coding computation. In the extended model, the fourth-layer units were qualitatively similar to the third-layer units, representing iso-oriented or convergent excitations with various inhibition types, except that the variation in the inhibitory fields appeared to be more complicated. In addition, the model reproduced two shape tuning properties in macaque V4, again qualitatively, quantitatively, and stably across certain model variations: 1) position-specific curvature tuning reported by Pasupathy and Connor (2001) and 2) spatial invariance for straight and low-curvature-tuned units suggested by Nandy et al. (2013). Although the above model had no unit representing smooth curves unlike often suggested in prior experimental studies of V4, a variant of the model trained only with face image patches did contain such units in both third and fourth layers. Taken together, a hierarchical model that performs sparse coding of natural images in a bottom-up way produces representations that are rather simple but able to explain physiological properties not only in V2 but also in V4.

Title: The tuning of human visual cortex to variations in the 1/f amplitude spectra of synthetic noise images

Authors: *Z. J. ISHERWOOD[1,2], M. M. SCHIRA[3,2], B. SPEHAR[1];
[1]Sch. of Psychology, Univ. of New South Wales, Sydney, Australia; [2]Neurosci. Res. Australia, Sydney, Australia; [3]Sch. of Psychology, Univ. of Wollongong, Wollongong, Australia

Abstract: Natural scenes are characterised by a specific distribution of spatial frequencies (SF) and associated luminance intensities, known as the $1/f^{\alpha}$ amplitude spectrum. For most natural scenes, this relationship is characterised by a power function with a slope between 1.2 and 1.4 and is thought to underlie both the scale invariance and fractal properties of natural scenes. Since the visual system has evolved in a natural environment, it is theorised to be optimally tuned to such statistical regularities. However, the neural response to natural SF distributions has not been explored in great detail. Methods Functional magnetic resonance imaging (fMRI) was used to

investigate responses in early visual cortex (V1, V2, and V3) to a variety of synthetic noise images. We used a range of 1/f slopes (0.25, 0.75, 1.25, 1.75, 2.25) across two RMS contrast levels (10% and 30%) (Experiment 1) and two image types (greyscale and thresholded) (Experiment 2). Stimuli were presented in a short block design (6 seconds on with a sequence of 5 images with a 200ms ISI), across two task conditions: aesthetic rating and central visual search. The BOLD response profile was analysed using a general linear model, and the β weights were then analysed using an ANOVA. Results and Discussion The ANOVA revealed a significant main effect of slope in both experiments (01: $F_{4,11} = 29.349$, $p < 0.000$; 02: $F_{4,10} = 11.726$, $p < 0.000$). We found the BOLD response profile to resemble an inverted U-shape peaking for images with "natural" 1/f slopes (1.25) across visual areas, task conditions, contrast levels, and image types. This suggests that the visual system is tuned to statistical properties such as the natural 1/f amplitude spectrum. To gain further insight on the tuning of the visual system to the 1/f amplitude spectrum, we investigated responses as a function of eccentricity. We found a significant main effect of eccentricity in both experiments (01: $F_{4,11} = 5.083$, $p = 0.002$; 02: $F_{4,10} = 29.620$, $p < 0.000$) whereby cortical responses from the fovea to the periphery revealed the peak of the response profile to shift from the shallowest to the steepest slope, across both contrast levels, image types, and task conditions; presumably reflecting the known preference for high SFs in the fovea and low SFs in the periphery. In conclusion, we find the response profile we obtain across eccentricities (an inverted U peaking at a slope of 1.25) to be consistent with the pooling of responses across low, medium, and high SF channels, providing further insight into the neural mechanisms underlying the tuning of visual cortex to natural scene statistics such as the 1/f amplitude spectrum.

Title: Spatial frequency selectivity in macaque V1, V2 and V4 revealed by intrinsic optical imaging

Authors: *Y. LU, H. GONG, J. YIN, Z. CHEN, I. M. ANDOLINA, W. WANG;
Inst. of Neuroscience, CAS, Shanghai, China

Abstract: One paradox in primate vision concerns the increasing complexity of encoded features while spatial frequency (SF) selectivity decreases drastically along the visual hierarchy. We know V1 holds the highest SF selectivity for fine spatial analysis, however the comparative SF processing in different functional stripes of V2 as well as in the downstream V4 is less clear. By simultaneous intrinsic optical imaging of macaque V1, V2 and V4, we quantitatively measured the population responses across these visual areas to sine-wave gratings with various SFs. As expected we found that the SF selectivity was the highest in V1 while most regions in V4 exhibited the lowest SF selectivity. The population responses of V1, V2, and V4 were subsequently confirmed by single-unit recordings in awake macaques. Compared with V1 and V4, V2 exhibited the strongest population response magnitude. We further investigated the SF selectivity across V2 functional stripes and found that the SF selectivity in thick stripes were lower than that in both thin and pale stripes. No significant SF difference was found between the thin and pale stripes. Our findings on the distinct SF selectivity across simultaneously imaged V1, V2, and V4 sheds lights on the spatial analysis along the visual hierarchy, which help to further our understanding and electrophysiological studies as well as computational modelling of the integration of local spatial features to form global representations.

Title: Responses of V4 neurons to stimuli defined by inhomogeneous luminance contrast

Authors: *M. MOSHTAGH KHORASANI, W. BAIR, A. PASUPATHY;
Biol. structure, Univ. of Washington, Seattle, WA

Abstract: It is well-established that V4 neurons are sensitive to visual form. We have recently demonstrated that many V4 neurons are also sensitive to stimulus contrast polarity and can be broadly classified into four categories, Bright, Dark, Contrast and Equiluminance cells, based on their preference for the luminance contrast of shapes relative to a uniform background (Bushnell et al, 2011). Because these categories are based on homogeneous stimuli, we do not know how these cells respond to more naturalistic stimuli, where boundaries are seldom defined by a fixed

luminance contrast, and whether the different cell classes have different functional roles for encoding objects. Using a set of stimuli defined by inhomogeneous luminance contrasts, here we investigate whether preference for contrast polarity in V4 neurons is simply based on the average signed contrast along the stimulus boundary or if the contrast at key angular positions dictate responses. We also relate the spatial characteristics of contrast preference to those of form preference in single neurons to determine whether these preferences are the result of a single unified computation. We studied the responses of 54 V4 neurons in an awake fixating macaque monkey to isolated shape stimuli presented in the preferred color of the cell against an achromatic background. Local luminance contrast along the boundary of the shape was modulated by a Gaussian region of contrasting luminance that varied in size, mean luminance and position along the boundary. We studied both cases, where the Gaussian spotlight was exclusively outside or exclusively inside the stimulus boundary. Results from a 2-way ANOVA suggest that, for a majority of neurons, either just the position of the Gaussian spotlight or the position and the luminance contrast of the spotlight, has a strong influence on the responses of the neuron. Furthermore, in many neurons, the influential feature position for contrast polarity coincides with the position of the preferred shape feature. These results support the idea that the preferences for contrast polarity and shape feature along the boundary may arise from a common local computation.

Title: Convergent integration of various local orientations to form a global orientation from V1 and V2 to V4 in macaque

Authors: ***J. YIN**, Y. LU, Z. CHEN, H. GONG, Y. LIU, I. M. ANDOLINA, X. LI, W. WANG; Inst. of Neuroscience, CAS, Shanghai, China

Abstract: A central question in vision is how the cortex integrates local cues to form global representations along the visual hierarchy. Orientation is a key feature of a given contour and the generation of orientation selectivity offers a great window to explore the neural mechanisms underlying visual information integration. The orientation selectivity in V4 is believed to be inherited through successive convergent projections from V1 and V2 neurons with the same orientation preference. However, for a stimulus like the zebra crossing, what happens when the

global orientation and the local orientations are not matched? We investigated this question of orientation integration by simultaneous optical imaging of V1, V2, and V4 and subsequent single-unit recordings in anesthetized and awake macaques, respectively. We found that for a given orientation stimulus, the orientation domains in V1, V2, and V4 all exhibited the same orientation preference to the stimulus. However, for a global orientation stimulus defined by different local orientations, only V4 encoded the global orientation whiles V1 and V2 signaled the local orientations, suggesting V4 can integrate feed-forward inputs from V1/V2 with different orientation preferences. These population results were later confirmed by electrophysiological recordings as 85% neurons in V4, in contrast to only 28% neurons in V2 and few neurons in V1, encoded the global orientation of such stimuli. Our results demonstrate that V4 orientation domain integrates feed-forward inputs not only from V1/V2 orientation columns with the same preference, but also from those with different preferences. Our findings thus reveal the orientation integration from local into global across different visual cortices.

Title: How do neurons in macaque visual cortex represent a high-dimensional perceptual space?

Authors: ***J. D. VICTOR**[1], Y. YU[1], D. J. THENGONE[1], J. WITZTUM[1], E. I. NITZANY[1,2], K. P. PURPURA[1];
[1]Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY; [2]Program in Computat. Biol. & Med., Cornell Univ., Ithaca, NY

Abstract: Perceptual spaces form the substrate for discrimination, categorization, working memory, and many other processes, and are thus a key element of mid-level vision. Color, an archetypal perceptual space, has three dimensions - but many others, such as faces and textures, have a much higher or undefined dimensionality. It is unclear how higher dimensional spaces are represented within the brain and how their representation supports further sensory processing and perceptual judgments. To probe the neural mechanisms underlying such spaces, we characterized responses of single neurons in macaque cortex to a well-characterized 10-dimensional domain of local elements of form. This space consists of black-and-white textures. Its 10 axes are determined by image statistics describing black/white balance and nearest-neighbor correlations

(Victor and Conte 2012). The space is a useful model because it captures the informative local image statistics of natural scenes (Tkačik et al., 2010). Human perceptual sensitivities are aligned to the most informative axes in the space (Hermundstad et al., 2014). Moreover, psychophysical studies suggest that this perceptual space is represented in two ways (SfN 2014): in an opponent fashion, used for detecting form near threshold, and in a distributed one, used for suprathreshold tasks. We made multi-tetrode recordings (177 sites) in V1 and V2 of 11 anesthetized and paralyzed macaques and measured neuronal tuning along and between axes in the space. Most neurons responded to multiple kinds of image statistics. Responses to 1- and 2-point statistics were common (~50%) in V1 and V2. Responses to 3- and 4-point statistics were rare (~10%) in V1, but more common (~20%) in V2, especially in the supragranular layers. Most responses indicated opponent-like tuning, but were often highly asymmetric - with a bias towards either positive or negative values of the image statistic. There was a strong bias towards sensitivity to darks in both V1 (Yeh et al., 2009, Kremkow et al., 2014) and V2. Responses were typically larger to mixtures of image statistics (i.e., along oblique directions between axes in the stimulus space) than to individual statistics (i.e., along the axes). These preferred directions varied widely across neurons, with no indication that tuning was clustered along cardinal axes. A few neurons responded in a non-monotonic fashion to variation in image statistics, suggesting that they participate in a distributed representation of the perceptual space. In sum, the study suggests that high-dimensional perceptual spaces may be represented via neurons with a wide range of preferred tunings that capture the dimensions of the spaces.

Title: Neural response variability in rat visual cortex

Authors: ***A. I. JASPER**[1,2], D. SUCHANEK[1,2], C. BOUCSEIN[3], A. AERTSEN[1,2], A. KUMAR[2,4];

[1]Fac. of Biology, Univ. of Freiburg, Freiburg, Germany; [2]Bernstein Ctr. Freiburg, Freiburg, Germany; [3]Multi Channel Systems MCS GmbH, Reutlingen, Germany; [4]Sch. of Computer Sci. and Communication, Royal Inst. of Technol., Stockholm, Sweden

Abstract: Noise correlations (NC) measure the trial-by-trial co-variability of the spiking activities of two neurons in response to a repeatedly presented stimulus. Previous studies have shown that the strength of these noise correlations depends on several factors, like the distance between the recorded neurons, the similarity of their tuning properties, and the local circuitry (1). Furthermore, NC in layer 4 of the primary visual cortex (V1) of macaques were shown to be significantly lower than in layers 2/3 or 5/6 (2,3). Macaques, and also cats used in similar studies, have a visual cortex with highly structured functional maps, resulting in neighbouring neurons sharing similar tuning properties. Furthermore, neurons with similar preferred orientations but located in different pinwheels are connected via long-range patchy connections. By contrast, rats have a visual cortex without such functional maps and it also lacks long-range patchy connections (4). It is, therefore, unclear whether NC in rats show similar properties as reported for species with structured cortices. Correlations in spontaneous activity in the rat visual cortex were shown to depend on the difference in preferred orientation, rather than on the distance between neurons (5). We further investigated this question by recording spontaneous and visual stimulus-evoked spiking activity in V1 of anaesthetized rats. We found that in layer 2/3 the NC in stimulus-evoked activity are significantly lower than in spontaneous activity ($p<0.002$, Mann-Whitney-test, Bonferroni corrected), whereas layer 4 showed no difference. We also found that NC in layer 2/3 were significantly higher than in layer 4 in both stimulus-evoked and spontaneous activity ($p<0.03$ and $p<0.0001$, same tests). Finally, we found that NC during evoked activity in layer 2/3 decreased with increasing difference in preferred orientation ($p< 0.01$, Kruskal-Wallis-test), whereas no dependency was found in layer 4. Our findings indicate that the neural response variability in rat visual cortex resembles that in species with structured functional maps and long-range patchy connections, suggesting that these features do not play a major role in shaping the neural response variability. Title: Divisive normalization in monkey inferotemoral cortex is biased in favor of familiar images

Authors: *T. MEYER, S. RAMACHANDRAN, C. R. OLSON;
CNBC, Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Images rendered familiar through repeated passive viewing over many days elicit weak neuronal responses in monkey inferotemporal cortex. Weakening arises from the fact that the population response, although it begins at normal strength, is sharply truncated at around 100 ms. In the experiment described here, we set out to determine whether weakening of the response is accompanied by a disadvantage in the competition for neuronal representation under conditions in which a familiar image and a novel image are presented simultaneously. We first gave the monkey prolonged exposure to 16 images of objects. While the monkey directed gaze at a central fixation spot, the 4°x 4° image was presented at an eccentricity of 4.6° in either the upper or lower visual field contralateral to the hemisphere destined for recording. Eight of the images were always presented at the upper location and the other eight were always presented at the lower location. Over the course of two months, the monkey experienced each image 830 times. During recording at each site, we selected for use two images that had been presented in the same quadrant during familiarization training and two session-specific novel images. The familiar images were presented only in the trained quadrant and the novel images only in the complementary quadrant. On interleaved trials, we recorded responses to each of the four images presented as a singleton and to each of the four combinations obtained by pairing a familiar image with a novel image. Each display lasted 600 ms. Upon analyzing data from 31 neurons in one monkey, we found that familiar and novel images elicited highly distinctive responses. The responses to familiar images in particular took the form of an oscillation phase-locked to stimulus onset at a frequency of around 5 Hz. To determine whether a neuron preferentially represented the familiar or the novel image during simultaneous presentation, we first determined which familiar image and which novel image elicited stronger firing during singleton displays. Then, using a best-minus-worst measure, we assessed the strength of each representation. We found that familiar images were represented markedly more strongly than novel images. We conclude that familiar images, although they elicit weak responses when presented alone, actually exhibit a competitive advantage relative to simultaneously presented novel images.

Title: An approach to the study of mid-level vision in the alert macaque monkey

Authors: *K. P. PURPURA, J. L. BAKER, J.-W. RYOU, J. D. VICTOR;
Feil Family Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY

Abstract: Early visual cortex in primates transforms the activity in the retinogeniculate pathway into signals that higher cortical areas use for making inferences about the surfaces, objects, and movements in the local environment that guides much of behavior. A complete description of the nature of these transformations at the mid-level of the visual cortical hierarchy (V1, V2, V3 and V4: V1-4) remains a central goal of visual neuroscience. V1-4 are well-defined neuroanatomical modules, each with distinct neurophysiological properties, yet these regions are also tightly interconnected and are nearly simultaneously active following the appearance of an image on the retina. Thus, to carry out an adequate investigation of mid-level vision in non-human primates it is necessary to collect neurophysiological signals, at both the single-unit and local population level, simultaneously from V1-4 and to do so in the context of visually-guided behavior. It also necessary to utilize sets of visual stimuli that will allow for the testing of hypotheses about the computations that underlie the transformations implemented in V1-4. We have developed an approach to the study of mid-level vision that can meet both challenges. To obtain recordings simultaneously from V1-4 we implanted a 32-microelectrode microdrive (GMR, Gray Matter Research Bozeman MT) above the lunate sulcus of a macaque monkey. Due to the folding of the cortex in and around the lunate, microelectrode tracks directed from the dorsal surface, from within an area several millimeters in diameter centered on the sulcus, are able to sample multiple sites across V1-V4 (Gattass et al. 1988). The geometry of the sulcus places many of the sites of interest at a range of depths with respect to the cortical surface, which the GMR allows us to access. We used a set of visual stimuli that provide a general framework for investigating the neural processing across V1-4. The stimuli consist of black-and-white textures that are drawn from a domain specified by image statistics that determine black/white balance and nearest-neighbor correlations (Victor and Conte 2012). These stimuli have been well-characterized psychophysically, capture informative aspects of natural scenes (Hermundstad et al 2014) and have used been used recently to determine how V1 and V2 contribute to the encoding of local elements of form and shape (Yu et al. 2015). Our preliminary studies with the approach described here show that stable, and well-isolated multi-area neural recordings can be obtained over months from V1-4, and that both inter-regional interactions and local activity carry signatures for stages of processing in mid-level vision.

Title: Spatially extended models of visual cortical networks with balanced excitation and inhibition

Authors: ***C. EBSCH**;
Univ. of Notre Dame, South Bend, IN

Abstract: In the primary visual cortex (V1), synaptic connection probabilities depend on location and functionality [1]. Connectivity structure in V1 is well-studied, but the relationship between between connectivity, network dynamics and visual coding remains an open problem. A clue to understanding visual cortical coding comes from the observation that V1 circuits operate in an inhibitory-stabilized or balanced regime in which strong recurrent excitation is balanced by strong inhibition [2,3]. We study the implications of balanced excitation and inhibition on visual coding using spatially extended models of visual cortical circuits. We extend the mean-field theory of balanced networks to account for arbitrary spatial structure. We find that, in the balanced state, firing rate profiles are determined by the solution to a linear Fredholm integral equation. Modeling the spatial structure of V1 circuits reveals that excitatory-inhibitory balance promotes the sharpening of orientation tuning curves and produces surround-suppression dynamics even when inhibitory neurons project more locally than excitatory neurons. We supplement our mean field analysis with simulations of integrate-and-fire network with biologically realistic parameters. [1] Bosking, W. H., Zhang, Y., Schofield, B., & Fitzpatrick, D. (1997). Title: Common modules of visual responses to naturalistic movies across macaque and marmoset an fmri study

Authors: *C.-C. HUNG[1], B. E. RUSS[2], J. R. DAY-COONEY[2], C. C. YEN[3], R. A. BERMAN[2], L. NOTARDONATO[3], A. C. SILVA[3], D. A. LEOPOLD[2];
[1]NINDS, NIH, Gaithersburg, MD; [2]NIMH, [3]NINDS, NIH, Bethesda, MD

Abstract: The ventral visual pathway of the primate brain supports important aspects of high-level vision, including those pertaining to social perception. Establishing the evolution of functionally defined subareas of the ventral pathway, as well as their homology across different primate species, is of great value toward understanding the organizational principles of the visual brain. The specialization for particular visual stimuli in ventral stream visual areas has been studied in great detail, generally using flashed static images or short clip of movement sequences. Recently, studies involving free viewing of extended, naturalistic videos have begun to complement this approach and reveal additional aspects of the brain's functional organization (Russ and Leopold, 2015). As it is straightforward to present the same video content to a wide range of experimental subjects, this set of methods has opened new doors for comparison of functional specialization across species (Mantini et al., 2012). Previously, we presented static images to the common marmoset to demonstrate the existence of multiple face-selective patches that bore a strong resemblance to those known to exist in the macaque (Hung et al., 2015). The present study investigates possible homological correspondence among these and other functionally defined visual areas based on whole-brain fMRI collected from both species watching the same set of videos. We analyzed the results from three perspectives. First, feature-based mapping revealed a broadly similar pattern of functional maps that were driven by video features such as image contrast, motion energy, and face content. Second, following Mantini et al., we created function maps based solely on the shared voxel time courses using independent component analysis (ICA). While these maps were generated without the knowledge of the movie contents in a data-driven way, they largely recapitulated the feature maps and suggest several parallel information processing stream along the ventral pathway. Finally, we used the relative weighting (loading) of the independent components to interrogate specific functional subregions, essentially generating a fingerprint of coefficients for a given voxel or region of interest. Initial results using this method suggest that individual face patches within each species have different fingerprints, with unique relative contributions of IC's associated with non-face attributes, such as motion energy and image contrast. These methods may be able to establish

putative correspondences between the specific face patches in marmosets, macaques, and humans.

Title: Spatiotemporal properties of neurons in the ventral stream of the cat visual cortex

Authors: *B. O. SOUZA[1], C. CASANOVA[2];
[1]École d'Optométrie, École D'Optométrie, Univ. De Montréal, Montreal, QC, Canada; [2]Ecole d'Optometrie, Ecole D'Optometrie, Univ. De Montreal, Montreal, QC, Canada

Abstract: The visual cortex is organised in a hierarchical manner in which higher cortical areas integrate different inputs in order to process complex visual features. Area 21 in the cat is considered as a homolog of area V4 in primates and is known to play an important role in form detection. While responses of area 21a neurons have been described in previous studies, there is little information, if any, about the spatiotemporal properties of the receptive fields (RFs) of cells in this cortical area. The aim of the present study was to determine the spatiotemporal profiles of 21a neurons. Visual stimuli were displayed on a screen subtending 110 x 90 deg of visual field. A white noise stimulus was used to characterize the spatio-temporal characteristics of area 21a receptive fields and consisted in a pseudo-randomized sequence of bright and dark squares (4x4 deg) briefly presented (35 ms) against a gray background. Full field drifting sinusoidal gratings with varying directions, spatial and temporal frequencies were also used to assess neuronal basic properties. First-order spatiotemporal profiles of 50 neurons were obtained. For most neurons, bright subfields were larger than dark ones (239.95 ± 26.5 vs 141.39 ± 13.2 deg2, Student's t test, $p<0.001$) and, for most cells (45/50), subfields were overlapping (33 ± 2% overlap), The average maximal spike probability of bright subfields was greater than that for dark subfields (0.043 ± 0.0061 vs 0.022 ± 0.0032, $p<0.001$). In the time domain, the activity of most subfields (45/50) overlapped but the bright subfields'activity peaked earlier than that of their dark counterpart (61.42 ± 8.68 vs 87.04 ± 12.3 ms, $p<0.001$). The spatio-temporal profiles of area 21a neurons receptive fields are considerably different from those described in the cat motion cortical area (i.e. the posteromedial part of the lateral suprasylvian cortex), supporting a distinct role of this cortical area in visual processing.

Title: Bottom-up and top-down priorities modulate responses in macaque visual cortex

Authors: ***P. C. KLINK**[1], J. A. M. LORTEIJE[2], B. VAN VUGT[1], P. R. ROELFSEMA[1]; [1]Netherlands Inst. For Neurosci., Amsterdam, Netherlands; [2]Fac. of Science, Swammerdam Inst. for Life Sci., Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: Goal-directed behavior requires selection of an appropriate response from among a broader repertoire of potential actions. Priority signals like bottom-up stimulus salience and top-down reward expectation influence this response selection process. While bottom-up saliency is often regarded a built-in feature of the visual system, active suppression of salient distractors has been reported in parietal cortex after extensive training (Ipata, Gee, Gottlied, Bisley, & Goldberg, 2006). Here we investigate the neural signature of bottom-up and top-down priorities for color and shape in macaque visual cortical area V4. We recorded multi-unit activity from two monkeys while they performed a visual search task in which they identified the odd-shape-out, either a circle among five squares or a square among five circles, by making an eye movement towards it. All stimulus shapes had the same color, red or green, except for one of the non-targets. This color singleton was drawn in the other color, making it a pop-out salient distractor. Animals were randomly rewarded with a large or small juice reward for correct target selection and stimulus color schemes were randomly switched on subsequent trials. On correct trials, neuronal responses to target shapes in the receptive field were enhanced relative to non-targets, whereas responses to salient distractors were suppressed. This priority-based response modulation was apparent approximately 150 ms after stimulus onset, which is considerably later than previously shown distractor suppressions in parietal cortex (Ipata et al., 2006) suggesting that top-down mechanisms might underlie the effects in visual cortex. Response times were furthermore negatively correlated with neuronal target responses, implying that neuronal target

facilitation improves target detection and response selection performance. The relatively little error trials in which animals selected the salient distractor instead of the target were characterized by weaker responses to target stimuli and markedly stronger responses to distractors. We did not observe any differences on behavioral or neuronal responses when we categorized trials according to preceding reward level and color changes, suggesting that the suppression and avoidance of salient distractors constitutes a higher priority for these highly trained animals than the amount of reward associated with a particular color. We conclude that the neuronal representation of bottom-up pop-out stimuli in visual cortex can be suppressed by top-down priority signals to facilitate goal-directed behavior.

Title: V2 neurons during free-viewing of static figure arrays: Surge of contour grouping at target of impending saccade

Authors: *L. A. ZHANG[1], R. VON DER HEYDT[2];
[2]Zanvyl Krieger Mind/Brain Inst., [1]Johns Hopkins Univ., Baltimore, MD

Abstract: Neurons in early visual cortex are selective for local visual features but their responses can also be influenced by border ownership and top-down selective attention. Most of what we know about the function of these neurons is based on neurophysiological studies in monkeys that hold their direction of gaze fixed while isolated visual stimuli are presented. However, during natural behavior, primates visually explore cluttered environments by changing gaze direction several times each second. We have previously proposed that border-ownership selectivity is best explained by a model in which contour selective neurons in low-level visual cortex are enhanced by feedback from grouping cells at a higher level. Object-based attention is thought to target these grouping cells. Thus, when a figure becomes the target of a saccade, this theory predicts that responses representing the figure contour should be enhanced, but only in neurons whose border ownership preferences point to the interior of the figure, because these are connected to the targeted grouping cell. We used a foraging task in which the monkey chooses where to look and when. Geometrical figures were displayed and the monkey was rewarded for

fixating the center of a figure for at least 200ms. In each trial an array of 10 figures (5 squares and 5 triangles) was presented, one of which was randomly associated with reward, and a cue informed the monkey whether it was a square or a triangle. The monkey sequentially fixated the cued shapes (and sometimes also the other shapes) in search for reward. Single neurons were recorded from area V2. After mapping the receptive field of a cell, the figure array was constructed so that fixating the center of a figure would, in most cases, bring an edge of another figure into the receptive field. We show that feature coding, border ownership selectivity and top-down modulation can be measured reliably with this method despite the fast pace of fixations (mean time between saccades about 350ms). Our results imply that contour grouping occurs in parallel for the objects in the display. Contour responses were further enhanced when the figure at the receptive field was the target of an impending saccade, but only in neurons with border-ownership preferences pointing to the interior of the figure, in support of the feedback grouping model. Thus, saccades are preceded by bursts of activity in neurons representing the contours of the selected object. We conclude that border ownership selectivity is the signature of grouping mechanisms that are fundamental for the individuation and perception of objects.

Title: Border ownership tuning predicts effective connectivity between V4 and V1 in macaque visual cortex

Authors: *M. W. SELF[1], D. JEURISSEN[1], A. F. VAN HAM[1], M. SENDEN[2], P. R. ROELFSEMA[1];
[1]NIN, Amsterdam, Netherlands; [2]Maastricht Univ., Maastricht, Netherlands

Abstract: The responses of cells in V1 are modulated by the perceived structure of the visual scene. Responses are higher on regions perceived as figures and lower on the background, an effect known as figure-ground modulation (FGM). This enhanced firing on figural surfaces is thought to group together different parts of the same object in perception. The mechanisms by which this modulation arises are unknown but they are thought to be due to feedback from higher

visual areas. Here we develop a new model of FGM in which connections between higher visual areas and V1 are governed by the border-ownership preferences of the cells in higher visual areas. Border-ownership (BO) is a property shown by many cells in V2 and V4 where the response of the cell to a boundary is modulated according to which side of the boundary is 'owned' by the figure. This property is thought to be important for grouping together the boundaries that belong to the same object. It is currently unknown how this modulatory effect relates to FGM. We propose that BO cells send feedback to V1 in the direction of their preferred side of figure while suppressing activity on the non-preferred side. We simulated a network of cells connected in such a way and demonstrate that it can reproduce the patterns of FGM observed in V1 for many types of figures. The model makes a key prediction that cells in higher visual areas will be more strongly connected to V1 cells with RFs located on their preferred side of ownership. We tested this prediction by making simultaneous multi-unit recordings from V1 and V4 of an awake behaving monkey. We observed many multi-units in V4 with strong BO preferences suggesting that cells with similar BO preferences may be spatially clustered in this area. We estimated connectivity using spontaneous noise correlations. We found that, as predicted by the model, noise correlations were strongest when the BO tuning pointed towards the spatial location of the V1 RF. Using the agreement between the BO tuning and the location of the V1 RF and the distance between the RF centers we could account for over 50% of the variance in spontaneous noise correlations between V4 and V1. Noise correlations were also modulated by figure-ground structure. Critically, noise correlations between V4 and V1 were highest when the V1 RF fell on a figure and the V4 RF was stimulated by its preferred boundary raising the possibility that the perceived structure in the scene enhances the effective connectivity between V4 and V1. The data suggest that FGM may arise through interactions between BO tuned cells in higher visual areas and cells in V1 leading to labeling of the surfaces of figures with enhanced firing-rates.

Title: The development of figure-ground segregation across time and space in the visual cortex of the macaque monkey

Authors: *D. JEURISSEN, A. F. VAN HAM, M. W. SELF, P. R. ROELFSEMA; Netherlands Inst. For Neurosci., Amsterdam, Netherlands

Abstract: The primate visual-system is well equipped to quickly recognize objects and segregate objects from their background. As visual information is sent to higher cortical areas, the complexity of the tuning of cells in the subsequent stages increases. Shape selectivity in ventral-stream areas is present very soon after stimulus onset. Some 50-60ms later, cells in primary visual cortex show an increased firing rate when their receptive field is on a figure compared to when it is on a background. This modulatory effect of contextual stimuli placed outside the classical receptive field is known as figure-ground modulation. Mid-level visual areas may play a crucial role in linking the information about the shape and identity of an object in ventral stream areas with the high-resolution information available in early visual areas. It has remained unclear how cells in mid-level visual-areas mediate interactions between lower and higher visual areas for figure-ground perception, what their degree of spatial selectivity is, and how this selectivity develops over time. To address these issues, we recorded multi-unit activity in mid-level visual area V4 in a macaque monkey while it viewed figure-ground stimuli. We mapped out the response to a square of different scales and defined by different cues. The initial responses showed a highly spatially specific response to boundaries. Surprisingly, the same multi-unit signals appeared to have large RFs when mapped with a small luminance defined square. At a later stage the response showed clear preferences for particular boundaries of the square, including cells that responded only to the corners. At even later times, the response surrounding the square became suppressed, creating a Mexican-hat profile. Overall we found little difference in the response profile between texture-defined and luminance defined shapes, suggesting that area V4 holds an abstract representation of the shapes that is relatively independent of low-level features. If the animal was required to make a saccade towards the figure this enhanced the representation of the interior of the figure. We conclude that V4 neurons encode different aspects of visual objects in different phases of their response in accordance with a crucial role in routing information between lower and higher visual areas.

Title: Global scene-interpretation affects figure-ground modulation and contrast perception

Authors: *A. F. VAN HAM, M. W. SELF, D. JEURISSEN, P. R. ROELFSEMA;
Netherlands Inst. For Neurosci., Amsterdam Zuidoost, Netherlands

Abstract: The process of figure-ground segregation requires local analysis of low-level features and global analysis of the visual scene in accordance with the Gestalt rules of visual perception. However, the influence of global scene-interpretation has been debated. Neural correlates of figure-ground segregation have been found in visual areas as early as V1. Neurons in macaque V1 show enhanced responses to figures compared to backgrounds, an effect known as figure-ground modulation (FGM). This suggests that global scene analysis influences activity at the earliest cortical processing stages. However, FGM has typically been measured using relatively small figures and therefore the possibility remains that FGM arises through local computations. Recent studies suggested that the impact of FGM is profound, because it may even influence the perception of contrast. However, also for this effect the possibility remains that it arises through local computations within early visual cortex. To address this issue, we studied whether global Gestalt laws influence perceived contrast in humans and monkeys and whether it causes FGM by recording multi-unit activity in V1 and V4 of monkeys. On each trial, we presented two horizontal strips of texture-defined shapes. One strip without Gestalt cues served as the baseline. In the other strip the Gestalt rules enclosure, convexity, symmetry, or the combination of these three cues induced a figure-ground organization. A contrast discrimination task performed on two superimposed Gabors allowed us to investigate perceived contrast. The behavioral results showed that the humans and monkeys perceived Gabors on figures as higher in contrast than Gabors on the background, suggesting that global scene-interpretation influences contrast perception. In humans, the change in perceived contrast depended on their subjective report of "figureness". These behavioral results were well explained by the neural data in V1 and V4 of the monkeys. We observed enhanced neural activity in V1 and V4 when receptive fields fell on figures compared to backgrounds. FGM occurred earlier in V4 than in V1, suggesting that global scene information from higher visual areas is fed back to lower visual areas to establish FGM. In addition, the Gestalt cues induced FGM of different strengths with strongest FGM when cues were combined, and the strength of FGM predicted the change in perceived contrast. We conclude that global scene-interpretation influences both FGM and contrast perception. These results imply that FGM is a global phenomenon that requires computations beyond the scope of early visual areas and presumably rely on feedback from higher visual areas.

Title: Distinct computational modules for forming central and peripheral parts of a receptive field in monkey anterior inferior temporal cortex

Authors: K. OBARA[1,2], *K. O'HASHI[1], M. TANIFUJI[1,2,3];
[1]Brain Sci. Institute, RIKEN, Saitama, Japan; [2]Dept. Life Sci. Med. Biosci., Waseda Univ., Tokyo, Japan; [3]Dept. Complexity Sci. and Eng., Grad. Sch. of Frontier Sciences, Univ. of Tokyo, Tokyo, Japan

Abstract: A remarkable aspect of object recognition is that we recognize a few objects embedded in a cluttered environment in our daily life.To recognize these objects unambiguously, it would be advantageous to have receptive fields (RFs) as small as the target objects. On the other hand, explanation of translational invariance in object recognition requires RFs to be large. In inferior temporal (IT) cortex of macaque monkeys, previous studies have shown that IT neurons have large RFs (ex, Kobatake and Tanaka, 1994; Op de Beeck and Vogels, 2000). For example, one of the studies with monkeys performing a fixation task showed the mean size of RFs to be as large as 10.3 degree (Op de Beeck and Vogels, 2000). On the other hand, another study reported that RF can be as small as 2.6 degree when monkeys performed a task to recognize a small stimulus presented near the fixation point (DiCarlo and Maunsell, 2003). Based on these findings, we believe that IT neurons have large RFs in a default mode, such as the RFs observed in monkeys with the above fixation task, and that the default mode RFs can be modulated by task demands. Modulation of the default mode RFs may be critical for explaining object recognition in a cluttered environment. Along this line, we have investigated neural circuit mechanisms along the ventral visual pathway for formation of the default mode RFs and modulation of the RFs with spatial attention as a factor associated with task demands. We have already reported that (1) central part of a RF of anterior IT neurons was processed significantly faster than peripheral part, (2) this difference in processing latency did not depend on spatial attention, but (3) the magnitudes of responses at different locations in RFs were modulated depending on the location of spatial attention (Obara, O'Hashi, and Tanifuji, Cosyne Abstracts 2015, Salt Lake City USA.). In the present study, to test whether these properties exist before visual information reaching IT cortex, we examined latency and attentional modulation of V4 neurons with RFs in peripheral and central parts of the visual field respectively. As a result, we found that differences in latency and attentional modulation of magnitude were not observed in V4 neurons. Thus, default mode processing of objects in central visual field and of objects in

peripheral visual field use different computational modules in areas between V4 and anterior IT (potentially, area TEO), and the attention modulates the output gain of the modules.

Abstract: Object categories are recognized at multiple levels of hierarchical abstractions. Psychophysical studies have shown a more rapid perceptual access to the mid-level category information (e.g. human faces) than the higher (superordinate; e.g. animal) or the lower (subordinate; e.g. face identity) levels. Mid-level category members share many features while few features are shared between members of different mid-level categories. To better understand the neural basis of expedited access to mid-level category information we examined neural responses of the inferior temporal (IT) cortex of macaque monkeys viewing a large number of object images. We found an earlier representation of mid level categories in the IT population and single unit responses compared to superordinate and subordinate level categories. The short latency representation of mid-level category information shows that visual cortex first divides the category shape space at its sharpest boundaries defined by high/low within/between group similarity. This short latency mid-level category boundary map may be prerequisite for representation of other categories at more global and finer scales.

Hosp. & Harvard Med. Sch., Charlestown, MA

Abstract: The ventral visual areas play a key role in object recognition and may act as the "object center" in the human brain. However, how the higher-order object information (e.g., category and identity) is extracted in these areas remains elusive: is this accomplished via pooling feedforward input from lower visual areas, or through inter- and intra-areal recurrent interactions? To address this question, here we recorded electrocorticography (ECoG) activity from fourteen epilepsy patients and investigated the spatiotemporal dynamics of object processing in both early visual cortex (EVC) and occipito-temporal cortex (OTC) along the ventral pathway. Each patient was presented 120 images of faces, places, and common objects (categories), which in turn can be subcategorized to male/female faces, houses/scenes, cars /chairs, respectively (classes). Class-specific responses were observed in both areas (EVC, n=53 electrodes; OTC, n=61) and object classes could be decoded on a single-trial basis. Consistent with the anatomically defined hierarchy, class recognition was earlier in EVC than OTC. We used representational dissimilarity matrices (RDM, at the level of classes) to characterize the time-varying neural codes in both areas. About 60 ms after stimulus onset, EVC built an RDM very similar to an image-based RDM (derived from pixel difference) whereas OTC showed a three-category RDM around 130 ms, consistent with previous observations. However, we found a categorical RDM emerged in EVC ~50 ms following the OTC processing, which was also invariant to non-categorical transforms (subcategory and image size). Additionally, the RDM in OTC was substantially refined over time both in structure (along the same trend as EVC with increasing processing order) and reliability (which drastically improved at the single trial level). Finally, we showed that OTC processed object category and identity at separate time windows: the identity-related activity peaked ~200 ms later than the category-related activity. In contrast, EVC processed various levels of information almost at the same time, with a much smaller yet opposite difference in latency (i.e. identity before category). Taken together, our data suggest a possible recurrent mechanism for cortical object processing: OTC first sums over EVC inputs to form a crude version of object code; and then the initial code is refined to enable reliable categorical representation, likely contributed by recurrent involvement of EVC. The more

specific information (i.e., object identity) is fully analyzed later, probably through interactions among and within high-level object areas.

Abstract: Converging evidence suggests that cortical visual processing is performed in a hierarchical network. In the primate object vision, visual information is thought to be processed along the following sequence of areas: V1, V2, V4, posterior part of the inferior temporal cortex (pIT), central part of IT (cIT) and anterior part of IT (aIT). Nonetheless, the direct physiological insight on the hierarchical processing has been constrained due to the lack of appropriate techniques. In particular, it is difficult to record neural activity simultaneously from wide cortical areas at high temporal resolution. Here we conducted electrocorticography using a 128-channel 2.5 mm spaced surface electrode, which covered ventral visual areas of pIT, cIT and aIT while the monkeys performed a passive visual fixation task to investigate how the process was embedded in spatiotemporal activities of these areas. The high spatiotemporal resolution recording captured dynamic propagation of the visually evoked activity and identified three repeated waves traveling from pIT to aIT after the stimulation onset. To quantify these activity dynamics, we employed symbolic local transfer entropy (SLTE) extracting spatiotemporal pattern in terms of information measure. SLTE quantified information flow between all neighbor electrodes then information potential was defined from the flow. We identified feedforward and feedback components, the information flow directing pIT to aIT and the reversed flow, respectively. The first feedback flow appeared as early as 60ms after onset of the visual stimulation. The feedforward flow appeared and peaked around 100-130ms after the onset followed by second feedback flow. Stimulus selectivity emerged during these fast information

traffic suggesting the importance of both feedforward and feedback information to generate visual selectivity. Furthermore by examining dynamics of the SLTE topography, we found this hierarchical network changed its shape drastically during the visual stimulation. A few specific spots oscillated as the information sink and source more significantly than the others. Small-world-ness measures indicated the network decreased its local connectivity and increased its global connectivity during visual stimulation, suggesting an enhancement of the global information integration. The spatial shuffling procedure conformed the necessity of the organized two-dimensional activity to acquire these network properties. These results provide the physiological basis of the dynamic hierarchical processing in the ventral visual stream and suggest that this process involves topographic changes in the information network.

Title: Hierarchical feed-forward visual models and recurrent semantic models predict fMRI pattern-information in the ventral object processing stream

Authors: ***B. J. DEVEREUX**[1], A. CLARKE[2], L. K. TYLER[1];
[1]Univ. of Cambridge, Cambridge, United Kingdom; [2]Ctr. for Neurosci., Univ. of California, Davis, Davis, CA

Abstract: Understanding visual objects involves both hierarchically-organized feed-forward processing and later more recurrent processing that yields detailed and perceptually-invariant information about object meaning (Schendan & Stern 2008; Clarke et al 2014). Convolutional neural networks have provided plausible models of the first part of this system, with successive layers of such networks capturing increasingly high-level visual information about the input. However, how such processing activates and interacts with semantic representations remains unclear. We combined a deep convolutional network model of vision (Krizhevsky et al 2012) with an attractor network model of concept semantics (Cree et al 2006) where information about object meaning is represented as a pattern of activation across distributed feature units. This integrated visuo-semantic model maps high-level visual representations onto semantic feature representations, encoding statistical information about semantic features (e.g. feature frequency) and their relationship to high-level visual information. We found that early stages of the semantic

model showed stronger activation for features shared by many objects and features which are visual in nature (e.g. “is long”), compared with distinctive and non-visual features. Using RSA (Kriegeskorte et al 2008), we tested the ability of the model to explain patterns of activation in fMRI data where 16 participants named pictures of 131 objects (Clarke & Tyler 2014). We calculated 8 dissimilarity matrices (DMs) corresponding to the 8 layers of the deep convolutional network and 20 DMs corresponding to the 20 processing stages of the attractor network. The 28 DMs delineate a trajectory through a space of representational geometries, from pixels to detailed object semantics. Layers of the deep convolutional network explained pattern similarities in early visual cortex, consistent with previous results (Khaligh-Razavi & Kriegeskorte 2014). However, DMs corresponding to the early stages of the attractor network, where activation of shared and visual semantic features is strong relative to non-visual and distinctive features, better explained pattern similarity in the posterior fusiform. The final stage of the semantic attractor network model, where detailed semantic representations, including both shared and distinctive features, are maximally activated, best explained pattern similarity in bilateral perirhinal cortex. Taken together, the results show how models integrating visual and distributed semantic representations can account for fMRI pattern-information throughout the ventral temporal object processing stream.

Title: The role of action information in thematic relations between objects

Authors: R. E. WITTENBERG[1], C. E. WATSON[2], L. J. BUXBAUM[2], *S. L. THOMPSON-SCHILL[1];
[1]Univ. Pennsylvania, Philadelphia, PA; [2]Moss Rehabil. Res. Inst., Philadelphia, PA

Abstract: Recent evidence suggests that object concepts may be organized both taxonomically (categorically) and thematically (in terms of associated roles in events). Thematic information, in particular, appears to be crucial for determining relationships between manipulable objects. This suggests that action information may play a role in the processing of thematic relationships between objects. One previous study found that stroke patients with lesions to left temporo-parietal cortex were less sensitive to the “action-relatedness” of thematically-related manipulable

objects than healthy controls or patients with other lesion loci, consistent with a critical role of this region in action-based object relationships. In the present study, we used fMRI with healthy participant (n = 13) to further investigate the role of action in semantic relations and their neural bases. On each trial, participants saw a triad of object photographs: a target object (top) and two related objects (bottom left and right). One of the related objects was always related to the target taxonomically ("Tax", wine/water bottle). The other related object was related thematically via a common action ("Th+A", e.g., wine/corkscrew) or thematically via co-occurrence in space and time rather than a common action ("Th-A", e.g., wine/cheese). Participants performed two tasks on these triads. During the Category task, participants selected the object that was taxonomically related to the target. During the Event task, participants selected the object that participates in the same event or scene as the target. We also included a baseline task in which participants performed an identity match with scrambled versions of the object triads. Comparison of all trials minus baseline showed greater activation in bilateral inferior parietal lobe and lateral occipitotemporal cortex. During the Event task, activation was greater in bilateral lateral occipitotemporal and medial fusiform cortex when judgments involved objects related via a common action versus objects related via co-occurrence in space and time (Th+A vs. Th-A). These data are consistent with an important role of these regions in action-based thematic object relationships.

Title: fMRI reveals representational similarity for objects that are used on the body vs. other objects

Authors: *S. D. SQUIRES[1], J. C. SNOW[2], K. M. STUBBS[1], J. C. CULHAM[1];
[1]The Brain and Mind Inst., Univ. of Western Ontario, London, ON, Canada; [2]Psychology, Univ. of Nevada, Reno, NV

Abstract: Neuroimaging research has revealed numerous brain regions that are more activated by viewing tools vs. other categories of visual stimuli (e.g., animals or non-tool objects). Here we investigated the neural representations for tools and other objects presented as either real objects or photos of those same objects. We wondered whether tool-selectivity would be

enhanced for real tools vs. photos of tools (to a greater degree than real non-tools vs. photos of non-tools) because real stimuli afford actual actions. Fifteen participants viewed real objects or photos matched for size and viewpoint. Individual objects and photos were mounted on semicircular plates (designed to abut the top of the scanner bore) and successively presented using a custom-designed conveyor belt called the DROID (Delivery of Real Objects for Imaging Device). Items were either tools (plastic whisks, toothbrushes or hammers) or non-tools of comparable size and elongation (socks, sunglasses and candles). Within each block, subjects viewed four exemplars (of different color, form, etc.) of one object type (e.g., whisks) in either real or photo format. Much to our surprise, we did not find higher activation for tools than non-tools (regardless of format). Interestingly however, data-driven multivariate representational dissimilarity analyses revealed an unexpected but interesting grouping of categories. Specifically, multidimensional scaling of the neural representations showed that the representations of socks, sunglasses, and toothbrushes were more similar to each other than to another grouping of hammers, whisks, and candles. These data suggest that tool-selective activation may be quite dependent on the choice of control category and driven in part by low-level factors like object size, elongation, and or actability. More interestingly, they reveal a new theoretical dimension that may account for differences in representations in the ventral visual stream: objects that are used to interact with the body may invoke different representations than objects that interact with other objects.

Title: Localizing tool- and hand-selective areas with fMRI: Comparing video and picture stimuli

Authors: *S. N. MACDONALD[1], F. M. Z. HEILIGENBERG[2], T. R. MAKIN[2], J. C. CULHAM[1];
[1]Neurosci., Western Univ., London, ON, Canada; [2]Nuffield Dept. of Clin. Neurosciences,, Univ. of Oxford, FMRIB, Oxford, United Kingdom

Abstract: Historically, tool- and hand-specific areas have been localized in the human brain by using functional magnetic resonance imaging (fMRI) to compare brain activity when participants view pictures of tools or hands versus when they view pictures of objects or scrambled images. In contrast to pictures, however, videos can fully depict the interaction between an effector and its target and likely engage attention to a greater extent. Thus, we hypothesized that videos would be more effective than pictures at localizing distinct tool- and hand-selective areas within

individuals, and videos would also be more likely to recruit areas involved in tool and hand actions. Ten healthy participants underwent fMRI while they viewed pictures and videos presented in a blocked design. Picture stimuli included tools, hands, objects, and scrambled images. Likewise, video stimuli included tools interacting with objects (hand omitted from the scene), hands interacting with objects, moving objects, and moving patterns (akin to scrambled images). The results show that tool and hand videos activate a more extensive network of dorsal stream areas compared to pictures. Specifically, areas in the action observation and execution network were more selective for tool and hand videos as compared to object videos. The robust activation elicited by videos facilitated the localization of tool- and hand-selective areas at the individual level. Interestingly, tool- and hand-selective areas localized using videos included the anterior portion of the lateral occipital temporal cortex (LOTC), which is selective for actions. In contrast, pictures widely activated a posterior part of LOTC associated with motion processing. In sum, videos are effective stimuli for localizing areas involved in the processing of tools and hands. Videos reliably activate tool- and hand-selective regions and, compared to pictures, better recruit areas likely involved goal-directed action.

Title: Word statistics in lager-scale texts explain the human cortical semantic representation of objects, actions, and impressions

Authors: ***S. NISHIDA**[1,2], A. G. HUTH[3], J. L. GALLANT[3], S. NISHIMOTO[1,2];

Abstract: Words in natural language have semantic structures that reflect the relationship between thousands of different semantic categories such as objects, actions, and impressions. Recently many language models have been proposed in order to extract such semantic structures from large-scale text corpora in an unsupervised fashion. Of these, the skip-gram learning algorithm has attracted broad interest because it constructs a semantic vector space that allows explicit linear translations of word representation in a manner congruent with our intuition (e.g., King - Man + Woman = Queen). To investigate whether and how the skip-gram vector space is reconciled with the semantic representation in the human brain, we built a voxelwise encoding model of human brain activity based on the skip-gram vector representation (skip-gram model). In order to test the validity of the model, we recorded whole-brain BOLD (blood oxygen level-dependent) activity of human subjects who watched natural movies and fit the model to individual voxels. We found that the skip-gram model predicted movie-evoked activity in many cortical areas, particularly in the occipitotemporal visual areas. The skip-gram model outperformed other corpus-based language models in terms of prediction accuracy. Analysis of the fit models revealed structured cortical semantic spaces associated with the meanings of words separately for objects (nouns), actions (verbs), and impressions (adjectives). Moreover, by using the skip-gram vector representation, we could also decode semantic contents of perceived movie scenes from the evoked activity. These results suggest that the skip-gram vector representation captures important features of the semantic representation in the human brain.

Title: Object-to-spatial property "crosstalk" improves scene recognition: a modeling study

Authors: *D. LINSLEY, S. MACEVOY;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Scene recognition is a key function of the visual system, supporting effective navigation through one’s surroundings and appropriate interactions along the way. Scene recognition mechanisms operate both on the objects within a scene and the scene’s spatial properties, with a single judgment of scene identity ultimately emerging from a combination of the two. We recently demonstrated that this convergence of object and spatial information begins in the visual system, with scenes’ encoded spatial scales biased towards the scales associated with the objects they contain (Linsley & MacEvoy, 2014). For instance, the spatial scale of a room containing an oven is perceived as more “kitchen-like” than if the oven were not present.

We have theorized that this bias aids scene recognition by harmonizing scenes' encoded spatial properties with their perceived object contents. In the present study, we used artificial neural networks to test the plausibility of this theory. Separate models simulated scene recognition based solely on scenes' objects, spatial properties, or a pooled combination of these sources that permitted but did not mandate a bias consistent with our previous observations. Consistent with representations of scenes inferred from behavior and measured with fMRI in the parahippocampal place area, the model that pooled object and spatial property information encoded scenes as more spatially similar to their category average when objects were visible than when they were obscured by wavelet masks. This model also produced similar errors as humans on a scene categorization pilot study, both when scene exemplars were intact and when their objects were masked. Finally, we observed that the model permitting bias yielded better scene recognition accuracy than the other two models. Additionally, because the model permitting bias pools information across objects spatial properties, redundant features were pruned, resulting in significantly more efficient scene representations. In summary, our model supports the theory that the perceptual convergence of information about scenes' objects and spatial properties benefits scene recognition by improving both accuracy and efficiency.

Title: Differential representation of man-made and natural scenes in scene-selective cortex

Authors: *I. I. GROEN, E. H. SILSON, C. I. BAKER;
Natl. Inst. for Hlth., Bethesda, MD

Abstract: Behavioral, computational and electroencephalography (EEG) results suggest that man-made and natural scenes are represented differentially (Oliva and Torralba, 2003; Greene et al., 2009; Groen et al., 2013), but the neural substrate of this global scene distinction is unclear. Three scene-responsive brain regions - the parahippocampal place area (PPA), transverse occipital sulcus (TOS) and retrosplenial complex (RSC) - have shown to be sensitive to various visual features that may contribute to scene naturalness, such as spatial layout, landmarks, object ensembles, and texture (Kravitz et al., 2011, Park et al., 2011, Epstein et al., 2014, Cant and Xu, 2011) as well as low-level properties such as spatial frequency and contrast (Rajimehr et al., 2011, Kaufmann et al., 2015). Here, we used high-resolution (7T) fMRI to examine neural

representations of man-made versus natural scenes and to characterize how these representations relate to potentially diagnostic scene features. As an initial test, we used a man-made/natural scene localizer across the whole brain, which revealed patches of enhanced activity for man-made compared to natural scenes within each of the three scene-responsive areas. Interestingly, in PPA, this patch was located anteriorly and medially, suggesting that in 3T data, it may have been obscured by increased susceptibility artifacts. Given this difference in univariate responses, we sought to investigate what scene information contributes to this difference using multi-voxel pattern analysis across 4 scene (man-made open, man-made closed, natural open, natural closed) and 4 isolated object (man-made, natural, buildings and faces) categories. The results revealed heterogeneous response profiles across the scene-responsive regions. Anterior PPA and RSC not only separated man-made from natural scenes but also man-made from natural objects, and man-made scenes clustered with buildings more strongly in anterior compared to posterior PPA. In contrast, TOS did not distinguish between isolated object categories, but did have a selectively distinct representation of closed natural scenes (which contain more textural components) compared with the other scene types. Preliminary results of consecutive transcranial magnetic stimulation (TMS)/fMRI indicate that TMS to TOS eliminates its man-made advantage, while the response in PPA remains largely intact. Together, these findings suggest that man-made and natural scenes could be differentially represented based on both object-based and textural properties, which are potentially extracted via distinct pathways involving PPA and TOS, respectively.

Title: In search of categorical object representation in the pigeon's nidopallium frontolaterale

Authors: ***C. KOENEN**, R. PUSCH, F. BROKER, S. THIELE, O. GUNTURKUN; Ruhr-University Bochum, Bochum, Germany

Abstract: How do pigeons see the world? Are visual objects represented in a similar manner in the avian visual system compared to the primate visual system? To elucidate these questions we examine the pigeon's nidopallium frontolaterale (NFL), a higher visual area and the putative analog to the inferior temporal (IT) cortex of primates. To investigate the visual response properties of the NFL we present different stimuli sets to freely moving and behaving pigeons

while recording single cell activity from the NFL. We present basic visual stimuli, namely simple forms in different colors as well as gratings with varying spatial frequencies and contrasts. Additionally, we show pictures of real-world objects from different categories. Kriegeskorte et al. (2008) presented the same pictures of real-world objects to humans and monkeys and revealed an activity pattern in IT in line with semantic categories. Moreover, the category clusters where highly similar between man and monkey, recorded with fMRI and single cell recording, respectively. With our approach we investigate the neural basis of perceptual discrimination in the NFL on different levels of complexity and compare the results to object representation in primate IT. Title: Role of superior colliculus in microsaccade generation as examined with electrical microstimulation

Authors: M. C. DORRIS, P. BAO, M. YANG, *G. YU;
Inst. of Neuroscience, Shanghai, Shanghai, China

Abstract: During attempted fixation, the eyes continue to make tiny saccades (typically <1°), called “microsaccades”. Previous studies found that neurons in the rostral pole of the primate superior colliculus (SC) display a burst of activity associated with microsaccade generation and pharmacological inactivation of SC can bias microsaccade direction away from the affected region. Here, we systematically manipulated activity with varying levels of electrical microstimulation at a range of locations across the SC map. Monkeys simply fixated a central stimulus for 2500ms. We applied microstimulation (0.25ms biphasic pulses) to the SC intermediate/deep layers for 500ms during the middle of this fixation period. The stimulation intensity for each experiment was determined by the current level (at 300Hz) required to consistently evoke saccades to the stimulation site. Stimulation frequency was then randomly varied across 7 levels: 0Hz (control), 10Hz, 25Hz, 50Hz, 75Hz, 150Hz and 300Hz. The

stimulation sites spanned the SC ranging from 0.2° - 30° saccade eccentricities. There were three main findings: 1) there was a transition from fixational microsaccades at low levels of stimulation to macrosaccades at the highest levels of stimulation, 2) low level stimulation biased microsaccade direction towards the stimulation site without otherwise changing microsaccade frequency, amplitude or velocity. The rostrocaudal location of the stimulation site had no effect, 3) the above two findings were further modulated by the recency of naturally-occurring microsaccades relative to the time of stimulation onset. This provides support for the hypothesis of an underlying rhythmicity within SC circuitry that influences microsaccade timing. In conclusion, our results demonstrate that direct low level SC activation biases the direction of microsaccades without affecting other motor properties of these movements. This suggests that previously documented sensory (e.g. onset of visual stimuli) and cognitive (e.g. visuospatial attention) effects on microsaccades generation may be mediated by their spatially specific activations upon the SC map.

Title: Visual error signal in the superior colliculus reflects the speed of saccade adaptation

Authors: *Y. KOJIMA;
Physiol. & Biophysics, Univ. of Washington, Seattle, WA

Abstract: Error signal that instructs cerebellar motor learning is calculated from the mismatch between the desired movement and the actual movement. In the Marr and Albus model, the error signal modulates climbing fiber activity that changes the synaptic strength of the parallel fibers on Purkinje cells. This model is known as cerebellar plasticity. Various neurophysiological studies of saccade adaptation support this model. The climbing fibers that project to the cerebellar oculomotor vermis (OMV) elicit Purkinje cell complex spikes that are correlated with visual error during saccade adaptation. Simple spike activity of OMV Purkinje cells changes during the adaptation. The superior colliculus (SC) via the medial accessory olive is the putative signal source of the OMV climbing fibers. Subthreshold electrical stimulation of the SC timed after the end of each saccade produces saccade adaptation. The same electrical stimulation also elicits Purkinje cell complex spikes in the OMV. Taken together, this evidence suggests that the SC is the origin of the OMV complex spikes that drives saccade adaptation. In this study, we

recorded the SC activity related to the visual error signal during saccade adaptation. We induced adaptation of 15° saccades along a neuron's optimal direction. The intrasaccadic step (ISS) paradigm produced a fixed visual error that was congruent with the neuron's optimal vector. Throughout the adaptation, although the visual error was fixed, the visual activity of the SC modulated proportionally to the natural variation of the speed of the adaptation. When the saccade amplitude adapted faster, the visual activity increased, and vice versa. Although the visual activity of the neuron highly correlated with the speed of adaptation, the corrective-saccade-related bursts did not. Because the timing of Purkinje-cell complex spikes in the OMV coincides with the SC visual activity (~80ms after the offset of the primary saccades), the visual signal from the SC may modulate the activity of complex spikes, therefore, it may also modulate the speed of adaptation.

Title: Local field potential signals related to saccade target selection in the superior colliculus

Authors: B. COOPER[1], *R. M. MCPEEK[2];
[1]Grad. Ctr. for Vision Res., [2]Biol. Sci., SUNY Optometry, New York, NY

Abstract: Neural activity related to saccade target selection in the primate superior colliculus (SC) has been studied extensively using single unit recordings, but few studies have investigated the local field potential (LFP) correlates of target selection in the SC. To investigate this, we trained monkeys in a top-down cueing task, in which physically identical potential saccade targets were initially presented in the periphery. After a delay, a cue at the fovea indicated which peripheral stimulus was the correct saccade goal. After another variable delay, the fixation point was extinguished and monkeys were rewarded for making a saccade to the cued stimulus. The delay periods allowed us to separate selection-related activity from movement-related activity. In the time domain, many, but not all, recording sites showed significant LFP modulation related to the onset of the foveal cue which indicated the correct target. These sites showed an increase in negativity when the cued target was in the response field (RF) vs. outside the RF. Other sites showed little response to the cue, but a significant increase in negativity occurring near the time of the saccade when the saccade goal was in the RF vs. out of the RF. In the frequency domain, in association with target selection in this task we saw an increase in power in the gamma band at

approximately 40-50 Hz, with little change in power in the beta band. This pattern of results contrasts with our findings in a pop-out color oddity selection task, reported last year, where saccade target selection was accompanied by an increase in power in the beta band (at approximately 25 Hz) in addition to an increase in gamma. To determine whether this difference was due to sampling of different LFP sites for the two tasks, we recorded LFP activity in both tasks at a small number of sites, and found similar frequency domain differences related to target selection in the two tasks. This suggests that signals related to bottom-up and top-down selection are processed differently in the SC, and that analyses of LFPs may help to distinguish these different components.

Title: The motor burst of saccade-related neurons in the deep superior colliculus during interceptive saccades

Authors: *L. GOFFART[1], A. L. CECALA[2], N. J. GANDHI[3];
[1]CNRS, Marseille, France; [2]Elizabethtown Col., Elizabethtown, PA; [3]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Neurons in the deep layers of the superior colliculus (dSC) emit a vigorous burst of action potentials during saccades toward a stationary target. A traditionally defined movement field identifies an optimal saccadic vector for which the neural discharge is maximal, and the level of activity decreases for saccades gradually deviated from this optimum. Neurons in the dSC also produce a burst during interceptive saccades made to foveally acquire a moving target. Keller et al. (1996) described peri-saccadic bursts during interceptive saccades aimed at targets that moved away from the initial fixation point and through the neuron's response field at a constant velocity (usually 60 deg/sec). Two salient observations were reported: 1) the dSC's movement field center was shifted towards larger amplitude saccades relative to the center of movement fields collected using stationary targets; 2) the peak discharge for interceptive saccades tended to be lower than for saccades to stationary targets. To further characterize the

apparent discrepancy in the bursts for saccades to stationary and moving targets, we recorded activity of dSC neurons in three head-restrained rhesus monkeys trained to produce interceptive saccades toward targets traveling in numerous paths and at various speeds. In all cases, the target travelled through the neuron's traditionally-defined movement field. Consistent with Keller and colleagues, we observed less vigorous peri-saccadic bursts during interceptive saccades, and this attenuation is associated with a reduction in peak velocity. However, we did not observe a robust shift in the movement field's optimal vector or boundaries for the slower target speeds used in our experiments. Furthermore, if a shift did occur it was not always symmetrical for targets moving towards or away from the center of the traditional movement field. These data demonstrate that dSC is involved in the generation of interceptive saccades to moving targets. Further analyses are required to confidently decipher whether and how much target motion-related signals contribute to the burst.

Title: Selective optogenetic activation of output pathways from mouse superior colliculus

Authors: ***K. ISA**[1], T. SOOKSAWATE[2], K. KOBAYASHI[3], T. ISA[1,4];
[1]Natl. Inst. Phisiol. Sci., Okazaki, Japan; [2]Dept. of Pharm. and Physiol., Chulalongkorn Univ., Bangkok, Thailand; [3]Sec. Viral Vector Develop., Natl. Inst. Physiol. Sci., Okazaki, Japan; [4]Grad. Univ. of Advanced Studies (SOKENDAI), Hayama, Japan

Abstract: It is known that the superior colliculus (SC) plays a major role in the control of orienting and avoidance behaviors to visual stimulation. Although it has been reported that the crossed tecto-reticular pathway controls orienting responses and that uncrossed tecto-reticular pathway is involved in avoidance behavior, the evidence was rather indirect (Redgrave et al., 1986). It is also reported that the former neurons were distributed in the caudo-lateral portion of SC and the latter neurons in its rostro-medial area. However, the functional dissection of these two groups of neurons had been difficult. Recently, by using a combination of two viral vectors, we succeeded in selective blockade of the crossed tecto-reticular pathway in intermediate layer of SC (SGI) by expression of tetanus neurotoxin (Sooksawate et. al., 2013). In the present study, first, we injected AAV-CAG-ChR2(H134R)-tdTomato into the intermediate layer of the mouse SC(SGI). By irradiating blue laser (473nm) under freely-moving condition, we could observe the

orienting response and/or avoidance response depending on the site of stimulation in the SC. We confirmed the optogenetic activation of the SGI neurons using *in vivo* electrophysiological recordings under anesthesia. Secondly, we applied the combination of two viral vectors to selectively activate the crossed or the uncrossed tecto-reticular pathway. We injected neuron-specific highly efficient retrograde gene transfer vector (NeuRet-CMV-MSCV-U3-nls/Cre) into the brainstem reticular formation, followed by injection of the anterograde viral vector (AAV-DJ-EF1a-double flex-hChR2(E123T/T159C)-YFP) into the SGI either on the contralateral or on the ipsilateral side to the brainstem injection. The orienting movements could be observed in both groups after optogenetic activation but cringing or escape behaviors could be observed only in the case of activating the uncrossed pathway. We confirmed the activation of SGI neurons in response to the laser irradiation electrophysiologically under anesthesia, and observed differential distribution of YFP expression histologically between the crossed and uncrossed tecto-reticular neurons. Thus, by introducing the pathway-specific gene expression technique, we could dissect the function of crossed and uncrossed tecto-reticular pathways.

Title: Resting-state functional connectivity changes following an ischemic frontal cortex stroke in a macaque

Authors: *R. ADAM[1], K. JOHNSTON[1], R. HUTCHISON[2], S. EVERLING[1];
[1]The Univ. of Western Ontario, London, ON, Canada; [2]Harvard Univ., Cambridge, MA

Abstract: Unilateral spatial neglect is a disorder of spatial attention commonly seen following right hemispheric stroke. It is characterized by an inability to attend to stimuli contralateral to the lesion, resulting in a saccade choice bias to the ipsilesional hemifield. Here, we aim to correlate the behavioural recovery of the saccade choice bias following stroke with changes in whole-brain functional connectivity (FC). We predict that increased FC within parietal areas will underlie the recovery of a saccade choice bias following a unilateral frontal cortex stroke. We created a macaque model of ischemic stroke using endothelin-1 injections to create lesions in the right dorsolateral prefrontal cortex and frontal eye field as verified by MRI. Following stroke, the animal exhibited both a profound ipsilesional saccade choice bias and increased contralesional saccadic reaction times. Resting-state fMRI scans obtained one week following stroke showed

reduced frontoparietal FC in the ipsilesional hemisphere and some increased FC between the contralesional frontal cortex and contralesional and ipsilesional posterior parietal cortex. Resting-state fMRI scans obtained four weeks following stroke showed strong increases in FC between contralesional frontal areas and both contralesional and ipsilesional posterior parietal cortex and between the contralesional and ipsilesional posterior parietal cortex. Results reveal functional reorganization following frontal cortex stroke and how changes in whole-brain FC relate to recovery of spatial neglect.

Title: A premotor eye field in the arcuate sulcus of macaque monkeys - comparison with FEF

Authors: *W. ZINKE, J. D. COSMAN, G. F. WOODMAN, J. D. SCHALL;
Dept. of Psychology, Vanderbilt Univ., Nashville, TN

Abstract: It is puzzling that the frontal eye field (FEF) in humans often is found in agranular area 6, while in macaques it is located within granular area 8. This different localization could be due to experimental modalities used to functionally determine FEF. In humans, the localization is primarily based on neuroimaging, whereas in monkeys it is based on microstimulation, neuronal recordings and anatomical connectivity. Several macaque neuroimaging studies report increased activation related to saccades in the posterior bank of the arcuate sulcus, consistent with the presence of a premotor eye field distinct from the FEF. Although neuronal responses to visual stimuli and with saccades were reported in the premotor cortex of monkeys, a direct comparison with FEF is still outstanding. Using linear microelectrode arrays in two macaque

monkeys (M. radiata) guided by high resolution structural MRI, neuronal activity was recorded in the anterior and posterior bank at the genu of the arcuate sulcus while the monkeys performed memory guided saccade and visual search tasks. Based on their response modulation, neurons were classified as visual, visuomovement, and movement. We identified a location at the spur of the arcuate sulcus where neurons showed clear visual responses during the tasks. The response characteristics were comparable to those of FEF neurons. We found similar proportions of neuron types in both areas, with slightly more visual neurons in the premotor area and more visuomovement neurons in FEF. We observed less transient visual responses and stronger pre-saccadic response in FEF as compared to premotor neurons. Both areas showed similar response latencies and predominantly contralateral receptive and movement fields. Our findings confirm the presence of a premotor eye field in the posterior bank of the arcuate sulcus of macaques with response properties mirroring several of those in FEF although with less saccade-related activity. The existence of functional comparable regions in nearby but cytoarchitectonical different cortical areas may explain the apparent discrepancy of FEF localization in humans and macaques.

Title: Comparison of saccade target selection in frontal and premotor eye fields of macaques

Authors: *J. D. COSMAN[1], W. ZINKE[2], G. WOODMAN[2], J. SCHALL[2];
[1]Dept. of Psychology, [2]Vanderbilt Univ., Nashville, TN

Abstract: The macaque frontal eye fields (FEF), located on the anterior bank of the arcuate sulcus, play a critical role in saccade target selection during visual search, with single unit responses evolving to select target locations relative to distractor locations prior to the initiation of a saccadic response. Further, such target selection is observed even in cases where a saccadic response is not required, suggesting that target selection represents a general attentional property of FEF rather than being specific to the overt allocation of attention. Importantly, similar target-selective responses have been observed in dorsal premotor cortex, posterior to the arcuate sulcus, during manual reaching tasks that require selection of a target among distractors. Interestingly, saccadic responses can be evoked in premotor cortex with low currents microstimulation, and macaque functional imaging studies have shown saccade related activation in premotor cortex. We investigated whether this putative premotor eye field is involved in both attentional selection and saccade production when saccadic but not manual target selection is required, mirroring FEF. Using linear microelectrode arrays in two macaque monkeys (M. radiata) guided by high resolution structural MRI, neuronal activity was recorded in the anterior and posterior bank at the genu of the arcuate sulcus while the monkeys performed a T/L search task in which they made saccadic responses to a target item in a field of distractors. We contrasted target selection across FEF and the premotor area, comparing the timing and magnitude of selection. Target selection was qualitatively similar between FEF and the premotor area with similar proportions of units showing target-selective responses. However, target selection occurred earlier in FEF than in the premotor area for all but the fastest reaction times. Also, response magnitude prior to the initiation of saccadic response to targets was much larger in FEF than in the premotor area.Taken together, our results suggest that both, prearcuate FEF and postarcuate premotor cortex, contribute to visuospatial attentional selection, but that selection in FEF may be more important for saccade generation on the basis of these attentional signals.

Title: Role of macaque dorsolateral prefrontal cortex in flexible and mnemonic attentional allocation during visual search

Authors: B. BELBECK, S. EVERLING, S. G. LOMBER, *K. D. JOHNSTON;
Univ. of Western Ontario, London, ON, Canada

Abstract: A critical aspect of visual selective attention is that it may be flexibly deployed based on the specific demands of the task at hand. Such may be the case when the features of target stimuli change frequently or when a representation of a target stimulus must be retained temporarily within working memory. Numerous lines of evidence have linked the prefrontal cortex (PFC) to cognitive flexibility and working memory, but the link between these processes and the deployment of attention has been less studied. Here, we investigated the role of the DLPFC in cognitive processes related to attentional allocation by reversibly cryogenically deactivating this area while two rhesus macaques performed a series of visual search tasks designed to vary systematically with respect to their cognitive demands. The animals performed three variants of a visual conjunction search task in which targets were defined by a unique conjunction of colour and shape. In the first, the search target was instructed at the beginning of, and remained constant throughout a given session. Correct performance of this task required that a single search target be retained throughout each session. In the second, the search target was cued at the beginning of each trial, and varied throughout a given session, requiring continuous updating of relevant target features on a trial-by-trial basis. In the third, a mnemonic demand was introduced by adding a delay period following the search target cue. In a given experimental session, the animals performed one of these tasks while the cortex lining the banks of the caudal principal sulcus was bilaterally deactivated. We observed deactivation-induced changes in task performance that varied as a function of the cognitive demands of the search task performed. During constant-target search, we observed no significant effects on performance accuracy, and inconsistent effects on reaction time. During the variable-target search task, response accuracy was unaffected, but consistent increases in reaction times were observed. The greatest effects were apparent in the variable-target delayed search task, in which both decreases in response accuracy, and increases in reaction times were found during DLPFC deactivation. These results suggest the DLPFC plays a critical role in the deployment of attention to a target when cognitive demands are high, as is the case when targets change frequently or must be maintained within working memory. These findings are consistent with the notion that the PFC contributes to attentional guidance by providing bias signals to other brain areas based on knowledge and goals of the current task.

Title: Effects of iontophoretic application of muscarinic agonists on mnemonic rule representation of monkey prefrontal neurons engaged in a rule-contingent saccadic task

Authors: *A. J. MAJOR, S. VIJAYRAGHAVAN, S. EVERLING;
Western Univ., London, ON, Canada

Abstract: The dorsolateral prefrontal cortex (DLPFC) has a well-studied role in executive function, including attention, working memory (WM), and rule-contingent processing. These functions are modulated by the ascending cholinergic neuromodulatory system. Cholinergic dysfunction is thought to be a contributing factor to neurological and psychiatric disorders such as Alzheimer's disease and schizophrenia, where morbidity of prefrontal-dependent functions such as attention and WM is observed. Further, cholinergic denervation of the DLPFC in macaques or systemic pharmacological blockade of muscarinic receptors disrupts WM processing. Local muscarinic modulation of rule-contingent mnemonic processing in DLPFC has not been examined in detail hitherto. We have previously shown that the muscarinic antagonist scopolamine suppresses rule-memory in prefrontal neurons in a rule-cued pro-/antisaccade task. Two receptor classes mediate muscarinic actions: the M1 receptor family, which is densely expressed in DLPFC, predominantly postsynaptic on pyramidal spines, and the M2 receptor family, located presynaptically, but also on postsynaptic spines in projections from DLPFC area 46 to DLPFC area 9. In this study, we examined the *in vivo* effects of three iontophoretically applied cholinergic agonists on macaque DLPFC neurons: nonspecific cholinergic agonist, carbachol; M1-preferring agonist, McN-A-343; and oxotremorine-M, an orthosteric muscarinic agonist with some relative selectivity for M2 receptors *in vivo*. Preliminary data indicate that all three agonists had both excitatory and inhibitory effects on DLPFC neurons encoding rule selectivity. We found carbachol both significantly inhibited (23/54) and excited (15/54) DLPFC neurons (rule-selective: 9/18 inhibited, 3/18 excited). McN-A-343 predominantly inhibited DLPFC neurons (18/26 inhibited, 4/26 excited; rule-selective: 7/12 and 3/12, respectively), while oxotremorine-M mostly excited DLPFC neurons tested (3/16 inhibited, 10/16 excited). These are the first results to report the effect of local muscarinic stimulation to primate DLPFC rule-contingent WM circuits, and support muscarinic receptors as pharmacological targets for treatment of cognitive deficits.

Abstract: Transcranial magnetic stimulation (TMS) is a technique for non-invasive brain stimulation that uses a high-intensity and brief electromagnetic induction to generate intracranial currents. Repetitive application of TMS pulse (rTMS) has emerged as a potential treatment option for several neurological disorders, including depression, neuropathic pain, and Parkinson’s disease (PD). PD is a type of movement disorder that causes a loss of dopaminergic neurons in the basal ganglia. In the treatment for PD, rTMS over the primary motor cortex, supplementary motor area, and dorsolateral prefrontal cortex at 1-10 Hz has been used. As the main pathological of PD is the death of dopaminergic neurons in the basal ganglia, cortical stimulation by rTMS somehow affects the function of large scale neural circuit including the cortical or subcortical regions. Exactly, previous imaging study using positron emission tomography reported that rTMS over the motor cortex induces a release of endogenous dopamine in the ventral striatum in humans and monkeys. Furthermore, study of functional magnetic resonance imaging for PD patients reported that the improvement in bradykinesia by rTMS is associated with activity increase in caudate nucleus. However, despite widespread use of rTMS, exactly how rTMS influences neural activity throughout an interconnected network, and how such influences ultimately change disease symptoms, remain unclear. Appropriate animal model is required to understand how rTMS influences large scale neural circuit and behavior. One potential model system is the oculomotor system of monkeys that is the one of the most well-established system of the brain, which include both cortical areas and basal ganglia nuclei, and contribution of each region to saccadic behavior is well characterized. Here we tested the effect of rTMS to oculomotor behavior in monkeys. In order to record eye movement and set TMS coil precisely and reproducibly, monkeys head were fixed by thermoplastic mask and cheek rest. rTMS were applied using a MagStim Rapid Transcranial Magnetic Stimulator with a figure-eight coil. Left and right eye positions and pupil size of monkeys were acquired with a fast video-based eye movement monitor (Eyelink1000).

Title: Neural activation and saccadic eye movements involved during letter and object naming speed tasks

Authors: *N. Z. AL DAHHAN, D. C. BRIEN, J. R. KIRBY, D. P. MUNOZ;
Queen's Univ. Ctr. for Neurosci. Studies, Kingston, ON, Canada

Abstract: Naming speed (NS) tasks, which measure how quickly and accurately subjects can name sets of highly familiar stimuli (e.g., letters) randomly presented in a visual array, have been shown to be a precursor and concurrent correlate of accurate and efficient reading. However, it is still not known what cognitive processes underlie this relationship. Functional magnetic resonance imaging (fMRI) was used to investigate the neural substrates and cognitive processes underlying performance during letter and object NS tasks. We used three methods to examine task performance: (a) changing stimulus composition to emphasize phonological and/or visual aspects; (b) decomposing NS times into pause and articulation components; and (c) analyzing eye movements and brain activation involved in a NS task. We recruited 19 healthy young adults (ages 21 - 26 years), and employed a block design consisting of a letter NS task and three variants that were either phonologically and/or visually confusing (Compton, 2003); and an object NS task with a variant in which the object names rhymed with one another, while subjects' eye movements and articulations were recorded. We examined how these manipulations influenced performance and whether they resulted in differences in neural activation. Behavioral analyses revealed that for the letter NS task, NS manipulations were associated with specific patterns of performance which were influenced by visual rather than phonological similarity. When the task was both visually and phonologically similar, participants had significantly longer naming times and fixation durations, and made more frequent saccades and regressions. However, for the object NS tasks participants' performance was not affected when the names of the objects rhymed with one another. This was indicated by a trend in which participants made shorter fixations and fewer saccades, and had significantly shorter naming times and made fewer regressions on the phonologically similar object task than the control task. fMRI results indicated significant activation during both letter and object NS tasks in brain areas involved in the reading network and in tasks that require eye movement control and attention in typical adult readers, such as the temporo-parietal area, inferior frontal cortex, superior temporal gyrus, and the ventral visual stream. Further analyses revealed that the different task manipulations target key structures within this reading network, such as the anterior cingulate cortex, precuneus, middle temporal gyrus, and thalamus. These findings reveal that NS tasks recruit the same network of neural structures that are involved in reading.

Title: Concurrent and directionally-compatible hand movements reduce fixation durations and increase peak velocity of sequential saccades

Authors: *B. PARSONS, R. IVRY;
UC Berkeley, Berkeley, CA

Abstract: Studies looking at the relationship between concurrent manual and ocular movements have tended to focus on the influence that gaze has on subsequent hand movements. When responding to a visual cue, the saccade reaction time and duration is faster than the manual response. Indeed, the saccade is typically completed before the reaching movement begins and the saccade may influence the metrics and kinematics of the arm movement. The reverse influence of manual movements on the saccade remains relatively unexplored. Studies that have looked at the phenomenon mostly report a delay in the initiation of saccades when concurrent hand movements are planned. We present evidence that during sequences of horizontal saccades, the maximum rate of the eye movements increases when the eye movements are accompanied by hand movements. This increase is the result of both shorter fixation durations and higher peak velocity. Changes in peak velocity and fixation duration were observed both in the presence and absence of saccadic inhibition of return (Hooge & Frens 2000), although the size of the effect is diminished in the latter condition. The saccade facilitation from arm movements requires that the two actions are directionally compatibility. When the hand moves in the direction opposite to the saccade, fixation durations are longer than in a saccade-only condition. Auditory cueing of saccade sequences produced a modest reduction in fixation duration, arguing against a purely attentional account of the effect. These results provide novel insight into the temporal coordination between saccade and arm motor systems during sequential movements.

Title: Refuting the hypothesis that a unilateral human parietal lesion impairs saccade corollary discharge

Authors: *K. RATH-WILSON, D. GUITTON;
Montreal Neurolog. Inst., Montreal, QC, Canada

Abstract: This study questions the current dominant hypothesis suggesting an impairment of saccade-related corollary discharges (CD) in patients with unilateral parietal lesions, especially of the right hemisphere. A CD is an efferent copy of the motor command for a saccadic eye movement which is distributed to various sensorimotor areas of the brain to update perceptual and motor systems about self-generated movements. In the classic double-step saccade task, used to investigate saccade-related CDs, two targets (T1 and T2) are briefly (80-140ms) flashed sequentially in the periphery. With the extinction of the fixation point and targets, subjects are asked to make two saccades, in the dark, to the remembered locations of the targets in the order they appeared (S1 to T1, S2 to T2). Duhamel et al (1992) and Heide et al (1995) argued that patients with a unilateral parietal lesion fail at generating an accurate second saccade when the first one is directed contralesionally, but not ipsilesionally, suggesting an impairment in contralesional CD generation. Here, we show first that this conclusion is oversimplified. We tested 5 parietal patients on a classic double step task. When given sufficient time and when corrective saccades were evaluated: 2 of 5 patients produced a CD for first saccades in either direction; 2 other patients produced a CD for first saccades only in the contralesional direction; and the last patient did not show evidence of CD. We hypothesize that the continued difficulties of some patients to successfully complete the task relates to well-described attentional impairments in parietal patients. We then tested the same 5 plus another parietal patient (4 left, 2 right) on a modified version of the double step task, designed to mitigate some of the common attentional deficits associated with parietal lesions. We presented T2 first for a longer period of time (800-1200ms) and then T1 (350ms). Patients, in the dark, were to look at where T1 had just appeared and then to the remembered location of T2. All patients who completed sufficient trials showed evidence of CD for ipsilesional and contralesional saccades on this task. Next, in a new task, a single target (T) was flashed and the patients had to first make a self-generated, “endogenous”, saccade of self-determined amplitude before making a second saccade to the remembered location of the previously flashed T. All patients used CD for both ipsilesional and contralesional first saccades on this task. Thus, contrary to current thinking, unilateral left, or right, parietal patients could produce a CD for both left and right saccades.

Title: A six-month exercise-training program improves cognitive-motor control in persons with an identified cognitive complaint: Evidence from the antisaccade task

Authors: ***M. D. HEATH**, C. GILLEN, J. WEILER, M. GREGORY, D. GILL, R. PETRELLA; Univ. of Western Ontario, London, ON, Canada

Abstract: The incidence of individuals reporting a subjective cognitive complaint or demonstrating objective cognitive deficits (i.e., cognitive impairment, not dementia; CIND) is twofold greater than that for Alzheimer's disease (AD) and related dementias. Recent work by our group has shown that a six-month targeted exercise intervention program in persons with CIND improves general cognitive performance and may decrease the risk for further cognitive decline. The goal of the present investigation was to determine whether an exercise intervention impacts goal-directed eye movements in persons with an identified cognitive impairment - a question that provides a framework to determine whether cognitive impairment and exercise influence the basic cognitive-motor processes underlying activities of daily living. Individuals with objectively measured cognitive impairment (Montreal Cognitive Assessment scores < 26) but not dementia (Mini Mental State Examination scores > 24) and their age- and sex-matched controls (individuals with no objectively measured cognitive impairment) participated in a six-month exercise intervention involving dual-task gait training and moderate intensity aerobic exercise on a specialized treadmill (30 minutes, 3 times/week). Prior to and following the intervention, participants completed goal-directed eye movements requiring responses to the veridical location of a target stimulus (i.e., prosaccade) and to the target's mirror-symmetrical location (i.e., antisaccades). In particular, we contrasted pro- and antisaccades because the latter task is cognitively demanding and is supported via cortical structures that have been linked to cognitive decline in dementia (i.e., dorsolateral prefrontal cortex). As expected, prosaccade reaction times (RT) were shorter than antisaccades. More notably, antisaccades - but not prosaccades - for persons with a cognitive impairment showed a selective decrease in RTs post-intervention. As such, we provide evidence that exercise can improve cognitive-motor function in persons with cognitive impairment. As well, our results suggest that a targeted exercise intervention program may serve to attenuate adverse structural changes to those cortical regions related to dementia.

Abstract: Eye movements can reveal where, what, why, and how the human brain processes the constant flow of visual information from the world. Here, we measured the eye movements of United States Marine Corps (USMC) combat aviators to understand the oculomotor effects of fatigue as a function of time-on-flight (TOF), expertise, and arousal during flight training. Saccadic velocities decreased after flights lasting 1h or more, suggesting that saccadic velocity could serve as a biomarker of aviator fatigue. We observed that USMC aviators can be significantly fatigued by simulator training. A follow-on study set out to determine, via oculomotor measures, if TOF affected the aviators' cognitive processes. To test this we examined oculomotor dynamics in response to emergency procedures in flight, and found that the effects of TOF on eye movements were alleviated temporarily by the addition of high-arousal stressful conditions. Finally, we tested whether novice pilots might benefit from passive viewing of expert eye position scanpaths. We tasked novice pilots with repeatedly resolving a serious emergency procedure (dual engine failure cascade), followed by watching a video with an expert solving the same emergency procedures: half of the novices saw the video with the expert eye position indicated, and the other half watched the video without eye movements superimposed. Pilots who were given the expert eye movement information performed better in a subsequent test, and specifically incorporated eye movement strategies from the expert in their behavior.

Title: Modulation of eye movements by down syndrome cell adhesion molecule-like 1

Authors: *M. M. MA, Y. A. PAN;
Dept. of Neurosci. and Regenerative Med., Georgia Regents Univ., Augusta, GA

Abstract: Normal brain function requires precise wiring of neuronal connections, established during gestation and childhood periods. Recent genetic studies of autism spectrum disorder (ASD) families have identified the Down syndrome cell adhesion molecule (DSCAM) and its close homolog, DSCAM-Like1 (DSCAML1), as potential causal genes for the disease. DSCAM and DSCAML1 are membrane adhesion molecules known to regulate dendritic outgrowth and selective cellular adhesion. It is still unclear, however, how DSCAM and DSCAML1 affect broader brain connectivity and behavior. To address these questions, we examined the role of DSCAML1 in visual function, using larval zebrafish, a small and transparent vertebrate, as the model. We generated a putative null allele in the zebrafish DSCAML1 gene by TALEN-directed mutagenesis. Mutant animals are grossly morphologically normal but never survive past 10 days post-fertilization. As DSCAML1 has previously been shown to affect development of the visual system, specifically the retina and its afferents, we tested whether loss of DSCAML1 affects an innate visual behavior, the optokinetic reflex (OKR). OKR involves eye movements in response to whole-field motion stimulus in the surroundings, which stabilizes the visual image on the retina. OKR is conserved among vertebrates and serves as a robust assay to investigate sensory processing, motor control, and diagnosis of brain lesions or abnormal development. In contrast to control, which can initiate OKR within the first two trials, DSCAML1 mutants required three or more trials to initiate OKR. Interestingly, once initiated, there was no significant difference between the mutants and the controls in OKR performance (speed over different contrast levels). In addition, mutant animals exhibited deficits in conjugated eye movements. These results suggest that DSCAML1 is required for establishing the neural circuitry for OKR, specifically the initiation and coordination of eye movements. The higher threshold for initiating OKR may potentially result from deficits in a gating mechanism within the mid-hindbrain OKR neural circuitry. These findings may be clinically relevant to the eye movements disorders seen in

individuals with ASD. Brain mapping analyses with transsynaptic vesicular stomatitis virus (VSV) are currently underway to identify the neural substrates for the OKR deficits.

Title: Compensatory changes of tetha oscillations in hippocampus after vestibular sensory loss in rats

Authors: *J. N. ERON, N. A. LOGINOVA, V. A. KORSHUNOV;
Inst. of Higher Nervous Activity and Neurophysiol., Moscow, Russian Federation

Abstract: The theta oscillations in hippocampus synchronize firing rate of hippocampal cells, which appear to encode an animal's location within the environment, and also play an essential role in spatial orientation and memory. It has been shown that vestibular sensory damage causes the reduction of theta rhythm in hippocampus and produces long-term changes in performance in a spatial reference memory tasks. Nevertheless, it is unknown whether the short-term compensatory changes of theta oscillations occur when the vestibular sensory input is completely loss. The aim of this study was to estimate the short-term changes of theta activity due to vestibular sensory loss. The local field potential oscillations were recorded in CA1 hippocampus in awaked freely moving animals (male Wistar rats, age >3 months) to estimate the phase-amplitude coupling of theta band rhythm. The rhythmic activity were tested before and again in 2, 4-6, 8, 10-12, 15 and 20-30 days after bilateral vestibular deafferentation (BVD) (n=7) or sham vestibular loss (n=7). After BVL the theta rhythm frequency shifted from 7-9 Hz to 4 Hz and the power significantly decreased; however, significant temporal recovery of the frequency range and power of theta rhythm was found by post-BVD day 12. There were no significant changes in spectral properties of theta oscillations in CA1 hippocampus in rats after the sham vestibular loss. Thus, the facilitation of theta oscillations in hippocampus was observed post-BVD term. Recently, we have reported about similar short-term recovery of synaptic transmission efficacy in CA1 hippocampus after BVD. Our results suppose that the facilitation of theta oscillations and synaptic transmission could occur due to increase of excitability in neuronal circuits, which could be associated with synchronization of neuronal responses in hippocampus during relearning to new inter-sensory interaction, when the vestibular sensory input is damaged.

Title: Effects of vestibular loss and parabolic flight on cell proliferation in the rat dentate gyrus

Authors: ***C. M. GLIDDON**[1,2], Y. ZHENG[2], P. AITKEN[2], L. STILES[2], M. HITIER[3], M.-L. MACHADO[4], B. PHILOXENE[4], P. DENISE[4], P. SMITH[2], C. DARLINGTON[2], S. BESNARD[4]; [1]Pharmacol. and Toxicology Dept., Univ. of Otago, Dunedin, New Zealand; [2]Brain Hlth. Res. Centre, Pharmacol. and Toxicology Dept., Dunedin, New Zealand; [3]Dept. of Otolaryngology Head and Neck Surgery, Caen, France; [4]Normandie Univ., Caen,, France

Abstract: There is evidence to suggest that alterations in gravity as experienced by astronauts can induce impairment in spatial learning and memory; however, the underlying mechanism remains to be elucidated. Dysfunction of the vestibular apparatus, which detects gravitational acceleration, has been linked to hippocampal malfunction and spatial learning and memory impairment. One possibility is that the impairment of spatial learning and memory following the alteration in gravity is due to changes in cell proliferation and neurogenesis within the hippocampal dentate gyrus, a well-known neurogenic area. The aim of this experiment was to determine if changes in gravity during parabolic flight, altered cell proliferation in the dentate gyrus of rats with either an intact vestibular apparatus (sham group) or no vestibular apparatus (bilateral surgical vestibular deafferentation, BVD) by measuring the number of bromodeoxyuridine (BrdU)-labelled cells. Male Long-Evans rats were randomly allocated to the following experiment groups: (1) sham surgery only (n = 5); (2) BVD surgery only (n = 5); (3) sham surgery and parabolic flight (n = 5); (4) BVD and parabolic flight (n = 6). At 6 weeks following the surgery, the animals were subjected to parabolic flight under anaesthesia (fentanyl, 0.2 mg/kg, s.c. and medetomidine hydrochloride, 0.5 mg/kg, s.c.). The parabolic flight was carried out on a modified Airbus A300 aircraft. The no flight animals were under the same anaesthesia for the same duration. Immediately after the parabolic flight, all animals were injected with BrdU (300 mg/kg, i.p). Twenty-four hours after BrdU injection, rats were anaesthetized and cardiac-perfused with saline followed by 4% paraformaldehyde. The brains were dissected out. Serial 40 μm sagittal sections throughout the hippocampus were cut

according to a random, systematic sampling design. BrdU immunolabelling was performed and the number of BrdU positive cells was quantified using a modified fractionator method. Data were analysed using a linear mixed model analysis in SPSS 22. There was a significant main effect of BVD ($F(1, 34) = 15.21$, $P \leq 0.0001$); however, side, flight, and all interactions were non-significant. The results indicate that BVD significantly decreased the number of BrdU-positive cells compared to sham-operated animals. However, brief cyclic periods of hypergravity and microgravity induced by a parabolic flight does not significantly alter the number of BrdU-positive cells in either sham or BVD rats, suggesting that changes in gravity do not alter the proliferation of cells within the dentate gyrus.

Title: Otolithic involvement in the organization of exploratory movements

Authors: L. A. CHEREP[1], P. A. BLANKENSHIP[1], S. N. BROCKMAN[3], A. D. TRAINER[3], J. D. BENSON[2], *R. M. YODER[3], D. G. WALLACE[1];

Abstract: Rodents use environmental and self-movement cues to organize their exploratory behavior. A portion of these self-movement cues appears to include signals from the otolith organs, given the marked path integration deficits of otoconia-deficient mice on a food-hoarding task in darkness. Access to environmental cues improves performance on this task in light, but some aspects of performance are still impaired. These deficits are not fully understood at the present time, but may involve disruptions in movement organization; however, no previous studies have evaluated the otolithic contribution to exploratory behavior. The organization of exploratory behavior was characterized in otoconia-deficient *tilted* mice when they moved about an open field under dark and light conditions. The open field was a circular table (d = 112 cm) with a transparent wall (15 x 20 cm) affixed to the edge that could serve as a polarizing tactile cue. An overhead video camera recorded all movements for offline analysis. Each mouse was released at the center of the arena and permitted to explore the entire apparatus for one 40-min

trial each day, across three days in darkness and three days in light. Movement characteristics were examined after the first bout of grooming. Exploratory paths were divided into stops and progressions. Several measures were developed to evaluate stops - number of stops, stop duration, change in heading, and locations of stops. Several measures were developed to evaluate progressions - number of progressions, peak speed, path circuity, and path length. In general, both groups of mice groomed and established a "home base" near the location of grooming in both darkness and in light. In darkness, but not in light, the concentration of stops was lower for *tilted* mice than control mice. Also in darkness, but not in light, *tilted* mice showed more circuitous progressions than control mice. Interestingly, *tilted* mice showed a greater change in heading after stops, in both darkness and in light. This pattern of results is consistent with impaired self-movement cue processing in the absence of signals from the otolith organs. Along with our previous studies, these results indicate an important role for otolithic information in the organization of exploratory movements.

Title: Galvanic vestibular stimulation in primates: Recording vestibular afferents during transmastoid stimulation

Authors: *A. KWAN[1], D. E. MITCHELL[2], P. A. FORBES[3,4], J.-S. BLOUIN[4], K. E. CULLEN[2];

Abstract: Every day the vestibular system detects head motion and provides the brain with information needed for our sense of balance. The vestibular sensors in the inner ear convert this head motion information into a neural signal, which is then carried by the primary vestibular afferents to the central nervous system. In the absence of actual motion, vestibular afferents can be artificially modulated by delivering electrical current in proximity of the inner ear, termed galvanic vestibular stimulation (GVS). GVS has become a popular tool to study human

vestibular function because unlike natural vestibular stimuli requiring physical motion, it generates vestibular signals without activating other sensory channels. GVS, which is applied to human subjects between surface electrodes on the mastoid processes behind the ears, induces ocular and postural responses, and virtual motion perception, attributed to the activation of the vestibular system. While there is growing interest in the applications of GVS in biomedical research and rehabilitation, to date, it is not fully understood how GVS activates the vestibular system. Although vestibular afferent responses have been recorded during electrical stimulation, these studies used stimulating electrodes implanted in the ear. Here, to better understand how transmastoid GVS affects vestibular nerve activity, we recorded vestibular afferent responses during GVS applied between surface electrodes on the mastoid processes of alert macaques. Stimulation protocols included constant current, typically used in human GVS studies, as well as single sinusoidal and band-limited noise current corresponding to the physiological relevant frequency range (0 - 25Hz). We found that GVS activates non-specifically all vestibular afferents, both semicircular canals and otoliths, with irregular afferents being more sensitive, consistent with previous studies. We show for the first time that during sinusoidal stimulation, otolith afferents, much like canal afferents, displayed an increase in both gain and phase lead as a function of frequency. These results contrast with previous studies using internal electrodes, which instead observed a flat frequency response (i.e. relatively constant gain and phase). While comparing the responses to noise and sinusoidal stimulation suggests that the afferents encode GVS linearly, surprisingly, the afferent responses to constant current GVS could not be predicted from the model fit to sinusoidal data. Specifically, the observed time constants were longer than estimated. Together, these results provide new insights into modelling the dynamics of GVS activation of the vestibular system.

Title: Effects of galvanic vestibular stimulation on vestibular cortex activity

Authors: *F. NOOHIBEZANJANI[1], C. KINNAIRD[1], S. WOOD[2], J. BLOOMBERG[3], A. MULAVARA[4], R. SEIDLER[1];

Abstract: Falls are the current leading cause of fatal and nonfatal injuries in older adults. The annual rate of falling is approximately one out of three in older adults above 65, and its direct medical cost is estimated as $34 billion. The aim of this study was to investigate the effects of Galvanic Vestibular Stimulation (GVS) on improving balance. GVS refers to the application of low-level electrical noise via electrodes placed on the mastoid bones. The addition of low-level noise to the sensory system increases the signal to noise ratio and results in more sensitivity to detecting the sensory signals. We assessed the effects of short-term and long-term exposure to GVS on brain activation and postural control. We hypothesized that low-level GVS increases vestibular cortex activity, which correlates with improvement in balance control. Further, we hypothesized that long-term GVS application leads to greater functional and anatomical alterations in the brain than short-term GVS. Subjects underwent three fMRI scans over the course of 6 days: baseline (day1), short-term effects (day2), and long-term effects (day6). We assessed the alterations in body sway on a force platform on day1 and day6 (i.e. pre and post intervention balance assessments). The GVS was applied for 4 days (days 2-5), 45 minutes per day. Since GVS increases the perception of sensory input, we evaluated subjects' threshold for signal detection prior to GVS application on each day, and modified the stimulation level accordingly. Using this method we were able to control for individual differences and day-to-day variability. The preliminary results suggest that short-term GVS effectively changes the functional activity of the vestibular cortex and other brain regions involved in sensorimotor processing. We found an overall decrease in activation of parietal-temporal regions (more directly involved with processing of vestibular input), along with increased activity of pre and post central gyri, and occipital regions (more directly involved in processing of visual and proprioceptive signals). These findings suggest that application of GVS could potentially elevate the sensitivity and function of the vestibular system in a way that there is less cortical allocation needed for processing the vestibular information, leaving the other regions involved in processing sense of motion with more resources to respond to vestibular stimulation. Our future analyses will determine the long-term effects of GVS and the extent to which the alterations in cortical activity correlate with balance improvements.

Title: EEG spectral signatures of spatial updating processes during whole-body motion

Authors: *T. P. GUTTELING, W. P. MEDENDORP;
Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: When moving around in the world, everything seems stable, although some objects may move along with you ('body-fixed'), while some stay fixed in the world ('world-fixed'). The latter has been studied in great detail during saccadic eye movements, revealing the existence of spatial updating mechanisms. Recently, we studied the role of such updating mechanisms during passive whole-body motion, where vestibular information is likely to drive the update. Using EEG, we found that world-fixed targets are dynamically updated, and are represented by lateralized alpha desynchronizations in parieto-occipital areas. While this shows an interaction between vestibular motion signals and dynamic updating, it is still unclear how their interaction comes about. Here we used a parametric design to examine this interaction between self-motion, target coding and spatial updating. Subjects were linearly accelerated using a translation sled, while 88-channel EEG and eye position were recorded. While subjects maintained body-fixed fixation, a peripheral target location was briefly flashed, which had to be either maintained or updated during the motion, depending on whether the target was world-fixed or body-fixed. After the motion, subjects had to indicate where the remembered target was located in space. Preliminary results show that self-motion processing, target coding and successful spatial updating are reflected in distinct oscillatory signatures that evolve during self-motion. Ongoing analyses and experiments aim to reveal the interplay between these processes that drive spatial updating, as well as manipulate ongoing cortical oscillatory processes using transcranial alternating current stimulation.

Title: Robotic assessment of wrist position sense in a 3d workspace

Authors: *F. MARINI[1], V. SQUERI[1], P. MORASSO[1], L. MASIA[2];
[1]Inst. Italiano Di Tecnologia, Genova, Italy; [2]nanyang technological university, Singapore, Singapore

Abstract: The ability of perceiving of our body position in space is an important component of proprioception. It plays a crucial role in human movement control, which is fundamental for every daily activity. The mechanisms underlying proprioception have been extensively

investigated and an increasing emphasis has been placed on quantitative assessment of proprioceptive acuity. One test that has garnered particular interest is joint position matching, in which participants must replicate a reference joint angle using just proprioceptive information (in the absence of vision). Although the assessment of joint position sense has become a common topic of research, no standard method for measuring it has been established and universally accepted in clinical practice. Recent advances in robotic interfaces designed for sensorimotor rehabilitation enabled the use of such devices for the assessment of proprioceptive functions. Just few studies focused on the wrist joint, and most of them examined just a single joint degree of freedom. With the aim of assessing wrist proprioceptive acuity we designed a joint position matching task that thirty healthy adults performed with a 3 degrees of freedom wrist exoskeleton. Specifically, we sought to characterize each degree of freedom (DoF) of the joint (Flexion/extension, radial/ulnar deviation, pronation/supination) in term of its position acuity, measured as the error made while actively replicating a reference joint angle. Besides the investigation of the isotropy (or anisotropy) of the wrist position sense across its DoFs, we wanted to study if our proprioceptive acuity changes if experienced targets are located in a smaller workspace meaning that we perceive differently targets which are closer to the center of the joint. Moreover, we examined whether the distance is remembered better or worse than the final position or, in other words, if distance cues are reliable as location cues and if matching errors could depend on the use of distance information rather than just on the end point information. What we found is a significant difference in the proprioceptive acuity of the three DoFs in particular for the radial/ulnar deviation, for which we found smaller positioning errors. Furthermore, we found a consistent higher accuracy in matching targets located in a larger workspace, closer to the limits of wrist's range of motion since greater errors were observed in the small workspace condition were targets were always overestimated. Finally, we could evaluate how much subjects rely on target distance as well as its position since subjects' performance was characterized by a higher variability when the distance information was missing.

Title: Multiple spatial representations are updated in parallel during self-motion

Authors: *J. J. TRAMPER, P. MEDENDORP;
Radboud University, Donders Inst., Nijmegen, Netherlands

Abstract: The brain encodes visual space in multiple spatial representations, including eye-centered and body-centered reference frames. When we move our body in space, these internal, egocentric representations are no longer in register with external space, unless they are actively updated. Whether the brain updates multiple spatial representations in parallel, or whether it pertains its updating mechanisms to a single reference frame from which other representations are constructed, remains an open question. We developed an optimal integration model to simulate the update of a visual target across body motion in multiple or single reference frames, assuming a biased estimate of body displacement and a noisy estimate of the sensory signals. To test this model, we designed an experiment in which participants had to remember the location of a briefly presented target, while being translated sideways, in complete darkness. The behavioral responses were in agreement with a model that uses a combination of eye- and body-centered representations, weighted according to the reliability in which the target location is stored, and updated in each reference frame. Our findings suggest that the brain simultaneously updates multiple spatial representations across body motion. Because both representations are kept in sync, they can be optimally combined to provide a more precise estimate of object locations in space than based on single-frame updating mechanisms.

Title: Spatial transformation of the vestibular control of standing in humans

Authors: P. FORBES[1], B. L. LUU[2], M. VAN DER LOOS[1], E. A. CROFT[1], J. INGLIS[1], *J.-S. BLOUIN[1];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Neurosci. Australia, Sydney, Australia

Abstract: The vestibular control of standing is tightly coupled to head orientation. The evoked muscles response must undergo spatial transformation to provide effective compensation and error correction. In this study we investigate two properties of this transformation and their effect on the vestibular evoked muscle response: 1) the effect of head position when the body is

constrained to a single anterior-posterior plane of motion, and 2) the effect of reversing the spatial relationship between the motor output (i.e. ankle moment) and the accompanying vestibular consequences (i.e., head motion). By using a robotic platform that simulates the mechanics of standing balance as an inverted pendulum, we can control the spatial properties of the motor signals and the subsequent vestibular sensory information. Subjects were exposed to binaural bipolar electrical vestibular stimulation applied to the mastoid processes while recording EMG from the right soleus. To address the effects of head position, subjects balanced the robotic platform under normal conditions with the head facing forward and with the head turned to the left at 15° increments up to 90°. To address the effects of spatial relationships between motor and sensory signals, subjects balanced the robotic platform with the head turned left while the torque output that generates natural body sway was reversed. We isolated the sensorimotor reversal to vestibular and motor signals. Across head rotations, the largest muscle response to vestibular stimulation was observed when the head was turned 90 degrees to the left, with the response diminishing as the head was turned towards a forward facing position. The change in peak-to-peak amplitude of the muscle response at intermediate head angles was described by the cosine transformation of the muscle response obtained with the head rotated 90 degrees. During vestibular sensorimotor reversals, the muscle response was reversed and delayed by about 30 msec in comparison to normal conditions, even though the postural sway remained in the direction expected of the electrical stimulus (i.e. sway towards the anode). The present study describes two key factors in the spatial transformation of the muscle response to electrical vestibular stimulation. First, that only the vestibular-motor pathways that are appropriate to counteract the electrically-induced sway are recruited as part of the balance response rather than a generalised response to all dependent postural muscles. And second, that the counteracting muscle response can be modified to account for changes in the spatial sensorimotor relationship but is accompanied with an increased processing delay.

Australia, Univ. of New South Wales, Sydney, Australia

Abstract: The vestibulo-collic reflex (VCR) in humans is well-defined for only the sternocleidomastoid (SCM) neck muscle. However, other neck muscles also receive input from the balance organs and participate in neck stabilization. We therefore investigated the sound-evoked VCR projection to the splenius capitis (SC) muscles. We compared surface and single motor unit responses in the SCM and SC muscles in 10 normal volunteers. We stimulated with 2 ms tone bursts of 500 Hz in the left and right ears. The strongest responses were recorded in the SCM ipsilateral to the stimulated ear and the SC on the contralateral side. In both cases there was a significant decrease or gap in single motor unit activity: in SCM at a median latency of 13 ms for 36/41 units, and in SC at 14 ms for 40/61 motor units. In contrast, there were very few significant responses in the contralateral SCM and ipsilateral SC muscles, and they tended to be increases in activity. Surface responses in the ipsilateral SCM consistently showed a biphasic positive-negative wave with peaks at 13 and 23 ms, while there were occasional/smaller negative-positive responses on the contralateral side. Surface responses over the ipsilateral SC were inconsistent, while those over the contralateral SC were positive-negative during neck rotation and negative-positive during neck extension. An initial decrease in single motor unit activity suggests an inhibitory projection, while an increase indicates an excitatory projection. The results thus demonstrate an uncrossed inhibitory vestibular projection to the ipsilateral SCM and a crossed inhibitory projection to the contralateral SC. There was a weak excitatory projection in some subjects in the complementary muscle pair. This pattern of activity is consistent with the agonist relationship between these muscles. Surface responses over SC were unreliable indicators of reflex polarity, while needle recordings unambiguously showed the polarity of the reflex.

Title: Our internal model of head and neck control incorporates electrical vestibular stimulation as a self-generated sensory signal

Authors: *P. A. FORBES[1,2], J. C. FICE[2], A. C. SCHOUTEN[1,4], G. P. SIEGMUND[5,3], J.-S. BLOUIN[2];
[1]Delft Univ. of Technol., Delft, Netherlands; [2]Sch. of Kinesiology, [3]Univ. of British Columbia, Vancouver, BC, Canada; [4]Univ. of Twente, Twente, Netherlands; [5]MEA Forensic Engineers & Scientists, Richmond, BC, Canada

Abstract: Differentiating sensory input from externally imposed movements (i.e., exafference) versus self-generated movements (i.e., reafference) is essential for orienting the head. Vestibular signals from self-generated movements are suppressed when actual sensory information matches expected sensory feedback using an internal model. Recent work suggests that this internal model is recalibrated (i.e. updated) to account for vestibular signals that are artificially modulated with the ongoing head motion. For example, in standing subjects, electrical vestibular stimulation (EVS) that is coupled to head angular velocity can be incorporated into the internal model after a conditioning period that includes reliable visual or somatosensory cues. Here, we directly tested this proposal during head-neck control by coupling EVS to head pitch velocity with the head constrained to move only in pitch. Our aim was to estimate how much of an exafferent head-coupled EVS can be transformed into a reafferent signal. Because EVS evokes a perceived head roll rotation (i.e., lateral bending), we expected lateral forces applied by the head to increase when the stimulus was applied and to return to normal after a conditioning period with eyes open (EO). Subjects voluntarily flexed and extended their head ±13° at 0.4 Hz while attached to a robot that constrained head roll and yaw. Head-neck forces and moments were measured while subjects moved continuously during 6 sequential trials: 1) baseline, no EVS with eyes closed (EC), 2) head-coupled EVS with EC, 3) head-coupled EVS with EO, 4) head-coupled EVS with EC, 5) no EVS with EC, and 6) no EVS with EO. During head-coupled EVS (Trial 2), lateral head-neck forces increased relative to no EVS with EC (Trial 1) and the force direction varied with the polarity of the EVS. Lateral forces quickly diminished when subjects opened their eyes and were given visual feedback of lateral forces (Trial 3). When subjects reclosed their eyes (Trial 4), lateral forces remained similar to equivalent no EVS conditions (Trial 1) despite receiving EVS. When EVS was then removed (Trial 5), lateral forces increased to levels similar to when EVS was first applied but in the opposite direction. These lateral forces were quickly diminished when subjects reopened their eyes (Trial 6) with visual feedback of their lateral forces. Our results show that for head-neck control, the central nervous system can recalibrate isolated exafferent vestibular only signals as reafferent signals by using reliable visual feedback of head motion and force. Moreover, this recalibration is complete, since when the external signal is removed, an equal and opposite effect occurs.

Title: Developmental and circadian regulation of the locomotor contribution to balance in zebrafish

Authors: *D. E. EHRLICH[1], D. SCHOPPIK[2];
[1]Neurosci. and Physiol., NYU Langone Med. Ctr., New York, NY; [2]NYU Sch. of Med., New York, NY

Abstract: While locomotion subserves goal-directed behaviors it can also promote the maintenance or restoration of balance. Tight regulation of balance is required for survival and must be acquired early in life. As balance improves throughout development, we hypothesized locomotion more effectively regulates posture with age. To this end, we defined the contribution of swimming to balance in developing zebrafish larvae (age 5 to 28 days). We constructed an apparatus that records both the orientation of the long axis of freely swimming fish relative to the horizon and their position in the water column. Fish were monitored over 48 hour periods with a 14/10 light/dark cycle. Zebrafish larvae swim in short, discrete bouts that correct deviations in pitch from the preferred, horizontal orientation. During intervals between bouts larvae steadily rotate in pitch, accruing eccentricity with time. Propulsive bouts produce compensatory rotations that negatively correlate with initial pitch. In addition, shorter latencies to propulsion are observed for more eccentric pitches. Fish produce larger propulsive rotations and deviate less from horizontal pitch as they mature. Early but not late in development, larvae deviate more from horizontal pitch in the dark phase than the light phase. Immature larvae in the dark phase reach more eccentric pitches before propulsion, exhibit longer delays between propulsive bouts, and generate propulsive rotations twice the magnitude of those in the light phase. Together, these data suggest rotations produced during locomotion compensate for pitch eccentricity, thereby restoring balance. In addition, zebrafish posture varies and balance is maintained more effectively across age and the light/dark cycle. Future experiments will address the causal relationship between pitch eccentricity and locomotor compensation.

Title: Swimming blindly: a role for vision in postural maintenance of larval zebrafish

Authors: *S. D. SUN[1], D. E. EHRLICH[2], D. SCHOPPIK[2];
[1]New York Univ., New York, NY; [2]NYU Sch. of Med., New York, NY

Abstract: Visual feedback is thought to modulate somatosensory and vestibular sensations, enabling both proper acquisition and maintenance of balance. This multisensory integration must happen on both short and long timescales to permit both rapid corrective movements and proper gait development. The precise mechanisms for such integration remain poorly understood. We have developed a novel behavioral paradigm using freely swimming zebrafish (Danio rerio) to explore how acute and chronic perturbations of visual input modulate posture. Of the three cardinal axes, previous work has characterized zebrafish movements in yaw and roll. Comparatively little is known about posture in pitch (nose-up/nose-down). We constructed an apparatus that records both the orientation of the long axis of the fish relative to the horizon and its position in the water column. We analyzed the static pitch, dynamic rotations, and translation of normal, dark-reared, and blind larval zebrafish swimming in both the light and dark. Blind zebrafish are most likely to be pitched level with the horizon, 0.4º±18º (mean±SD). In contrast, wild-type zebrafish have a slight nose-up bias to their posture 10.1º±14º. Dark-reared zebrafish are pitched similarly to blind zebrafish, near the horizon; however, their posture varies like that of wild-type zebrafish at 1.3º±13°. Zebrafish larvae swim in short discrete bouts. We observed a strong rotational component during both the inter-bout interval and the swim bout itself. On average, all fish rotated nose-down during the inter-bout interval, and appear to compensate during the bout with a nose-up rotation. Both blind and dark-reared larvae swam less frequently than sighted siblings. As such, there were larger nose-down deviations in posture before a corrective propulsive bout. During corrective propulsion, blind and dark-reared larvae exhibit higher peak angular velocities than sighted fish, compensating for these larger nose-down deviations. We infer that blind and dark-reared larvae detect nose-down changes later than normal larvae and as a result must correct more for such changes. Interestingly, though dark-reared zebrafish exhibit some postural characteristics similar to blind zebrafish, they appear to have longer propulsive bouts than both sighted and blind fish. Our data suggest that visual information is fundamental to maintain a normal pitch, and may help to guide compensatory movements for pitch changes during periods of inactivity. These results provide a foundation for

further investigation into the role of vision in the maintenance of balance and posture during larval zebrafish development.

Abstract: How cats move their heads while walking has not been studied in detail so far. Given that cats are a popular and otherwise well-researched animal model for studies of posture and visual control of locomotion, this is an important shortage. The goal of this study was to investigate head movement in the cat during walking. Three cats walked in a chamber 2.5 meters long and 0.3 meters wide either under normal laboratory illumination or complete darkness. Position and orientation of the head was recorded with a motion capture and analysis system (Visualeyez, PTI, Canada) using three infrared LEDs placed on the head. 3D positions of cats' right shoulder and forelimb wrist were also recorded using LEDs. The sampling frequency of all recording was 200 Hz. Under the two lighting conditions, cats walked steadily through the test corridor with average speed of 0.59 ± 0.12 m/s (mean ± SD). The head accelerated in the fore-aft direction twice per step cycle: at the beginning and end of stance phase. The head oscillated along the vertical axis in a 12.0 ± 3 mm range twice during the cycle, with one peak in middle of swing and one in middle of stance of the right forelimb. Peaks of vertical acceleration with a range of ± 2 m/s^2 occurred at beginning and end of stance. The head oscillated in the medio-lateral direction in a 7.6 ± 2.2 mm range one time during the cycle, with maximal displacement to the left at beginning of stance of the right forelimb. Lateral acceleration to the left was highest in the middle of stance. Pitch of the head oscillated from -16 to -32 degrees and the range was 7.4 ± 1.6 degrees peak to peak. There were two oscillations for every step cycle: pitch was lowest in middle of swing and in middle of stance. Pitch velocity also oscillated twice per step cycle, and was highest near the end of swing and end of stance. Roll of the head on average ranged by 2.0 ± 0.4 degrees, and had one peak per step cycle: maximum roll to the left occurred

at beginning of stance of the right forelimb. Yaw of the head was 1.9 ± 0.9 degrees. Yaw rotations did not follow any obvious pattern between trials. Two of three cats had similar walking trends (velocity, stride length, step duration, stride duty factor) in the darkness and under illumination. These cats, in darkness, walked closer to the chamber's central wall by 10 mm and rotated their head toward it by 5 degrees. The other cat displaced its head downward 10 mm and also rotated it downward 7.5 degrees during walking in darkness. The data showed that, during walking on the flat surface, the head of the cat rhythmically displaces and rotates in all directions in synchrony with the step cycle. The differences between light and dark conditions were small.

Title: Evidence for sensory signal filtering for perceptual decision-making

Authors: *D. M. MERFELD, F. KARMALI;
Otol & Laryngol, Harvard Med. Schl, Boston, MA

Abstract: Perception can be attended in different ways. For example, when the vestibular system transduces self-motion, subjects can focus on different aspects of the perception. More specifically, during rotation, humans can focus on the amount of rotation perceived, or the perceived direction of rotation. Different perceptual features utilize different neural pathways that likely include signal processing appropriate to the perception of interest. For example, high-pass filter characteristics have been described for perception of rotational velocity (1), for perceptual thresholds during a direction recognition task demonstrate (2,3,4), as well as for semicircular canal afferent signaling (5). Some authors have suggested that each of these filters is distinct, while others have suggested that some may reflect the same underlying processing. To investigate this question, we measured both the magnitude of perceived angular yaw rotation and perceptual yaw rotation direction recognition thresholds in a population of 8 human subjects on a low-vibration rotator. Thresholds were measured by asking subjects to report whether they perceived a leftward or rightward rotation when rotated using cosine velocity profiles at different frequencies. As reported before, we found that thresholds increased as frequency decreased. As for earlier studies a high-pass filter time constant consistent with the data was determined using

generalized linear model fits. Magnitude of perceived rotation was measured by rotating the same subjects using 50 deg/s velocity steps and asking them to press a button every time they rotated through 90 deg. All subjects demonstrated an exponential decay in perceived angular velocity. We found the average time constant for magnitude estimation was 20 s; the average time constant for direction recognition was 1.2 s. These values are substantially and significantly different (paired t-test, p=0.0006). These results suggest the existence of a high-pass filter specifically for the decision-making process, which is distinct from other high-pass filtering for vestibular sensation and perception. Title: Can vision be used to recalibrate vestibular feedback for perturbation recovery?

Authors: *A. J. TOTH[1], L. R. HARRIS[2], L. R. BENT[1];
[1]Human Hlth. and Nutritional Sci., Univ. of Guelph, Guelph, ON, Canada; [2]Ctr. for Vision Res., York Univ., Toronto, ON, Canada

Abstract: Background: The successful recovery of balance in response to a perturbation requires the appropriate integration of somatosensory, visual, and vestibular feedback. Through the use of galvanic vestibular stimulation (GVS), previous work has shown that vestibular information is used during the later stages of perturbation recovery as the body realigns to a perceived representation of vertical [1]. We also know that the vestibular signal for verticality can be recalibrated using visual feedback as shown during gait [2]. The current study asks whether vestibular input is also calibrated to a visual vertical for perturbation recovery.
Methods: Subjects stood on a motion platform and received binaural bipolar GVS at a level 2X their vestibular threshold (threshold: lowest current able to evoke head movement). Subjects wore PLATO visual occlusion spectacles (Translucent Technologies Inc.)**,** used to control the timing and availability of visual information. Kinetic and kinematic data were collected to estimate centre of pressure (CoP) and centre of mass (CoM) movements. During test conditions, subjects received GVS for 4 seconds in the absence of vision. With ongoing GVS, subjects

regained vision for 4 seconds and realigned their altered body position to their visual surround. Vision was then re-occluded and GVS turned off 500ms prior to an antero-posterior (A-P) platform perturbation. GVS and perturbations in control conditions were identical to those used in the test condition. However, subjects were not provided a period of visual availability with which to aid postural realignment. **Preliminary results** indicate that both the peak ML CoM and CoP late responses to the A-P perturbation in the test condition, following the end of the GVS signal, had significantly greater alterations of final equilibrium position relative to vertical compared to controls (CoM; $p = 0.045$, CoP; $p = 0.046$). These findings suggest that a prior period of visual feedback can affect how vestibular information is used to realign posture during perturbation recovery. By using vision to facilitate postural realignment in the presence of GVS, we believe subjects are recalibrating vestibular input to align with the visual vertical. After this recalibration, turning off GVS during perturbation recovery will, at least temporarily, alter the final equilibrium position to the newly 'set' visual/vestibular vertical. The implications of this work align with the consequences of recalibrating vestibular input to erroneous visual signals; these may have profound effects on balance control in elderly populations. Title: Human spatial orientation is distinctly task-dependent

Authors: ***N. BURY**, O. BOCK;
Inst. for Physiol. and Anat., German Sport Univ. Cologne, Cologne, Germany

Abstract: Spatial orientation in humans is based on three reference frames - gravicentric (pull of Gravity), allocentric (alignment of familiar visual objects) and egocentric (orientation on the own body). We have shown before that in absence of allocentric information, participants rely mainly on egocentric rather than on gravicentric cues for control of their hand movements. Here we evaluate whether egocentric cues prevail for other response types as well. Twenty-four participants (12 male, 12 female; 22.1 ± 2.9 years) were placed in-to three angles of pitch (upright 0°, supine -90°, head-down tilt -110°) inside a gym wheel. They were blindfolded to eliminate allocentric cues. In test T1, their task was to adjust the pitch angle of a schematic tree drawing until "⋯the leaves are at the top and roots are at the bottom"; in test T2, their task was to stop their passively moved forearm when it intuitively appeared horizontal or vertical; in test T3, their task was to verbally indicate their own body orientation with respect to the thought face

of a clock. At -90° and -110° pitch, responses in T1 were bimodally distributed such that one mode coincided with the gravicentric and the other mode with the egocentric reference frame. In contrast, responses in T2 and T3 were unimodal, coinciding with only the gravicentric reference frame. We conclude that different perceptual judgements utilize gravicentric and egocentric cues differently, and motor responses utilize them yet differently. In consequence, there seems to exist more than one single internal representation of space.

Title: The influence that modulation of subjective postural vertical decrease awareness of body orientation

Authors: *T. SHIOZAKI, Y. OKADA, S. MORIOKA;
Kio Univ., Nara-Ken, Japan

Abstract: Background Subjective postural vertical (SPV) is a method used to assess perception of verticality. It is reported that in patients who exhibit contraversive pushing, the bias of SPV is larger than in other stroke patients, and as the patients improved with respect to pushing, the bias of SPV disappeared. Use of visual information has been used as a treatment strategy for pushing and it is proposed that gaining vertical position repeatedly and being consciously aware of their verticality produces favorable results. Therefore, we investigated whether the bias in the perception of body verticality influenced decreasing awareness of body orientation, and whether it can be regained with visual information. Methods Subjects were young healthy volunteers. A rotating chair was used for assessing the SPV tilt by 1.5 deg per second on the frontal plane. The SPV corresponding to the angle of body tilt relative to the direction of earth's gravity was measured with a spatial accuracy of 0.1deg. To induce a bias in the SPV experimentally, and in order to assess whether the participants were objectively tilted but subjectively upright, participants were laterally tilted for 5 min at 20 deg. They were then slowly brought back toward earth's vertical, and were asked to press the switch when they had reached a subjective upright position. In the condition in which participants were subjectively and objectively tilted, the participants were brought back to the position of the biased SPV measured in the previous condition. We assumed that the subjects perceived the tilt of their own bodies when a picture of a rich landscape was shown to indicate verticality. We tested whether the reaction time differed in the two conditions. SPV was measured under the conditions when a landscape picture was shown, and it was investigated whether tilt of a body could be recognized accurately by the

visual information. Results The SPV bias was 3.21±2.31°from the earth's vertical under normal conditions. The SPV after lateral body tilt (5.01 ± 2.82°) was statistically different from normal ($P < 0.05$). The participants who were objectively tilted but subjectively upright showed a delay in reaction time and judged their own direction of tilt in comparison with subjective and objective tilt. The angle was 1.34 ± 1.14° and the SPV bias in which visual information was used was small compared with the normal and after the lateral body tilt. Conclusion These data suggest that inducing SPV bias for lateral body tilt decreases awareness of body orientation. Futures studies will need to investigate the mechanism of improvement of regaining awareness of body orientation by using of visual information.

Title: Drift of torsional eye movements and perception of upright during prolonged head tilts

Authors: *J. OTERO-MILLAN[1], A. KHERADMAND[2];
[1]JOHNS HOPKINS UNVIVERSITY, Baltimore, MD; [2]Neurol., Johns Hopkins Unversity, Baltimore, MD

Abstract: Torsional eye movements are rotations of the eye around the line of sight and they occur when we tilt our head towards the shoulder. Perception of upright is usually assessed by a psychophysical task known as subjective visual vertical (SVV) which quantifies the orientation of a visual line that a subject perceives as aligned with the direction of gravity. Torsional eye movements change the orientation of the visual stimulus on the retina thus playing a critical role in our perception of upright. Previous studies have shown that both torsion and SVV can drift over time during prolonged head tilts. Here we directly compared the amount of drift of torsion and drift of SVV during continuous recordings of 15 minutes. We used a novel video tracking method to measure torsion and an adaptive paradigm to continuously measure SVV. We found that torsion always drifted towards zero (the eye position during upright) by an average of 1.5 degrees and between 0 and 3 degrees depending on the subject. SVV on the other hand was much more variable across subjects with a drift ranging from 0 to 10 degrees and an average of 4 degrees towards the direction of the head tilt. The amount of drift in torsion and SVV was not correlated across subjects. That is, subjects with larger torsional drifts did not necessarily have

larger SVV drifts. The mechanisms for the drifts of torsion and SVV remain unknown but our results suggest that they are independent. The precision of SVV measured with the psychometric curve remained constant in spite of the drifts of the accuracy of SVV suggesting that fatigue or lack of attention are not the sources of the drift.

Title: Bayesian analysis of perceived eye level

Authors: *E. E. ORENDORFF[1], R. T. PALUMBO[2], M. V. ALBERT[3];
[1]Biol., [2]Psychology, [3]Computer Sci., Loyola Univ. Chicago, Chicago, IL

Abstract: Perceived eye level (PEL) is a self-reported measure of elevation angle based on visual and internal (proprioceptive/vestibular) cues. It is a valuable reference point when judging height and distance. We applied a Bayesian framework to estimate the underlying computations performed by subjects in the determination of PEL from sensory inputs. The model assumes normal distributions of PEL from individual cues combine to produce a single normal distribution. We calculated separate variance estimates for each input, using the experimental data available - where internal cues were controlled and visual cues consisted of short-12° or long-64° pitched-from-vertical lines, with pitches ranging from -30 to 30°. In total darkness, relying on internal input alone, PEL was near true eye level with SD = ±1°. When subjects were presented with one short line stimulus, visual input had greater variance (SD = ±2.46°), than when subjects were presented with one long line stimulus (SD = ±1.45°). Using these variance estimates to predict the effect of two short or two long line stimuli on PEL, the predicted means were close to those observed (SEE = ±0.73 and ±3.52, respectively). Our model provides a parsimonious explanation for the additive effect of low fidelity cues and the averaging effect of high fidelity cues, as found in other Bayesian cue combination psychophysical studies. The model accurately predicts perceived eye level and provides a means of deriving an appropriate analytical function. We demonstrate this model in a re-interpretation of results by Matin and Li (2001). Vision Res. 41:2845-2872.

Title: Aging and the vestibular system

Authors: *C. DE WAELE[1,2], E. CHIAROVANO[3,4], G. LAMAS[2], P.-P. VIDAL[3];
[1]Cognac G, CNRS UMR 8257, Paris, France; [2]Pitie Salpetriere Hosp., Paris, France; [3]Cognac G, Paris, France; [4]Univ. Paris Descartes, Paris, France

Abstract: Objectives: To investigate the vestibular receptors function and the static equilibrium in seniors. We tested the hypothesis that vestibular dysfunction may vary in function of the type otolithic or canalar tested. Methods: Data were obtained in 166 patients over 65 years of age in the ENT department of the Pitie-Salpetriere hospital. Vestibular function was assessed using caloric, vHIT test and ocular and cervical VEMPs. VHIT consisted of passive and unpredictable, head rotation in the vertical (LARP and RALP) and in the horizontal planes (lateral). Cervical and ocular vestibular evoked myogenic potentials were recorded in response to air conductive or bone conductive stimulation (BK 4810). The Sensory Organisation Test (EquiTest) was used to quantify the role of vestibular, visual and proprioceptive inputs in maintaining balance. The velocity of the displacement of the center of pressure of the feet was measured on the wBB and on the wBB plus foam in eyes open and eyes closed conditions. Finally, patients were asked to fill in the Dizziness Handicap Inventory (DHI) questionnaire. Their cognitive function was analyzed using CANTAB. The aim was to try to detect the risk of falls. Results: We failed to observe a dysfunction of the horizontal and anterior canal receptors using calorics and vHIT in senior. In contrast, vHIT data in the vertical plane showed lower gain when the posterior canal was tested compared to healthy young subjects. We also showed a decreased in the excitability of the utriculo-ocular (n1-p1 waves, 52%) and sacculo-spinal pathway (P13-N23 waves, 37%). Abnormal Equitest (falls in condition 5 or 6) was more often observed in patients with low scores to DHI. Finally, Equilibrium was normal on foam in eyes open conditions. However, 20% of the seniors fell when tested in the foam in eyes closed condition. The velocity of XY pathway of the COG on the foam eyes closed was 4.5±1.0 cm/sec for seniors 80-89 aged and 2.65±0.5 cm/sec for young 30-39 aged. Conclusion: This study showed an alteration of the function of some vestibular receptors with age: utricle, saccule and posterior canal. In addition, the performances of standing upright on foam in eyes closed condition decreased. These results suggested that falls in seniors may be partly related to dysfunction of otolith and posterior vestibular. In eyes closed, vestibular inputs provide absolute information about the body's orientation explaining why standing upright became more difficult and increased mental load.

Title: Sensory and reflexive hypersensitivity in mal de debarquement syndrome

Authors: *R. C. FITZPATRICK, S. R. D. WATSON;
Univ. of New South Wales, Sydney, Australia

Abstract: *Mal de Debarquement* (MdD) is a persistent imbalance syndrome classically after a sea voyage. It presents as abnormal non-vertiginous motion sensations, typically rocking and bobbing. There is no consensus on pathogenesis and aetiology other than it is probably not primary vestibular as clinical vestibular function tests are normal and it is unresponsive to vestibular treatment. We aimed to determine if MdD patients are hypersensitive to vestibular signals of rotation with the hypothesis that they would show perceptual but not reflex hypersensitivity. Patients (N=8, 7F, 27-60yrs) and matched controls were studied. All had normal vestibulo-ocular head impulse and caloric tests. *Perceptual sensitivity* to whole-body yaw and lateral rocking were determined by psychophysical tests. In dark, seated subjects were rotated 30-180° over 5s before pointing to their start positions. Illusory motion evoked by galvanic vestibular stimulation (GVS: 1.5mA, 10s) was used to assess pure vestibular perception. *Sensory thresholds* for detecting the direction of yaw were determined by forced-choice tracking and fitting a psychometric function to identify the amplitude that produced 50% correct responses. Rocking sensitivity was determined sitting on a motorised swing with a roll axis aligned with the head. Subjects reported perceptions of rocking (1-4°, 0.3Hz) using a visual scale. Rocking sensitivity was similarly determined using sinusoidal GVS (0.25-4mA) while stationary. Balance during standing was assessed by forceplate posturography with eyes open and shut, and standing on a rigid floor and foam. *Vestibulospinal reflexes* were assessed by binaural bipolar GVS (≤1mA) measuring medium-latency lateral shear forces. Posturographic measures from MdD patients were not different to those of control subjects. MdD patients showed exaggerated senses of self-motion during real yaw ($P=0.02$ by ANOVA) or virtual yaw ($P<0.001$). However, MdD thresholds for detecting yaw direction were increased ($P=0.007$). MdD patients showed exaggerated senses of roll self-motion during real rocking ($P=0.02$) and virtual rocking ($P<0.001$). Against our hypothesis, MdD showed markedly increased and delayed medium-latency GVS responses during standing ($P<0.001$). *Conclusions.* MdD is characterised by perceptual motion hypersensitivity and vestibulospinal hyper-reflexia, but normal VOR responses. The results indicate separation of perceptual, balance and ocular processing of

vestibular afference. MdD could reflect disordered autoregulation of vestibular sensitivity or integration with somatosensory and visual afference as occurs in normal subjects.

Title: Local field potential changes in the lateral thalamic nuclei of behaving rats using modified Gi protein coupled receptor

Authors: *J. N. STRAND[1], C. STINSON[2], Y. B. PENG[1], L. L. BELLINGER[2], P. KRAMER[2]; [1]Univ. of Texas At Arlington, Arlington, TX; [2]Dept. of Biomed. Sci., Baylor Col. of Dentistry, Texas A&M Univ., Dallas, TX

Abstract: The present study analyzes the summated electrical activity of the lateral thalamic nuclei compared to pain behaviors in a trigeminal model of pain in freely behaving rats. The lateral thalamus processes somatosensory information from the head and facial muscles and is therefore pivotal in the perception of pain from nociceptive input at those sites. Changes in the neuronal activity of the lateral thalamus should influence changes in pain perception as seen by pain behaviors. To affect changes in neuronal activity, a recently developed approach of DREADD (Designer Receptors Exclusively Activated by Designer Drugs) is used to activate a modified G protein coupled receptor (mGPCR) in the targeted region. Activation of the mGPCR triggers the inhibitory Gi protein; Gi is expected to facilitate neuronal silencing. Using local field potential to record the thalamic neuronal activity changes due to mGPCR in freely moving animals provided a novel viewpoint of monitoring lateral thalamic neural activity during active pain. In these studies the lateral thalamus of Sprague-Dawley rats were injected with an adeno-associated virus vector (AAV8) containing a construct that expresses a modified acetylcholine receptor that had been modified to bind to clozapine-N-oxide (CNO) instead of its native ligand, acetylcholine. CNO activation of the virus induces activation of the mGPCR, changing the neuronal activity level in the targeted lateral thalamic region. 30 minutes after CNO injection (1 mg/kg), 50µL of 3% formalin was injected into the masseter tendon, inducing nociception. LFP and behavioral responses were recorded simultaneously in both drug and control groups. We found that the pain behaviors are significantly reduced in the drug group compared to the no drug group. We have further found that summated electrical activity is increased in the lateral thalamic region for the drug group, especially in the beta and gamma frequency bands. The

results from this study suggest that LFP can be a useful tool to monitor pain behavior in freely behaving animals.

Title: Electrophysiological characterization of trigeminal neurons innervating the anterior structures of the eye

Authors: ***B. SANTIAGO**, M. C. ACOSTA, J. GALLAR, C. BELMONTE;
Inst. De Neurociencias UMH-CSIC, San Juan De Alicante, Spain

Abstract: The functional properties of the trigeminal ganglion neurons (TGN) innervating the cornea, conjunctiva, and eyelids and mediating sensations of pain and discomfort are incompletely known. The aim of this work was to characterize *in vivo* the firing characteristics of the different sensory types of TGN innervating the anterior structures of the eye. Anesthetized Wistar male rats (350±25g) were placed in a stereotaxic frame and units from the right TG were recorded extracellularly with tungsten electrodes (2-5MΩ). The signal was amplified, filtered and recorded using an ADC interface and software for off-line analysis. TGN were identified by stimulation eye tissues with a fine brush or approaching a cooled metal probe. The receptive field (RF) and the mechanical threshold (MT) were determined using von Frey filaments. Thermal (saline drops at 21ºC or at 50ºC) and chemical (98% CO2 gas jet; 100µM menthol; 850mOsm hyperosmolar saline) stimuli were applied onto the RF. Electrical pulses (Ag/AgCl bipolar electrode, 0.1-2ms, 5-30V) were applied to measure conduction velocity (CV). TGN innervating the bulbar (n=15) and tarsal (n=21) conjunctiva; the upper (n=15) and lower (n=15) eye lids, and the cornea (n=38) were analyzed. TGN were classified depending on their responses to the stimuli as polymodal, mechanical and cold TGN. All these types were found in the conjunctiva and cornea, while only mechanoreceptors were found in the eyelids, some associated to the eyelashes. A part of the polymodal TGN showed spontaneous activity that increased markedly with CO2 stimulation and mechanical pressure; MT was similar in all territories (0.14±0.06mN,

0.17±0.05mN, 0.21±0.04mN; cornea, bulbar and tarsal conjunctiva respectively). Mechanoreceptor neurons had no spontaneous activity and MTs that varied among tissues (0.08mN, 0.6±0.37mN, 0.19±0.05mN, 0.51±0.16, mN; eyelids, cornea, bulbar and tarsal conjunctiva respectively). Cold TGN fired rhythmically, increasing their frequency of discharge when cooling and silencing with heating. Two subpopulations of cold thermoreceptor neurons (low and high threshold TGN) were found in the cornea, distinguished by their spontaneous activity (8.01±0.81 imp/s, n=13 vs. 1.83±0.42 imp/s, n=10), cold threshold (-0.11±0.01ºC vs. -0.61±0.37ºC) and peak frequency (41±4.64imp/s vs. 17.2±3.56 imp/s). All TGNs explored showed CVs in the range of C (<2m/s) and Aδ fibers (>2m/s), regardless of the type and ocular region of origin. Finally, differences in stereotaxic coordinates showed the corneal and bulbar conjunctiva units more posterior and deep than tarsal units.

Title: Satellite glial cell activation via extracellular signal-regulated kinase phosphorylation, associated with phenotypic change in trigeminal ganglion neurons, is involved in lingual neuropathic pain

Authors: ***A. KATAGIRI**[1], H. SAITO[4], K. OHARA[2], M. SHINODA[3], A. TOYOFUKU[5], K. IWATA[3];
[2]Dept. of Endodontics, [3]Dept. of Physiol., [1]Nihon Univ., Chiyoda-Ku Tokyo, Japan; [4]Dept. of Prosthodontics, Nihon Univ. Sch. of Dent., Chiyoda-ku Tokyo, Japan; [5]Dept. of Psychosomatic Dent., Tokyo Med. and Dent. Univ. Grad. Sch., Yushima Bunkyo-ku Tokyo, Japan

Abstract: Satellite glial cell (SGC) activation and associated phosphorylation of extracellular signal regulated kinase (ERK) in the trigeminal ganglion (TG) are known to be involved in trigeminal neuropathic pain associated with trigeminal nerve injury. However, the involvement of these molecules in orofacial neuropathic pain mechanisms is still unknown. Phosphorylation of ERK in lingual nerve crush (LNC) rats was observed in SGCs. In order to evaluate the role of neuron-SGC interactions in tongue neuropathic pain, calcitonin gene related peptide (CGRP)-immunoreactive (IR) neurons, phosphorylated ERK (pERK)-IR SGCs and glial fibrillary acidic protein (GFAP)-IR SGCs in the TG were studied in LNC rats. The number of CGRP-IR TG

neurons and TG neurons encircled with pERK-IR SGCs or GFAP-IR SGCs was significantly larger at day 3 after LNC than for sham or naïve rats. Percentage of medium and large sized CGRP-IR TG neurons was higher in LNC rats compared with sham or naïve rats. Following CGRP receptor blocker CGRP8-37 or mitogen-activated protein kinase/ERK kinase 1 inhibitor PD98059 administration into the TG for 3 days after LNC, the number of CGRP-IR neurons and neurons encircled with pERK-IR SGCs or GFAP-IR SGCs, activated SGCs, was decreased. The decreased nociceptive thresholds to mechanical and heat stimulation to the tongue were also significantly recovered. The present findings suggest that CGRP released from TG neurons activates SGCs through ERK phosphorylation resulting in the enhancement of TG neuronal excitability. The phenotypic switching of large myelinated afferent TG neurons expressing CGRP may account for neuropathic pain behavior.

Title: Mental nerve constriction alters the motivation for self-administration of a sucrose solution, study in rats

Authors: *N. E. GUTIÉRREZ[1], D. QUIÑONEZ[2], A. GARCÍA URBINA[2], R. MORALES[2], I. O. PEREZ MARTINEZ[2];
[1]Univ. Nacional Autónoma De Mexico, Cuautla, Mexico; [2]Fes Iztacala, Univ. Nacional Autónoma De Mexico, Mexico, Mexico

Abstract: Chronic pain causes depression, anxiety and cognitive deficits that have as common feature a decrease in the motivation to complete goal-directed actions, and reductions in pre-pain activities, motivation is regulated by structures like hypothalamus and nucleus accumbens.The aim of this research is to evaluate how motivation of sucrose consumption changes during orofacial chronic pain caused as a result of trigeminal nerve injury.This study develops a method to measure motivation for sucrose(10%) consumption in a self-administration schedule and the modifications after orofacial chronic pain generated by mental nerve constriction.To measure motivation we used male Wistar rats (n=6 by group),weight 250 ±25 gr., food ad libitum,they were water deprived for 23 hrs. previous each session of operant self-administration, they had to press a lever to obtain a reward in a fixed ratio(FR) schedule, sessions were 40 minutes long and reward was water, when rats learnt the behavior, water privation was removed and rats had food and water ad libitum, rats continue on a fixed ratio schedule(1:1),but now reward was sucrose

(10%).Rats were two weeks in FR1,two days in FR2,two days in FR3, two days in progressive ratio(PR) schedule in which it becomes progressively more difficult to earn each subsequent reward, the first day they were in PR with step size 3, and the second the step size was 5.We divided animals in two groups, mental nerve constriction group and sham group.After the surgery they were with the same protocol of operant self-administration.The point at which the rats give up, provides a measure of motivation to work for reward.Finally, we used the two-bottle preference test to evaluate the effect of trigeminal nerve injury on sucrose preference behavior.We found that the latency time for the first response during FR1 was shorter in nerve injury group(ANOVA, p=0.007)compared with sham group.There is no significant differences in the number of rewards neither number of lever responses.During the PR, we found differences higher significant between the sham group and the nerve injury group both for rewards(t test, p=0.005) as for responses(t test, p=0.006), showing a significant decreasing in the motivation for sucrose produced by mental nerve injury.In the two-bottle preference test results show that the preference for 10% of sucrose is higher than water in both groups, but comparing sham group versus lesion group the preference for sucrose is lesser(t test, p=0.04)but not for water intake(t test, p=0.32).We have a very clear results that mental nerve injury decreases motivation for intake sucrose, therefore we can use this behavioral analysis as measure of orofacial pain.

Title: Imaging of the excitatory transmission in the trigeminal subnucleus caudalis within the sliced medulla oblongatae of mice

Authors: ***M. HIRAHARA**, N. FUJIWARA, K. SEO;
Niigata Univ., Niigata, Japan

Abstract: Introduction: In order to characterize the signal transmission in the trigeminal subnucleus caudalis (Vc), where the functional structure of local neuronal circuit has not been well understood, we applied a calcium imaging technique to observe excitatory signal propagation using slices of mice medulla oblongatae. We have succeeded in optically recording calcium images of the Vc in response to electrical stimulation at the entry zone of the trigeminal nerve root by creating new oblique sectioned slices. Materials and methods: The medulla

oblongatae were removed from 6-7 week-old male mice (C57/BL6J), weighing 18-25g, under deep anesthesia following an intraperitoneal injection of 4% chloral hydrate (480 mg/kg). These medullae were sliced in thicknesses of 600 μm in an oblique plane which contained the nerve root and the Vc in ice-cooled Krebs solution. Next, the slices were incubated with Rhod-2-AM for 90 minutes in order to load the fluorescence calcium indicator. After the loading of the indicator, each slice was perfused with the Krebs solution in the measurement chamber at 31 degrees. A bundle of fibers in the vicinity of the nerve root was stimulated with a single electrical pulse (current: 100μA, duration: 200μsecs). Successive fluorescence images of the stimulated slices were recorded every 1.2 msecs and the pixels that had increased were extracted to produce the calcium images. Results: The stimulation to the bundle of fibers around the trigeminal nerve root evoked an increase in intracellular calcium concentration ([Ca2+]in) in the Vc within several msecs. This elevated [Ca2+]in gradually decreased but partially remained for at least 300 msecs. Notably, the evoked elevation of [Ca2+]in was inhibited in the presence of CNQX, and the response of [Ca2+]in partially recovered after being washed out for 15 minutes. Conclusion: The evoked elevation of [Ca2+]in was observed in the newly created slice preparations and retained the communication between the trigeminal nerve root and the Vc. Our findings suggest that these calcium responses may be induced mainly in post synaptic neurons by excitatory transmission via glutamate receptors from trigeminal primary afferent inputs.

Title: Temporal alterations of morphological and physiological features in experimental tooth movement model rats

Authors: ***N. HASEGAWA**[1], A. SASAKI[1], K. TAKAHASHI[2], G. YU[2], N. SUDA[1], H. SAKAGAMI[2], K. ADACHI[2];
[1]Orthodontology, [2]Pharmacol., Meikai Univ. Sch. of Dent., Sakado, Japan

Abstract: There are animal models to investigate effects of orthodontic treatment, and many of them focused on morphological alterations. Although some investigations evaluated behavioral alterations, which induced by orthodontic force (e.g., intensity of face-grooming and head-withdrawal reflex excitability), establishment of objective experimental methods those allow us

to evaluate orthodontic force-induced pain quantitatively is still required. Recently, we have reported that alteration of jaw-opening reflex (JOR) excitability is able to be the one. In this model, continuous orthodontic force was applied by Ti-Ni coil spring to only right maxillary first molar and electrical current (200 μs) was applied to bilateral maxillary first molar at one (D1), three (D3) and seven (D7) days after the placement of coil spring to compare physiological features of JOR (e.g., threshold, latency and AUC) between left and right sides. In brief, orthodontic force-induced pain increased excitability of nociceptive reflex in right, but not in left, side, and excitation was observed as significant reduction of threshold for inducing JOR at D1 (55.4 ± 7.8 % vs left). The reduction of threshold was returned to the intact level at D3 and this was seen up to D7. Loading of continuous orthodontic force induced medial movement of the first molar, which was increased with progression of postoperative days (D1: 0.12 ± 0.14 mm, D3: 0.19 ± 0.05 mm, D7: 0.42 ± 0.02 mm). Interestingly, moving distance of the first molar was negatively related with JOR threshold alteration, which is also seen in the orthodontically-treated patients. To investigate the role of acid secretion from mature osteoclasts in JOR excitability alteration, the number of tartrate-resistant acid phosphatase positive osteoclasts was counted (D1: 3.5 ± 0.5, D3: 11.5 ± 0.5, D7: 31.5 ± 0.5) and negative relationship between the number of mature osteoclasts and JOR excitability alteration was suggested. Since the activation of satellite glial cells (SGCs) in the trigeminal ganglion (TRG) was induced by the trigeminal inflammation, glial fibrillary acid protein (GFAP) immunoreactive SGCs in TRG were investigated and activated SGCs were observed in the bilateral TRG. At D1, treatment with aspirin (100 mg/kg, 3 times/day) immediately after the placement of coil spring significantly increased right side threshold compared with left side. Taken together, 1) unilateral orthodontic force application increased excitability of bilateral sensory processing and 2) tonic inhibition of cyclooxygenase reduced the excitability at only inflamed region were suggested.

Title: TRPV1 and TRPA1 contribute to mechanical hyperalgesia and spontaneous pain in craniofacial muscle inflammation

Authors: S. WANG, Y. ZHANG, J. RO, *M.-K. CHUNG;
Neural & Pain Sci., Univ. Maryland Dent. Sch., Baltimore, MD

Abstract: The most prevalent symptoms in temporomandibular joint disorders (TMD) patients are pain in response to pressure on the muscles and spontaneous pain. However, the mechanisms underlying pressure-evoked pain or spontaneous pain in craniofacial muscles are not fully understood. TRPV1 is a receptor of capsaicin, which is also activated by noxious heat and acid. In addition to its role in thermal hyperalgesia in skin, TRPV1 mediates glutamate-induced mechanical hyperalgesia in craniofacial muscles. TRPA1 is activated not only by natural compounds, such as mustard oil, but also by multiple endogenous electrophilic substances. Since TRPA1 is implicated in cutaneous and muscle mechanical hyperalgesia in the spinal system, it is possible that TRPA1 is also involved in mechanical hyperalgesia of craniofacial muscles. The objective of this study was to determine whether TRPV1 and TRPA1 are involved in mechanical hyperalgesia and spontaneous pain following inflammation of the masseter muscle. Injection of complete Freund's adjuvant (CFA) into rat masseter muscle induced mechanical hyperalgesia that lasted more than two weeks. The mechanical hyperalgesia was partially and reversibly inhibited by TRPV1 antagonist, AMG9810, or TRPA1 antagonist, AP-18, suggesting TRPV1 and TRPA1 are involved in mechanical hyperalgesia under muscle inflammation. To evaluate spontaneous pain behaviors, we performed two assays. First, we evaluated changes in the facial grimace scale. Second, we counted a characteristic face wiping responses over the ipsilateral cheek. In both rats and mice, masseter injection of CFA showed significantly greater facial grimace scales than the vehicle injected group, which was maintained up to 3 days following CFA injection. The face wiping responese were also significantly greater in CFA- than the vehicle-injected group. When AMG9810 or AP-18 was injected into masseter muscle 1 day after CFA treatment, both facial grimace scale and face wiping responses were significantly attenuated. Such analgesic effects of the antagonists disappeared after 24 hours. Furthermore, when TRPV1-expressing afferents were ablated by preemptive intramuscular injection of capsaicin in mice, CFA-induced changes in facial grimace scale and face wiping responses were significantly less than those observed from the group pre-injected with the vehicle. These results suggest that TRPV1 and TRPA1 are not only involved in mechanical hyperalgesia but also in spontaneous pain under craniofacial muscle inflammation and that TRPA1 and TRPV1 molecules as well as the nociceptive afferents expressing these two channels could be salient targets for treating TMD.

Title: Neuropathic pain in a mouse model of chronic constriction nerve injury does not correlate with changes in chloride reversal potential in trigeminal nucleus caudalis neurons

Authors: *A. M. CASTRO[1], W. GUO[2], C. RAVER[1], F. WEI[2], R. DUBNER[2], A. KELLER[1]; [1]Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Neural and Pain Sci., Univ. of Maryland Dent. Sch. & Program in Neurosci., Baltimore, MD

Abstract: Changes in chloride reversal potential in rat spinal cord neurons have previously been associated with persistent pain in nerve injury and inflammation models. These changes correlate with a decrease in the expression of the potassium-chloride transporter, KCC2, and with increases in neuronal excitability. Here, we test the hypothesis that similar changes occur in mice with neuropathic pain induced by chronic constriction injury of the trigeminal infraorbital nerve (CCI-ION). Our mouse CCI-ION pain model allows us to distinguish between an acute pain phase (3-5 days after injury) from a persistent pain phase driven by descending brain stem mechanisms (12-14 days after CCI-ION). CCI-ION induced significant decreases in mechanical pain thresholds in both the acute (72% decrease) and persistent (86% decrease) phases. To estimate chloride reversal potentials in laminae I/II neurons from trigeminal nucleus caudalis, we obtained whole cell recordings *in vitro*, using the gramicidin perforated patch clamp technique. We recorded from slices obtained from transgenic mice in which inhibitory, GABAergic neurons express GFP under the GAD65 promoter. We identified projection neurons by their content of fluorescent beads, retrogradely transported from the parabrachial nucleus. Chloride reversal potential decreased significantly during the acute phase (3 to 5 days), from -71±2mV in control animals to -65±4.7mV in CCI-ION animals. Projection neurons and unidentified neurons accounted for this change, whereas no significant changes occurred in GABAergic (GFP expressing) interneurons. In contrast, at 12 to 14 days after CCI-ION chloride reversal potential recovered to normal values (-70±2 mV in CCI-ION animals) in all types of neurons. Analysis of western blots of KCC2 revealed no statistically significant changes in protein expression at either 3 to 5 days or 12 to 14 days after CCI-ION, compared to control animals. These findings indicate that CCI-ION in mice results in transient and modest changes in chloride reversal potentials, and that these changes do not persist during the late pain phase. We suggest that in the mouse model of CCI-ION, changes in chloride reversal potential do not contribute to the central sensitization mechanisms leading to chronic pain.

Title: Central role of calcitonin gene-related peptide in promoting peripheral sensitization of trigeminal nociceptive neurons

Authors: *L. CORNELISON, J. L. HAWKINS, C. HYDE, P. L. DURHAM;
Missouri State Univ., Springfield, MO

Abstract: Objective: To investigate the role of calcitonin gene-related peptide (CGRP) on the initiation and maintenance of a nocifensive withdrawal response to mechanical stimulation following activation of primary trigeminal sensory neurons. Background: Temporomandibular joint disorder (TMD) is characterized by peripheral and central sensitization of trigeminal nociceptive neurons. Although CGRP is implicated in the development of central sensitization by stimulating glial activation via its receptor, the mechanism by which CGRP promotes and maintains sensitization of trigeminal nociceptive neurons is not well understood. Methods: The direct role of CGRP was investigated in adult male Sprague Dawley rats following intrathecal injection of CGRP alone or co-injection with the CGRP receptor antagonist CGRP8-37. The effect of CGRP8-37 was evaluated in animals subjected to prolonged jaw opening to mimic pathological aspects of TMD. Nocifensive withdrawal response to mechanical stimulation of trigeminal nerves utilizing von Frey filaments was investigated daily up to 14 days post treatment. Cytokine levels were determined in upper spinal cord tissue using protein arrays. To provide evidence of bidirectional signaling in the trigeminal system, animals were co-injected intrathecally with CGRP and Fast Blue dye and fluorescent microscopy used to localize the dye in neuronal cell bodies within the trigeminal ganglion. Results: Intrathecal injection of CGRP and prolonged jaw opening increased nocifensive responses to mechanical stimulation up to 48 hours and up to 7 days, respectively, when compared to vehicle injection and naïve controls. Co-injection of the antagonist peptide CGRP8-37 with CGRP repressed CGRP's sensitizing effects on trigeminal nociceptive neurons. Similarly, injection with CGRP8-37 prior to prolonged jaw opening decreased the average number of nocifensive responses. CGRP and prolonged jaw opening promoted the expression of numerous cytokines in the spinal cord when compared to control levels. Staining for Fast Blue was observed in the cell bodies of trigeminal ganglion neurons following injection of the dye in the upper spinal cord. Conclusion: The ability of CGRP8-37 to repress nocifensive behavior supports the benefit of targeting CGRP or its receptor as a treatment strategy for diseases involving trigeminal activation. Our findings with respect to CGRP and Fast Blue support the notion of bidirectional signaling within the trigeminal system whereby changes within the spinal cord associated with central sensitization can facilitate a corresponding response within the trigeminal ganglion to promote peripheral sensitization.

Title: Corneal reflexes in dry eye: evidence for altered amino acid transmission in trigeminal brainstem

Authors: K. SHIOZAKI[1], M. RAHMAN[2], K. OKAMOTO[2], R. THOMPSON[2], *D. A. BEREITER[2];
[1]Oral Anat., Tsurumi U Sch. of Dent. Med., Yokohama, Japan; [2]Diagnos. & Biol. Sci., U of Minnesota Sch. of Dent., Minneapolis, MN

Abstract: Corneal reflexes are evoked by ocular surface stimulation and serve to protect the eye and maintain the integrity of the tear film. The ocular surface is innervated by trigeminal sensory neurons that form the afferent limb of the corneal reflex and terminate in two spatially discrete regions of the trigeminal brainstem nuclear complex (TBNC), the subnucleus interpolaris/caudalis transition (Vi/Vc) and the caudalis/upper cervical cord junction (Vc/C1). Dry eye (DE) is a common ocular pain condition and is associated with increased spontaneous eye blinks and altered corneal reflexes. Although ocular surface input is integrated at the TBNC to mediate corneal reflexes, the effects of DE on brainstem mechanisms that underlie corneal reflexes are not well defined. The aim of this study was to determine if GABAergic and NMDA receptor mechanisms, acting at the Vi/Vc transition and Vc/C1 regions, affect corneal reflexes in a model for DE. Male rats were anesthetized (urethane) and corneal reflexes (orbicularis oculi activity, OOemg) were evoked by hypertonic saline (HS, 2.5M) 14d after exorbital gland removal, a model for tear-deficient DE. HS-evoked OOemg activity in DE rats was more than twice that of sham controls. Microinjection of the GABAaR agonist, muscimol (0.1-1mM, 0.3µl) into the Vi/Vc transition 10 min prior to HS caused a dose-related inhibition of OOemg and at a lower threshold dose in DE than sham rats, whereas injection into Vc/C1 inhibited OOemg similarly in both groups and at a higher dose. Microinjection of the NMDAr antagonist, AP5 (0.01-1mM, 0.3µl) into Vi/Vc also caused a dose-related inhibition of HS-evoked OOemg activity that was greater in DE than sham rats, whereas injection into Vc/C1 had a similar inhibitory effect in both groups. These results suggested that GABAergic and NMDA receptor mechanisms acting at the Vi/Vc transition and the Vc/C1 junction were necessary for corneal reflexes in sham rats. By contrast, GABAergic and NMDA contributions to corneal reflex

activity were enhanced at the Vi/Vc transition, but not at the Vc/C1 junction, in DE rats. These data support the hypothesis that altered amino acid transmission and synaptic plasticity of ocular neurons at the Vi/Vc transition contribute to abnormal corneal reflexes and sensations in DE.

Title: Innervation of the external nares: implications for initiation of the mammalian diving response

Authors: K. A. LAHRMAN, K. M. DINOVO, *P. F. MCCULLOCH;
Physiol., Midwestern Univ., Downers Grove, IL

Abstract: The purpose of this research was to determine the central projections of nerves innervating the external nares of rats that may be involved in initiating the autonomic cardiorespiratory reflex known as the diving response. The anterior ethmoidal nerve (AEN), a branch of the ophthalmic division of the trigeminal nerve that innervates the nose and external nares, is thought to provide the afferent signal that initiates the apnea, bradycardia, and selective increase in peripheral vascular resistance that occurs in response to underwater submersion. However recent research has indicated that rats retain the complete diving response even after bilateral AEN sectioning, suggesting that other nasal nerves can also provide the afferent signal to initiate this response. The transganglionic tracer Wheat Germ Agglutinin (WGA) was directly injected 5-10 mm into the left nasal passages of Sprague-Dawley rats (N=4). After immunohistological processing and fluorescent brainstem tissue visualization with a Nikon AR1 confocal microscope, central tracer terminations were found densely within the ventral tip of the left spinal trigeminal nucleus caudalis (medullary dorsal horn; MDH), especially along the transition with nucleus interpolaris; sparsely within the right MDH; bilaterally within the nucleus tractus solitarius (NTS); within the left dorsal trigeminal tract; and near to the left Botzinger complex. In other rats WGA was injected into the left nasal passages after the AENs had been sectioned bilaterally (N=4). Label in the ventral MDH was now less prominent and label near the Botzinger complex was absent, while label in the NTS was still present. WGA injected directly into the AEN (N=4) produced labeling within the ventral MDH, especially along the transition

with nucleus interpolaris, and near to the Botzinger complex, but no labeling within the NTS. WGA was also injected directly into the Infraorbital nerve (ION; N=7), a branch of the maxillary division of the trigeminal nerve that innervates the external nares and upper lip. Label after ION injection was found within the ventral MDH. Results indicate that the ION, in addition to the AEN, could possibly be an anatomical pathway that provides the afferent information necessary to initiate the mammalian diving response. Results also suggest that innervation of the nasal passages projecting to the NTS does not do so via the AEN or ION.

Title: Ginger-contained shogaol and gingerol inhibit oral ulcer-induced pain through sodium channel blockage

Authors: *S. HITOMI[1], K. ONO[1], K. YAMAGUCHI[1], K. TERAWAKI[2], Y. OMIYA[2], K. INENAGA[1];
[1]Kyushu Dent. Univ., Fukuoka, Japan; [2]Tsumura & Co, Ibaraki, Japan

Abstract: Recently, some clinical studies have demonstrated that the Japanese herbal medicine Hangeshashinto alleviates oral mucositis-induced pain in patients. Hangeshashinto contains seven herbal extracts, coptis rhizome, ginseng, glycyrrhiza, jujube, pinellia tuber, processed ginger, and scutellaria root. However, pharmacological mechanism underlying the analgesic effect of Hangeshashinto has not been investigated. Firstly, we selected 21 chemical ingredients in Hangeshashinto. In screening analysis systems (automated patch clamp recording and fluorescence imaging plate reader), the ingredients were evaluated in antagonistic and agonistic effects on nociception-related channels, a sodium channel Nav1.8 and transient receptor potential vanilloid 1 (TRPV1), respectively. Among the 21 ingredients, [6]-shogaol and [6]-gingerol showed strong antagonistic effects on Nav1.8, as the same as lidocaine. [6]-shogaol and [6]-gingerol also showed strong agonistic effects on TRPV1, as reported in previous studies. Therefore, we investigated analgesic effects of processed ginger and a mixture of [6]-shogaol and [6]-gingerol on pain-related behaviors in oral ulcer rat model treated by acetic acid. Processed ginger and the mixture of [6]-shogaol and [6]-gingerol did not change the mechanical pain hypersensitivity. However, by co-application with the other herbal extract the ginseng,

which abundantly contains saponins, these ingredients supressed the mechanical pain hypersensitivity. The ginseng extract accelerated cell membrane permeability of the fluorescence substance FluoroGold in the ulcer region where the epithelial barrier was destroyed. These results suggest that the oral ulcer-induced mechanical pain hypersensitivity is by antagonistic effect of [6]-shogaol and [6]-gingerol on sodium channels, via ulcer region with drug delivery acceleration due to other saponin-containing herbal extracts.

Abstract: Orofacial pain is a common and disabling problem. Despite current therapies, in the present research there is still a limited understanding of the nociceptive pathophysiology of pain. The aim of this research is the study of changes in the oral somatosensory perception because of trigeminal nerve injury. We assess the adaptive response to oral ethanol administration and the

modifications in this adaptation generated by the mental nerve constriction. We used two groups of male Wistar rats, they were water deprived for 23hours(h) previous each session. As baseline, the rats were given 3 days of water in their home cages every 23.5h for 15minutes(min), the volume consumption was registered. On days 4 to 8, the subjects were tested to response by the presentation of 8% ethanol solution for the group 1, and 20% ethanol solution for the group 2, for 15min. Then they received access to water for 15min. to ensure that all animals consumed their daily fluid requirement. To evaluate the subsequent motivation after the adaptation to ethanol consumption we use the two-bottle preference test (ethanol/water) before and after the trigeminal manipulation. Each rat was separated, and giving free access to the two bottles: water/ethanol (8%/20%, it depends on previous concentration used for each rat). The position of bottles was changed after 24h to prevent position preference. The avarage measure was obtained across 48h, and corrected for body weight of subjects. We found that the mental nerve transection produces changes in the perception of ethanol directly in the tongue. Differently to Augier et.al.(2014), in our project the ethanol 20% works like an aversive stimuli when it is presented at first (20% vs 8%, t test, p=0.04), however, the behavior is adapted regarding to persistent administration producing a gradually increasing of intake, we posit that the trigeminal system suffers molecular changes in free ends of the nerve, these changes could be the decreasing of the TRPV1 in the epithelial tissue of tongue. Furthermore, we found that the preference by ethanol decreases after mental nerve constriction in 20% (t test, p=0.001, water vs ethanol and t test, p=0.017, ethanol before surgery vs ethanol after surgery). The same by 8% of ethanol (t test, p=0.007, water vs ethanol and t test, p=0.19, ethanol before surgery vs ethanol after surgery). Comparisons between both water-intake before and after surgery not produces changes. We are showing the evidence that the injury in the mental nerve produces changes in the somatosensorial processing of ethanol during intake, these may be related to changes in the molecular characteristics of the trigeminal nerve ends.

Title: Sensitization of the trigeminovascular system following environmental irritant exposure in rodents: characterization of a novel model of chronic headache

Authors: P. E. KUNKLER[1], L. ZHANG[1], *G. S. OXFORD[2,1], J. H. HURLEY[1];
[1]Stark Neurosciences Res. Inst., Indiana Univ. Sch. of Med., Indianapolis, IN; [2]Indiana Univ. Sch. Med., Indianapolis, IN

Abstract: Headache is one of the most common neurological disorders, yet remains poorly understood and undertreated. Air pollution and environmental irritants have been associated with the initiation of headache however the neurobiological link between these chemical triggers and the induction of headache attacks remains unknown. Headache pain is thought to be caused by the release of inflammatory substances from trigeminal sensory nerve endings, resulting in neurogenic inflammation and vasodilation in the dura. Supporting this notion, we previously reported that acute nasal administration of environmental irritants increases meningeal blood flow via a TRPA1-dependent mechanism involving the trigeminovascular system. In addition, repeated inhalation exposure of subacute doses of acrolein potentiated blood flow responses to both TRPA1 and TRPV1 agonists suggesting trigeminovascular sensitization as the mechanism for enhanced headache susceptibility. We hypothesize that the nasal-to-meningeal neuronal pathway activating the trigeminovascular response involves trigeminal intraganglionic signaling, as we observed that nasal and meningeal nerve terminals arise from adjacent but distinct soma in the trigeminal ganglion. Also, inhibition of NMDA and/or CGRP receptors only in the trigeminal ganglion compromised the nasal-to-meningeal responses, implicating intraganglionic transmission. Here we investigated behavioral, anatomical and trigeminovascular responses induced by repeated acrolein inhalation exposure to further characterize the effect of environmental irritants on the trigeminovascular system. Laser Doppler flowmetry confirmed that daily repeated acrolein exposure significantly ($p < 0.05$) potentiated meningeal blood flow responses to acute nasal administration of mustard oil compared to room air controls ($n = 8$ per group). Periorbital allodynia tests show that repeated acrolein exposure significantly enhanced cutaneous mechanical sensitivity ($p < 0.05$) both immediately following the last inhalation exposure and 24 hrs later. Enhanced cutaneous allodynia was further confirmed with touch-induced c-Fos expression. c-Fos staining in the spinal trigeminal nucleus of rats repeatedly exposed to acrolein is significantly increased compared to room air controls. Taken together these results demonstrate trigeminovascular sensitization following environmental irritant exposure. This novel model may allow us to gain a better understanding of migraine triggers and perhaps the progression to chronic migraine.

Title: Chicken broth aac1 as a dietary supplement represses nocifensive behaviors and pka expression caused by prolonged jaw opening

Authors: *J. L. HAWKINS, P. L. DURHAM;
JVIC/CBLS, Missouri State Univ., Springfield, MO

Abstract: Objective: The goal of this study was to determine if the dietary inclusion of the commercially available chicken broth AAC1 could repress nocifensive behaviors and PKA expression associated with a clinically relevant model of temporomandibular joint disorder (TMD) caused by prolonged jaw opening. Background: Routine dental visits for molar extractions or root canals, or to the orthodontist can result in an injury to the TMJ or muscles of mastication if the jaw is held open for long periods of time or is opened to near maximal even for a short period of time. However, the pathophysiological and cellular mediators that underlie the development of chronic orofacial pain associated with TMD are not well understood. Chicken broth has been often thought of as having beneficial immune effects and may represent an innovative and safe alternative treatment for chronic inflammatory diseases. Methods: Male Sprague-Dawley rats were used to investigate the effects AAC1 on behavioral and cellular changes associated with prolonged jaw opening. A surgical retractor was placed around the bottom and top incisors and the jaw held at near maximal opening for 20 minutes. Withdrawal responses to mechanical stimuli were determined following jaw opening for up to 7 days by applying calibrated von Frey filaments to the cutaneous area over the masseter. Some animals received 0.5% solid (w/v) AAC1 dissolved in their drinking water for two weeks prior to jaw opening. After 7 days, animals were euthanized and the upper spinal cord and trigeminal ganglia were removed to study changes in the expression of PKA utilizing immunohistochemistry. Results: Near maximal jaw opening was sufficient to induce sustained increased nocifensive responses to mechanical stimuli over the masseter area for 7 days. This increased sensitivity correlated with increased levels of PKA expression in both the upper spinal cord and the trigeminal ganglia. Interestingly, dietary inclusion of AAC1 was able to suppress nocifensive behaviors and PKA expression associated with prolonged jaw opening. Conclusion: Our findings provide evidence that dietary inclusion of chicken broth AAC1 suppresses mechanical hyperalgesia and increased PKA expression associated with peripheral and central sensitization of the trigeminal system and thus, may by a potential nutraceutical supplement that may help manage inflammatory pain associated with TMD.

Title: A three dimensional assessment of 7T tractography of the trigeminal nerve through anatomical dissection

Authors: *A. M. EL-NASHAR[1,2], J. SEIN[5], J. TOKAREV[3], B. JAGADEESAN[4], P.-F. VAN DE MOORTELE[3], A. W. GRANDE[2], C. LENGLET[3];
[2]Dept. of Neurosurg., [3]Ctr. for Magnetic Resonance Res., [4]Dept. of Radiology, [1]Univ. of Minnesota, Minneapolis, MN; [5]Univ. of Aix-Marseille, Marseille Area, France

Abstract: The anatomy of the trigeminal nerve fiber tracts is complex. In the brain stem, tracts arise from four separate nuclei located between the mesencephalon superiorly, and the cervical cord inferiorly. At mid-pons level, emerging fibers twist in the prepontine cistern, enter Meckel's cave, form the Gasserian ganglion and finally divide into three main divisions [1]. Ultra high field MRI techniques (using systems 7 Tesla and above) enable accurate in-vivo examination of the fiber tracts [2] including both the motor fibers and the sensory fibers within the three main divisions. In this study we validate the data obtained using these techniques by comparing them with the data from human cadaver fiber tract dissection. Healthy volunteers were scanned using a 7T MRI system (Siemens, Erlangen, Germany) equipped with a volume transmit, and a 24-channel receive head coil (Nova Medical, Inc. Wilmington, MA, USA). Diffusion MRI was acquired with voxel size=1.2x1.2x1.2 mm3 (reconstructed at 0.6x0.6x1.2 mm3 with zero filling), 18 slices, TR/TE=5000/64 ms, 100 gradient directions, b-value=1000 s/mm2, 11 b=0 volumes. Following correction for distortions and head motion, and fiber orientation mapping [3], we placed seeding masks in the floor of the fourth ventricle and the cisternal segment of the trigeminal nerve. We employed probabilistic tractography using FMRIB Software Library to identify fibers within the trigeminal nerve pathway. Separately, white matter fiber dissection technique was used to study the microsurgical anatomy of formalin-fixed brainstems from human cadavers. The generated fiber tracts, using diffusion MRI and tractography, were visualized in three dimensional space using Amira, and compared to the tracts obtained from fiber dissection. Trigeminal nerve sensory and motor pathways from the brain stem out to the trigeminal divisions were visualized as reproducibly distinct structures from one another in the 7T data and highly correlated to anatomic fiber dissection. However, limitations with the 7T data were seen when assessing the topographic representation within the brain stem, where there was a limited correlation with the fibers obtained from dissection. 7T diffusion MRI produces reliable imaging of the trigeminal fiber tracts when compared to anatomic dissection. Clinically, this enables us to study the pathophysiology of trigeminal neuralgia from neurovascular conflict as it may relate to the observed frequency of involvement of the individual divisions in patients with

trigeminal neuralgia. References: [1] Joo et al., Clinical Anat., 2014. [2] Lenglet et al., ISMRM, 2014. [3]Behrens et al, Neuroimage, 2007.

Title: Local KOR agonist reduces TMJ-evoked activity of trigeminal subnucleus caudalis neurons in an estrogen-dependent manner

Authors: *A. TASHIRO, Y. NISHIDA;
Natl. Def. Med. Col., Tokorozawa, Saitama, Japan

Abstract: Painful temporomandibular joint disorders (TMD) occur more often in women than men and are difficult to treat. Sex difference in kappa opioid analgesia have been reported under a variety of test conditions in animal and human studies; however, the influence of estrogen (E2) on kappa opioid receptor (KOR) of nociceptive processing related to craniofacial pain is not well defined. To address this issue, single temporomandibular joint -responsive neurons (TMJ neuron) were recorded in laminae I-II at the spinomedullary (Vc/C1-2) junction from ovariectomized female rats (OvX) treated for 2 days with high E2 (20μg/day; HE2) or low E2 (2μg/day; LE2) under isoflurane anesthesia. TMJ neurons in Vc/C1-2 region were activated by test injections of ATP (1mM, 20μl) through a cannula placed in the TMJ joint space. The KOR agonist, U50488 (30-300μM) was applied topically to Vc/C1-2 surface 10 min before test injections of ATP. Topical U50488 caused a doses related inhibition of ATP-evoked unit activity in HE2 rats ($P < 0.01$), while units in LE2 rats displayed inconsistent effects. BNI (selective KOR antagonist) caused at least partial reversal of kappa opioid inhibition. U50488 also reduced significantly ATP-evoked response duration of units from HE2 ($P<0.01$), but not LE2. KOR activation had only minor effects on spontaneous unit activity of TMJ units in OvX female rats (HE2 and LE2). High dose U50488 caused small reduction in size of convergent cutaneous receptive field in HE2 rats, but not LE2 rats. These results indicated that estrogen status

differentially affected KOR agonist-modulation of TMJ unit activity in superficial laminae at Vc/C1-2 junction in female rats. The site for estrogen influence on KOR agonist-induced modulation of TMJ unit activity was the medullary dorsal horn. It is concluded that selective activation of KOR in medullary dorsal horn produce estrogen dependent attenuation of TMJ pain.

Title: Persistent sensitization of trigeminal neurons promotes gut dysbiosis

Authors: *P. L. DURHAM, J. L. HAWKINS, R. NORTON;
JVIC-CBLS, Missouri State Univ., Springfield, MO

Abstract: Objective: To investigate changes in the gut microbiota that promotes an imbalance or dysbiosis in response to prolonged sensitization of primary trigeminal sensory neurons. Background: Diseases involving the head and face represent some on the most common pain sites in the body. Neck muscle pathology and sleep deprivation are reported as risk factors by orofacial pain patients. Another pathological condition often associated with orofacial pain is irritable bowel syndrome (IBS), which is characterized by dysbiosis. Understanding the relationship between increased nociceptive signaling in the trigeminal system and the gut microbiota is essential to fully understand the gut-brain axis and subsequent negative health outcomes associated with gut dysbiosis. Materials: Sprague-Dawley rats were injected with complete Freund's adjuvant (CFA) in the trapezius to cause prolonged inflammation and REM sleep deprived for 24 hours. Nocifensive behavioral changes were monitored for up to 14 days post CFA injection using von Frey filaments. Fecal samples were collected from each animal at day 0 and day 14. Total DNA was extracted and amplified from the V3-V4 region of the 16S rRNA gene with sample-specific barcode sequences prior to 454-pyrosequencing. Returned sequences were assigned taxonomic classification using the SILVA rRNA database. Microbial community analysis was performed using phylogenetic packages in R. Results: Animals with neck muscle inflammation and also REM sleep deprived exhibited a sustained sensitivity to mechanical stimuli (nociception) that temporally correlated with significant changes in the composition of the gut microbiota. Sequence analysis revealed large-scale shifts in the phyla Bacteroidetes and Proteobacteria, including Bacteroides species that have been implicated in

intestinal and organismal health. Prolonged sensitization resulted in a loss of commensal bacteria and the emergence of bacteria not abundantly seen in healthy animals. Conclusion: Our results provide evidence that inflammation in the trapezius followed by one night of REM sleep deprivation is sufficient to induce sustained sensitization of trigeminal neurons and dysbiosis along the gut-brain axis. Based on our findings, we propose that sensitization of the neurons associated with orofacial pain changes the composition of the gut microbiota, and thus our results may help to explain the reported high co-morbidity of chronic orofacial pain and IBS. Title: The dry eye sensitizes cold cell sensitivity to capsaicin mediated by TRPV1

Authors: ***M. KUROSE**[1], A. HATTA[1], K. YAMAMURA[1], I. D. MENG[2];
[1]Niigata Univ. Grad. Sch. of Dent., Niigata, Japan; [2]Dept. of Biomed. Sci., Col. of Osteo. Medicine, Univ. of New England, Biddeford, ME

Abstract: Previous studies have found that cold cells innervating the cornea are sensitive to the ocular fluid status of the corneal surface and may be responsible for the regulation of basal (ongoing) tear production. We had focused on the encoding property of cold cells, and shown the facilitation of cold-evoked activity after application of TRPM8 agonist menthol and suppression of cold-evoked activity after application of TRPV1 agonist capsaicin. In addition, we have shown that an experimental dry eye condition produced by the lacrimal gland excision modifies the thermal and menthol responses in these neurons. In the present study, we examined the effect of dry eye on the sensitivity of cold cells to the capsaicin. Forty-five male SD rats weighing 200-225 g at the time of surgery were used. Under isoflurane anesthesia, unilateral dry eye was created by excision of the left exorbital and infraorbital lacrimal glands. Extracellular, single-unit recordings were performed in urethane-chloralose anesthetized animals 1 week after lacrimal gland excision and in age matched controls. Electrodes positioned in the trigeminal ganglion were used to isolate and characterize cold-sensitive corneal neurons. Responses to thermal

stimulation were examined 5 min after the application of capsaicin (3 nM- 3 μM) and its vehicle. At low concentrations (<300 nM), capsaicin did not affect cold cell activity in control animals; in contrast, ongoing activity was facilitated and cold-evoked activity was significantly suppressed in dry eye animals. High concentrations of capsaicin (≥300 nM) suppressed the ongoing and cold-evoked activity in both groups of animals, with an overall greater suppression in dry eye animals. We applied the TRPV1 antagonist, capsazepine (10 μM) 30 min before capsaicin application in dry eye animals. Capsazepine blocked the capsaicin-induced modulation of cold cell activity. These results indicate that dry eye sensitizes cold cells to capsaicin-mediated inhibition via TRPV1.

Title: Somatosensory and motor corticospinal projections respond differently to peripheral and central spinal injuries in monkeys

Authors: ***C. J. DARIAN-SMITH**[1], K. M. FISHER[1], A. L. LILAK[1], K.-A. IRVINE[2], J. GARNER[1];
[1]Comparative Med., Stanford Univ. Sch. of Med., Stanford, CA; [2]Dept. of Neurol., UCSF and SFVAMC, San Francisco, CA

Abstract: The primate corticospinal tract (CST) originates from >9 functional regions of the neocortex, and forms the major descending pathway involved in voluntary hand movements. We have previously shown that these discrete CST subcomponents respond quite differently to different spinal injuries affecting sensory pathways. Thus, following a cervical dorsal rhizotomy (DRL), terminal projections from the primary somatosensory cortex (S1) shrink to 60% of normal, while the motor CST projection territory remains robust and even expands (Darian-Smith et al., 2013, JCN 521:2359-72). The motor CST is therefore dominant in circuitry remodeling following a DRL alone. In contrast, when a DRL is combined with a cervical DCL (dorsal cuneate fasciculus at C5), both the S1 and motor CSTs respond dramatically (Darian-Smith et al., 2014 JNeurosci 34:12267-12279), sprouting bilaterally and caudally (>2cm) well beyond their normal terminal distribution territories. While these data indicate that the central injury (the DCL) and associated immune response are critical to the dramatic S1 and motor CST outgrowth, it was not clear if the DCL alone was responsible, or if there was some combinatorial

effect; we addressed this issue directly in the present study. Monkeys from our previous investigations (above), that had received either a DRL (involving C5-C8 rootlets innervating just the thumb (D1), index (D2) and middle fingers (D3)), or a DRL/DCL, were compared with two animals receiving a DCL alone (cuneate fasciculus at C5 or C6). Three months following the DCL lesion, electrophysiological recordings were made within the somatosensory cortex to identify the reorganized region of D1-D3 representation. Anterograde tracers (LYD, BDA) were then injected bilaterally into the reorganized cortex (S1 and primary motor), to assess axon terminal distribution patterns in the cervical and thoracic cord. Preliminary data have been analyzed from one of two monkeys. In this animal, terminal projections from S1 were found to extend well beyond their normal range, occupying the intermediate zone bilaterally from C1-rostral T1, in addition to the dorsal horn (C5-T1). Sparse projections were also observed within the ventral horn in C5-C8. Motor CST terminations were also robust, and more extensive than in normal animals. In contrast to animals with a combined DRL/DCL, neither the motor nor the S1 CSTs sprouted caudally beyond their normal range. Our preliminary findings suggest a combinatorial effect of the two lesions on CST outgrowth. We will present our final analysis, including a multifactorial statistical comparison of the changes following the three different lesions (a DRL, DRL/DCL, and a DCL).

Title: Effect of trasplant of pedegenerated peripheral nerve and bone marrow stromal cells over axonal regeneration and remyelinitation in a rat model of transection spinal cord injury

Authors: *V. BUZOIANU ANGUIANO[1], S. OROZCO-SUAREZ[2], S. CABALLERO-CHACÓN[3], I. GRIJALVA[2];
[1]Home, Mexico City, Mexico; [2]Unidad De Investigation Medica En Enfermedades Neurologicas, Insitituto Mexicano Del Seguro Social, Mexico City, Mexico; [3]Department De Farmacologia De Y Fiologia, Facultad De Medicina Veterinaria Y Zootecnia, Universidad Nacional Autonoma De Mexico, Mexico City, Mexico

Abstract: Recovery of the spinal cord (SC), is limited because of the low cell regeneration and axonal growth, also due to the failure of replacement of damaged myelin, which prevents functional recovery of neuronal connections. Some treatments such as predegenerated peripheral nerve transplantation (PPN) and bone marrow stromal cells (BMSc) have shown to promote

axonal regrowth as well as remyelinitation of central and collateral SC axons in complete section model. It has shown that there is the presence of proteins such as GAP-43, Neuritin and myelin basic protein PBM which favor a permeable micro-environment for axonal regrowth and remilinizacion after a TCSI. The aim of this study was to determine the expression of these proteins in animals with transplants of PPN and PPN+BMSc after a chronic transection of the spinal cord. Thirty eigth female Fisher 344 rats were subjected to a whole spinal cord transection at thoracic 9 (T9); after four weeks of the evolution, they were ramdomly distributed in 4 groups, group 1 (TSCI without treatment); group 2 (TSCI+Fibrin Glue); group 3 (TSCI+ Fibrin Glue+ PPN transplantation) and group 4 (TSCI+ Fibrin Glue+ PPN transplantation + BMSc transplantation). After eight weeks post-trasplant, the animals were sacrificed and spinal cord was obtained by histological study; areas proximal and distal to the site of the transplant were prepared to determine the expression of GAP-43, Neuritin and PBM proteins by fluorescence density. Results: GAP-43 and Neuritin expression both proximal and distal stumps of groups 3 and 4 were higher than group 1 and 2 ($P< 0.05$). PBM expression of proximal stump was also higher in groups 3 and 4 than groups 1 and 2 ($P < 0.05$); moreover, it was seen higher expression in distal zone of 4 than group 3 ($P< 0.001$). In conclusión: PPN and BMSc transplantation promote axonal regrowth and remyelination in a rat model of chronic SCI transection.

Title: Use of peripheral nerve stimulation to locate interneurons associated with group i and group ii afferents in intact mouse spinal cords

Authors: B. N. PHAM, Jr.[1], H. ZHONG[2], R. ROY[2,3], *N. J. TILLAKARATNE[2,3], V. EDGERTON[2,5,4,3];
[1]Bioengineering, [2]Dept Integrative Biol. and Physiol., [3]Brain Res. Inst., [4]Neurosurg., UCLA, Los Angeles, CA; [5]Ucla, Neurobio., Los Angeles, CA

Abstract: The role of proprioceptive input on locomotor recovery after a spinal cord injury (SCI) has been shown behaviorally and electrophysiolgically, but more work needs to be done at the cellular and network levels. Group I and Group II afferents can be recruited selectively by

stimulating peripheral nerves at varying intensities above motor threshold. In a previous study, Group I afferents were recruited when different muscle nerves were stimulated at 1.5-1.8X motor threshold whereas Group II afferents were recruited at 2.5X motor threshold. To identify neurons associated with Group I or Group II afferents, we stimulated the isolated soleus nerve of intact C57Bl6 adult mice at either 1.5 or 3.5X motor threshold, respectively. In addition, the isolated soleus nerve also was stimulated at 3.5x motor threshold in a group of mice whose spinal cords were completely transected at a mid-thoracic level. All muscles of the upper and lower leg were denervated to isolate the soleus nerve: the stimulating electrode was placed on the distal portion of the soleus nerve. After 20 min of stimulation, the mice were maintained in a deep anesthetic state for 60 min (to maximize c-fos expression) and then perfused with paraformaldehyde (intracardially). The lumbar spinal cords were removed and cryosectioned (30-µm thick) and immunostained for c-fos (an activity marker). Intact mice stimulated at 3.5X motor threshold showed activated neurons throughout laminae I-VIII and X, with the majority localized in the ipsilateral dorsal horn. Intact mice stimulated at 1.5X motor threshold had less neuronal activation than those stimulated at 3.5X, but showed a similar laminar distribution. Mice stimulated at 3.5X threshold also showed a higher percentage of Fos^{+} cells in ipsilateral laminae IV-VIII and in the lateral funiculus. Spinal mice stimulated at 3.5X motor threshold showed less activation of neurons compared to intact mice stimulated at 3.5X motor threshold, but similar to that observed in intact mice stimulated at 1.5X motor threshold. These results show when the soleus nerve is stimulated the spinal neurons that process different types of afferent input have unique locations within the spinal grey matter and that a SCI decreases the excitability of these spinal interneurons.

Title: Activity-dependent improvement of full weight-bearing standing with epidural stimulation in chronic complete paraplegics

Authors: *E. REJC, C. ANGELI, S. HARKEMA;
Kentucky Spinal Cord Injury Res. Ctr., Univ. of Louisville, Louisville, KY

Abstract: Clinically complete spinal cord injury (SCI) is associated with the inability to stand or walk, and a drastic decrease in quality of life for affected individuals. The mammalian lumbosacral spinal cord can regain the ability to generate some level of weight-bearing standing after a complete SCI. Activity-dependent rehabilitation alone allowed the recovery of weight-bearing standing and stepping in complete spinal cats, while its interaction with lumbosacral spinal cord epidural stimulation was needed to achieve similar results in complete rats. The aim of this study was to investigate the effects of stand training with epidural stimulation in four clinically complete SCI individuals, who were implanted with an epidural electrode array over the segments L1-S1 of the spinal cord. EMG, kinematics and ground reaction forces were recorded during standing experimental sessions performed before and after 80 stand training sessions (1 hour of standing per session, 5 days/week). Before training, all four participants needed external assistance at hips and knees to maintain upright posture, even in the presence of epidural stimulation. EMG pattern of several lower limb muscles often consisted in the alternation between EMG bursts and periods of little activity, resulting in overall unstable assisted standing. Throughout the training, epidural stimulation parameters were optimized and all participants achieved full weight-bearing standing without external assistance for knee extension. The longest knee-independent standing bout achieved by each participant was substantially different, ranging from 4.3 (participant B07) to 63.0 minutes (participant A45). After training, EMG patterns were overall more continuous, and lower levels of external assistance were needed to stand with the same stimulation parameters tested before training. However, stable standing with the least amount of assistance was achieved with individual-specific stimulation parameters optimized during training. On the other hand, without stimulation, little or no EMG activity was recorded from the analyzed muscles of all research participants, who maintained upright posture because of the trainers' assistance at the knees and hips, and because of the weight-bearing action performed by their upper limbs. Part of the standing ability improvement after training can be explained by the enhanced motor output promoted by the reinforcement of the neural pathways directly and repetitively involved during stand training. However, the appropriate selection of stimulation parameters is critical to further improve standing after chronic complete paralysis in humans.

Title: Multi muscle neuromuscular electrical simulation of the lower limbs: Effect on intra and inter limb motor pools

Authors: *G. F. FORREST[1], M. BUGRAHAN BAYRAM[2], R. PILKAR[2], A. RAMANUJAM[2], M. MITCHELL[2], E. GARBARINI[2];

Abstract: Acute spinal cord injury often leads to rapid muscle atrophy in the paralyzed limbs. Recently, we have shown that an intense novel form of standardized multi-muscle neuromuscular electrical stimulation (NMES) combined with dynamic standing retraining tasks may potentially restore muscle structure and function after sub acute to chronic, motor-complete SCI. Specifically, we have presented data for a large number of standardized repetitive task specific training sessions of multi-muscle NMES of the lower limbs combined with mechanical loading to demonstrate an increase in bilateral muscle volume in conjunction with a significant increase in flexor and extensor muscle activation amplitude during continuous stepping. Albeit the phasic coordination of the flexor and extensor muscle activation pools were inappropriate for stepping. However, very little is known about the effect of multi-muscle NMES during mechanical loading on the motor pools of the ipsilateral and contralateral flexors or extensors during stimulation. We will present data on a series of experiments to illustrate intra and inter limb neuromuscular response for several individuals who have cervical motor complete SCI as well as several able bodied controls undergoing a standardized NMES and mechanical loading testing protocol. These data show that during repeated bouts of a ramping stimulation protocol to the lower limb extensor muscles while standing there was concomitant recorded stimulation to multiple muscle sites of contralateral limb. For both motor complete SCI and able bodied controls, there were significant increases in muscle activation amplitudes for both ipsilateral and contralateral extensors during NMES ramping protocol. Moreover these data reflected changes in spatial and temporal characteristics of the standardized repeated bouts of NMES train as well as the changes in the ipsilateral and contralateral loading forces and net center of pressure. We propose that our experiments potentially demonstrate that for the intact human spinal cord and for the motor complete individual, single muscle stimulation and multi-muscle stimulation may play a significant role in intra/inter limb neural circuitry changes.

Title: Impact of BDNF/TrkB signaling on functional recovery across motor behaviors after cervical spinal cord injury

Authors: *H. M. GRANSEE[1], C. B. MANTILLA[1,2], Y. WANG[1], V. HERNANDEZ-TORRES[1], W.-Z. ZHAN[1], G. C. SIECK[1,2];

Abstract: A C_2 cervical spinal cord hemisection (SH) disrupts descending inspiratory-related drive to phrenic motoneurons, paralyzing the ipsilateral diaphragm muscle. There is gradual recovery of rhythmic diaphragm muscle activity ipsilateral to injury over time, consistent with neuroplasticity and strengthening of spared synaptic inputs to phrenic motoneurons. Phrenic motoneurons are recruited across a range of motor behaviors to generate varying levels of diaphragm muscle force. Intrathecal delivery of brain-derived neurotrophic factor (BDNF) near the level of phrenic motoneurons enhances recovery of ipsilateral diaphragm activity after SH during eupnea. We hypothesized that intrathecal BDNF enhances diaphragm activity across both ventilatory and non-ventilatory motor behaviors after SH. An intrathecal catheter was placed in Sprague-Dawley rats at C_4 to chronically infuse artificial CSF (aCSF) or BDNF (180 ng/day) using an osmotic pump. Diaphragm EMG electrodes were implanted bilaterally to record activity across motor behaviors, i.e., eupnea, hypoxia-hypercapnia (10% O_2 and 5% CO_2), deep breaths, sustained airway occlusion, and sneezing. Functional recovery during eupnea at 14D was evident in 100% of BDNF treated rats and 38% of aCSF treated rats. During eupnea and hypoxia-hypercapnia, root mean square (RMS) EMG amplitude at 14D after SH was significantly greater after BDNF treatment compared to aCSF treatment. Diaphragm RMS EMG amplitude during sneezing was also greater after BDNF treatment compared to aCSF treatment; however, BDNF had no effect during deep breaths or sustained airway occlusion. Enhancing BDNF/TrkB signaling at the level of the phrenic motoneuron pool via intrathecal infusion is sufficient to promote recovery of diaphragm activity during ventilatory behaviors but not during all non-ventilatory behaviors.

Title: Electromyographic patterns in the contralateral limb in response to muscle stretch in rats with moderate spinal cord injuries

Authors: *A. KELLER[1], K. NORD[2], A. WADE[2], A. SHUM-SIU[3], D. S. K. MAGNUSON[3]; [2]Bioengineering, [3]Neurolog. Surgery, [1]Univ. of Louisville, Louisville, KY

Abstract: Stretching remains a leading technique utilized by physical therapists to manage spasticity and contractures in patients with spinal cord injuries (SCI). Previously, we found that stretching negatively impacts locomotor recovery in rats with mild acute thoracic SCIs as well as in animals with moderately-severe acute and chronic SCIs. Clinical relevance of the stretching phenomenon is currently not known. Using electromyography (EMG), the goal of the present study was to characterize patterns of muscle responses to stretching that could provide a potential translational cue. Eight female Sprague-Dawley rats were used for this study (stretch EMG group n=4, non-stretch non-EMG controls, n=4). Stretch EMG group animals were instrumented with implantable telemetry-based transmitters connected to EMG electrodes (DSI). The body of the transmitter was placed subcutaneously on the back between the shoulder blades while EMG electrodes were inserted into the belly of the right knee flexors (Biceps Femoris) and extensors (Rectus Femoris). Twenty days later animals received moderate contusion (12.5 g/cm, NYU) SCIs at T10. Starting two weeks post-injury the left limb was taken through a 12 minute stretching protocol twice a week while EMG responses of the contralateral limb were recorded. In addition, we measured the forces that the rat "physical therapists" applied during stretching using a custom designed "force glove" and LabView software. We collected kinematics of the limb position in order to calculate the torques applied during stretching. Recurring EMG patterns in the right limb in response to stretching include spasms characterized by low to medium amplitude co-activation of flexors and extensors and clonus-like activity characterized by medium amplitude bursts at 4-6Hz. These responses occurred in the contralateral limb that was not being manipulated or touched in any way. Conclusions: We observed at least two responses, clonus and spasms, in our animals in response to muscle stretch that commonly occur in chronic incomplete SCI patients. In order to draw further implications about possible negative effects of stretching in human subjects, however, stretching studies in patients need to be conducted using similar protocols and outcome measures.

Title: Sympathetic-somatomotor coupling is disrupted in spinal cord injury

Authors: ***T. ONUSHKO**[1], T. G. HORNBY[2], B. D. SCHMIT[1];
[1]Biomed. Engin., Marquette Univ., Milwaukee, WI; [2]Rehabil. Inst. of Chicago, Chicago, IL

Abstract: The regulation of the cardiovascular system during muscle activity is poorly understood in people with incomplete spinal cord injury (SCI). While previous research has looked at sympathetic and somatomotor systems separately, changes in the interactions between these systems may affect motor output. Thus, the purpose of this study was to understand how the sympathetic system interacts with the somatomotor systems below the level of injury in people with incomplete SCI. We hypothesized the interaction between sympathetic and somatomotor systems is disrupted in people with incomplete SCI. We recruited 4 motor-incomplete SCI subjects (ASIA classification D; injury level above T1) and 9 healthy age-matched adults. Subjects were seated upright and their right leg strapped into an instrumented chair. The right knee was flexed 90° and aligned with a 6 degree of freedom load cell. We tested sympathetic function using 3 different stressors: 1. cognitive stressor (counting backwards by 13,), 2. cold pressor test (CPT; foot immersed in ~3° C ice water), and 3. pain (100 Hz electrical stimulation applied near the naval), while simultaneously monitoring changes in patellar tendon tap reflexes, maximal voluntary knee extension, and cardiovascular parameters. The sympathetic stressors were applied during the first 3 minutes of a 6-minute trial, and we continued to monitor changes for 3 additional minutes after the stressor was removed. Somatomotor measurements include electromyograms (EMG) and knee torque. Measurements of sympathetic function include heart rate, blood pressure and femoral artery blood flow using Doppler ultrasound. Measurements were made before the stressor was applied (baseline) and then every 1 minute during the 6-minute trial. Preliminary results show that the reflex responses to the sympathetic stressors differed between incomplete SCI and healthy adults. During the CPT, the reflex EMG responses increased in SCI subjects and remained elevated compared with healthy adults. We observed no trends in maximal knee extension torque during any of the conditions. We also observed differences in cardiovascular responses between SCI and healthy controls. The heart rate in SCI subjects decreased in response to the sympathetic stressors, while blood flow of the

femoral artery increased in response to pain and cold, which was the opposite compared with the healthy adults responses. Additionally, we observed a dulled response in mean arterial pressure in SCI subjects compared with the healthy adults. These data demonstrate that motor responses to sympathetic stressors is altered in people with incomplete SCI. Supported by NIH R01-NS079751

Title: Histological and functional characterization of a mid-cervical contusion injury in rats

Authors: ***S. RANA**[1], H. M. GRANSEE[2], S. CORREA-CARDONA[2], M. PAREJA-CAJIAO[2], W. Z. ZHAN[2], G. C. SIECK[2,3], C. B. MANTILLA[2,3];

Abstract: Damage to the spinal cord is a coalesced result of the primary insult to the cord and the secondary injury cascade that follows the impact. In order to identify therapeutic targets for spinal cord injuries (SCI), we must be able to use an injury model that closely represents a clinical setting. Mid-cervical contusion injury is one of the most common types of SCI and can lead to respiratory impairment via complete or partial paralysis of the diaphragm muscle. Thus, it is important to characterize the injury and extent of loss in the phrenic motor neuron (PhMN) pool that compromise respiratory function. In this study, we assessed the degree of damage following a 100kD unilateral C4 contusion injury in rats. We hypothesized that PhMN loss, cystic cavity formation and tissue scarring, as measured by chondroitin sulfate proteoglycans (CSPGs) expression, should increase progressively past 3 days post-injury (D) and stabilize by 7D and 14D. Intra-pleural injections of Alexa 488-conjugated cholera toxin subunit B were employed to label the PhMNs in the spinal cord. Immunohistochemical analysis by Wisteria Floribunda Agglutinin that labels perineuronal net formation was used to assess the extent of tissue scarring at the injury site. Quantitative confocal microscopy was used to compute volume of the cavity formed following injury and to compare loss of PhMNs ipsilateral and contralateral to the injury. Functional assessment of the injury was performed by obtaining diaphragm EMG recordings for ventilatory behaviors (eupnea, hypoxia-hypercapnia (10% O2 and 5% CO2)) and non-ventilatory behaviors (sustained airway occlusion, sighs, and sneezing). Our results show

that there is no difference between cyst volume at 3D, 7D, and 14D. There is progressive PhMN loss between 3D to 7D, and PhMN counts are comparable at 7D and 14D. Our results, thus, reveal that PhMN loss and tissue scarring progress past 3D to 7D, whereas cyst formation has plateaued by 3D. Ventilatory behaviors are not impacted by unilateral contusion, with no difference between ipsilateral and contralateral sides. Hence, assessment of higher force behaviors (e.g., coughing, sneezing) is imperative. Collectively, these findings illustrate the loss in tissue integrity and formation of an inhibitory environment at the injury site post contusion injury. These results also corroborate that a C4 unilateral contusion model is a useful tool in the assessment of effective therapeutic strategies for SCI, although, an earlier intervention might be needed to assess effectiveness on PhMN loss.

Title: Assessment of diaphragm EMG activity recovery following upper cervical spinal cord injury

Authors: *O. U. KHURRAM[1], Y. B. SEVEN[2], R. M. S. VASDEV[2], G. C. SIECK[2,3], C. B. MANTILLA[2,3];

Abstract: Motor units are normally recruited in an orderly manner in order to accomplish a range of behaviors. Across a range of ventilatory and non-ventilatory behaviors, the duration of non-stationarity in electromyographic (EMG) activity of the diaphragm muscle (DIAm) provides an estimate of the period of motor unit recruitment. Motor unit recruitment reflects central drive to the DIAm, which can be estimated by the root-mean-squared (RMS) EMG value 75 ms after the EMG burst onset (RMS75) in rats. Following unilateral DIAm paralysis induced by upper cervical spinal cord hemisection at C2 (SH), increased activity of the contralateral (uninjured) DIAm is sufficient to maintain ventilation. Over time following SH, there is spontaneous recovery of ipsilateral DIAm EMG activity, which may mitigate the compensatory increase in contralateral activity. We hypothesized that contralateral DIAm EMG measures such as duration of non-stationarity and RMS75 can quantitatively inform about recovery of ipsilateral DIAm activity following upper cervical spinal cord injury. Using chronic DIAm EMG recordings,

recovery of ipsilateral DIAm activity was observed in a subset of animals by 14 days post-SH (D14). However, peak DIAm RMS EMG activity was reduced compared to the pre-injury baseline in all cases. The contralateral DIAm displayed increased peak RMS EMG activity post-SH but there was no change in the duration of non-stationarity whether animals displayed recovery of ipsilateral EMG activity or not. By D14, contralateral DIAm RMS75 values were reduced in rats displaying recovery of ipsilateral DIAm activity compared to rats that did not. These results suggest that the period of DIAm motor unit recruitment (estimated by the duration of non-stationarity) during ventilatory behaviors did not change with SH or ipsilateral recovery. Central drive (contralateral DIAm RMS75) increased post-SH and returned to baseline in animals displaying recovery, and thus may be used to evaluate the extent of recovery of ipsilateral DIAm activity following spinal cord injury.

Title: Minimally invasive approach to medular hemisection in rats. Technical advance

Authors: *F. A. ROCHA, R. RAMOS ZUÑIGA, G. GUDIÑO CABRERA;
U De G, Guadalajara, Mexico

Abstract: Spinal cord injury (SCI) interrupts the nerve connections between the brain and the rest of the body, and results in paralysis and loss of sensation below the level of injury. In the model of spinal cord hemisection in rats, it is necessary to have good access to the site that will be injured. Indeed, it is required to make a laminectomy in two vertebras at the level where the spinal cord injury will be. With this approach, a biomechanical destabilization occurs in the backbone of the animal, done by the removal of bone and supraspinous and interspinous ligaments. In the present work; we analyzed an approach that would maintain intact the spinous process and all the ligaments in the injury area, the main objective is to produce a minimum biomechanical injury. Males wistar rats were supplied by animal house of Centro de Investigaciones Biomedicas de Occidene (CIBO) of Instituto Mexicano de Seguro Social (IMSS), and mantainted in our animal house, with constant temperature (22 ± 2 °C) and 30 to 40% of relative humidity. The animals were maintained in acrylic cages, with rodent laboratory chow (PMI Nutrition International LLC, EUA) and tap water ad-libitum. All surgeries were done

under stereo microscope (ecleris, OM100f1) in sterile surgical room and with sterile surgical equipment. The laminectomy was done at the level T9 using an electric motor (Lynx, EM20K) with round dental drill. The spinal cord hemisection was performed with a homemade punch (silver, 3mm in diameter), in order to assure the lesion reproducibility and also, extract a portion of spinal cord. We analyzed the anatomy in-vivo with a computer axial tomography, and the locomotion with BBB scale. Our result shows a favorable recovery in 3 days, and observing minimal inflammation. With the computerized axial tomography we observed that the contralateral lamina, all the ligaments and the spinous process were preserved in the site of the injury and also were not being altered all the transverse process. In all spinal cord injury sites, we observed a cavity done with the punch. In conclusion, we designed a customized surgery and an hemisection device based on our requirement, satisfying all the parameters to withstand a standard animal model for spinal cord hemisection at the thoracic level without compromising the lesion reproducibility.

Title: The effect of combination therapy in the regeneration and locomotor recovery in rats with chronic spinal cord injury

Authors: *F. R. ADRIÁN, ESQ;
Proyecto Camina AC, México, Mexico

Abstract: The spinal cord injury (SCI) is a terrible condition that affect more than 250,000 people ever year around the world; the lesion produces an impairment not only of locomotor and sensitive capacities but also provokes deregulations of normal physiology. The acute phase is characterized by the activation of immunological response that progressively become permanent and continues in the chronic phase. The inflammatory response has an active participation in the formation of glial scar (GS), different researches had shown that GS exerts a negative effect on axon growth and stop the attempts made by the organism to reconnect neuronal pathways lost by the injury. A91 is a modified peptide that modulates the immunologic response when is applied after SCI, the effect is produced by the production of anti-inflammatory cytokines like IL-10, IL-4 and TGF β. This effect can be profited in a combinatory strategy directed to the restructuration of damage tissue and for consequence this could be used as alternative therapy to treat chronic SCI. The aim of this study is to evaluate the effect of a combinatory therapy in rats with chronic SCI and evaluate the locomotor recovery for 2 months and finally process the portion affected by

the injury and measure the numbers of axons positives to tyrosine hydroxylase and serotonin by an immunohistochemistry technic. For this purpose we evaluated the effect of five different combination therapies, the groups studied are: 1) Rats subjected to chronic SCI without further treatment; 2) Rats subjected to chronic SCI + scar removal; 3) Rats subjected to chronic SCI + scar removal + A91 immunization; 4) Rats subjected to chronic SCI + scar removal + A91 immunization + tissucol with mesenchimal cells; 5) Rats subjected to chronic + A91 immunization + tissucol with mesenchimal cells. The locomotor evaluation showed a higher recovery in the animals of group 5, this result is correlationed with the higher number of marked fibers with immunochemistry test. The results of this work demonstrate that a combinatory strategy in chronic SCI can profit positives the effects of different therapeutial approaches that had shown locomotor recovery and neuronal reconnection when are used as a unique treatment. Key words: A91, combination therapy, chronic spinal cord injury, locomotor recovery.

Title: Kinematic analysis of disordered locomotion in common marmosets with spinal cord hemisection

Authors: *A. UCHIDA[1], T. KONDO[2], K. YOSHINO-SAITO[2], H. J. OKANO[5], M. NAKAMURA[3], H. OKANO[2], J. USHIBA[4];
[1]Grad. school of Fundamental Sci. and Technol., Keio Univ., Kanagawa, Japan; [2]Dept. of Physiol, [3]Dept. of Orthopaedic Surgery, Keio Univ., Tokyo, Japan; [4]Dept. of Biosci. and Informatics, Keio Univ., Kanagawa, Japan; [5]Sch. of Med., Jikei Univ., Tokyo, Japan

Abstract: Spinal cord injury (SCI) results in motor and sensory deficits below the level of the injury. Recently, some preclinical studies using non-human primates to establish treatments for recovery of impaired functions after SCI have been reported. These studies suggest the importance of combination of various therapeutic interventions such as stem cell transplantation and rehabilitations. However, conventional evaluation metrics of motor function after these interventions are lack in quantitativity and objectivity. In addition, few researches have focused on changes in the internal state of the neural system underlying behavioral changes after SCI. Information about the change in the internal state of the central nervous system (CNS) combined with reliable behavioral evaluations may greatly improve our understanding of the recovery process after SCI. Moreover, in order to enhance reacquisition of normal motor and sensory functions, we need to evaluate both performances and internal states of the CNS. In this study, to

establish new evaluation protocols for spontaneous recovery of locomotor function after hemisection SCI at C4/C5 level in common marmosets (N = 4), we developed the kinematic recording method and estimated the change in the internal state of the CNS by using principal component analysis (PCA) for the kinematic data. First, we established the motion capture system with 2 high speed cameras to record walking of common marmoset from both sides with sampling rate of 150 Hz. Sixteen reflective markers (3.97 mm diameter) were attached on 16 joints to track joint displacements in all-limbs. We analyzed the kinematic data in 4 time points before and after SCI. Horizontal shift between the shoulder and the metacarpophalangeal joints during walking was evaluated. At 2 weeks after the lesion, the forward horizontal shift was decreased and the backward shift was increased. However, at 12 weeks after the lesion, the horizontal shift recovered close to that before the lesion. Next, we estimated the internal state of the CNS in each time point by applying PCA for the data of temporal changes in 4 joint angles of paralyzed hindlimb in gait cycles. From the results of percent variance of principle components (PCs), the walking pattern before the lesion was coordinated such that PC1 and PC2 are weighted similarly. However, at 2 weeks after the lesion the pattern strongly depended on PC1. At 12 weeks after the lesion, the balance of PC1 and PC2 recovered close to the variance before the lesion. The current results suggest that our evaluation metric may provide novel insights for the recovery process of locomotor function after SCI, and contribute to future clinical researches on SCI.

Title: Comparison of cervical cerebrospinal fluid flow between healthy participants and persons with spinal cord injury using cine velocity-mapping MRI

Authors: ***A. M. WILLHITE**[1], K.-J. JUNG[2], N. SETTIPALLE[1], B. WELLMAN[4], D. LORENZ[3], M. BOAKYE[1], S. J. HARKEMA[1];
[1]Neurolog. Surgery, [2]Radiology, [3]Bioinformatics & Biostatistics, Univ. of Louisville, Louisville, KY; [4]Radiology, Univ. of Louisville Hosp., Louisville, KY

Abstract: Purpose: The cerebrospinal fluid (CSF) flow in the cervical spine is expected to be reduced in persons with spinal cord injury (SCI) as a result of an increased resistance to the flow from stenosis in the subarachnoid space (SAS) and a reduced stroke volume of the heart. Therefore, the CSF flow in the SAS space at the cervical spine was compared between healthy volunteers and individuals with SCI using MRI. Methods: The flow velocity in the craniocaudal direction was acquired at the C4 spine level using a retrospectively gated phase-contrast cine sequence with a peripheral pulse taken from a finger and a velocity encoding range of 10 cm/s at 3 T MRI with head-neck and spine RF coils. The baseline velocity due to eddy current was corrected automatically using a specially designed algorithm which addressed the spatially dependent nature of eddy current. The region of detectable flow in SAS was segmented semi-automatically using a spectral analysis of the cine images of a complex data format. The flow in the segmented SAS was automatically analyzed for flow area, average peak velocities, average of standard deviations of systolic peak velocities, and average time to the velocity peaks using a customized analysis program. The extracted flow parameters were compared between 9 healthy volunteers and 9 participants with SCI. Mean values from healthy participants and SCI subjects were compared with a linear mixed effects model to account for repeated measurements from several subjects. Results:The heart rate was slower (877ms vs. 1094ms, $P<0.02$) and the time to the systole velocity peak was increased (70% vs. 82% of the cardiac cycle from the trigger, $P<0.11$) in SCI patients compared to healthy volunteers.. The flow area was reduced (122 mm2 vs. 108mm2, $P<0.23$) and both systolic (2.1 cm/s vs. 3.0 cm/s in the caudal direction, $P<0.03$) and diastolic (1.2 cm/s vs. 1.3 cm/s in the cranial direction, $P<0.09$) peak velocities were higher in participants with SCI than in healthy volunteers. In addition, the standard deviation of the systolic peak velocities in SAS was increased in SCI participants (2.1 cm/s vs. 3.0 cm/s, $P<0.03$). Conclusions: The flow velocity of SCI subjects was faster than that of healthy volunteers in both diastolic and systolic cardiac phases. This finding is contrary to the expected result of reduced flow velocity given that a slower heart rate and a reduced ejection fraction and stroke volume is often seen in SCI patients. Therefore, the reduced flow area may be a contributing factor to the increased velocity and the increased distribution of the systolic peak velocities in the flow area of the SAS.

Ctr., Cleveland, OH; [4]German Ctr. for Neurodegenterative Dis., Bonn, Germany; [5]MetroHealth Med. Ctr., Cleveland, OH; [6]Case Western Reserve Med. Sch., Cleveland, OH

Abstract: More than half of all spinal cord injuries (SCI) are at the cervical level. These injuries can result in the disruption of the respiratory motor pathways leading to the innervation of the diaphragm, resulting in the need for mechanical ventilation. To examine the neuronal circuitry involved in cervical SCI and potential interventions, our laboratory utilizes a C2 lateral hemisection. This model induces paralysis of the hemi-diaphragm ipsilateral to the hemisection. By leaving one side of the diaphragm still active, this model allows us to examine the breathing circuitry affected and spared by cervical SCI without the need for artificial ventilation of experimental subjects. A recent investigation has shown that the microtubule stabilizer paclitaxel (Taxol) can improve outcomes in thoracic injury. In the thoracic injury model, paclitaxel has been shown to reduce the perineuronal (PNN) net and increase serotonin (5-HT) after injury. However, its application in cervical injury is untested. Here we examined the therapeutic potential of paclitaxel on the recovery of breathing after a C2 spinal hemisection. Subjects received various (0.5mg, 0.25mg, & 0.125mg) doses of systemic i.v. paclitaxel at 48 hours post-injury. Preliminary data indicate that cervical SCI subjects that receive Taxol have improved respiratory motor function compared to vehicle treated animals in a dose dependent fashion. Based on these encouraging results investigating a combination treatment of paclitaxel and rehabilitative therapy is warranted. Future studies examining this multi-modality strategy are planned.

Title: Inoculation of neural antigens into the anterior chamber of the eye as a neuroprotective strategy after spinal cord injury in rats

Authors: *D. TOSCANO[1], B. PINEDA[2], A. IBARRA[2];
[1]Univ. Anahuac, Ciudad de Mexico, Mexico; [2]Univ. Anahuac, Mexico City, Mexico

Abstract: Objective Spinal cord injury (SCI) is considered a catastrophic disease due to the profound functional impairment and detriment in quality of life that it can cause to patients who suffer from it. Currently, there is no effective treatment for SCI. Inflammatory response is one of the main components of SCI pathophysiology as it is responsible for secondary damage. Anterior chamber associated immune deviation (ACAID) is a phenomenon that reduces the inflammatory response by producing tolerance to antigens inoculated in the anterior chamber of the eye. The aim of this study was to evaluate if the induction of ACAID with neural peptides represents a potential anti-inflammatory and neuroprotective strategy capable of improving motor function recovery after SCI in rats. Methods One-month-old Sprage Dawley rats were divided into two groups and inoculated in the anterior chamber of the eye with neural antigens (ACAID group) or PBS (control group). When rats reached the age of 2.5 months, moderate SCI was performed in both groups with the IH-0400 impactor at 200kdyn of force. Motor function and sensory recovery was assessed for 8 weeks with the BBB scale, Footprint test and von Frey Hair test, respectively. Results A statistically significant improvement in motor function recovery, as measured by the BBB scale, was observed between the ACAID group and controls ($p < 0.0001$). Also, a better performance in the footprint test was observed in the ACAID group. This was consistent with a higher number of motor neurons in the morphological analysis of the ACAID group compared to controls. As for sensory recovery, there was a tendency towards an increased improvement in the ACAID group. Conclusion This study supports immunomodulation achieved through anterior chamber associated immune deviation as a plausible neuroprotective strategy that could improve motor function recovery after traumatic SCI.

Title: Trans-spinal direct current stimulation changes the number and migration pattern of spinal cord adult-born cells

Authors: *Z. AHMED, S. SAMADDAR;
The Col. of Staten Island, Staten Island, NY

Abstract: Adult born cells (neurons or glia) in the nervous system are continuously produced throughout life. Recent studies implicated these adult born cells in learning (e.g. motor skill

learning). In the current study, we investigated the effects of trans-spinal direct current stimulation (tsDCS) on the number of adult born cells and their migratory pattern. Animals were implanted with tsDCS electrodes. Adult mice underwent tsDCS for five consecutive days and were simultaneously injected with 5'-bromo-deoxyuridine (BrdU). Cathodal tsDCS causes an increase of the number of BrdU-labeled cells to accumulate at the dorsal aspect of the spinal cord. Anodal tsDCS causes a shift of location of the BrdU-labeled cells toward the ventral aspect. In general, there was attraction of BrdU-labeled cells toward the cathode and repulsion from the anode. There was a significant increase in the number of labeled cells after anodal and cathodal stimulation. See figure (right). A, sham-control; B, cathode on the dorsum of the spinal cord; C, anode on the dorsum of the spinal cord. These reults could provide a novel mechanism of how tsDCS modulate function of the spinal cord. More importantly these results identfy a new approach to manipulate adult born cells that could be very useful in augmenting functional recovery after injuries.

Title: The effects of hindlimb stretching and positioning exercise on locomotor function after spinal cord injury in rats

Authors: *E. SONG[1,2], H. JEON[1,2], S.-C. HAM[1,2], Y. KIM[3], Y. YOON[3], J. KIM[1,2];
[1]Korea Univ. Col. Hlth. Sci., Seoul, Korea, Republic of; [2]Rehabil. Sci. Program, Dept. of Publ. Hlth. Science, Grad. School,, Seoul, Korea, Republic of; [3]Korea Univ. Col. Med., Seoul, Korea, Republic of

Abstract: Rehabilitation exercise has been applied to prevent the progress of sensorimotor impairments in patients with spinal cord injury (SCI). In particular, most of all mainly have been focused in the effect of locomotion training. However, the effects of other rehabilitation approaches applied in patients with SCI except for locomotion training are still unclear and thus investigation for additional approaches is needed. Thus, we examined the effects of passive stretching exercise (SE) and positioning training (PT) on recovery of locomotor function. Spinal contusion was made in male Sprague-Dawley rats using NYU impactor on T12 spinal cord under anesthesia. Rats were randomly assigned to SE (n=10), PT (n=9), combined SE and PT (C, n=10) and no exercise (control, n=9). SE applied 6 muscles on hindlimb for 1 minute in each

motion alternately side repeated 2 sets. PT held quadripedal posture with plantar contact for 30 min. C performed 1 set of SE and 15 min of PT. These interventions were applied 5days/week for 4weeks. Locomotion recovery was assessed by BBB open field locomotor scale and combined behavior score (CBS). Hypersensitivity after SCI was evaluated by paw withdrawal threshold (PWT) with up - down method. Average, maximum speed and travelled distance that reflect the ability of physical activity were measured by using Panlab's smart tracking system. Luxor fast blue and cresyl violet staining was used to measure areas of cavities on epicenter. In the PT group, BBB was significantly increased at 10, 11, 12 and 13 days after SCI, and CBS also significantly decreased at 10, 11 and 12 days after SCI compared to control. BBB and CBS in the PT group slightly increased compared to them in the SE group during intervention. PWT in the PT group was significantly increased from 18 days to 28 days than it in the control. In all rehabilitation exercise groups, values of physical activities showed increased tendency on chronic stages and then only maximal velocity in the PT group were significantly faster than control group. Areas of epicenter cavity were no difference between each group. These results suggest that SE was no effect to locomotion recovery whereas PT with manually partial support may be more helpful than SE to recovery of locomotor function and hypersensitivity after SCI. This study suggests positive potential for therapeutic exercise to improve locomotor function in SCI rats, though the more work related with mechanism is still needed. This research was supported by the convergence technology development program for bionic arm through the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT& Future Planning (2014M2C1B2048632).

Abstract: Neurodegenerative diseases are often characterized by a reduction in cell viability and density. The recruitment and integration of endogenous neural stem cells is a promising treatment strategy for the replacement of compromised cells in neurodegenerative disease. Stromal derived factor-1 (SDF-1) is a chemokine which functions as a signaling molecule, involved in differentiation, cellular locomotion, survival, and proliferation. Bone marrow derived mesenchymal stem cells were virally transfected to overexpress SDF-1 for treatment of spinal cord injury, with the goal of controlling cellular loss post-injury and inducing chemotaxic migration of endogenous neural stem cells to the lesion site. SDF-1 overexpressing MSCs were co-cultured with maturing stem cell derived neurons *in vitro* to determine the effects of secreted factors from SDF-1 overexpressing MSCs on process length, and electrical activity. Under-agarose chemo-attractant assays were performed to assess directional chemotaxis of multipotent neural stem cells towards the SDF-1 overexpressing stem cells. SDF-1 MSCs were determined to increase growth of neurons in co-culture models and induce directional chemotaxis superior to non-overexpressing MSC populations. MSCs, which overexpress modulatory chemokines, show potential for novel treatments targeting spinal cord injury and neurodegenerative diseases.

Abstract: Numerous studies have focused on promoting axonal regeneration; however, only a few of them are directed to stimulate neural regeneration after a chronic spinal cord (SC) injury. Different laboratories have demonstrated the neuroregenerative effect of immunizing with neural-derived peptides (INDP). Additionally, evidence suggests that grafted mesenchymal stem cells (MSC) are able to stimulate neuroregeneration at the site of injury and its effect is potentiated when transplanted along with biological matrices, or with glial scar removal. These findings have led us to believe that combination therapies could result in higher neurological recovery. To the date, there is no information regarding the effect of INDP with other therapies. In the present study we combined INDP with scar removal and implantation of MSC impregnated in a biological matrix to evaluate neuroregeneration after chronic SC injury. This combination strategy was performed two months after SC injury. During the first set of experiments, we evaluated motor recovery and IL-4, IL-10, TNFα, IGF1, TGFβ, BDNF, NT3 and GAP43 gene expression in rats with SC contusion. After two months of injury, adult Sprague Dawley rats were allocated into 5 different groups: 1) Rats with no treatment; 2) Rats subjected only to scar removal; 3) Rats with scar removal and INDP; 4) Rats with no scar removal + INDP + fibrin glue impregnated with MSC; 5) Rats with scar removal + INDP + fibrin glue impregnated with MSC (n=12 per group). Results showed a significant improvement in motor recovery and higher expression of IGF1, TGFβ, IL-4, IL10, NT3, BNDF and GAP43 genes at the site of injury of rats treated with the combination therapy. In the the second experiment, rats were subjected to a complete SC transection. After two months of injury, animals were allocated into 2 groups: 1) Rats with no treatment; 2) Rats with scar removal + INDP + fibrin glue impregnated with MSC (n=6 per group). In this case, somatosensory evoked potentials (SSEP) and motor recovery were evaluated to demonstrate axonal regeneration. In the SSEP evaluation, comparison of latency and amplitude of the different components of the waves showed a significant improvement in rats treated with the combination therapy. Results suggest that this combination therapy could improve axonal regeneration at the site of injury and promote better motor recovery in rats with chronic SC injury.

Title: Hand-related cortical sensorimotor activity after chronic tetraplegia

Authors: *D. A. ROYSTON[1,2,3], S. T. FOLDES[4,2,6], M. RANDAZZO[5], J. L. COLLINGER[4,6,2]; [2]Ctr. for the Neural Basis of Cognition, [3]Bioengineering, [4]Physical Med. and Rehabil., [5]Neurolog. Surgery, [1]Univ. of Pittsburgh, Pittsburgh, PA; [6]VA Pittsburgh Healthcare Syst., Pittsburgh, PA

Abstract: In spinal cord injury (SCI), somatic motor and sensory innervation is severely disrupted, which can substantially alter the function of related brain areas. Cortical activation changes during attempted and imagined movements have been observed in lower-limb paralysis, but the effects of tetraplegia on upper limb representations are still poorly understood. A deeper understanding of how this activity changes is needed to develop new rehabilitation strategies and would provide insight into the nature of neural plasticity. The objective of this study was to elucidate the effects of chronic tetraplegia on sensorimotor neural activity. We hypothesized that subjects with SCI would display decreased activation in sensorimotor-related areas during attempted hand movements compared to able-bodied controls, but increased activation during imagined movements. Fourteen able-bodied volunteers and eight participants with cervical SCI underwent functional magnetic resonance imaging (fMRI) to investigate cortical activity during attempted and imagined right hand grasps. We compared the peak activation between groups in several bilateral regions of interest (ROIs), including pre- and post-central gyri, supplementary motor areas (SMA), and posterior parietal cortex. Both subject groups showed significant task-related activity in all ROIs during both attempted and imagined grasps ($p<0.05$). Subjects with SCI showed lower activation during attempts than controls in contralateral pre- and post-central gyri ($p<0.01$), but greater activation in ipsilateral SMA and post-central gyrus ($p<0.05$). In contrast, subjects with SCI had greater cortical activation during imagery than controls ($p<0.05$) in bilateral pre- and post-central gyri and ipsilateral SMA and parietal cortex. Activity during attempts was much greater than that during imagery in contralateral pre- and post-central gyri ($p<0.001$) for controls, while this difference was not significant in subjects with SCI. Our findings show that individuals with chronic tetraplegia display less activity in cortical sensorimotor areas during attempted grasping and greater activity during imagined grasping compared to controls. Furthermore, control subjects showed much stronger peak activation in primary motor and sensory cortex during attempted movements than imagined movements, but the SCI group did not, possibly indicating a decrease in kinesthetic feedback during attempts or a decrease in motor inhibition during imagery. Continued investigation into the nature of these changes could aid in the development of better rehabilitation applications and neuroplasticity research.

Abstract: Cerium nanoparticles (CeNPs) are known to reduce reactive oxygen species (ROS) and effective for the neuronal regeneration. ROS increment following spinal cord injury (SCI) arise secondary injury and finally lead to permanent functional dysfunction. In this study, we aim to delineate the effectiveness of CeNPs on the hydrogen peroxide-damaged cortical neurons and SCI rats for the first time, and to find the optimal dose of CeNP for neuronal regeneration *in vivo*. *In vitro* condition, we found that the optimal concentration of CeNPs (25-500μg/ml) increased survival rate of primary cultured cortical neurons following hydrogen peroxide application, and also decreased iNOS activity *in vitro*. Then CeNPs were applied into the injured spinal cord of rats with variable concentration (50μg-4mg/ml). We found that the cavity size and inflammatory cells were decreased at 1 and 8 weeks following SCI, and the locomotor function was improved more in CeNP-treated rats within the therapeutic range (250μg-1mg/ml) than in controls. The mRNA levels of iNOS and pro-inflammatory cytokines were decreased and interleukin-10 was increased at 1 week following CeNP application in a dose-dependent manner. We concluded that the application of the optimal concentration of CeNPs into injured spinal cord decrease iNOS and inflammation, and might be helpful to restore the locomotor function following SCI.

Abstract: Stimulation of the spinal cord has been shown to have great potential for improving function after motor deficits caused by injury or pathological conditions. Using a wide range of animal models, many studies have shown that stimulation applied to the neural networks intrinsic to the spinal cord can result in a dramatic improvement of motor ability, even allowing an animal to step and stand after a complete spinal cord transection. Clinical use of this technology, however, has been slow to develop due to the invasive nature of the implantation procedures and the difficulty of ascertaining specific sites of stimulation that would provide optimal amelioration of the motor deficits. Moreover, the development of tools available to control precise stimulation chronically via biocompatible electrodes has been limited. Herein, we outline the use of novel technology in the spinal rat model, demonstrating the ability to identify and stimulate specific sites of the spinal cord to produce discrete motor behaviors in spinal rats using a multisite epidural array. The results demonstrate that spinal rats can stand and step when the spinal cord is stimulated tonically via epidural electrodes located at specific sites on the spinal cord. The quality of stepping and standing is dependent on the location of the electrodes on the spinal cord, the specific stimulation parameters, and the orientation of the cathode and anode during bipolar stimulation. Spinally motor evoked potentials (sMEP) produced during standing and stepping are critical tools to study selective activation of interneuronal circuits via responses of varying latencies. The present results provide evidence that the assessment of functional networks in the background of behaviorally relevant physiological states is likely to be a physiological tool of considerable importance in developing strategies to facilitate recovery of motor function after a number of neuromotor disorders.

Title: Characteristics of responses based on electrode and frequency selection during epidural stimulation in humans following SCI

Authors: *C. A. ANGELI[1,2], E. REJC[2], Y. CHEN[2], S. J. HARKEMA[2,1];
[1]Frazier Rehab Inst., Louisville, KY; [2]Univ. of Louisville, Louisville, KY

Abstract: Epidural stimulation of the lumbosacral spinal cord has been shown to facilitate standing and voluntary movement in individuals with complete spinal cord injury. Motor activity can be modulated in the presence of epidural stimulation by intent or sensory input. The location of the electrode array, selection of electrode combinations and stimulus frequency and intensity all influence muscle recruitment. In the present study we investigated the impact of selected stimulation configurations on motor evoked responses and generation of rhythmic motor patterns in the absence of volitional control. We compared configurations to previous work performed with a quad electrode and tested additional configurations with the increased flexibility allowed by the 5-6-5 electrode array. Stimulation was performed using a 5-6-5, 16-electrode array placed around L1-S1 spinal cord level in six individuals with motor complete injury. Stimulation frequencies ranged from 2- 60Hz with intensities ranging from 0.5V to 10.0V. Bipolar

stimulation was performed selecting 2 electrodes along the middle column of the array (27 mm longitudinal separation) to replicate previous work performed with a quad electrode. Bipolar stimulation was compared to wide field stimulations with a larger number of electrodes activated. Activation of lower extremity muscles varied according to location, intensity and frequency of stimulation. Higher voltages produced an oscillatory rhythmic pattern through a larger range of frequencies when compared to lower voltages. Configurations using a larger number of electrodes also produce greater motor activation and rhythmic responses when compared to bipolar stimulation. Detailed mapping of muscle recruitment and understanding responses through a wide frequency range is critical for optimization of stimulation configurations used in standing, stepping and voluntary activity.

Title: Recovery of locomotion is paralleled by time-dependent cortical plasticity after incomplete spinal cord injury

Authors: ***A. R. BROWN**, M. MARTINEZ;
Cell Biol. and Anat., Hotchkiss Brain Institute, Univ. of Calgary, Calgary, AB, Canada

Abstract: After an incomplete spinal cord injury (iSCI) at thoracic level, supraspinal structures, which initiate movement, and spinal circuits, which generate them, remain partially connected through residual descending pathways. In this scenario we and others have shown that, even after extensive iSCI, animals consistently recover voluntary quadrupedal locomotion spontaneously with minimal sensory inputs. What are the mechanisms of locomotor recovery and what structures contribute? Although the motor cortex is crucial for the execution of voluntary motor acts, its function over hindlimb locomotion after iSCI is poorly understood. In this study, we evaluated, for the first time, the cortical mechanisms of hindlimb locomotor recovery after iSCI in rats. Using intracortical microstimulation (ICMS) applied to the output layer V of the motor cortex to evoke movement, we examined the topographic arrangement of hindlimb movements within both motor cortices (motor maps) for a two-month period after iSCI (unilateral hemisection at T8). Locomotor performance was evaluated using well-established locomotor tasks. In intact rats, the location and size of the hindlimb motor maps was consistent between

animals, and maps contained representations of contralateral hindlimb joints exclusively. After iSCI, rats exhibited motor deficits on the side of the lesion that gradually recovered over the first five weeks. During this period, the hindlimb motor maps on the contralateral side (de-efferented cortex) disappeared, demonstrating that the contralateral motor cortex did not exert a control over the affected hindlimb. By contrast, the ipsilesional motor cortex dynamically reorganized over the same period to develop a novel representation of the ipsilateral hindlimb. The critical point here is that ICMS applied on the ipsilesional motor cortex evoked bilateral hindlimb movements, indicating that, after iSCI, the ipsilesional motor cortex functionally reorganizes to encode bilateral hindlimb movements. After the first five weeks of recovery, new plastic changes occurred within both motor cortices. The hindlimb motor maps within the ipsi- and contralateral motor cortex returned to normal showing that the motor cortices regain a normal control over the hindlimb. These data strongly suggest that cortical mechanisms actively participate in the re-establishment of a consistent bilateral locomotor pattern after iSCI. Importantly, these novel insights into the neural basis of recovery will help identifying therapeutic strategies to harness cortical activity and catalyze functional recovery following iSCI.

Title: Physiological correlates of depression in a rodent model of spinal cord injury

Authors: ***M. HOOK**[1,2], A. ACEVES[1], M. ACEVES[2];
[1]Neurosci. and Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr., Bryan, TX; [2]Texas A&M Inst. for Neurosci., College Station, TX

Abstract: Previously, we have shown that a subset of rats exhibit depression-like behaviors following spinal cord injury (SCI). These subjects display decreased sucrose preference, decreased open field activity and social exploration, and increased immobility on the forced swim test. These behaviors are thought to reflect symptoms of depression (i.e., decreased interest or ability to experience pleasure, psychomotor retardation, fatigue) that are analogous to those found in human patients. The current study extends these findings by examining the relationship between depression-like behavior and physiological function. Subjects were given a moderate contusion or sham injury and then assessed for depression-like behavior, on days 9-10, 19-20, and 29-30 post SCI, with a battery of established behavioral tests (sucrose preference, social

exploration, open field activity, burrowing activity, and appetite deviation). Using implantable telemetry devices, 24 hr recordings of home cage activity, body temperature, heart rate and heart rate variability were collected throughout the duration of the experiment. Locomotor performance (BBB scale) and measures of pain reactivity (girdle, tactile, and tail flick tests) were also assessed throughout the recovery period, to further examine the relationship between psychological and physical well-being. Using principal components and hierarchical cluster analyses, subjects were classified into two groups: exhibiting behaviors indicative of depression or no depression. The depressed and not-depressed groups displayed significant differences in both behavior and physiological function. Subjects characterized as depressed had significantly higher heart rates, and decreased heart rate variability, relative to intact and not-depressed SCI subjects. Body temperature and home cage activity did not differ between depressed and not-depressed SCI subjects, although both groups displayed lower activity levels than the intact controls. Replicating our previous study, therefore, we show that a subset of rodent subjects display signs of depression following SCI. Moreover in addition to behavior, the depressed and not-depressed subjects differ on measures of physiological function (e.g., decreased heart rate variability) that are also associated with depression in humans. These physiological differences further validate the rodent model of depression after SCI.

Title: Computerized 3D gait analysis as a quantitative functional endpoint of spinal cord injury in African green monkeys

Authors: S. A. LIDDIE[1], R. J. GOODY[1], A. A. LEWIS[1], X. G. MORTON[1], D. FRANK[1], V. WOODS[1], M. STRUHARIK[1], *D. E. REDMOND, Jr[2], M. S. LAWRENCE[1];
[1]Res., RxGen, Inc., Hamden, CT; [2]Dept Psych & Neurosurg., Yale Univ., New Haven, CT

Abstract: The ability to assess quantitative functional recovery following musculoskeletal or neuromotor impairment or therapeutic intervention critically depends on establishing robust and reproducible means of assessing limb movement in the course of natural behaviors. We have applied computerized 3D gait analysis to evaluate hind limb gait parameters and joint angles to support longitudinal analysis of experimental models of spinal cord injury (SCI) in African green monkeys. A positive reinforcement training program was used to acclimate animals to treadmill

activity prior to data acquisition using a 4-camera analysis system (KinemaTracer™, Kissei Comtec, Japan). Mean and standard deviation for gait parameters (assessed from both hind limbs) recorded at 3 mph including cadence, stance duration, swing duration, percent time spent in double stance phase, stride length and step length were 199.8912.32 steps per minute; 0.360.03 sec; 0.250.02 sec; 0.060.02 sec; 46.369.33 cm and 25.112.7 cm, respectively. Characterizing baseline gait component measures, and associated data capture and analytic methods, has permitted our application of this test system to support various study designs including SCI efficacy studies. In addition to SCI, kinematic analysis also offers utility in other diseases that affect locomotion including stroke, osteoarthritic pain and Parkinson's, and combination of this approach with other quantitative measures such as plantar pressure analyses offers a powerful and highly translatable preclinical platform for evaluating motor deficits of the leg and associated recovery.

Abstract: Regeneration of lesioned fibers is limited in the adult mammalian CNS, but many individuals that sustain incomplete spinal cord injuries undergo spontaneous functional recovery. Cortical plasticity is one mechanism thought to underlie this recovery, but how the motor cortex responds to spinal cord injury longitudinally is largely unresolved. We applied optogenetic motor

mapping in Channelrhodopsin-2 expressing mice before and at multiple time points after a C3/C4 dorsal column lesion to map changes in motor cortical topography and output within the same animals following bilateral ablation of the dorsal corticospinal tract and dorsal column sensory afferents. We find that cortical motor maps of the limbs are greatly diminished in area and magnitude in the early stages of injury. However, by 2-3 weeks post-injury, pre-injury forelimb and hindlimb output, map area, and short latency to movement are re-established. Anterograde tracing of the motor cortex revealed spontaneous axonal outgrowth to the red nucleus in injured animals compared to sham operated animals, suggesting that the re-establishment of motor cortical output occurred through cortico-rubrospinal circuits in addition to corticospinal circuits. To investigate how this plasticity impacts motor behaviour, we performed pharmacogenetic inactivation of dorsolateral corticospinal fibers and of cortico-rubrospinal fibers in injured and uninjured animals and found so far that dorsolateral corticospinal silencing led to the re-appearance of deficits in a ladder beam task that occurred early after injury. Optogenetic motor mapping provides a quantitative assessment of motor cortical output, can be performed repeatedly in individual animals from acute to chronic stages of injury, and represents a novel longitudinal quantitative assay to assess treatment following SCI.

Title: Nociceptive stimulation increases blood brain barrier permeability following spinal cord injury

Authors: M. K. BRUMLEY[1], J. A. REYNOLDS[1], J. D. TURTLE[1], Y.-J. HUANG[1], S. M. GARRAWAY[3], *J. W. GRAU[2];
[1]Texas A&M Univ., College Station, TX; [2]Dept Psychol, Texas A&M Univ., College Sta, TX; [3]Emory Univ., Atlanta, GA

Abstract: Following spinal cord injury (SCI), noxious input disrupts normal physiology around the injury site and dramatically affects the recovery process. Noxious input provided by uncontrollable electrical stimulation increases cell death, promotes inflammation, impairs

locomotor function, and induces neuropathic pain (Garraway, 2014, Pain, 155: 2344; Grau, 2004, J Neurotrauma, 21: 1795). Others have shown that peripheral nerve injury induces an alteration within the spinal cord that increases blood-brain barrier (BBB) permeability through an inflammatory signaling pathway (Beggs, 2010, Mol Pain, 6: 74; Echeverry, 2011, J Neurosci, 31: 10819). Here, we explored how noxious stimulation affects BBB permeability after a spinal contusion injury. Subjects received a moderate spinal contusion injury at T12 using the MASCIS device. Twenty-four hours later, six minutes of intermittent electrical stimulation was applied to the tail and tissue was collected from the lesion site 1 hour, 3 hours, and 24 hours later. Full spectral analysis of protein isolates showed absorbance peaks at 420nm in subjects that received noxious input, indicating an increased concentration of hemoglobin. To confirm these results, immunoblotting of the protein isolates was performed. Noxious input induced increased concentrations of hemoglobin alpha in the lesion site. We propose that increased levels of hemoglobin alpha indicate increased permeability of the BBB, which allows for increased passage of cells into the damaged tissue. Therefore, our data suggest that the detrimental effects of noxious input following SCI may involve aberrant BBB permeability. Preliminary data suggest that the increase in BBB permeability is linked to the activation of cell death pathways and purinergic signaling. Future work is examining additional markers directly related to BBB permeability as well as the trafficking of other cell types across the BBB. Title: PDGFRα-positive progenitor cells form myelinating oligodendrocytes and Schwann cells following contusion spinal cord injury

Authors: *P. L. ASSINCK[1], G. DUNCAN[1], J. PLEMEL[2], M. LEE[1], J. LIU[1], D. BERGLES[3], W. TETZLAFF[1];
[1]ICORD/University of British Columbia, Vancouver, BC, Canada; [2]Hotchkiss Brain Institute,, Univ. of Calgary, Calgary, AB, Canada; [3]Johns Hopkins Univ. of Med., Baltimore, MD

Abstract: Contusive spinal cord injury (SCI) results in considerable demyelination of spared axons, which impairs signal transduction and may leave axons vulnerable to degeneration. Both oligodendrocytes (OL)s and Schwann cells remyelinate denuded axons in the subsequent weeks and months following SCI. NG2 cells, characterized by the near ubiquitous co-expression of platelet derived growth factor receptor α (PDGFRα) in the uninjured central nervous system (CNS), are oligodendrocyte progenitors (OP)s which may serve as a source of new OLs following SCI. PDGFRα-CreERT mice were crossed with Rosa26-YFP mice and administered tamoxifen to label OPs two weeks prior to contusive thoracic spinal cord injury. In the uninjured spinal cord we found that YFP was expressed in NG2+ OPs at very high efficiency, as well as vascular associated cells (pericytes) and fibronectin+ fibrocytic cells in the spinal roots. Following injury, many recombined cells continue to express the PDGFRα+, Olig2 and NG2, indicative they have remained as OPs, but substantial differentiation into new oligodendrocytes (CC1+) was observed, responsible for de novo ensheathment of >30% of the myelinated axons by three months. Strikingly, the majority of P0+ Schwann cells in the spinal cord expressed YFP, suggesting they originated from central nervous system PDGFRα+ OPs. Furthermore, analysis of Olig2-CreERT:Rosa26-YFP mice and P0-CreERT:Rosa26-YFP mice suggests that after injury, Schwann cells are derived from both a centrally derived Olig2 positive population and a peripherally derived P0 positive population (nerve roots or meninges). Overall, this work reveals phenotypic plasticity of PDGFRα precursors following spinal cord injury as a source of the new remyelinating Schwann cells and oligodendrocytes in the injured spinal cord.

Title: Significant gene expression and localization of fatty acid binding protein 4 following spinal cord injury in rats

Authors: ***J. C. LICERO CAMPBELL**, M. SERRANO ILLÁN, K. CORDERO CABAN, A. DURAN, J. FIGUEROA, M. DE LEON;
Loma Linda Univ., Loma Linda, CA

Abstract: The pathology of traumatic spinal cord injury (SCI) results from both the initial mechanical insult and the secondary processes that occur over hours and days following injury.

This secondary insult represents an important window for intervention and is characterized by a marked deregulation in lipid metabolism leading to inflammation. The present study investigates the expression and roles of fatty acid-binding protein 4 (FABP4) in rats post spinal cord injury. The multicenter animal spinal cord injury study (MASCIS) injury model was used to generate a contusion to the T-10 spinal segment of rats. Spinal cord samples were collected at 1, 3, 7, 14, and 28 days post-injury and analyzed to determine the spatiotemporal expression of FABP4 using immunohistochemistry and real-time RT-PCR. Here, we show that injury to the spinal cord results in a dramatic up- regulation in the mRNA and protein levels of FABP4. Notably, this expression was most prevalent in bone marrow derived M1 macrophages, and microglia. To investigate the potential role of this protein in functional recovery after SCI, the rats received intrathecal administration of the FABP4 inhibitor, BMS 309403. We show that animals receiving the FABP4 inhibitor exhibited improved locomotion after injury when compared to vehicle treated rats. Interestingly, this beneficial effect was not associated with the regulation of pro-inflammatory cytokines mRNA levels in the injured spinal cord. Altogether, our findings are the first to show a robust increase in protein and mRNA levels of FABP4 following SCI and a possible functional role in this context. These data suggest that FABP4 may play a major role in hyper- acute inflammatory responses and functional recovery after injury, representing an attractive target for intervention.

Title: Influence of cervical propriospinal interneurons in recovery of forelimb function after spinal cord injury

Authors: *I. S. SHEIKH, Y. LIU, K. KEEFE, X. TANG, G. SMITH;
Neurosci., Temple Univ. Sch. of Med., Philadelphia, PA

Abstract: Spinal cord injury (SCI) effects approximately 100,000 people/year resulting sensory and motor paralysis below the level of injury. SCI causes demyelination, degeneration of axon tracts and neuronal death at the site of injury. Attempts to improve axon regeneration from supraspinal centers have proven difficult due to the long distances required, presence of inhibitory molecules and diminished regenerative program. Propriospinal interneurons (PNs) are

found throughout the spinal cord, forming simple and complex circuits between different spinal segments. PNs function by integrating supraspinal motor and sensory information to organize locomotion. Studies postulate that spared PNs can reorganize and contribute to functional recovery by establishing relays between lesioned axons and motor neurons. However, to what extent PNs contribute to recovery of forelimb reaching and grasping following SCI is not known in rodents. In our first study, we examined a novel two-viral vector technique for silencing cervical PNs in adult rats. The first is a retrograde transportable lentivirus expressing tetracycline-inducible tetanus toxin injected at PN synaptic terminals near motor neurons. The other is AAV expressing tet-On, which is injected at the PN cell bodies. No forelimb deficits were manifested post-injections in normal animals. Doxycycline administration produced no observable forelimb deficits in paw preference, grooming and grip-strength. Histological analysis showed neuronal GFP tagged tetanus toxin expression in the cervical spinal cord. In our second study, we tested recovery of forelimb motor function following a unilateral C5 hemisection. We observed partial recovery of forelimb deficits in the IBB forelimb test and in grip-strength 6 weeks post-lesion, which was lost upon doxycycline-induced silencing of C3/C4 PNs. No recovery was observed in paw-preference and grooming behaviors. These findings may indicate that PNs play a minor role in forelimb motor function in normal rats. However, after loss of direct supraspinal input, they may participate in recovery of forelimb function following a spinal cord injury. Further studies are required to determine the extent PNs are involved in forelimb recovery and the endogenous supraspinal connections onto PNs in the rat.

Title: Assessing the functional relevance of compensatory vs. regenerative sprouting of reticulospinal fibers after incomplete spinal cord injury using DREADD

Authors: ***A. ENGMANN**[1,2], M. SCHNEIDER[1], A. JESKE[1], N. RAPPO[1], R. SCHNEIDER[1], O. WEINMANN[1], H. KASPER[1], M. WIECKHORST[1], M. E. SCHWAB[1,2];

[1]Univ. Zürich, Brain Res. Inst., Zürich, Switzerland; [2]ETH Zurich, Hlth. Sci. and Technol., Zurich, Switzerland

Abstract: The brainstem has often been thought to be hardwired, and bulbospinal fiber growth after spinal cord injury has not been well studied. However, recent data suggest differently: Following axotomy after a spinal cord lateral hemisection in adult rats, the gigantocellular reticular nucleus (NRG), one of the main components of the reticular formation, has been shown to sprout vigorously rostral to the lesion site (regenerative sprouting). Some of these severed fibers re-connect to propriospinal neurons, which run down on the intact hemicord and re-cross (plastically) caudal to the lesion, thereby relaying bulbospinal commands to denervated target areas (Filli & Engmann et al., J Neuroscience 2014). Interestingly, the spared NRG axons on the contralesional side also show sprouting in the lumbar spinal cord, projecting branches across the midline into the denervated hemicord (compensatory sprouting, Zörner & Bachmann et al., Brain 2014). Animals and humans with this type of incomplete spinal cord injury have been described to show pronounced recovery of hindlimb function: Six to eight weeks after the lesion, overground locomotion of the hindlimbs nearly recovered back to baseline levels. In order to investigate the functional relevance of regenerative vs. compensatory NRG sprouting, we used a pharmacogenetic neuromodulative approach: We used two viral vectors (AAV-DIO-DREADD in the NRG and AAV-Cre in the spinal cord) which we injected in animals that had recovered from a unilateral spinal hemisection injury at the spinal level C4. This technique allowed us to introduce the inactivating DREADD receptor hM4Di in a projection-specific way either into the axotomized NRG neurons that had sprouted rostral to the lesion site (regenerative sprouting fibers), or into the intact NRG neurons that had sprouted over the midline in the lumbar spinal cord (compensatory sprouting). Detailed functional analyses of joint movements and limb kinetics during overground walking, wading and swimming under conditions where one or the other (or both) of these novel NRG projections are inactivated will lead to a more detailed understanding of the functional relevance of the different modes of plastic fiber tract rearrangements that occur spontaneously after a major but incomplete spinal cord injury.

Title: Olfactory ensheathing cells reduce inhibitory factors at the astroglial scar-border after a complete mid-thoracic spinal cord transection

Authors: R. R. KHANKAN[1,2], K. L. INGRAHAM[1,2], J. R. HAGGERTY-SKEANS[1], K. G. GRIFFIS[1,2], P. K. MANN[1], H. ZHONG[1], R. R. ROY[1,3], V. R. EDGERTON[1,3], *P. E. PHELPS[1,3];
[1]Integrative Biol. and Physiol., [2]Molecular, Cell. & Integrative Physiol. IDP, UCLA, Terasaki Life Sci. Building, Los Angeles, CA; [3]Brain Res. Inst., UCLA, Los Angeles, CA

Abstract: After spinal cord injury, astrocytes and meningeal fibroblasts up-regulate and secrete chondroitin sulfate proteoglycans (CSPGs) that contribute to the inhibitory environment formed at the lesion site. We asked if CSPGs were reduced in olfactory ensheathing cell (OEC) and skin fibroblast (FB, control) transplanted spinal cords after a complete T8-9 transection. We quantified anti-CS-56 luminance at the astroglial border and within the lesion core of every 16th spinal cord section for each spinal rat. CS-56-immunoreactivity was lower in OEC compared to FB-treated rats in both rostral and caudal GFAP-positive scar borders and in the lesion core at 2 and 4 weeks post-injury. We evaluated the presence of inhibitory myelin after injury by staining for Oil Red O, a marker of myelin debris. OEC-treated spinal cords had lower levels of myelin debris than those treated with FBs at 2 weeks post-injury. Oligodendrocyte progenitor cells (OPCs) also can contribute to the inhibitory scar formed after a spinal cord injury, and therefore we examined the number of OPCs at the scar border with glutathione-S transferase-pi (GST-pi) immunolabeling. GST-pi is uniquely expressed by OPCs and oligodendrocytes in the CNS: however, the localization of GST-pi in the nucleus is transient in early oligodendrocyte progenitors and then translocates to the cytoplasm during maturation. We quantified cells with distinct nuclear GST-pi and found that at both 2 and 8 weeks, fewer cells with nuclear GST-pi were found in OEC compared to FB-treated rats at both the rostral and caudal borders. Collectively, these data imply that OECs can modulate the presence of inhibitory factors at the lesion site after a spinal cord injury. Previously we reported that both OECs and FBs migrate widely into the lesion core 1 week after transplantation. By 2 weeks both cell transplants are eliminated from the lesion core and remain only in the rostral and caudal stumps. While OECs survive longer than FBs, neither cell type survived beyond 8 weeks. Our data suggest that the prolonged presence of OECs may further promote a beneficial tissue healing response. To enhance cell survival we administered cyclosporine-A (CSA) to suppress immune-mediated rejection and then compared how OECs and FBs modify inhibitory molecules associated with the injury site at 2 and 8 weeks post-lesion. CSA enhanced the survival of both OECs and FBs at both ages as more OECs and FBs were found in the lesion core with than without CSA treatment. In some CSA-treated spinal cords OECs survived at 8 weeks and formed a bridge between the rostral and caudal stumps.

Title: Systemic LPS increase rehabilitative training efficacy after cervical chronic spinal cord injury in rats

Authors: *A. TORRES ESPÍN, A. LING, J. FORERO, K. K. FENRICH, K. FOUAD; Physical Therapy, Univ. of Alberta, Edmonton, AB, Canada

Abstract: Unfortunately, there are still no treatments to repair the injured spinal cord. However, in the clinical setting, rehabilitative training is currently one of the most successful therapies to promote recovery. Such training augments functional recovery through various mechanisms referred to as neuroplasticity including strengthening of spared connections, neurite outgrowth, changes in cellular properties and fine-tuning of these rearranged networks. A significant challenge for rehabilitative training following spinal cord injury (SCI) is the timing of the training onset. Similar to findings after brain injuries, various studies have reported that starting training in the early stages (subacute) following injury is much more effective in promoting recovery than delaying training onset to the chronic phase, weeks after the trauma. However, considering that accidents causing SCI are often poly-traumatic events, rehabilitative training of motor tasks in the subacute phase is frequently not an option. Thus, finding approaches to increase the training efficacy during chronic SCI becomes mandatory. Here we investigated the increase of inflammation as a possible attempt for enhancing neuroplasticity and training efficacy after chronic SCI. Thus, we analyzed whether the systemic administration of lipopolysaccaride (LPS), that induced neuroinflammation, in the chronic SCI can improve the training efficacy in a specific task such as single pellet reaching. Three groups of animals were studied. One group of rats received training during 8 weeks starting 8 weeks after cervical SCI, another group of rats received the same training plus the LPS administration and a third group of rats received the LPS administration only. Our results demonstrated that rehabilitative training efficacy of arm/forelimb reaching during the chronic phase of SCI can be increased by the systemic application of LPS. Thus, we propose that neuroinflammation may play a role in the window of opportunity for rehabilitative training success after SCI. The modulation of this neuroinflammation can be a new approach to reopen the window for rehabilitative training even weeks after SCI.

Title: Kinematics analysis by the Frechet dissimilarity method in intact and spinal cord injury rats treated with tamoxifen and exercise

Authors: *L. P. OSUNA CARRASCO[1], J. R. LÓPEZ RUIZ[1], G. MENDIZABAL RUIZ[1], I. JIMÉNEZ ESTRADA[2], J. BAÑUELOS PINEDA[1], S. H. DUEÑAS JIMÉNEZ[1];
[1]Univ. of Guadalajara, Guadalajara, Mexico; [2]CINVESTAV-IPN, México, DF., Mexico

Abstract: Pharmacological treatments, and bipedal or quadrupedal treadmill training have been made in spinal cord injured rats. Although treadmill training has been recognized to improve locomotion and tamoxifen demonstrated it neuroprotective effects in the nervous system, the combined application shows better results in the movement integration of the hindlimbs. The purpose of this study is to quantify the kinematics parameters in intact rats and in the same animals 15 and 30 days after injured and with tamoxifen, exercise and tamoxifen plus exercise treatments. A penetrating injury was made in the T13-L1 spinal cord segment. Kinematics of hindilmbs was quantified by a software developed in our laboratory that uses Frechet dissimilarity algorithm, designed to qualify the normal trace of the angular joint and pendulum like movement behavior and comparing with the traces obtained from the strides reconstruction at 15 and 30 days post-injury in the same injured rats. At 30 days post-injury, the ipsilateral hindlimb pendular curves had a statistical significant reduced frechet dissimilarity than 15 days post-injury. This results are due mainly by exercise benefits. The Frechet dissimilarity was large in untreated rats. In the contralateral hindlimb pendular curves there was no statistical significance between 15 and 30 days post-injury rats. At 30 days post-injury, there was a statistical significant decrease in frechet dissimilarity occurred in contralateral knee and ankle joint values as compared with 15 days post-injury in the exercise treated rats. A qualitative, hematoxilin and eosin histological evaluation of the spinal cord indicates a regenerative process in rostral and caudal to the injury level. The tissue was better preserved in tamoxifen, exercise or combined treatments. Our results favored a combinatorial treatment for repairing spinal cord penetrating injury.

Title: Sprouting and 'side-switch' of contralateral corticospinal fibers in the spinal cord after large unilateral cortical stroke

Authors: *J. KAISER[1,2], A.-S. WAHL[1], M. SCHWAB[1,2];
[1]Brain Res. Inst., Zürich, Switzerland; [2]Dept. Hlth. Sci. and Technol., ETH, Zurich, Switzerland

Abstract: Following a large unilateral stroke of the sensory-motor cortex, the contralateral, spared cortex was shown to be activated for restoring a certain low level of function. On the spinal level, the remaining, intact corticospinal tract forms newly outsprouting fibers within the cervical enlargement, a process that is causally related to the functional recovery of the forelimb. Little is known about the time course, the anatomical details and the underlying molecular mechanisms of this sprouting process. Adult mice are subjected to a unilateral photothrombotic stroke of the right primary as well as pre-motor cortex ablating >90% of the descending projections of the corticospinal tract. The corticospinal tract of the contralesional motor cortex is labeled using an anterograde tracer to label spinal projections in healthy as well as stroked C57/Bl6 wild type mice. In comparison, the corticospinal fibers of mutant animals, in which the growth inhibitory protein Nogo-A protein was knocked out conditionally or conventionally, are studied to assess the sprouting profile in a more growth permissive environment. All animals are analyzed for their cervical sprouting, branching and midline crossing profile at different time points after the thrombotic insult. This analysis will focus on the three possible types of fibers descending from the contralesional cortex that could play a key role in functional recovery: ipsilateral projections, pre-existing (re-)crossing projections as well as newly forming midline crossing fibers. Additionally, using transgenic reporter mouse lines, different cell types are also characterized for their potential involvement in this sprouting/branching process.

Title: Treadmill training reduces mechanical allodynia and thermal hyperalgesia after chronic mouse spinal cord contusion injury

Authors: *C. SLIWINSKI, T. NEES, M. MOTSCH, N. WEIDNER, A. BLESCH;
Spinal Cord Injury Ctr. Univ. Hosp. Heidelberg, Heidelberg Univ., Heidelberg, Germany

Abstract: A large proportion of patients suffering from spinal cord injury (SCI) develop chronic neuropathic pain (CNP). Despite its frequently severe and disabling nature, pharmacologically effective treatment options are still lacking and a causal relationship between aberrant structural remodeling and the development of CNP has not been clearly established. Previously, we and others have shown that sensorimotor training early after SCI can ameliorate mechanical allodynia but not thermal hyperalgesia. To determine whether similar training paradigms are effective in the subchronic / chronic phase of SCI, correlates of below level neuropathic pain including mechanical and thermal abnormalities were analyzed in the hindpaws between 35 and 70 days after a moderate T11 spinal cord contusion injury (50 kDyn) in female C57BL/6 mice. Treadmill training was initiated 6 weeks post-injury to investigate the effect of moderate physical therapy on pain behavior and associated morphological changes. Untrained SCI mice showed mechanical allodynia measured with small-diameter von Frey filaments (0.16g) at 35 days post-injury (dpi), which was stable until the end of the experiment (ANOVA $p<0.05$; PLSD $p<0.05$ at 70dpi). Interestingly, when tested for normally noxious stimuli using stronger filaments (0.6g; 1.4g), SCI mice showed a significant hyporesponsiveness compared to sham animals (ANOVA $p<0.001$, PLSD $p<0.0001$ at 70dpi). In addition, SCI animals showed a significant decrease in the response latency to heat stimuli at 35 dpi compared to sham mice, which remained stable (ANOVA $p<0.001$ at 70dpi). Moderate treadmill training was performed 2 x 15 minutes/day, 5 days/week over 5 weeks increasing the velocity of the treadmill from 0.15 m/s to 0.26 m/s to adapt to the recovery of SCI mice. Treadmill training positively influenced both mechanical allodynia and thermal hyperalgesia. The response rate to light mechanical stimuli (0.16g) was significantly reduced in trained SCI mice compared to untrained SCI mice starting at 4 weeks of training (ANOVA $p<0.05$; PLSD $p<0.05$). A significant reduction in thermal hyperalgesia was evident as early as 2 weeks after initiation of training (55 dpi) in the SCI group and remained stable until the end of the experiment (ANOVA $p<0.001$; PLSD $p<0.05$). Current data further suggest a training-mediated normalization in the thermal place preference test (22°C vs. 17°C) with trained SCI spending similar times on the 22°C side as sham animals. Potential mechanisms underlying the observed pain-related behavior including sprouting of peptidergic nociceptive fibers and changes in inhibitory interneurons in the dorsal spinal cord are currently analyzed.

Title: Kinematics analysis of locomotor function following treatment with epidural stimulation, locomotor training and intraspinal chondroitinase-ABC in a severe contusion injury

Authors: *R. M. ICHIYAMA[1], Y. D. AL'JOBOORI[1], C. C. SMITH[1], K. O. CHEN[1], S. CHAKRABARTY[1], J. W. FAWCETT[2], E. M. MUIR[3];

Abstract: Electrical epidural stimulation (ES) of the lumbar spinal cord (L2 to S1) has previously been shown to improve locomotor function in complete transection models of rat spinal cord injury in conjunction with monoaminergic and serotonergic agonists and bipedal locomotor training; however, this functional improvement has only been observed under training conditions (i.e., bipedally, body weight supported, under ES) and previous evidence has shown that rehabilitation up-regulates chondroitin sulphate proteoglycan in the lumbar spinal cord therefore likely restricting synaptic plasticity. We hypothesized that adding lentiviral chondroitinase (LV-ChABC) locally after injury would facilitate synaptic plasticity and thus allow for enhanced functional recovery. Here we demonstrate that the use of ES (40 Hz; L2) and locomotor training following severe spinal contusion injury (T9/10) leads to improved locomotor function in both saline and LV-ChABC groups. Adult Sprague-Dawley rats received a severe spinal contusion injury (T9/10), epidural electrode implantation at segmental levels L2 and S1 and intra-spinal injections of LV-ChABC or saline (control). Rats were then randomly assigned to one of four groups: cage control, training only, ES only or ES+training. Rats in either trained group stepped bipedally-quadrupedally on a body weight supported treadmill (5-16 cm/s) (5 days/week, 20 mins/day) for 8 weeks. By the end of the 8-week period rats in the Saline/LV-ChABC+ES+training group showed improvements not only in supported treadmill stepping ability but also in open field locomotion (BBB), with combination saline/LV-ChABC treated animals achieving the highest overall increase in mean BBB score compared to Saline/LV-Chase

controls. Kinematics analysis revealed more detailed differences in stepping characteristics and pattern following 8 weeks of training. Rats in the LV-ChABC+ES+training group showed greatest coordination and consistency in stepping patterns compared to all other groups. Therefore these results suggest that a combination of step training and ES in an incomplete model of SCI successfully improved locomotor function further than either therapy administered alone with LV-ChABC+ES+training group improving the most overall; with animals not only improving in treadmill step performance but were also able to transfer this skill to an open field task.

Title: Combined effects of anti-Nogo-A antibody treatment and delayed locomotor training in rats with spinal cord injury

Authors: *K. CHEN[1,3], M. COWAN[1], B. C. MARSH[1], C. C. SMITH[1], Y. AL' JOBOORI[1], S. GIGOUT[1], N. GAMPER[1], N. MESSENGER[2], M. E. SCHWAB[4], R. M. ICHIYAMA[1]; [1]Sch. of Biomed. Sci., [2]Ctr. for Physical Educ. and Sports Sci., Univ. of Leeds, Leeds, United Kingdom; [3]Sch. of Biol. Sci. and Med. Engin., Beihang Univ., Beijing, China; [4]Brain Res. Inst., Univ. of Zurich, Zurich, Switzerland

Abstract: An increasing number of studies are being conducted to explore the combined effects of rehabilitation with other strategies for promoting axonal regeneration on the recovery of limb function after spinal cord injury (SCI), believing that tailored combinations of strategies with scientific basis will lead to cumulative improvements in SCI outcomes. When we previously examined the effects of anti-Nogo-A antibody treatment (11C7) and treadmill training in rats with thoracic SCI, their simultaneous application did not show synergistic effects. Since recovery mechanisms of these treatments were not only different but also possibly competitive, the synchronous delivery had likely interfered with each other. We therefore hypothesize that the combinatorial therapy of 11C7 with locomotor training can express positive interactive effects in SCI recovery, if the onset of the training is delayed long enough to minimize the treatments interfering with each other. To test the hypothesis, this study examined the effects of anti-Nogo-

A antibody treatment and two-week delayed onset weight supported locomotor training in a rat model of SCI. All procedures were approved by the UK Home Office. A T-shaped lesion to T9 was made using iridectomy scissors on 25 adult female Sprague-Dawley rats under anesthesia. The animals were divided into 4 treatment groups: 1) non-trained/IgG (n = 7), 2) trained/IgG (n = 6), 3) non-trained/11C7 (n = 6), 4) trained/11C7 (n = 6). Antibody was delivered to the injury site for 2 weeks i.p. with an osmotic pump. Locomotor training started 2 weeks from the end of the antibody treatment. After 8 weeks of locomotor training (5 times/day, 20 min bipedal + 20 min quadrupedal), their behavior and histology were examined. It was found that the trained/11C7 group had better recovery than the other groups in open-field locomotion (mean: 16 vs. 13, BBB score). Training and antibody were shown to improve consistency and dragging in step kinematics, respectively. Antibody reduced the number of errors in inclined climbing. No differences were observed in the nociception assay and lesion volume among the groups. The neuronal activation to induce locomotion in the lumbar spinal cord was reduced with both treatments compared to non-trained/IgG controls (cfos staining). The sprouting supraspinal axons did not show changes far caudal from the lesion site (T13 and L1, BDA staining). Afferent fibers in L2 were increased with antibody but decreased with training (VGLUT/ChAT staining). The results indicate that the combinatorial therapy of 11C7 with delayed training can express positive interactive effects in SCI recovery through refinement of local circuitry.

Abstract: Combination therapies are likely to be necessary for the treatment of spinal cord injury (SCI). Rehabilitation is routinely used as a clinical treatment and administered early within the sub-acute recovery phase therefore any additional treatment must work synergistically with this. Previous evidence has shown that rehabilitation up-regulates chondroitin sulphate proteoglycan in the lumbar spinal cord likely restricting synaptic plasticity. The current study demonstrates the use of electrical epidural stimulation (ES) of the lumbar spinal cord (L2 to S1), previously shown to improve locomotor function in rat complete transection models in conjunction with bipedal locomotor training and the application of chondroitinase-ABC (delivered in a lentiviral vector; LV-ChABC) in a severe contusion injury of the thoracic spinal cord. Adult Sprague-Dawley rats received a severe spinal contusion injury (T9/10), epidural electrode implantation at segmental levels L2 and S1 and intra-spinal injections of LV-Chase or saline (control). Rats were then randomly assigned to one of four groups: cage control, training only, ES only (40 Hz; L2) or ES+training. Rats in either trained group stepped bipedally/quadrupedally on a body weight supported treadmill (5-16 cm/s) (5 days/week, 20 mins/day) for 8 weeks. Saline+ES+training and ChABC+ES+training groups showed improvement in supported treadmill stepping ability and open field locomotion (BBB). Surprisingly, none of these animals showed any EMG response of hindlimb following cortical stimulation and no increased sensitivity to mechanical pain stimulation. These behavioural results suggest that a combination of step training and epidural stimulation in an incomplete model of SCI successfully improved locomotor function in both treadmill stepping and the open field through changes in local spinal networks. Results from immunohistochemical analysis of synaptic plasticity, axonal sprouting and glial scar morphology will also be discussed.

Title: The effect of neonatal spinal cord transection on modulation of the monosynaptic reflex during postnatal development

Authors: *C. C. SMITH[1], S. CHAKRABARTY[1], J. F. R. PATON[2], R. M. ICHIYAMA[1]; [1]Univ. of Leeds, Leeds, United Kingdom; [2]Sch. of Physiol. and Pharmacol., Univ. of Bristol, Bristol, United Kingdom

Abstract: Spinal cord injuries in neonates are often accompanied by a greater ability to spontaneously recover function and respond to locomotor treadmill rehabilitation compared to

adults. This is partly due to the remarkable plasticity of the cord caudal to the lesion; however the mechanisms underlying such recovery are poorly understood. The development of locomotion in the rat occurs relatively rapidly with maturity reached after 3 weeks postnatally (PN). During this epoch, the circuitry of the spinal cord establishes and refines its organisation with descending and afferent input competing for innervation in an activity dependant manner. Clarification of how the circuitry of the spinal cord is altered after neonatal injury may offer insight into the mechanism of enhanced recovery. By studying the development of the monosynaptic reflex (MSR), the basic unit of the central pattern generator, we aim to gain insight into how the circuitry of the lumbar spinal cord is altered throughout post natal development in injured and intact animals. We propose that following neonatal spinal cord transection, afferent input becomes the primary modulator of locomotor output and may guide circuit development in a way which promotes recovery of weight bearing locomotion. Mid-thoracic spinal cord transections (tx) were performed on neonates anaesthetised with isoflurane at post natal day 5(PN5). An artificially perfused whole rat preparation was used to illicit MSRs at ages PN10 (5dpi), PN14(9dpi) and PN21 (16dpi). Rats were decerebrated under anaesthesia and then perfused with a modified, oxygenated ringer's solution containing 1.25% ficcol with temperature maintained at 32°C. The tibial nerve was isolated and stimulated using a bipolar hook electrode and ENGs were recorded from the gastrocnemius-soleus (Gs) nerve. Immunohistochemistry was used to assess excitatory and inhibitory inputs to alpha motoneurones (αMN). Compared with intact controls, transected animals exhibited characteristics of increased excitability with reduced paired pulse inhibition, particularly at longer time intervals. This was corroborated by a greater quantity of vesicular glutamate transporter 1 (VG1+) positive terminals on αMNs at PN21. Results suggest that a neonatal transection prevents retraction of Ia afferents from the ventral horn resulting in greater excitatory input to αMNs. These alterations to the normal development of the circuitry of the lumbar spinal cord may contribute to the propensity for recovery afforded to animals injured as neonates.

Title: The pattern of reinnervation of sprouting corticospinal tract fibers after spinal cord injury in macaques

Authors: *H. NAKAGAWA[1], T. NINOMIYA[1], T. YAMASHITA[2], M. TAKADA[1]; [1]Primate Res. Institute, Kyoto Univ., Inuyama, Aichi, Japan; [2]Mol. Neurosci., Osaka Univ., Suita, Osaka, Japan

Abstract: The pattern of intraspinal innervation of corticospinal tract (CST) fibers differs in rodents and primates during development. In addition, manual dexterity strongly relates to the development of the CST in mammals and, therefore, becomes severely impaired after spinal cord injury (SCI). Thus, the sprouting of CST fibers after SCI is critical to recovery of motor functions. In rodents, the CST fibers after SCI sprout beyond the lesion site into the medial gray matter to connect with interneurons. However, the neuroanatomical mechanism underlying the functional recovery through sprouting CST fibers remains unclear in primates. Here we investigated the pattern of reinnervation of CST fibers below the lesion site after SCI in adult macaques. Unilateral lesions were made at the C7/C8 border of the spinal cord. In our SCI model, the dorsolateral funiculus was fully injured to remove laterally-situated CST fibers. The extent of spontaneous recovery of manual dexterity was assessed with a reaching/grasping task. The impaired manual dexterity was recovered gradually over 3 months after SCI. When anterograde tract tracing with biotinylated dextran amine was performed to identify the intraspinal reinnervation of sprouting CST fibers, it was found that their laminar distribution was reorganized. The sprouting CST fibers extended preferentially into lamina IX where the spinal motor neuron pool was located, to innervate the motor neurons directly. Instead, few, if any, CST fibers were distributed in the dorsal laminae. The present results indicate that number of CST fibers sprouting beyond the lesion site after SCI are reorganized for recovery of manual dexterity in macaques.

Title: Glial activation is necessary for the morphine-induced attenuation of locomotor recovery after SCI

Authors: *M. ACEVES[1,2], A. R. ACEVES[1], S. GONG[1], M. A. HOOK[1,2];
[1]Neurosci. and Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr., Bryan, TX; [2]Texas A&M Inst. for Neurosci., College Station, TX

Abstract: Opioids are one of few effective analgesics for the treatment of pain following spinal cord injury (SCI). Unfortunately, however, we have shown that morphine administered in the acute phase of SCI, irrespective of the route of administration, compromises recovery of locomotor function, increases mortality and pain reactivity, and suppresses weight gain in a rodent contusion model (Hook et al., 2007, 2009, 2011; Woller et al. 2012, 2014). In order to develop safe and effective strategies for opioid use, we have begun to characterize the cellular changes that accompany morphine treatment after SCI. Our recent studies have shown that the adverse effects of morphine depend on activation of the κ-opioid receptor (KOR), which also appears to be upregulated on astrocytes and microglia after SCI. In the current study we tested whether activation of these glial cells is necessary to produce the adverse effects of morphine. Subjects received a moderate spinal contusion (T12), and an intrathecal cannula was implanted. Baseline locomotor function (BBB) and pain reactivity (tail-flick) were assessed 24 hours following injury. Subjects were then administered minocycline (0, 50, or 100 μg), a glial inhibitor, followed by morphine (0 or 90 μg). Pain reactivity was re-assessed 30 minutes after drug treatment. Recovery was evaluated across a 21-day period, with additional tests of motor and sensory function conducted after day 21. Our results show that pretreatment with minocycline blocked the morphine-induced attenuated recovery, without affecting the acute analgesic effects of morphine. Minocycline may protect against the adverse effects of morphine by decreasing the inflammatory response that is synergistically augmented by opioids and injury. Indeed, the neuroprotective effects of minocycline, an FDA-approved drug, are currently under investigation in multiple clinical trials. Our research suggests that this, and similar drugs, should be further investigated as adjuvants to opioid treatment after SCI.

Title: Reawakening trunk motor function with optogenetics in adult spinal transected rats

Authors: *K. A. SCHMIDT, S. F. GISZTER;
Drexel Univ., Philadelphia, PA

Abstract: After a complete T9/T10 spinal cord transection in rats, injury and alteration of motor efferents and sensory afferents force reorganization in the sensorimotor cortex, leaving cortical areas below bregma that previously controlled trunk and hindlimbs silenced to motor function. Rats transected as neonates (NTX) can be trained to weight support (WS) on a treadmill if an elastic field is applied at the pelvis by a Phantom haptic robot. A decrease in the force needed to maintain the elastic field is related to an increase in WS by the rat. These robot/treadmill trained NTX rats show a reorganization of trunk motor areas in cortex, evident from intracortical microstimulation (ICMS) mapping, such that the center of gravity (COG) of the trunk motor area is shifted toward or into areas below bregma (Oza and Giszter, 2015). Since a caudal shift of trunk COG in NTX rats is related to motor recovery after rehabilitation, we asked if we could improve recovery in rats transected as adults (ATX) by inducing plasticity in the trunk motor cortex to 'reawaken' motor areas below bregma using optogenetic subthreshold stimulation. Using viral delivery, we introduced either Channelrhodopsin (CHR2) [AAV5-CamKIIa-hChr2(H134R)-EYFP] or a control fluorophore [AAV5-CamKIIa-EYFP] into pyramidal cells of the sensorimotor cortex below bregma. Three groups of rats were prepared: ATX with ChR2 (ATX-ChR2) current N=3, ATX-ChR2 rats also with AAV5-BDNF injected into the lumbar spinal cord to induce alternation of the hindlimbs (ATX-ChR2/BDNF) current N=3, and a control group (ATX-EYFP) current N=1. All rats were robot/treadmill trained for five weeks for 20min/day during which constant light stimulation was applied from a pair of high powered blue LEDs mounted at craniotomies over cortex below bregma. After five weeks, rats underwent a terminal ICMS map of the motor cortex. A caudal shift in trunk COG was observed in both ChR2 groups (total N=6). The number of cortical sites eliciting trunk motor responses below bregma was increased in both groups compared with ATX maps. Robot force progressively decreased throughout training in the ATX-ChR2/BDNF group as a result of WS stepping improvements. The enhanced plasticity in trunk motor cortex of ChR2 treated rats may facilitate recovery by engaging cortical resources not otherwise available during rehabilitation.

Title: Human lumbar cord reflex activity to sustained epidural electrical posterior roots stimulation motor behavior during absence and partial presence of brain motor control

Authors: *M. R. DIMITRIJEVIC[1], W. MAYR[2], M. KRENN[2];
[1]Baylor Col. Med., Houston, TX; [2]Univ. of Vienna, Department of Physics and Biomedical Engineering, Austria

Abstract: Human lumbar cord reflex activity to sustained epidural electrical posterior roots stimulation motor behavior during absence and partial presence of brain motor control. Milan R. Dimitrijevic, Matthias Krenn, Winfried Mayr In individuals suffering from complete accidental spinal cord injury (SCI), sustained electrical stimulation of the posterior roots of the lumbar cord disconnected from brain motor control can elicit tonic and rhythmical activity (1). We shall demonstrate the electrophysiological characteristics of mono- and polysynaptic spinal reflex responses elicited by sustained electrical stimulation. Additionally, we include non-reflex configurations of the interneuron network. In incomplete human SCI, the subjects have partial preservation of brain motor control. Studies of the spinal reflex and lumbar cord network activity elicited by epidural stimulation of posterior structures of the lumbar cord show that performing volitional motor tasks has the potential to modify, enhance, and suppress spinal reflex activity and motor behavior. We present a series of interaction characteristics between volitional motor tasks and repetitive spinal reflex response. The recordings show that volitional motor tasks can elicit generalized facilitation or suppression of the excitability of the lumbar network. Future studies may examine localized configurations of the lumbar network. Overall, our findings illustrate that volitional motor tasks and sustained epidural stimulation can improve or replace already existing segmental configuration. Title: Skin-derived precursor schwann cell grafts after complete spinal cord injury in rats

Authors: *Z. MAY[1], R. KUMAR[2], T. FUEHRMANN[3], J. FORERO[1], M. SHOICHET[3], J. BIERNASKIE[2], K. FOUAD[1];
[1]Univ. of Alberta, Edmonton, AB, Canada; [2]Univ. of Calgary, Calgary, AB, Canada; [3]Univ. of Toronto, Toronto, AB, Canada

Abstract: Spinal cord injury (SCI) disrupts the transmission of ascending and descending information from the brain to the spinal cord, leading to motor and sensory dysfunction. Axonal regeneration of spinal tracts is seen as important for the recovery of motor function after SCI. There are many inhibiting factors to regeneration in the CNS, including the formation of a cavity at the injury site. A common approach is to fill the cavity with Schwann cell (SC) grafts to bridge the injury. However, there are many issues associated with culturing Schwann cells from peripheral nerves, including the necessity for an invasive biopsy, the tendency of fibroblasts to overtake cultures, and a lack of SC proliferative capacity. We employ Schwann cells generated from an alternate source: Skin-derived precursors (SKPs), which are multipotent cells found in the dermis. Our experimental goal is to use these SKP-SCs as a scaffold for axonal regeneration after complete transection of the rat thoracic spinal cord. We chose a complete model, because the capacity of SKP-SCs to enhance regeneration in severe models has not been shown, even though patients with tetraplegia make up a meaningful percentage of persons with SCI. Another advantage of a complete model is that it is easier to analyze regeneration, as any axons growing must be regenerated axons. Therefore, in experiment 1, SKP-SCs were transplanted after complete transection of the rat thoracic spinal cord. The rats received one of the following three treatments: lesion only, injection of cell media into the lesion cavity, or injection of GFP+ SKP-SCs into the cavity. After we tried this, we quickly realized the cells did not survive. In our experiments, SKP-SCs were obtained from and grafted into inbred F344 rats, and, thus, immune rejection was not a concern. However, F344 rat sub-strain, *ex vivo* culturing, and viral transduction of the cells may have induced rejection of the graft. Therefore, the aim of experiment 2 was to improve cell survival via immune suppression. Rats received SKP-SC transplants and either daily saline or cyclosporine injections until euthanasia. Cell survival was significantly improved ($p<0.0001$) by administration of cyclosporine (15 mg/kg). Unfortunately the surviving SKP-SCs did not form a bridge across the injury site. Instead, the cells migrated rostral and caudal to the lesion. So, our next goal is to provide a biochemical substrate at the lesion site supportive of cell survival. This project is funded by the Canadian Institutes of Health Research (CIHR).

Abstract: All mechanisms for stabilizing gait are not equal. Individuals with neurologic impairments rely heavily on general stabilization strategies that are present every step to resist potential perturbations. General stabilization strategies (e.g. increasing step width) decrease the necessity of sensing and responding to specific perturbations, but inherently limit speed and decrease energetic efficiency and maneuverability. Thus, training individuals to utilize specific stabilization strategies (e.g. corrective steps) when needed could potentially improve walking ability. However, engaging individuals in practice of specific stabilization strategies is difficult because general stabilization strategies can act as a physiological crutch that overrides the need to make specific corrective actions. Our purpose was to try to reduce reliance on general stabilization strategies during gait in ambulatory individuals with incomplete spinal cord injury (iSCI) by exposing them to a brief period of external lateral stabilization. Two ambulatory subjects with chronic iSCI completed 600 steps of treadmill walking. The first 200 steps were a Baseline measure of unassisted walking. The next 200 steps were done in the presence of a Viscous lateral force field. The field was then removed and subjects walked for another 200 steps to measure After-Effects. Forces were applied to the subjects' hips via cables attached to linear motors. The applied forces varied proportionally to the subjects' lateral center of mass velocities and had the effect of resisting subjects' lateral motion. During the After-Effects period, medio-lateral motion of center of mass, step width variability, and margin of stability variability all increased when compared to Baseline (Figure 1). Step width mean and margin of stability mean both tended to decrease. These results suggest that a temporary period of reduced reliance on general stabilization strategies during gait can be induced in individuals with iSCI by exposing them briefly to external lateral stabilization during walking.

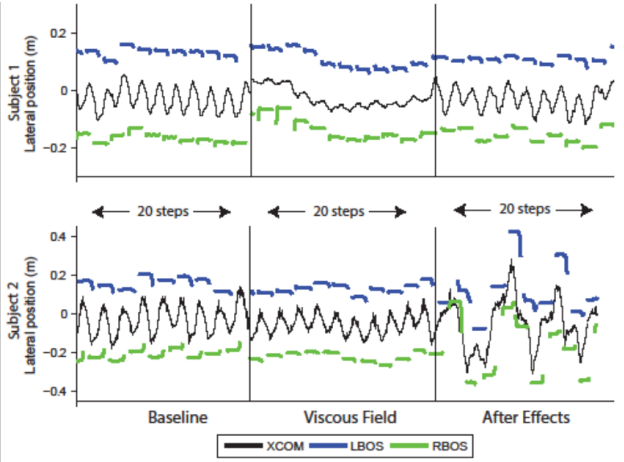

Figure 1: Extrapolated center of mass (XCOM), left base of support (LBOS), and right base of support (RBOS) data for two iSCI subjects walking during Baseline, exposure to a Viscous lateral force field, and After-Effects period immediately after removing the forces. Data shown is for 20 steps at each condition.

Title: The efficacy of functional neuromuscular stimulation using kHz to stimulate gait rhythm in rats following spinal cord injury

Authors: ***T. KANCHIKU**, H. SUZUKI, Y. IMAJO, Y. YOSHIDA, N. NISHIDA, T. TAGUCHI;
Yamaguchi Univ. Grad. Sch. of Med., Ube/Yamaguchi, Japan

Abstract: Background: Rehabilitation facilitates reorganization of residual/regenerated neural pathways, and is key in improving motor function following spinal cord injury. Functional neuromuscular electrical stimulation (NMES) has been reported as being clinically effective. While it can be used from the acute phase post-injury, the optimal stimulation condition to improve motor function remains unclear. Here, we examined the effectiveness of functional electrical stimulation with kHz in gait rhythm stimulation therapy. Methods: Tests were performed using 20 mature female Fischer rats. Incomplete spinal cord injuries (T9 level) were made with an IH impactor at a force of 150 kdyn and NMES was administered for three days from seventh day post-injury. The needle electrodes were inserted percutaneously near the motor

point of each muscle in conscious rats, and each muscle on the left and right leg was stimulated for 15 min, at two frequencies, 75 Hz and 8 kHz, to induce a gait rhythm. Motor function was evaluated using BBB scores and three-dimensional (3D) gait analysis. Rats were divided into four groups (5 rats/group), including the NMES treatment 75 Hz group (iSCI NMES 75Hz), 8 kHz group (iSCI NMES 8 kHz), injury control group (iSCI-NT), and normal group (Normal-CT), and compared. Results: There was no significant difference in BBB scores at any point between the four groups. In 3D gait analysis, compared with the injury control group, the 8 kHz group showed a significant improvement in synergistic movement of both hindlimb. Conclusion: We suggest that kHz stimulation is effective in gait rhythm stimulation using NMES.

Title: Spinal electromagnetic stimulation following spinal cord injury: safety of titanium implants used for spinal stabilization

Authors: *H. A. PETROSYAN[1,3], V. ALESSI[1,3], J. SNIFFEN[2], S. A. SISTO[2], R. DAVIS[4], M. KAUFMAN[3], V. L. ARVANIAN[1,3];

Abstract: In our recent experiments, we demonstrated favorable effects of non-invasive, repetitive spinal electromagnetic stimulation (SEMS) following spinal cord injury in adult rats. SEMS application over intact thoracic spinal cord was able to strengthen transmission and synaptic plasticity in preserved fibers after contusion and hemisection injuries. Chronic administration of SEMS application in combination with exercise induced significant improvements of locomotor function in chronic contused adult rats. The promising properties of this SEMS technique prompted the examination of possible safety concerns for human

applications. Particularly considering that the most spinal cord injured patients have implanted metal devices used for spinal stabilization. In this study, we examined the effects of SEMS on potential heating and displacement of titanium rods used for spinal stabilization. Using adult rats, we have also examined possible effects of implanted titanium rods on motor-evoked potentials (MEPs) recorded from hindlimb muscles, and other physiological parameters such as heart rate and respiratory rate. Magstim-Rapid^2 stimulator with figure of eight D-70^2 coil was used in this study. Maximum intensity (100%) was used to examine possible temperature changes and displacement of titanium rods (used in Stony Brook Hospital for spinal stabilization), and similar rods made of other metals, such as stainless steel, aluminum and copper. Potential heating of rods exposed to electromagnetic stimulation was examined by recording the rod temperature, coil temperature and ambient temperature surrounding rods and coil using high sampling rate thermocouple probes and infrared thermometers. Potential displacement of rods was examined using a force transducer to measure force exerted on the rods during electromagnetic stimulation. To examine possible effects of SEMS on MEPs and physiological parameters, two titanium rods were implanted bilaterally at the thoracic level in adult rats and MEPs, heart rate and respiratory rate were recorded both with and without titanium rods during SEMS application. Results demonstrate that SEMS does not induce any discernable movement and temperature changes in titanium rods. The presence of the rods did not affect MEPs and the threshold intensity to evoke MEPs. Heart rate and respiratory rate were also unaffected. In addition, a post-mortem examination of the spinal cord and surrounding tissues revealed absence of SEMS induced physical damage. These results suggest that SEMS application, even with the presence of spinal titanium implants, does not induce adverse effects and thus may be a safe approach for patients with SCI

Abstract: Neuropathic pain is a devastating and often intractable consequence of SCI in up to two-thirds of patients with many reporting a negative impact on quality of life (QOL). Here we report divergent sensorimotor recovery after SCI in a transgenic mouse line that, for the first time, allows differential study of sensory pathways involved in neuropathic pain. This model will provide valuable molecular targets for treatment of sensory dysfunction after CNS injury. Severe SCI contusion (SCI) or transection (TX) was performed at T9 in Thy1-EGFP/M+ (TG+; SCI n=12, TX n=3), Thy1-EGFP/M- (TG-; SCI n=4) littermates, and C57BL/6 (WT; SCI n=10) mice. Thermal and mechanical sensation was examined prior to and 42 days post injury (dpi) using Plantar Heat and Von Frey Hair Test, respectively. Motor recovery was evaluated in the open field using the Basso Mouse Scale pre-injury, 1 dpi, and weekly to 42 dpi. Precise hindlimb motor control during locomotion was tested on a grid walkway. Percent tissue sparing at the epicenter indicated lesion severity. TG+ and TG- SCI groups had significantly greater locomotor performance in the open field compared to historic WT SCI controls by 7 dpi (WT SCI = 2.4±0.7, TG+ SCI = 4.8±0.5, TG- SCI = 5.0±0.0; $p<.01$) and remained higher at 42 dpi (WT SCI = 5.6±0.4, TG+ SCI = 6.5±0.3, TG- SCI = 7.5±0.0; $p<.01$). Precise paw placement was severely impaired in TG+ and TG- animals (% success; TG+ SCI Pre = 97.2%±1.0, Post= 6.8±2.5; TG- SCI Pre = 98.8±1.3, Post= 5.8±1.8). Thermal hyperalgesia occurred following SCI and TX in TG+ and TG- groups (TG+ SCI Pre = 9.2sec±1.0, Post = 5.5±0.7; TG- SCI Pre = 7.6±2.0, Post = 2.3±0.5; TG+ TX Pre = 7.9±0.8, Post = 4.0±0.3; $p<.001$). Interestingly, mechanical hypoalgesia rather than allodynia emerged after SCI in both TG+ and TG- groups (TG+ SCI Pre = 0.37g±0.06, Post = 0.89±0.12; TG- SCI Pre = 0.75±0.10, Post = 2.18±0.61; TG+ TX; Pre = 0.67±0.17, Post = 4.33±0.33; $p<.001$). Tissue sparing was also greater in TG+ SCI animals (WT SCI = 12.9%±2.3; TG+ SCI = 38.8±2.5; $p<.001$). Using clinically-relevant SCI, we describe an innovative genetic model which demonstrates hypersensitivity to pain yet hyposensitivity to touch. This divergent profile allows a unique opportunity to examine mechanisms underlying sensory recovery essential to improving QOL for people with SCI. Current experiments aim to determine the location and impact of the Thy1-EGFP transgene insertion and associated mutations.

Title: Improving walking and inducing neuroplasticity after chronic SCI by training in the ReWalk exoskeleton

Authors: *A. KHAN[1], D. LIVINGSTONE[2], J. MISIASZEK[3], R. STEIN[4], M. GORASSINI[5], P. MANNS[2], J. YANG[2];
[1]Neurosci. and Mental Hlth. Inst., [2]Physical Therapy, [3]Occup. Therapy, [4]Physiol., [5]Biomed. Engin., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Recent developments in powered exoskeletons such as the ReWalk have shown promise to restore walking ability in people with severe spinal cord injury (SCI). Objective: Determine the effects of training in the ReWalk exoskeleton on walking function and neuroplasticity. Participants were individuals with complete or incomplete SCI, ≥1 yr post-injury, with arm strength to control forearm crutches, and who use the wheelchair as their primary mode of mobility. Training consisted of ~1 hr/day, 5 days/wk for 12 wks, progressing from sit-to-stand, stand-to-sit, balancing in standing, walking on smooth ground, turning while walking, to walking on uneven ground, ramps, curbs and stairs. Measurements were taken 2-3 times at baseline, then 6 and 12 weeks into training. Walking function included the maximum walking distance without a rest, the 10-m walk test, and the 6-min walk test (6MWT). Effort of walking was estimated with the physiological cost index (PCI) during the 6MWT. Postural stability was measured on a force platform, including the limits of stability (area enclosed by maximum leans in 8 directions) and postural sway with eyes open and closed. Plasticity in the motor pathways was determined by single-pulse, transcranial magnetic stimulation to induce motor evoked potentials in the paravertebral muscles. Spasticity was estimated with the Spinal Cord Assessment Tool for Spasticity and the cutaneomuscular reflex induced by stimulation of the posterior tibial nerve. Plasticity in sensory pathways was determined with the electrical sensory perceptual threshold. Pain was estimated weekly using the McGill Pain Questionnaire. A field test was conducted towards the end of training to determine the feasibility of the ReWalk for use in the home and community. Results: All participants were able to achieve over ground walking of ~1 km without a rest after ~50 sessions of training. Walking speeds ranged from 0.3 to 0.5 m/s in the ReWalk at the end of training. PCI was <3 heart beats/m (HB/m) during the 6MWT (uninjured: 0.6 HB/m; with hip-knee-ankle-foot orthosis after complete SCI: ~14 HB/m). All participants showed dramatic improvements in postural stability. Some individuals showed plasticity in motor and sensory pathways, and reduction in pain and spasticity. Most participants could walk easily indoors and outdoors with the device, but stairs, curbs and other tasks were difficult. Conclusion: These preliminary results suggest ReWalk training enabled over ground ambulation for individuals with severe SCI, and generated useful neuroplasticity. We believe it is a good device to incorporate into the retraining of walking and balance after severe SCI.

Title: Investigating combination therapies of robot-driven epidural stimulation, robot rehabilitation, and viral delivery of Brain-derived neurotrophic factor (BDNF) in treating adult spinal cord injury (SCI)

Authors: *J. LEE, S. F. GISZTER;
Neurobio. & Anat., Drexel Univ., Philadelphia, PA

Abstract: A complete transection at T10 in an adult rat (ATX) is a useful model to investigate locomotor rehabilitation in SCI. Based on previous work in our lab, we employ a unique trunk-based robotic intervention focused at a rat's pelvis to significantly improve locomotor function with treadmill training in various treatment paradigms: animals transected as neonates (NTX), ATX animals treated with AAV5 delivery of BDNF, and with epidural stimulation. Our prior work showed that nearly 30% of ATX rats treated with AAV5-BDNF develop hyperreflexia after initial training improvements, leaving them functionally unable to fully alternate and extend their hindlimbs. We hypothesized that we can mitigate this "collapse" of function with the use of robot-driven epidural stimulation. However, it may also exacerbate the collapse and/or its frequency. To test the effects of this combination therapy on outcome, we designed a treatment regimen combining epidural stimulation, robot rehabilitation, and AAV5-BDNF. We prepared two groups of rats (current n=3/group) with stimulating electrodes placed on the surface of the spinal cord at L2 and S2, and with microinjections in the spinal cord caudal to the transection site: one group received AAV5-BDNF, and the other received a sham virus. After recovery, animals were treadmill trained with robotic pelvic rehabilitation therapy and epidural stimulation for six weeks. To examine the effects of combination therapy on locomotor recovery, we compared stepping measures and stimulation parameters between the two groups. Specifically, we examined (1) stimulation intensity needed to induce locomotor activity, and (2) the threshold to induce locomotor activity as a function of time over weeks of recovery. The group treated

with AAV5-BDNF showed a marked decrease in stimulation intensity to induce locomotion, and these effects lasted throughout recovery. Thus far epidural stimulation is not inducing increased collapse of rehabilitation - no rats have shown this in the combined groups. However, the numbers of rats are not yet at criterion levels to support a conclusion. With the emergence of neuroprosthetics and other combined therapies, we believe this work provides a model for testing interactions between robotic, bionic, and viral biological therapies in the treatment of SCI.

Title: Responses of CSF-contacting cells in the spinal cord to activation of purinergic receptors

Authors: *C. MACLEAN[1], J. DEUCHARS[1], L. PEERS[1], S. LARRINGTON[1], N. COHEN[2], S. A. DEUCHARS[1];

Abstract: The central canal region of the spinal cord may be considered to be one of the adult neurogenic niches and there are well documented increases in proliferation of the ependymal cells in this area after injury (Lacroix et al, 2014). Other cell types are also present in this area including the CSF-contacting cells (CSFcCs) that send a process into the central canal. In mammals, the role of these cells has yet to be fully elucidated but they may be important in signalling the response to injury. This study examines responses of CSFcCs to activation of purinergic receptors as these have previously been implicated in damage recognition systems in other cell types (Lahne and Gale, 2010) and P2X receptors containing the $P2X_2$ subunit are expressed by the CSFcCs present in this area (Stoeckel et al, 2003). Anaesthetised 11 day old Wistar rats were perfused with sucrose aCSF, followed by sectioning of thoracic/lumbar spinal cord regions at 300 μm with a vibrating microtome. Whole-cell patch clamp electrophysiology was used to obtain single cell recordings from CSFcCs in these spinal cord slices. ATP was applied using a puff electrode connected to a PicoPump. Post-recording and post-fixation visualisation was enabled by inclusion of a fluorescent and a DAB-reactive dye, respectively, to confirm cell type classification. Local application of ATP (300 μM) elicited fast depolarisations in both spiking and non-spiking subtypes of CSFcC (types 1, 2 and 3 (Corns et al, 2013)). Bath application of the broad-spectrum purinergic antagonist Suramin (50 μM) reduced the magnitude of these responses from 21.50 ± 5.16 mV to 9.73 ± 3.03 mV and delayed the onset of the depolarisations. The $P2X_{2/3,\ 3}$-specific antagonist A317491 (1 μM) had no effect in one group, produced partial reduction in magnitude of depolarisation in a second group and complete

elimination of depolarisation in the remaining CSFcCs. Immunohistochemical analysis of the P2X subtypes in this area revealed a sub-population of CSFcCs, predominantly in the ventral area of the region around the central canal that expressed $P2X_3$ in addition to $P2X_2$-containing receptors indicated by previous research. The presence of fast acute responses to ATP and spatial variation in receptor subtypes suggests a role for purinergic signalling in the functioning of the CSFcCs in this area that may include responding to damage.

Title: Hemispheric stroke induces major structural changes in paretic muscles

Authors: ***M. K. CHARDON**, Y. DHAHER, N. SURESH, W. Z. RYMER;
SMPP, Rehabil. Inst. of Chicago, Chicago, IL

Abstract: In addition to altering motor control, stroke-induced spastic paresis is believed to alter the architecture of impaired skeletal muscles. Describing such changes is important in our understanding of the mechanisms of stroke-induced muscle impairment. At the musculotendon unit level, descriptions of passive mechanics have thus far only been addressed obliquely, to the best of our knowledge. Spastic Achilles tendon was shown to be longer and softer while we reported a stiffer spastic musculotendon unit using tendon indentation (Zhao 2009; Chardon 2014, 2010). A full description of the passive mechanical properties of the musculotendon unit is thus needed. We set out to measure these mechanical properties in passive musculotendon units of chronic stroke survivors and controls. Using in combination, an ultrasound machine and a position controlled tendon indenter, we recorded ultrasound movies of the biceps brachii as its distal tendon was being mechanically indented. The indentation force at the tip of the indenter was also recorded. The mechanical properties were initially extracted by tracking features found along the proximal to distal axis of the biceps brachii throughout all frames of the ultrasound movies. We then related the motion of the features to the indentation force. We distilled this data to two parameters: the Transition Point which is the indentation location at which the motion switches from a non-linear to linear behavior and the Stiffness. We report that the affected musculotendon unit of our stroke cohort has a statistically lower transition point and a greater stiffness than the contralateral and control. On aggregate the affected side will transition 61%

and 50% sooner and is 40% and 57% stiffer than the contralateral and control. We also report that in contrast to the contralateral and control, the transition point and stiffness of the affected musculotendon unit are statistically invariant throughout the ultrasound imaging window. The affected musculotendon unit thus appears to be homogenous. Using this novel method, we report in-vivo a clear demarcation of the affected musculotendon unit passive mechanics from the others. Furthermore, we show that these differences are also structural in that the affected side has a homogenous mechanical behavior. In other words for the inhomogeneous passive mechanical properties of healthy skeletal muscle to disappear, stroke-induced spastic paresis must fundamentally rearrange the internal architecture of the musculotendon unit. As to which mechanism is responsible for the rearrangement, many point to fibrosis however more evidence is needed.

Title: The impact of altering cholinergic activity on nmjs in normal and stress conditions

Authors: *S. SUGITA[1], L. FLEMING[2], G. VALDEZ[3];
[1]Virginia Tech., Roanoke, VA; [2]Biol. sciences, Virginia Tech., Blacksburg, VA; [3]VTCRI, Virginia Tech., Roanoke, VA

Abstract: The motor system undergoes significant changes with age and the progression of diseases, in part due to dysregulation of synaptic function. In this study, we sought to determine the impact of increasing and decreasing cholinergic neurotransmission on aging and ALS-afflicted neuromuscular junctions (NMJ). We examined transgenic animals for the vesicular acetylcholine transporter (VAChT), a protein required to package acetylcholine into synaptic vesicles. These mice have higher (VAChT-Hyper) or lower (VAChT-KD) acetylcholine levels and release at synaptic sites. We first asked if altering cholinergic activity impacts the normal development of NMJs. Using light microscopy, we found no obvious differences in the size, architecture and rate of synaptic elimination between NMJs in 9 days-old VAChT-Hyper and control mice. In young adult mice, however, we discovered age- and disease-related structural and molecular alterations. Many NMJs were found denervated and fragmented in VAChT-Hyper transgenic compared to control mice. Not surprisingly, $SOD1^{G93A}$ mice overexpressing VAChT die prematurely. In contrast, NMJs appear structurally normal in VAChT-KD mice. Additionally, $SOD1^{G93A}$ with reduced levels of VAChT live longer compared to $SOD1^{G93A}$ mice.

These results indicate that fine tuning cholinergic activity in muscles may be a therapeutic approach to slow down the progression of age and ALS-related motor deficits.

Title: Muscle fiber length-dependent, intramuscular variation in damage-induced remodeling of neuromuscular junctions in a mouse model of muscular dystrophy

Authors: *Y. LEE[1], R. MASSOPUST[2], W. J. THOMPSON[1,2];
[1]Dept. of Biol., [2]Inst. for Neurosci., Texas A&M Univ., College Station, TX

Abstract: Duchene muscular dystrophy (DMD), a recessive X-linked degenerative muscle disease, results from missense mutations within the dytrophin gene. In addition to the well-documented segmental necrosis of skeletal muscle fibers, there is a loss of force generation by muscles and alterations in the morphology of the neuromuscular junction (NMJ) - the site of synaptic communication from a motor neuron to a skeletal muscle fiber. These alterations include “fragmentation” of postsynaptic neurotransmitter receptor (acetylcholine receptor; AChR) aggregates that may further compromise proper functioning of the neuromuscular system, and be a compounding factor in DMD pathology. An overwhelming body of evidence supports the hypothesis that lack of functional dystrophin protein leads to muscle fiber fragility - and subsequent cycles of damage and regeneration. The mechanism(s) responsible for alterations of the NMJs, however, remain controversial. It has been argued that dystrophin contributes to synaptic aggregation of AChR, although evidence also exists to support the idea that junctional alterations arise primarily as a result of damage and regeneration of synaptic segments of muscle fibers. Our examination of an expiratory muscle, triangularis sterni (TS) in a mouse model (mdx) revealed that, at ~5 weeks of age, only a minority of NMJs have the fragmented morphology associated with dystrophy; the remainder of the junctions appear normal and indistinguishable from those found in control muscles. This is in stark contrast to the TS of ~9 weeks-old mdx, where most junctions appear fragmented. Interestingly, in both age groups, there are clear differences between NMJs at anterior and posterior portions of the muscle in the degree to which the NMJ morphology is altered. Such a gradient in morphological alterations may be functionally correlated to the lengths of muscle fibers in TS - the shortest and longest fibers at anterior and posterior ends of the muscle, respectively. In addition, there appear to be, at a subset of

fragmented NMJs, an increased number of terminal Schwann Cells (tSCs) with altered morphology. Our preliminary findings, thus, suggest that 1) NMJs are formed normally in absence of functional dystrophin, 2) junctional alteration progresses against the known anterior-posterior gradient in neuromuscular maturation and 3) tSCs, which participate in sculpting of neonatal endplates, may become activated in response to muscle fiber injury.

Title: Pre- and postsynaptic changes at the neuromuscular junction in two models of duchenne muscular dystrophy

Authors: *S. HADDIX[1], Y. LEE[2], J. N. KORNEGAY[3,1], W. THOMPSON[1,2];
[1]Inst. for Neurosci., [2]Dept. of Biol., [3]Col. of Vet. Med. and Biomed. Sci., Texas A&M Univ., College Station, TX

Abstract: Duchenne muscular dystrophy is an X-linked disease that causes a loss of expression of dystrophin. This protein is a key component of the dystroglycan complex providing a link between the contractile apparatus of myofibers and the extracellular matrix, stabilizing the sarcolemma. As such, dystrophin loss results in increased damage to contracting muscle. It is also well documented that dystrophy leads to postsynaptic changes at the NMJ, whose ultimate cause remains elusive. To assess the underlying mechanisms of synaptic change, we examined NMJs in dogs (GRMD) and *mdx* mice that have dystrophin gene mutations leading to dystrophy. By fluorescently staining GRMD muscles for acetylcholine receptors (AChR), neurofilament and synaptic terminal markers, Schwann cell (SC) proteins, and acetylcholine esterase (AChE) we recorded morphological changes of dystrophic NMJs. Abnormalities to AChR endplate structure that mirror the *mdx* mouse were observed. Many dystrophic endplates are dispersed into fragments and are larger when compared to pretzel-shaped controls. The similarity to junctional alterations in muscles treated with myotoxic drugs suggests that a process of myofiber degeneration and regeneration, a hallmark of dystrophic muscle pathology, is producing these synaptic changes. Furthermore, the alterations of the postsynaptic apparatus correlate with changes to the presynaptic structure. In particular, the axon terminal is more branched as compared to controls. Additionally dystrophic NMJs have more terminal SCs apposing the endplate. It is possible that these phenomena may have roles in restructuring the postsynaptic

surface following degeneration and regeneration of the muscle fiber. Interestingly the presynaptic structure appears to remain in place during muscle fiber necrosis. This is evidenced by areas that stain highly for nerve and AChE, but lack corresponding AChR stain. As the axon itself is known to have roles in receptor clustering via agrin signaling, a simple hypothesis for fragmentation and enlargement of the endplate is that the axon terminal at some point makes additional contacts to the myofiber, forming new aggregates. Additionally, terminal SCs have been shown to be capable of altering synaptic morphology, which may tie into the changes seen at dystrophic endplates. Finally, adjacent muscle fibers in GRMD are sometimes innervated by the same axon suggesting motor unit size increase. As many of these changes are also observed in the *mdx* mouse, further research will use this model to investigate what the exact cause of endplate fragmentation and enlargement is, and whether it contributes to the dystrophic disease state.

Title: Spinal muscular atrophy amelioration by genetic inhibition of the JNK pathway

Authors: *L. D. GANGWANI, N. K. GENABAI, Z. ZHANG, X. JIANG;
Biomed. Sci., Texas Tech. Univ. Hlth. Sci. Ctr., El Paso, TX

Abstract: Mutation of the Survival Motor Neurons 1 (SMN1) gene causes spinal muscular atrophy (SMA), an autosomal recessive early childhood neurodegenerative disorder. Degeneration of spinal motor neurons caused by SMN deficiency results in progressive muscle atrophy and death in SMA. The molecular mechanism underlying neurodegeneration in SMA is unknown. No treatment is available to prevent neurodegeneration and reduce the burden of illness in SMA. We report that the c-Jun NH2-terminal kinase (JNK) signaling pathway mediates neurodegeneration in SMA. The CNS specific isoform JNK3 is required for neuron degeneration caused by SMN deficiency. JNK3-deficiency reduces degeneration of cultured neurons caused by low levels of SMN. Genetic inhibition of JNK pathway *in vivo* by Jnk3 knockout results in amelioration of SMA phenotype. JNK3-deficiency prevents the loss of spinal cord motor

neurons, reduces muscle degeneration, improves growth, motor function and increases lifespan of mice with SMA that shows a systemic rescue of phenotype by SMN-independent mechanism. JNK3 represents a potential (non-SMN) therapeutic target for the treatment of SMA.

Title: Changes in polyglutamine repeat length alter disease progression in a mouse model of Kennedy's Disease

Authors: J. ZENCHAK[1], M. ALTEMUS[1], *J. A. JOHANSEN[2];
[1]Neurosci. Program, [2]Col. of Med., Central Michigan Univ., Mount Pleasant, MI

Abstract: Kennedy's disease (KD, also known as spinal bulbar muscular atrophy) is a neurodegenerative disorder that exhibits myopathic as well as neuropathic characteristics, which include progressive muscle weakness, atrophy, and a loss of motor neurons in the spinal cord and brain stem. The molecular basis of this disease is an expansion in the number of CAG repeats located in the androgen receptor (AR) gene that will result in a misfolded and dysfunctional protein. One popular mouse model to study KD is the AR113Q model. This model contains 113 CAG repeats in the androgen receptor gene resulting in a loss of motor function and early death. Unfortunately, the number of repeats contracts in each generation in this mouse model. The purpose of this study was to determine whether AR113Q mice with a contracted CAG repeat length ranging from 90-92 will still exhibit a loss of motor function. In this study, 24 male mice (n=12 wt and n=12 tg) were subjected to a series of behavioral tests (open field, grip strength and stride length) from three to seven months of age. No significant differences were found between the wt and tg mice at these ages. However, tg mice with 90-92 CAG repeats exhibited early death, with mean age of survival at 17.5 weeks. This suggests that the contracted AR may still be toxic, but that longer repeat lengths may be required to observe motor deficits.

Title: Decreased activity and increased ubiquitin-mediated degradation of human choline acetyltransferase by mutation of an N-terminal proline-rich motif

Authors: *T. M. MOREY[1], S. ALBERS[1], B. SHILTON[2], R. J. RYLETT[1];
[1]Physiol. and Pharmacol., [2]Biochem., Western Univ., London, ON, Canada

Abstract: Choline acetyltransferase (ChAT) is essential for the function of cholinergic neurons as it mediates synthesis of the neurotransmitter acetylcholine. Mutations within ChAT have been linked to congenital myasthenic syndrome (CMS), a rare neuromuscular disorder characterized by cholinergic dysfunction of the neuromuscular junction. One CMS-related ChAT mutation, Val18Met, reduces both enzyme activity and protein steady-state levels. Interestingly, though residue Val18 is not located within the ChAT active-site, it is located within a highly-conserved, surface-exposed proline-rich motif at residues 14-PKLPVPP-20 that shares homology with SH3-domain binding motifs. It is currently unknown if this motif regulates ChAT function. In the present study, we demonstrated that N-terminal truncation that includes this proline-rich motif, as well as mutation of both residues proline-17 and -19 to alanine (P17A/P19A) dramatically reduces ChAT steady-state protein levels (80%) and produces a catalytically-inactive enzyme compared to wild-type (WT) ChAT when expressed in cholinergic SN56 neural cells. The *in vitro* specific activity of bacterially-expressed recombinant P17A/P19A-ChAT is also reduced (76%), though this is not due to gross changes in protein secondary structure or thermal stability as measured by circular dichroism. Using a novel fluorescent-biorthogonal pulse-chase protocol in SN56 cells, we determined that the half-life of P17A/P19A-ChAT protein (2.2 hours) is substantially reduced when compared to WT-ChAT (19.7 hours). By using heterologously-expressed HA-tagged ubiquitin, we found that ChAT is ubiquitinated and that polyubiquitination of P17A/P19A-ChAT is increased when compared to WT-ChAT. Further investigation reveals that both WT and P17A/P19A-ChAT can undergo proteasomal degradation through both lysine-48 (K48)-linked and K48-independent polyubiquitination. Lastly, treating SN56 cells with the proteasome inhibitor MG132 increases P17A/P19A-ChAT half-life (16.8 hours) and steady-state protein levels when compared to DMSO-control, though failed to restore its catalytic activity. These results identify a novel mechanism for the regulation of cellular ChAT protein levels through the ubiquitin-proteasome system that is influenced by the conserved N-terminal proline-rich motif of ChAT. T.M.M is a recipient of an Ontario Graduate Scholarship.

Title: A novel cell-based serological assay for myasthenia gravis using Xenopus tissue cultures

Authors: ***C. LEE**, H. L. YEO, J. Y. LIM;
Dept. of Physiol., Natl. Univ. of Singapore, Singapore, Singapore

Abstract: Myasthenia gravis (MG), the most common autoimmune disease of neuromuscular junction (NMJ), is heterogeneous in terms of pathophysiology, which is determined by the pathogenic antigen of autoantibodies targeting to synaptic proteins at the NMJs. Currently, patients suspected with MG are routinely screened for the presence of autoantibodies against acetylcholine receptor (AChR) or muscle-specific kinase (MuSK) using a cell-based assay (CBA) that involves the expression of target synaptic membrane protein in heterologous cell lines. However, some autoantibodies may only show reactivity for binding to densely clustered AChR in the physiological conformation, while AChR clustering is known to involve signaling events orchestrated by over a dozen of postsynaptic proteins. To improve the existing serological diagnosis of MG, this study explored the possibility of using the well-established Xenopus primary culture system as a novel CBA for MG. Here, by examining the pathogenic effects of four MG human plasma samples, we found that the samples from both seropositive and seronegative MG patients effectively induced the disassembly of aneural AChR clusters in cultured Xenopus muscle cells, as well as the nerve-induced AChR clusters in the nerve-muscle co-cultures. Importantly, the disassembly of AChR clusters was spatio-temporally correlated to the disappearance of actin depolymerizing factor (ADF)/cofilin, an actin regulator involved in AChR trafficking and clustering. Taken together, this study develops a reliable CBA using Xenopus primary cultures for screening the pathogenicity of human MG plasma samples, and providing a platform for investigating the pathogenic mechanisms underlying the endocytic trafficking and degradation of AChRs at NMJs in MG patients.

Title: Early detection and characterization of neurological function in SOD1 G93A mice

Authors: I. MORGANSTERN, B. FERETIC, K. HOMA, S. A. MALEKIANI, M. NILGES, N. E. PATERSON, N. ROBERTS, E. SABATH, G. SARDARYAN, L. THIEDE, *T. HANANIA; PsychoGenics Inc., Tarrytown, NY

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease. Transgenic mice over-expressing human SOD1-G93A are commonly employed as an animal model of familial ALS. The present study was aimed at identifying behavioral tests that are most sensitive to the emergence of behavioral/neurological deficits in male and female SOD1 G93A mice (SOD-1) compared to wild-type (WT) controls. Specifically, the test battery consisted of commonly used metrics such as fore- and hind-limb grip strength, rotarod, open field and more complex proprietary algorithm-based behavioral platforms such as NeuroCube® and SmartCube® Systems. The results of the present study indicated that both fore- and hind-limb grip strength as well as rotarod performance declined with age and disease progression. The open field test revealed time-dependent changes in locomotor and rearing performances in SOD-1 mice of both genders, with relatively stable performance in WT controls. In addition to these routine tests of neurological and motor function, sophisticated algorithm-based systems were employed and determined a strong phenotype effect in the SOD-1 mice at a much earlier age. Specifically, by using the NeuroCube® system to measure gait deficits, we found that SOD-1 mice showed a reduction in step and stride length and an increase in stride, stand and swing duration compared to WT mice, which was evident as early as 8 weeks and progressed with age. Similarly, by using our SmartCube® technology that measures whole animal behavior, we identified behavioral changes as early as 6-7 weeks of age in the SOD-1 mice. Interestingly, at young ages the mutant mice showed a unique hyperactive phenotype consisting of increased mobility, exploratory behavior, grooming and sniffing compared to WT mice which declined with disease progression. In summary, the platform of behavioral tests employed here demonstrate that while routine behavioral paradigms are able to detect neurological and motor function deficits in SOD-1 versus WT mice as early as 13-15 weeks of age, more advanced computer vision systems are able to identify distinctive behavioral patterns and discriminate the phenotype as early as 6-8 weeks of age. This earlier period of disease identification presents a valuable model in which to explore and improve future assessment of potential therapeutic approaches for ALS.

Title: Reactivation of lysosomal calcium efflux rescues abnormal lysosomal storage in fig4 deficiency

Authors: ***J. LI**[1,2,3], J. ZOU[1], B. HU[1], S. ARPAG[1], Q. YANG[1], A. HAMILTON[1], Y. ZENG[2], C. VANOYE[3];
[1]Dept. of Neurol., Vanderbilt Univ., Nashville, TN; [2]Sun Yat-sen Univ., Guangzhou, China; [3]Northwestern Univ., Chicago, IL

Abstract: Loss-of-function of FIG4 leads to Charcot-Marie-Tooth disease type-4J, Yunis-Varon syndrome, or an epilepsy syndrome. FIG4 is a phosphatase with its catalytic specificity towards 5'-phosphate of phosphatidylinositol-3,5-diphosphate (PI3,5P2). However, the loss of FIG4 decreases PI3,5P2 levels likely due to FIG4's dominant effect in scaffolding a PI3,5P2 synthetic protein complex. At the cellular level, all these diseases share similar pathology with abnormal lysosomal storage and neuronal degeneration. Mice with no FIG4 expression (Fig4-/-) recapitulate the pathology in humans with FIG4 deficiency. Using a flow cytometry technique that rapidly quantifies lysosome sizes, we detected an impaired lysosomal fission, but normal fusion, in Fig4-/- cells. The fission defect was associated with a robust increase of intralysosomal Ca2+ in Fig4-/- cells, including FIG4-deficient neurons. This finding was consistent with a suppressed Ca2+-efflux of lysosomes, since the endogenous ligand of lysosomal Ca2+-channel TRPML1 is PI3,5P2 that is deficient in Fig4-/- cells. We reactivated the TRPML1 channels by application of TRPML1 synthetic ligand, ML-SA1. This treatment reduced the intralysosomal Ca2+-level and rescued abnormal lysosomal storage in Fig4-/- culture cells and ex-vivo dorsal root ganglions (DRG). Furthermore, we found that the suppressed Ca2+-efflux in Fig4-/- culture cells and Fig4-/- mouse brains profoundly down-regulated the expression/activity of dynamin-1, a GTPase known to scissor organelle membranes during fission. This down-regulation made dynamin-1 unavailable for lysosomal fission. Taken together, our study revealed a novel

mechanism explaining abnormal lysosomal storage in FIG4 deficiency. Synthetic ligands of the TRPML1 may become a potential therapy against diseases with FIG4 deficiency.

Title: Drug discovery using a transgenic model of the slow channel syndrome

Authors: ***C. M. GOMEZ**[1], C. WEI[1], K. ROBINSON[1], B. J. BHATTACHARYYA[2];
[1]Dept Neurol., Univ. Chicago, Chicago, IL; [2]Neurol., Northwestern Univ., Chicago, IL

Abstract: The slow-channel congenital myasthenic syndrome (SCS) is a dominantly inherited disorder of neuromuscular transmission caused by distinct point mutations in the genes encoding the subunits of the muscle acetylcholine receptor (AChR). The SCS is characterized by progressive weakness and fatigability of the voluntary muscles, electrophysiological evidence of an impaired safety factor of neuromuscular transmission, and prolonged endplate currents caused by leaky, mutant AChRs. The leaky AChRs lead to Ca2+ overload degeneration of the post synaptic region. Agents such as the open ion channel blockers, quinidine and fluoxetine, which preferentially block mutant ion channels improve neuromuscular transmission and are neuroprotective in a transgenic model for SCS (mSCS). These two agents are not ideal because of adverse side effects. Here we used our mSCS model (expressing the εL269F mutation) to test new open ion channel agents (amitriptyline, imipramine, memantine and ketanserin) for their capacity to normalize prolonged synaptic currents at the neuromuscular junction and improve neuromuscular transmission presumably by selective blocking of mutant AChRs in SCS mice. Using two microelectrode voltage clamp technique we have recorded spontaneous miniature end plate currents (MEPCs) and evoked end plate currents (EPCs) from excised phrenic nerve diaphragm muscle of εL269F and wild type mice. We found that prolonged MEPC decays (tau) observed in εL269F (19.35±2.8ms compared to wild type 2.4±0.14ms) are significantly reduced in the presence of amitriptyline (IC50~I uM) (10.09±1.9ms; $p<0.05$); we found a similar effect on MEPC decays for each of the other drugs with the following potency range as expressed by IC50 <imipramine (IC50~4uM)<memantine (IC50~6uM) and ketanserin (IC50~12uM). The doses used in this study in the IC50 dose range did not alter either the MEPC frequencies or MEPC amplitudes of εL269F mice, arguing against a presynaptic mechanism of action, and

suggesting that they will be safe for this indication. To further explore the post synaptic mechanism of action of amitriptyline we measured the characteristics of evoked EPCs. After low frequency repetitive stimulation (a rate similar to normal motor neuron firing rate), amitriptyline caused voltage-, as well as concentration-dependent decrease of the decay time constant of the EPCs. These results demonstrate the feasibility of using a transgenic mouse model for SCS to screen for new potential therapeutic agents for this disease. Furthermore, we have detected at least two potentially useful agents to treat mSCS, that are appropriate for preclinical neuroprotective studies.

Title: Mutations that suppress structural and functional decline of muscle in a *C. elegans* model of Duchenne muscular dystrophy

Authors: C. BERON[1], A. VIDAL-GADEA[1], J. COHN[1], *J. T. PIERCE-SHIMOMURA[2]; [1]Univ. of Texas at Austin, Austin, TX; [2]Univ. Texas, Austin, Austin, TX

Abstract: Duchenne muscular dystrophy (DMD) is a lethal neurodegenerative disorder characterized by progressive muscular weakness, degeneration, and death. Despite its prominence, a cure has not yet been found for this disease. Previous studies have used animals to model the genetic background of the disease, but have failed to replicate the severity of muscle decline of DMD in humans. The nematode Caenorhabditis elegans has been similarly constrained by these limitations. We developed an assay capable of modulating muscular exertion and recapitulated the human phenotype of DMD in *C. elegans*. Modeling the genetics, locomotor decline, and muscular degeneration characteristic of the disease in *C. elegans*, we performed the first genetic screen to rescue muscle and motor degeneration in an animal without the aid of sensitizing mutations. We isolated several mutations capable of suppressing the locomotor and muscular decline characteristic of DMD. Mapping and cloning of the affected genes will help us identify conserved pathways through which suppressor mutations accomplish their rescue. This will help us produce novel molecular approaches to combat the muscular and locomotor decline characteristic of humans with DMD.

Title: Muscle specific kinase autoantibodies: their impact upon the postsynaptic membrane scaffold at the neuromuscular junction

Authors: ***W. D. PHILLIPS**[1], N. GHAZANFARI[1], E. L. T. B. LINSAO[1], S. TRAJANOVSKA[1], S. W. REDDEL[2];
[1]Physiology, Bosch Institute, Univ. of Sydney, Sydney, Australia; [2]Mol. Med. & Neurology, Concord Clin. Sch., Univ. of Sydney, Sydney, Australia

Abstract: A subset of myasthenia gravis (MG) patients possess IgG4 autoantibodies that target Muscle Specific tyrosine Kinase (MuSK) and cause MG when transferred into mice. *In vitro* studies have revealed two mechanisms by which MG patient anti-MuSK could interfere with MuSK at the neuromuscular junction (NMJ). Anti-MuSK disrupted the binding of MuSK to collagen Q (which is thought to tether MuSK in the postsynaptic membrane). Anti-MuSK also blocked the binding of LRP4 to MuSK, thereby inhibiting the activation of MuSK by extracellular neural agrin. Repeated daily injections with MuSK MG IgG for two weeks causes mice to develop myasthenic weakness due to progressive declines in postsynaptic acetylcholine receptor (AChR) density and endplate potential amplitude. Here we have used this mouse passive transfer model to examine the acute *in vivo* effects of MuSK MG IgG at NMJs. Healthy motor endplates in the tibialis anterior muscle displayed strong immunostaining for phosphorylated targets of the MuSK cascade (pSrc and pAChR beta subunit). Phosphorylation of both Src and AChR was reduced 24hours after the first intraperitoneal injection of MuSK MG IgG. In contrast, the efficient targeting of MuSK-EGFP to the endplate was not altered at this early timepoint in the anti-MuSK injection series. These results suggest that suppression of MuSK kinase signaling precedes the loss of MuSK and AChR from the postsynaptic membrane in our mouse model of MuSK MG. Intramuscular injection of adeno associated viral vector was used to force expression of MuSK-EGFP. In healthy mice, MuSK-EGFP targeted to the endplate where it appeared to compete with endogenous MuSK to saturate a postsynaptic MuSK scaffold. In mice receiving a series of daily injections of MuSK MG IgG, endplate immunostaining for MuSK was reduced, but less so in muscles expressing MuSK-EGFP. Endplates expressing MuSK-EGFP also retained most of their original AChR density, when compared to contralateral

control muscles (injected with empty vector). Our results suggest that MuSK autoantibodies cause synaptic disassembly through a process that involves immediate inhibition of MuSK followed by displacement of MuSK from the postsynaptic MuSK scaffold and a slow progressive wastage of endplate AChRs.

Title: Deficient RNA metabolism as a novel target in neuromuscular disease

Authors: *R. HORVATH;
Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: Deficient RNA Metabolism as a Novel Target in Neuromuscular Disease Rita Horvath, Michele Giunta, Veronika Boczonadi, Juliane Müller, Hanns Lochmüller The John Walton Muscular Dystrophy Research Centre, MRC Centre for Neuromuscular Diseases, Institute of Genetic Medicine, Newcastle University The importance of RNA processing in neurodegeneration is highlighted with a rapidly increasing number of human neurogenetic diseases caused by mutations in proteins involved in mRNA metabolism including spinal muscular atrophy (SMA) and pontocerebellar hypoplasias (PCH). A novel mechanism of RNA-associated neurodegeneration has been suggested by the identification of mutations in genes encoding human exosome components. The exosome is a multi-protein complex, required for degradation of AU-rich element (ARE) containing mRNAs, which is an important regulatory step in gene expression. However the human exosome may also regulate gene expression via diverse RNA processing reactions. Mutations in EXOSC3 were reported in pontocerebellar hypoplasia and spinal motor neuron abnormalities (PCH1), and our group recently identified mutations in a novel gene EXOSC8, encoding a core component of the human exosome in children with overlapping symptoms of cerebellar hypoplasia, spinal muscular atrophy and hypomyelination. In a single patient with spinal muscular atrophy (SMA) a potentially disease-causing mutation was detected in RBM7, a co-factor of the exosome complex which binds non-coding PROMoter uPstream Transcripts (PROMPT)s. Despite the complex and central role of the exosome in RNA metabolism in all cell types it is so far not known why and how only specific neuronal cells are affected by exosomal protein deficiency. We investigated how

abnormal RNA metabolism due to defect of exosomal proteins affect gene expression in different human cells *in vitro* and in parallel we studied zebrafish models of exosomal protein deficiencies. Identifying the biochemical pathways of RNA metabolism alterations due to different types of exosome dysfunction may explain why mutations in separate components of the exosome cause different disease presentations, and may identify potential pathways which can be targeted to develop experimental therapies.

Title: Functional and structural evidence of central motor pathway involvement in genetic subtypes of Charcot-Marie-Tooth Disease

Authors: *H. W. LEE[1], M. LEE[1], C.-H. PARK[1], H.-K. CHUNG[1], Y. CHOI[1], J. YOO[2], B.-O. CHOI[3];
[1]Dept. of Neurol., [2]Dept. of Diagnos. Radiology, Ewha Womans Univ. Sch. Med., Seoul, Korea, Republic of; [3]Neurol., Samsung Med. Center, Sungkyunkwan Univ. Sch. of Med., Seoul, Korea, Republic of

Abstract: Background: Charcot-Marie-Tooth (CMT) disease is the clinically and genetically heterogeneous peripheral nervous disorder. There have been a few reports of white matter involvement in some of CMT patients, but detailed pathophysiologic abnormalities in central motor pathways in CMT especially in different genetic subtypes are not fully understood yet. In this study, we investigate the motor cortical excitability and central white matter alterations in CMT patients using transcranial magnetic stimulation (TMS) and Diffusion Tensor Images (DTI). **Methods**: Fifty patients with genetically confirmed CMT (10 CMT1A, 14 CMT1B, 15 CMT2A, 11 CMTX) and 30 control subjects were enrolled. We measured TMS indices for motor cortical excitability including resting motor threshold (RMT), motor evoked potential (MEPs), cortical silent period (CSP), central motor conduction times (CMCT), intracortical inhibition(ICI) and intracortical facilitation (ICF) at different stimulus intensities in upper and lower extremities. DTI was used to analyze the fractional anisotropy (FA), axial (AD), radial (RD) and mean diffusivities (MD). **Results:** In CMT group, RMT increased, CMCT and cortical MEP latencies prolonged, ICI decreased and MEP amplitude decreased in arm and leg muscles

compared to controls. Patients with CMT1B showed more prolonged CMCT and MEP latencies at all TMS stimulus intensities tended to be prolonged than other CMT subtypes. In DTI study, increased FA, AD, MD and reduced RD were noted in bilateral diffuse long white matter tracts in CMT1B group, whereas decreased FA, increased AD, MD and increased RD were noted in more restricted white matter tracts including body of the corpus callosum in CMTX patients. **Conclusion:** Central nervous system involvement in various subtypes of CMT patients was studied using TMS and DTI methods. We found that decreased ICI and delayed CMCT in CMT patients, which means intracortical integrity and central motor pathway alterations in CMT patients. And DTI revealed white matter alterations in mainly CMT2A and CMTX patients. TMS and DTI investigation in CMT patients suggests involvement in central as well as peripheral motor pathways with different pathophysiologic changes in CMT1B and CMTX patients.

Title: Severity of both demyelinating and axonal neuropathy mouse models are modified by genes affecting sodium channels at nodes of Ranvier

Authors: *R. W. BURGESS[1], K. L. SEBURN[2], K. H. MORELLI[3], E. L. SPAULDING[3], D. G. SCHROEDER[2], G. A. COX[2];
[1]The Jackson Lab., Bar Harbor, ME; [2]The Jackson Lab., BAR HARBOR, ME; [3]Graudate Sch. of Biomed. Sci. and Engin., The Univ. of Maine, Orono, ME

Abstract: The genetic basis for the variable severity of Charcot-Marie-Tooth disease (CMT) is being investigated using mouse models of both axonal and demyelinating neuropathy. We identified a mouse strain at the Jackson Laboratory that developed progressive weakness and hind limb dysfunction, leading to paralysis and death by five months of age. A combination of genetic mapping and exome sequencing revealed a double mutation in Sh3tc2 and Neural-glial Related Cell Adhesion Molecule (Nrcam), an Ig-superfamily member cell adhesion molecule involved in development and sodium channel localization at nodes of Ranvier. Independently, the phenotype of Sh3tc2 mutant mice closely resembles previously reported knockout mice

modeling CMT4C, whereas Nrcam mice have only a subtle reduction in nerve conduction velocity and occasional abnormalities in sodium channel (NaV1.6/Scn8a) localization at nodes, but no overt neuropathy phenotype. However, in combination, these mutations result in progressive loss of hind limb function and severe sprouting at neuromuscular junctions, suggesting a failure in action potential propagation in peripheral nerves. This led us to hypothesize that otherwise innocuous or subclinical changes in sodium channel function at nodes (such as those caused by Nrcam mutations) could synergize with mutations affecting the passive propagation of depolarization (the axonal length constant, caused by thin myelin in the Sh3tc2 mutation) to produce a more severe phenotype. We tested this hypothesis by breeding the Nrcam mutation into a Gars mutant background, a mouse model of CMT2D that compromises the axonal length constant by reducing axon diameter without effecting myelination. Loss of Nrcam also exacerbated the Gars phenotype in two different Gars mutant alleles, indicating a synergy of the Nrcam phenotype with axonal as well as demyelinating neuropathy. We validated that the mechanism is due to impaired sodium currents by breeding the Gars mice to Scn8a heterozygous mice, which like Nrcam, have no overt phenotype and only a subtle reduction in nerve conduction velocity. We achieved a very similar enhancement of the Gars phenotype in the Scn8a heterozygous background, supporting our hypothesized mechanism of reduced sodium currents in the Nrcam mutation. Thus, we have established that mutations with minor effects on sodium currents at nodes of Ranvier interact with mutations that reduce the axonal length constant, including both demyelinating and axonal neuropathies, to cause a more severe phenotype. In considering the spectrum of possible modifier loci for CMT, genes encoding node-associated proteins should be considered.

Abstract: Mutations in GDAP1 (Ganglioside-induced differentiation associated protein 1) gene causes Charcot-Marie-Tooth (CMT) neuropathy, the most common inherited neuromuscular disorder. GDAP1 protein is located in the outer mitochondrial membrane and interacts with the vesicle-organelle trafficking proteins suggesting that GDAP1 may participate in the movement of mitochondria. GDAP1 silencing in neuroblastoma SH-SY5Y cells induces abnormal distribution of the mitochondrial network, decreases the contact between mitochondria and endoplasmic reticulum (ER) and reduces 1) Ca inflow through store-operated Ca entry (SOCE) following mobilization of ER-Ca and 2) SOCE-driven Ca entry in mitochondria (1). Any Ca signal causes ATP breakdown by Ca pumps or exchangers in order to restore Ca levels. In addition, Ca regulates oxidative phosphorylation via two different methods: a) Ca entry in mitochondria and activation of mitochondrial dehydrogenases or b) extramitochondrial Ca activation of metabolite transport (2). As SOCE-driven Ca entry in mitochondria is reduced in GDAP1-KD neuroblastoma cells (1), we have investigated mitochondrial respiration during SOCE activation. We find that SOCE drives a marked stimulation of respiration in neuroblastoma cells, which is reduced (by 41%) in the GDAP1 silenced cell line. We have next investigated the effect of different pathological GDAP1 missense mutations in SOCE activity, after transient expression on GDAP1-silenced cells. Recessive mutations in GDAP1 located inside the α-loop (protein-protein interactor domain), such as p.S130C, fail to restore SOCE activity in GDAP1-KD cells. In agreement with this GDAP1 silencing in HEK293T cells decreases SOCE-driven stimulation of respiration and the recessive mutation p.S130C fails to revert the decrease. We now find that cerebellar neurons obtained from Gdap1-knockout mice (3) show reduced Ca inflow through SOCE channels both in soma and neurites compared with WT neurons. Further, in neurites, SOCE-driven Ca entry in mitochondria is abolished. In addition, we have found lower ER-Ca levels in Gdap1-/- neurons, and lower stimulation of respiration by Ca-mobilizing agonists. SOCE-induced stimulation of respiration is also decreased

in Gdap1-/- cerebellar neurons. These findings support a role of altered SOCE and ER-Ca driven Ca uptake and/or signaling in mitochondria in the pathophysiology of GDAP1-related CMT neuropathies, which could impair neuronal respiration and bioenergetics. 1. Title: Electrophysiological and morphological properties of motoneurons in mild and severe mouse models of SMA

Authors: *E. REEDICH[1,2], K. QUINLAN[2], C. J. HECKMAN[2], C. DIDONATO[1];

Abstract: Spinal muscular atrophy (SMA) is a motoneuron disease caused by reduced levels of the survival motor neuron (SMN) protein. Disease severity runs along a spectrum that is generally determined by SMN dosage. Our laboratory has recently generated a mild SMA mouse that exhibits longevity and recapitulates symptomology of mild SMA patients, including motor axon loss and functional deficits. In this mild SMA mouse, the progression of electrophysiological alterations underlying motoneuron loss can be much more clearly delineated than in mouse models of severe SMA, revealing new insights into disease progression and potential treatment windows that precede motoneuron degeneration. Here, we compare the electrophysiological properties of motoneurons from the lower thoracic to upper lumbar spinal cord of neonatal mild and severe SMA mice. Whole-cell patch clamp was performed on medial motoneuron pools in 350μm transverse spinal cord slices from T10 - L2. Properties were analyzed in voltage clamp to study persistent inward currents and in current clamp to study action potential and after-hyperpolarization characteristics as well as frequency-current relationships. We find that while severe SMA motoneurons exhibit overt hyperexcitability, mild SMA motoneurons demonstrate more subtle electrophysiological alterations including increased membrane time constant (τ), decreased cell capacitance (Cm) and increased whole cell input resistance (Rinput). To determine whether smaller motoneuron soma size in mild SMA mice

accounts for these observed electrophysiological abnormalities, three-dimensional anatomical reconstructions were performed on patch-clamped motoneurons. Mild SMA motoneurons tend to have smaller maximal cross sectional areas, soma surface areas, and soma volumes than those of heterozygous control mice, although these values did not reach significance. Currently in progress is a second method to confirm soma size of L1 motoneurons via ventral root backfilling with fluorescent dextrans and those results will be presented. Overall, this work serves to clarify the sequence of electrophysiological changes within motoneurons that precipitates the disease state in SMA.

Abstract: While the impact of aging on neuromuscular junctions (NMJs) has been well-documented in mice, it is unclear if the same structural and molecular changes occur in primates. Here, we examined NMJs in the gastrocnemius muscle from adult and aged rhesus monkeys using light microscopy. As in mice, we found significant structural changes in old NMJs that include fragmentation of post-synaptic sites and denervation of muscle fibers. Our analysis also revealed that perisynaptic Schwann cells fail to properly cover aged NMJs. Along with these structural features, we found changes in the level and distribution of NMJ-associated molecules, particularly those associated with the synaptic basal lamina and resident molecules of the post-synaptic apparatus. In addition to the NMJ, we examined α-motor neurons and their synaptic inputs in aged rhesus monkeys. Our analysis revealed a significant reduction in the number of VAChT and VGluT1 positive synapses on the somata of α-motor neurons. The reduced number of synapses in aged spinal cords closely correlates with increasing levels of lipofuscin in the cytoplasm of α-motor neurons. These findings indicate that similar structural and molecular changes occur at the NMJ of rhesus monkeys as previously found in rodents. They also demonstrate the impact of aging on the soma of α-motor neurons and suggest that spinal neuronal circuits are severely impaired in aged monkeys.

Title: Accelerated motor endplate degeneration in agrin deficient mice after traumatic nerve injury

Authors: D. ZHU[1], J. SU[1], J. JUNG[1], T. ONISHI[1], W. WANG[1], *T. MOZAFFAR[2], R. GUPTA[1];

Abstract: Regenerating axons must navigate over long distances to reinnervate their target muscle; however, muscle atrophy and destabilization of the neuromuscular junction (NMJ) usually occurs before the denervated muscle becomes reinnervated. Agrin has been well characterized as an essential component of NMJ formation during development. We hypothesized that agrin deficient mice would undergo a more rapid and severe atrophy of the motor endplate after denervation with the hopes that agrin delivery could rescue this phenotype. Wildtype and agrin deficient mice were denervated by excision of a 10mm segment of the right sciatic nerve. Wet muscle weight of tibialis anterior muscles were measured and cross sectional areas were evaluated. Protein levels of phosphorylated muscle specific kinase (MuSK) and AChR alpha1 subunits and clustering were evaluated via immunofluorescence. Denervated muscles in agrin deficient mice had a significantly lower wet muscle weight percentage compared to their wildtype counterparts (5.26±0.23 vs 6.20±0.30; p=0.033). Phosphorylated MuSK on the uninjured and injured side was approximately 2-fold and 1.5-fold higher in wildtype mice than in agrin deficient mice at 2 weeks and 4 weeks, respectively. AChR subunits were significantly higher after transection in wildtype than in agrin deficient mice at 4 weeks (1±0.30 vs 1.94±0.24; p=0.032). After denervation, pixel density and AChR area decreased more severely in agrin deficient mice than in wild type mice by 8 weeks. Furthermore, morphological assessment of AChR revealed a rapid shift in the receptor morphology towards plaque-like profiles in agrin deficient mice when compared to wildtype mice at both 2 and 8 weeks. Heterozygous agrin deficient mice have depleted agrin levels at their denervated motor endplates. After traumatic nerve injury, these mice exhibit decreased phosphorylation of MuSK and accelerated disassembly of AChRs when compared to their wildtype counterparts. Most importantly, this data presents novel data to support further study of agrin and its essential role in adult NMJ stability and maintenance after injury.

Title: Functional evaluation of the effects of aging and genetic manipulations on motor behavior

Authors: ***B. MAREIN**[1], N. LOZIER[2], S. DE LACALLE[2];
[1]Col. of Arts & Sci., Athens, OH; [2]Biomed. Sci., Ohio Univ., Athens, OH

Abstract: Finding ways to slow and reverse muscle wasting remains an urgent task for an increasingly aging society, and myostatin (Mstn) has been presented as an attractive therapeutic candidate for the treatment of muscle wasting because its inactivation results in muscle hypertrophy. Our laboratory has started to analyze changes in motor behavior with aging, using two different animal models. First, we investigated motor function in an aged group (19 months of age, n=7) vs. a young adult group (6 months of age, n=8) of C57/BL6 male mice. While hind limb grip strength scores were not significantly different when normalized to body weight, the young adult group significantly outperformed the aged group on the rotarod test of endurance and balance. Then we set to investigate whether Mstn signaling plays a role in age related muscle function decline. We have developed a mouse model in which a critical segment of the Mstn gene (exon 3) is flanked by loxP (floxed) and also contains a Doxycycline(DOX)-inducible Cre recombinase transgene, dubbed DOX-inducible MSTN KO mice. Treatment with DOX renders the Mstn gene non-functional by excising the DNA flanked by the LoxP sequences. As expected, following 14 weeks of DOX administration in the chow, we found a significant increase in triceps surae weights of the DOX treated (7 months of age, n=11) vs. the untreated male mice (7 months of age, n=9), resulting in significantly higher absolute hind limb grip scores in treated mice, but there was no significant difference between hind limb grip scores when normalized to body weight. Biceps and triceps brachii muscles, though not significant, were slightly larger in DOX treated mice, but there was no difference between the groups in absolute forelimb grip strength or when normalized to body weight. DOX treated mice exhibited significantly larger masseters, but there was no significant difference in absolute bite force or when normalized to masseter weight. Likewise, there was no significant difference in time spent on the rotarod. These results suggest that Mstn inhibition in the young adult, while increasing muscle size, does not positively affect muscle function. Tests of an aging group of DOX-inducible MSTN KO mice are currently underway, and may enhance our understanding of the role of Mstn in the behavioral correlates of muscle aging.

Title: Identifying new targets to promote muscle regeneration

Authors: ***J. T. EHMSEN**[1], R. MI[1], G. COPPOLA[2], A. HOKE[1];
[1]Johns Hopkins, Baltimore, MD; [2]UCLA, Los Angeles, CA

Abstract: Skeletal muscle atrophy is a loss of muscle mass and corresponding loss of function that occurs in response to diverse stimuli including disuse/immobility, hyperthyroidism, diabetes, glucocorticoid treatment, cancer, aging, and denervation. Denervation is a significant contributor to muscle wasting in trauma, degenerative diseases, and age-associated sarcopenia in humans. Muscle satellite cells possess the unique capacity to proliferate and regenerate in settings of muscle injury, but regenerative capacity becomes depleted during chronic denervation. Applying microarray and RNA-Seq approaches, we are investigating mechanistic features of atrophy during acute and chronic denervation in both muscle and muscle satellite cells of mouse gastrocnemius using a tibial nerve denervation model, with the intention of identifying novel targets for minimizing atrophic changes and/or sustaining or enhancing muscle satellite cell proliferative and regenerative capacity.

Title: Mutant FUS mediated impairments in mRNA trafficking and protein translation at NMJ

Authors: *K. KRISHNAMURTHY[1], N. ALAMI[3], J. P. TAYLOR[4], D. TROTTI[2], P. PASINELLI[2];
[1]NEUROSCIENCE, [2]Neurosci., Thomas Jefferson Univ., Philadelphia, PA; [3]Stanford Univ., California, CA; [4]Cell & Mol. Biol., St. Jude Children's Res. Hosp., Memphis, TN

Abstract: Amyotrophic lateral sclerosis (ALS) is an adult-onset rapidly progressing neurodegenerative disease that leads to fatal paralysis. About 10% of ALS cases are familial (fALS), and are associated with mutations in one or another of several genes including the DNA/RNA binding protein Fused in Sarcoma (FUS). Like for other forms of ALS, the hallmark of FUS-ALS is destruction of the neuromuscular junction (NMJ). Accordingly, we showed that NMJ defects, and specifically, defects in synapse structure and function precede motor neuron degeneration in a *Drosophila* model of FUS-ALS (Shahidullah et al., 2013). We also showed mutant FUS reduces levels of the presynaptic proteins SV2 and synaptophysin in motor neurons without causing significant changes in their mRNA transcripts. At the functional level,mutant FUS impairs neurotransmitter release (Krishnamurthy et al., 696.04/F5 SFN 2014). Here we study the mechanism(s) by which NMJs become dysfunctional in mutant FUS models. We show that expression of mutant FUS in NSC-34 cells and motor neurons results in the up-regulation of ER stress marker phospho-eIF2α, and possible impairment of the axonal trafficking and translational machinery

Title: Persistent motor-unit specific synaptic alterations at the neuromuscular junction in the SOD1G37R mice

Authors: *E. TREMBLAY, É. MARTINEAU, R. ROBITAILLE;
Univ. De Montréal, Montreal, QC, Canada

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal late-onset neurodegenerative disease characterized by the progressive loss of motoneurons. Denervation of the neuromuscular junction (NMJ) is an early pathological event in various ALS models. Motor units (MU) appear unequally

susceptible to denervation, the fast fatigable (FF) MU being the most vulnerable and the slow (S) MU the most resistant. While previous studies in several ALS models have consistently reported alterations in synaptic transmission, their findings have been contradictory. Interestingly, the MU types were not taken into account in these studies, which could explain these discrepancies. We hypothesized that the MU selective vulnerabilities observed in ALS will be associated with MU-specific NMJ alterations throughout the disease course. We studied synaptic transmission and plasticity of different types of MU in the fast-twitch Extensor Digitorum Longus (EDL; fast fatigable (FF) MU) and the slow-twitch Soleus (SOL; slow (S) and fast fatigue resistant (FR) MU) of the SOD1 mice and their WT littermates. MU types were identified using immunohistochemical labelling of the respective myosine heavy chains. At a presymptomatic stage (P160), while no morphological alterations of NMJs were seen in both muscles, synaptic activity was altered in a MU-specific manner in SOD1 mice. S and FR MU had an increased mEPP frequency whereas no difference was seen for FF MU in SOD1 compared to WT. Similar changes were observed in evoked activity where FF MU from SOD1 mice showed a decrease in EPP amplitude and quantal content whereas S MU showed a higher quantal content. FR MU of SOD1 showed no difference in evoked activity compared to WT. Long-term synaptic plasticity was significantly reduced in the FF MU of SOD1. At preonset (P400), various morphological alterations were seen in the mutant mice, most strikingly in the EDL muscle, including denervation, partial innervation and nerve sprouting. Evoked activity was altered in a similar way as was observed at P160 for all MU types. In contrast, spontaneous activity was now reduced in the mutant FF MUs, whereas mEPP frequencies of S and FR MU were no longer different compared to WT. Interestingly, the increase in quantal content of the S MU was almost absent at disease onset. Surprisingly, paired-pulse facilitation was not altered in any MU type and at any age despite changes in synaptic strength. Taken together, these results reveal that NMJ function is differentially altered according to MU susceptibility in ALS. This study provides insights for a better understanding of NMJ physiology during the illness that is crucial to the development of a proper NMJ-targeted treatment in ALS.

Title: Muscle dysfunction occurs prior to symptom onset and motor neuron degeneration in a mouse model of Spinal Bulbar Muscular Atrophy

Authors: *L. V. ANNAN, A. L. GRAY, B. MALIK, L. GREENSMITH;
Sobell Dept. of Motor Neurosci. and Movement Disorders, UCL Inst. of Neurol., London, United Kingdom

Abstract: Spinal and bulbar muscular atrophy (SBMA), otherwise known as Kennedy's disease, is an X-linked, late-onset progressive neurodegenerative disease, which predominantly affects males. SBMA is characterised by the selective loss of spinal and bulbar motor neurons and progressive muscle weakness. The disease is caused by an expansion in the CAG repeat in the androgen receptor (AR) gene which encodes a polyglutamine (poly-Q) tract in the mature protein (La Spada et al., 1991, Fischbeck, 2001). The polymorphic trinucleotide CAG repeat normally ranges from 9 to 36, but an expansion of greater than 38 repeats results in disease. Although the underlying pathophysiology of the disease remains largely unknown, it appears to be related to abnormal accumulation of the pathogenic androgen receptor protein within the nucleus. Although widely considered a neurodegenerative disease affecting motor neurons, emerging evidence suggests that SBMA may involve a primary muscle deficit. In this study we examined this possibility by systematically characterising hindlimb muscle function and histopathology at different stages of disease progression in the AR100 mouse model of SBMA, which recapitulate the key features of the human disease. Our results show that muscle atrophy, denervation and mitochondrial dysfunction are evident during early stages of disease in AR100 mice, prior to any loss of motor neurons. Using *in vivo* physiological recordings in anaesthetised mice, we detected a significant reduction in muscle force by 6 months of age. We also observed a reduction in motor unit survival at 6 months, indicative of muscle denervation, although motor neuron death was only detected at 18 months. Furthermore, the muscle deficits were much more pronounced in the fast twitch muscle tibialis anterior (TA) than the slow twitch soleus muscle, which remained largely unaffected, even at 18 months. The deficits observed in TA were accompanied by a change in the histochemical properties of the muscle fibres, which showed an increase in oxidative capacity, as revealed by staining for the mitochondrial respiratory enzyme, succinate dehydrogenase. Taken together, these results support the proposal that skeletal muscle is a primary target of pathology in SBMA, which may be important for the development of therapeutic strategies for SBMA. Title: Fine motor kinematic analysis in the MDX mouse model of Duchenne muscular dystrophy a study of chronically exercised versus non-exercised MDX mice

Authors: P. J. SWEENEY[1], T. BRAGGE[1], *T.-K. STENIUS[1], A. NURMI[1], T. HEIKKINEN[1], T. AHTONIEMI[1], D. WELLS[2];
[1]Charles River Discovery Services, Kuopio, Finland; [2]Royal Vet. Col., London, United Kingdom

Abstract: Duchenne muscular dystrophy (DMD) is caused by mutations in the dystrophin gene that is on the X chromosome; lack of dystrophin causes a progressive muscle necrosis which leads to progressive decrease in mobility for those suffering from the disease. There is currently no cure for this disease and those suffering from DMD generally die in their twenties or early thirties. The MDX mouse (a murine model with a mutation causing dystrophin deficiency) has been used to study the efficacy of drugs aimed at DMD especially beyond the 'critical period' of 3 to 7 weeks when MDX muscles show significant spontaneous signs of damage under histopathological examination as well as with magnetic resonance imaging (MRI). While there are many 'traditional' assays employed to assess the degree of muscle weakness at various ages it has become apparent that MDX mice do not develop clear muscle weakness or manifest observable changes in gait or motility at ages older than the 'critical period'. Moreover, the clinical utility of these traditional assays has been questioned and this has increased the need to create novel assays that are more sensitive to subtle deficits in motor function In this study we employed high speed kinematic analysis with a unique algorithm in order to track, record and analyze the fine motor movement of MDX mice that had been chronically exercised versus MDX mice that had not been exercised. In this analysis the relationships between specific body parts are measured with a high speed camera as the mouse walks through a mirrored chamber. The movement of the animal is recorded from below and from the right and left in order to assess multiple body parts from three angles allowing for a comprehensive analysis of motor function. The resulting analysis by the algorithm provides a view of subtle changes in gait and a principle component analysis that allows the operator to see the relationships between certain key anatomical areas during a single or multiple strides. In addition, by breaking the behavior into components, we have been able to provide a much richer characterization of the motor deficits that are apparent in the MDX animal model. The results show that there are no clearly significant differences in principle components in the unexercised MDX mouse relative to the WT mouse at all ages but, more importantly, there are significant changes between exercised and non exercised MDX mice at all ages. These data provide further support for the use of the high precision kinematic assay as a tool for assessing motor function in more sensitive and comprehensive manner.

Abstract: Duchenne muscular dystrophy (DMD) is an X-linked and lethal muscle wasting disease and considered the most severe form of muscular dystrophy. There currently exists no treatment and most sufferers die between the second and fourth decade of life. The MDX mouse model has been extensively employed as a tool to study drug efficacy in DMD but there does not currently exist an extensive longitudinal profile utilizing non-invasive imaging with T2 MRI and 1H-MRS. In addition, imaging has not been used to compare animals with a phenotype that has been exacerbated in order to create a progressive muscle damage that is more severe with those, aged matched, that have not been chronically exercised and in so doing attempt to gauge a wider therapeutic window. In this study we employed an 11.7 T small animal Bruker MRI in order to compare the temporal profiles of exercised vs unexercised MDX mice over a 12 month period. Altogether 25 male MDX mice (mice with the mutation characteristic of DMD) and 25 male wild-type (WT) mice were profiled for baseline MRI/MRS and plasma creatine kinase (pCk) starting at 7 weeks of age and again at the 3 months, 6 months, 9 months and 12 months time points. At the age of approximately 7 weeks 15 MDX and 15 WT mice were subjected to a chronic exercise regime. These were later compared with aged matched controls (non-exercised) MDX and WT mice. The exercised mice were subjected to a chronic regime that consisted of running and avg of 3 times per week 20 minutes at a max speed of 14 meters/min on an inclined treadmill in an attempt to exacerbate muscle damage associated with the underlying disease pathology. The longitudinal development of this pathology was examined and compared using T2 MRI and 1H-MRS in order to obtain a morphological and metabolic profile from the gastrocnemius muscle and the tibialis posterior muscle of all mice at various ages. The results indicate that the temporal metabolic and morphological profile is significantly different between those MDX mice that are chronically exercised beyond the “critical period” mice and those MDX mice that are not subjected to the exercise regime. This information shows that a widened therapeutic window is apparent and can be used to study these mice for longer periods of time. In addition, this information indicates that high field MRI and MRS are useful tools for the quantification of muscle damage in the MDX mouse.

Abstract: The absence of polyunsaturated fatty acids (omega-3 PUFAs) specifically DHA (docosahexaenoic acid) is related neuropathology as Parkinson's disease. Furthermore DHA appears to have neuroprotective and restorative effect, which has caused broad interest to know the effects of DHA in brain function. However, little is known of their involvement in parkinsonism. The aim of study was to describe electromyography mandibular tremors induced by subchronic treatment with haloperidol in rats previously supplemented with DHA. Rats were previously subjected to chronic supplementation of 6 weeks (21-63 days old) the esophageal route with DHA, and then were induced by subchronic administration mandibular tremors (14 days) of haloperidol (Ip) in a model of parkinsonism. The amplitude of the EMG activity and the number of bursts per second was analyzed using generalized linear models (GLM) with a design of fixed factors and nested with pseudoreplication. The supply of DHA did not fully compensate the motor deficits induced by haloperidol and does not eliminate the tremors, but there were changes electromyographic (EMG) activity in the basal and during temporal mandibular muscle tremors. In contrast, DHA was effective to reduce the animal's immobility time and reduced latency in a spontaneous exploration open field test. Suggesting neuroprotection on difficulty initiating movements, acinesia. The beneficial effects of DHA were evident in the electromyographic activity of animals which were supplemented with DHA only about rats supplied with haloperidol.

Title: Correlation of neuromotor apparatus disruption and required dosage of neuromuscular blocking agent during anesthesia in children with cerebral palsy

Authors: ***S. K. YEAGER**, K. G. ROBINSON, R. E. AKINS, Jr;
Nemours Alfred I. Dupont Hosp. For Children, Wilmington, DE

Abstract: The cerebral palsies (CP) are static encephalopathies arising during fetal or early post-natal life and characterized by disordered movement. Previous reports indicate that children with CP are resistant to non-depolarizing neuromuscular blocking agents (ND-NMBAs) during surgery. ND-NMBAs competitively inhibit nicotinic acetylcholine receptors (AChRs) at neuromuscular junctions (NMJs), and differences in dosing can indicate disruption of NMJ components. Patients with denervating trauma, burns, or injury have elevated expression of the non-junctional, fetal AChR isoform resulting in resistance to ND-NMBAs. Gene expression studies, however, indicate that fetal AChR subunits are not present in CP patients, and an alternative explanation is needed to account for the ND-NMBA resistance in CP patients. Microanatomic and ultrastructuctural studies indicate that patients with CP have disorganized NMJs, and we suspect that ND-NMBA resistance correlates with the degree of NMJ disruption. To test this idea, pediatric patients were enrolled in an IRB-approved study after obtaining informed consent and assent for muscle sample collection during surgery. Total doses of rocuronium (ROC), a frequently used ND-NMBA in pediatric surgery, were derived from the patient's surgical record. The standard ROC dosage in children is 0.6mg/kg, but additional ROC may be used to achieve the desired muscle relaxant effect as assessed by train-of-four monitoring. Biopsies of erector spinae, extra-ocular, cremaster, vastus lateralis, and rectus femoris muscles were obtained from surgeries then snap-frozen in liquid nitrogen chilled isopentane, sectioned, and stained for synaptic acetylcholinesterase (AChE), laminin β2, and nicotinic acetylcholine receptor (AChR). The degree of NMJ disruption within the sample was determined using a validated score based on the microanatomic distribution of NMJ components determined based on fluorescently tagged probes. Dysmorphism was quantified as the degree of

non-co-localization of these components using fluorescence microscopy and a co-localization algorithm. The greatest NMJ dysmorphism related to spastic CP was staining of AChE relative to laminin β2 ($p < 0.001$). ROC doses for the CP and non-CP groups were also significantly different ($p=0.002$) with the non-CP patients requiring 0.66 + 0.07 mg per kg (mean + SD; n=20) and the CP patients requiring 1.38 + 0.80 mg per kg (n=20). Specific correlations between ROC dosage and NMJ disruption score for each patient are being carried out. The present findings indicate that children with CP have disrupted NMJs and a higher requirement for ROC.

Title: Quantitative study of pallidotegmental projections contacting cholinergic, calbindin-, and calretinin- immunoreactive neurons in the rat pedunculopontine and laterodorsal tegmental nuclei

Authors: S. MONGIA[1], E. LUQUIN[1], *E. MENGUAL[2];
[1]Anatomía, Fac Med, Univ. de Navarra, Pamplona, Spain; [2]Depto. Anatomía, Fac Med, Univ. De Navarra, Pamplona, Spain

Abstract: The pedunculopontine tegmental nucleus (PPTg) is a brainstem target of basal ganglia output particularly implicated in gait and posture. Deep brain stimulation of the PPTg in Parkinson's disease patients has provided partial alleviation of gait disorders, although the mechanism of action of this therapy is not fully understood. This could be partly due to the lack of anatomical data about the fine circuitry in PPTg and the associated laterodorsal tegmental nucleus (LDTg). Specifically, the phenotype of the target cells of pallidotegmental projections is not known yet. PPTg and LDTg comprise intermingled cholinergic, GABAergic and glutamatergic cells; in addition, glutamatergic and GABAergic cells generally coexpress a calcium-binding protein, either calretinin (CR) or calbindin (CalB). As a first step to phenotypically characterize the cell targets of pallidotegmental projections, injections of the anterograde tracer biotinylated dextran amine (BDA) were carried out in the rat ventral pallidum and entopeduncular nucleus, followed by triple fluorescence labeling to visualize the BDA-labeled fibers, the cholinergic - choline acetyltransferase-immunoreactive (ChAT-ir) - neurons, and either CR-, (CR-ir) or CalB-immunoreactive (CalB-ir) neurons in single coronal sections.

Confocal images were analyzed using the analysis software- Fiji - a plugin of ImageJ - which reveals 'slice by slice' colocalization, that is, the positive voxels within a given area where colocalization is detected throughout the stack, facilitating the quantification of potential BDA contacts with defined cell populations. Putative synaptic contacts were observed with each of the three populations analyzed, and the mean percentage of contacts received by each was very similar in the PPTg and LDTg (CR-ir: 46% and 47% of contacts, respectively; ChAT-ir: 32% and 34%; CalB-ir: 22% and 19%). These results indicate that: 1) almost 1/3 of contacts are made on cholinergic neurons, in contrast to previous estimations; this anatomical evidence supports a significant role of PPTg and LDTg cholinergic cells in basal ganglia circuitry, consistent with the pathological results observed in Parkinson's disease post-mortem tissue; 2) pallidotegmental fibers preferentially target CR-ir neurons in both PPTg and LDTg; and 3) over 2/3 of contacts are made with either CR- or CalB-ir neurons: as previous studies have shown that 2/3 of either subpopulation are glutamatergic, the present data suggest that the largest postsynaptic target of pallidotegmental fibers in PPTg and LDTg is glutamatergic.

Title: Direct dopaminergic projections from the SNc modulate tectal motor responses

Authors: *J. PÉREZ-FERNANDEZ, A. KARDAMAKIS, B. ROBERTSON, S. GRILLNER; Karolinska Inst., Stockholm, Sweden

Abstract: In the lamprey, as in mammals, dopamine plays a key role in movement control by modulating the excitability of projection neurons in the striatum. The direct "go" pathway neurons express the dopamine D1 receptor and mediate a net facilitation of motor actions desinhibiting the pallidal GABAergic output neurons, whereas the indirect "no go" pathway, through the D2 subtype, mediates motor suppression. The dopaminergic modulation of the striatum derives from the nucleus of the posterior tuberculum, the homologous region of the mammalian substantia nigra pars compacta (SNc). It shows the same connectivity with the other

basal ganglia subnuclei observed in mammals, and receives pallial (cortex in mammals) and tectal input as the evolutionary basis for salience/novelty detection. The importance of this dopaminergic innervation in the lamprey is reflected in the fact that, when depleted, it gives rise to a marked hypokinesia, as in Parkinson's disease. One important feature is that the SNc in lamprey, as in mammals, sends direct dopaminergic projections to motor command centres, including the diencephalic and mesencephalic motor regions and the output layer of the optic tectum. The nigral dopaminergic control of motor responses is thus likely to be more complex than generally assumed, involving additional pathways to the widely studied striatal projection. Here, we explore how dopamine modulates motor responses in the optic tectum, the homologous region of the mammalian superior colliculus. Tectum shows in all vertebrates, including the lamprey, similar features, with a laminated structure, controlling eye, orienting and evasive trunk movements. Tracer injections combined with immunocytochemistry show that dopaminergic fibers from the SNc innervate the deep layer premotor cells, which express D1 and D2 receptors. Patch-clamp recordings show that D1 and D2 cells are separated populations, and dopamine increases the excitability of D1 cells, whereas it decreases the excitability of D2 cells, so that dopaminergic modulation changes their responsivness to sensory inputs reaching the optic tectum. Electromyography (EMG) recordings in the eye muscles show that motor responses elicited by retinal stimulation can be modulated by locally injected dopamine agonists in the optic tectum. Our results indicate that dopamine directly modulates motor responses in premotor regions and, given the high degree of conservation of the basal ganglia and the presence of direct dopaminergic projections from the SNc to the superior colliculus in rats, this previously unexplored mechanism is likely to also be present in higher vertebrates including primates.

Title: Optogenetic interrogation of the Parkinsonian subthalamic nucleus-external globus pallidus network during cortical slow-wave activity

Authors: *R. F. KOVALESKI[1], J. W. CALLAHAN[2], M. D. BEVAN[2];
[2]Physiol., [1]Northwestern Univ., Chicago, IL

Abstract: The reciprocally connected subthalamic nucleus (STN)-external globus pallidus (GPe) network is a key component of the movement-suppressing hyperdirect and indirect pathways of the cortico-basal ganglia-thalamo-cortical circuit. The symptomatic expression of experimental and idiopathic Parkinson's disease (PD) is associated with the emergence of abnormally persistent, widespread, correlated, rhythmic (1-30 Hz) cortico-basal ganglia-thalamo-cortical circuit activity. Because the STN-GPe network is a candidate amplifier of abnormal activity throughout this circuit, we applied optogenetic silencing and concurrent multisite recording in control and unilateral 6-hydroxydopamine (6-OHDA)-treated mice to determine how parkinsonian STN-GPe network activity is generated. In control mice under urethane anesthesia, STN neuron firing was largely entrained to the active component of the slow cortical oscillation, whereas GPe neurons discharged in a relatively tonic manner. In 6-OHDA-treated mice, the phasic activity of STN neurons increased (by 75%) and the proportion of GPe neurons that exhibited firing that was correlated with cortical slow-wave activity (SWA) increased (control = 61%; 6-OHDA = 85%), with neurons firing in anti-phase (control = 14%; 6-OHDA = 75%), in-phase (control = 47%; 6-OHDA = 10%), or with no significant phase preference (control = 39%; 6-OHDA = 15%). Cre-dependent expression of ArchT-eGFP in PV+ GPe neurons confirmed their prototypic nature, i.e. their extensive projection to the STN. In 6-OHDA-treated mice, optogenetic silencing revealed that PV+ GPe neurons discharged in anti-phase to SWA (52%) or tonically (48%). Optogenetic inhibition of PV+ GPe neurons increased the firing of STN (control = 92%; 6-OHDA = 102%) and PV- GPe neurons (control = 48%; 6-OHDA = 56%). Optogenetic inhibition of STN neurons decreased the firing of GPe neurons in both control and 6-OHDA-treated mice (control = 16%; 6-OHDA = 32%) and promoted anti-phasic discharge relative to SWA in the latter. In dopamine-depleted mice, optogenetic inhibition of D2-expressing striatal projection neurons (D2-SPNs) disinhibited GPe neurons and eliminated anti-phasic firing relative to SWA. Together these data suggest that following loss of dopamine, hyperexcitable D2-SPNs excessively inhibit prototypical PV+ GPe-STN neurons leading to disinhibition of STN and PV- GPe neurons and excessive cortical patterning of the STN-GPe network.

Title: The dopamine innervation of the primate pallidum: A comparison between the internal and external segments

Authors: *L. EID, M. PARENT;
Psychiat & Neurosci Dept, Univ. Laval, Quebec, QC, Canada

Abstract: The internal (GPi) and external (GPe) segments of the pallidum are innervated by dopamine (DA) axons that arise mainly from the substantia nigra pars compacta. The present light and electron microscopic study provides a detailed description of this innervation in squirrel monkeys (*Saimiri sciureus*), by using an antibody raised against tyrosine hydroxylase (TH), the DA synthesizing enzyme. At the light microscopic level, our data gathered with an unbiased stereological approach indicate a similar density of TH+ axon varicosities in the GPi ($0.17 \pm 0.01 \times 10^6$ axon varicosities/mm^3 of tissue) and the GPe ($0.19 \pm 0.02 \times 10^6/mm^3$), the anterior sector of the GPi ($0.23 \pm 0.01 \times 10^6/mm^3$) and the GPe ($0.24 \pm 0.01 \times 10^6/mm^3$) being twice as much densely innervated than their posterior counterparts (0.10 ± 0.01 and $0.14 \pm 0.02 \times 10^6/mm^3$, respectively). A decreasing gradient of innervation also occurs along the dorsoventral axis of both pallidal segments (0.21 ± 0.01 vs. $0.14 \pm 0.01 \times 10^6/mm^3$ in the GPi and 0.22 ± 0.01 vs. $0.17 \pm 0.01 \times 10^6/mm^3$ in the GPe) and along the mediolateral axis of the GPe (0.29 ± 0.02 vs. $0.12 \pm 0.01 \times 10^6/mm^3$). When considering the neuronal density of the GPi ($2.69 \pm 0.18 \times 10^3$ neurons/mm^3) and the GPe ($3.47 \pm 0.15 \times 10^3$ neurons/mm^3), our data indicate that the ratio of TH+ axon varicosities/pallidal neuron is two times higher in the GPi (68 ± 15) than in the GPe (28 ± 3). Our electron microscopic analysis reveals that the TH+ axon varicosities in the GPi are significantly larger than those in the GPe. Moreover, the TH+ axon varicosities observed in the GPi are significantly larger than unlabeled profiles selected at random. All TH+ axon varicosities detected in the GPi and GPe are filled with synaptic vesicles, but very few are engaged in synaptic contacts ($15 \pm 4\%$ in the GPi and $17 \pm 3\%$ in the GPe). These rare synaptic contacts are of the symmetrical and asymmetrical type in equal proportions. Large myelinated TH+ axons also occur in both pallidal segments. Our ultrastructural analysis shows that DA axons can either directly modulate pallidal neurons through synaptic contacts, or indirectly through volume transmission. This diffuse mode of release may allow DA to bind on postsynaptic receptors located on pallidal neurons, as well as on presynaptic receptors located on incoming pallidal afferents. Our findings provide a detailed picture of the regional distribution and fine morphological features of the DA innervation of the primate pallidum. They indicate that, in addition to the action they exert at the striatal level, nigral DA neurons have a direct access to pallidal neurons and their afferents, including neurons of the GPi, which are major output elements of the basal ganglia.

Title: Distribution of GABA-A receptor alpha 1 subunit and GABA-B receptor R2 subunit immunoreactivities in the pedunculopontine and laterodorsal tegmental nuclei in the rat

Authors: *E. LUQUIN, B. PATERNAIN, E. MENGUAL;
Dpto. Anatomia, Fac. De Medicina, Univ. De Navarra, Pamplona, Spain

Abstract: The pedunculopontine tegmental nucleus (PPTg) is a brainstem target of basal ganglia output particularly implicated in gait and posture. Deep brain stimulation of the PPTg in Parkinson's disease patients has provided partial alleviation of gait disorders, although the mechanism of action of this therapy is not fully understood. This could be partly due to the lack of anatomical data about the fine circuitry in PPTg and the associated laterodorsal tegmental nucleus (LDTg). The output projections of the basal ganglia are GABAergic, and the presence of functional GABA-A and GABA-B receptors in PPTg and LDTg has been pharmacologically and electrophysiologically demonstrated; however, their postsynaptic localization has not been determined yet. PPTg and LDTg comprise intermingled cholinergic, GABAergic and glutamatergic cells, although previous anatomical studies suggest that the targets of pallidotegmental and nigrotegmental projections are largely non-cholinergic cells. As a first step to understand the neural circuitry within these two nuclei we investigated the localization of GABA-A and GABA-B receptors in PPTg and LDTg. Thus, coronal brainstem sections were first processed for NADPH-diaphorase (NADPH-d) staining to establish PPTg and LDTg boundaries, followed by immunoreactivity against either GABA-A receptor alpha 1 subunit (GABAA-alpha1-ir) or GABA-B receptor R2 subunit (GABAB-R2-ir). GABAA-alpha1-ir was light in both nuclei, whereas GABAB-R2-ir was moderately dense in both the neuropil and cell bodies. The potential localization of GABAB-R2-ir in cholinergic (NADPH-d positive) cells observed at the light microscope was confirmed at the confocal microscope using dual immunofluorescence. The quantitative analysis of dually labeled neurons revealed that around 80% of PPTg and LDTg cholinergic cells were also GABAB-R2-immunoreactive (GABAB-R2-ir). Triple labeling using the neuronal marker NeuN showed that 90-95% of GABAB-R2-ir profiles were also NeuN-immunoreactive; thus, in the final series NeuN-ir was not included and all GABAB-R2-ir elements were quantified as neurons. The quantification revealed that GABAB-R2-ir neurons were approximately 2:1 and 4:1 in relation to cholinergic neurons in PPTg and LDTg, respectively. These data provide anatomical evidence of the presence of postsynaptic GABAB receptors in both cholinergic and non-cholinergic neurons in PPTg and LDTg, supporting a potential direct innervation of the two subpopulations by both pallidotegmental and nigrotegmental fibers.

Title: Direct dopaminergic regulation of autonomous and cortically patterned activity in the subthalamic nucleus

Authors: *A. LAHIRI, H.-Y. CHU, M. D. BEVAN;
Northwestern Univ., Chicago, IL

Abstract: The subthalamic nucleus (STN) is a key gatekeeper of information flow through the cortico-basal ganglia-thalamo-cortical circuit. In addition to facilitating cortically driven basal ganglia output via the indirect and hyperdirect pathways, STN neurons exhibit a high degree of autonomous activity and receive direct neuromodulatory input from substantia nigra dopamine neurons that degenerate in Parkinson's disease (PD). We have used a combination of dopamine receptor-selective drugs and optogenetic stimulation of cortico-subthalamic (M1-STN) afferents in mouse brain slices to investigate the effects of dopaminergic neuromodulation on autonomous and synaptically patterned activity in the STN. Exogenous dopamine (0.1 - 50 μM) elicited a dose-dependent increase in the frequency of STN neuron autonomous firing. This effect was reproduced by co- but not individual application of D1-like (SKF 81297) and D2-like (quinpirole) dopamine receptor agonists, consistent with postsynaptic expression of D5 and D2 receptors, respectively. We are currently working to validate these findings through optogenetic stimulation of ChR2(H134)-expressing dopaminergic axon terminals in the STN, and by blocking the dopamine-dependent increase in autonomous activity using D1/5 (LE 300) and D2/3 (sulpiride) antagonists. Motor cortical afferents in STN express D4 receptors and are also subject to neuromodulation by dopamine. Exogenous dopamine reduced the amplitude of EPSC1 upon optogenetic paired-pulse stimulation of M1-STN axon terminals. Application of a D4 agonist (PD 168077) mimicked this effect and also produced an increase in the paired-pulse ratio, suggesting that dopamine can activate presynaptic D4 receptors to reduce the initial probability of M1-STN glutamate release. Experiments are in progress to block this presynaptic effect with a D4 antagonist (L-745,870). With the loss of dopamine in PD, M1 and STN exhibit abnormal, synchronous beta band activity. To test the impact of dopaminergic neuromodulation on cortical patterning of STN activity, M1-STN axon terminals were optogenetically stimulated at 20 Hz for 1 second in the presence and absence of 0.5 μM dopamine. Dopamine significantly reduced cortical excitation of STN neurons (control = 10.6 spikes; dopamine = 4.6 spikes; $n = 9$; $p < 0.05$) while elevating STN autonomous firing (median frequency change = 8.5 Hz).

Together, these findings support a direct role for dopamine in regulating autonomous activity, glutamatergic transmission and synaptic integration in the STN. Loss of direct dopaminergic neuromodulation may contribute to excessive M1-STN patterning in PD.

Title: Specialized populations of substantia nigra neurons mediate basal ganglia output signaling to brainstem and thalamus

Authors: ***L. E. MCELVAIN**, R. M. COSTA;
Champalimaud Ctr., Lisbon, Portugal

Abstract: The basal ganglia are a network of subcortical nuclei involved in the learning and performance of diverse behavioral actions. Despite their broad importance for behavior, how the basal ganglia ultimately influence downstream circuitry to mediate specific motor, cognitive, and emotional functions remains poorly understood. Here, we investigate the largest output nucleus, the substantia nigra pars reticulata (SNr), to delineate the organization of basal ganglia efferent signaling. Using a combination of anatomical tracing methods and electrophysiological recordings, we 1) define the complete set of brainstem and thalamic regions targeted by SNr, 2) map the extensive collateralization patterns of SNr projections, and 3) characterize the intrinsic electrophysiological properties and topographical organization of independent SNr projection populations. Anterograde tracing from GABAergic and parvalbumin-positive SNr neurons in mice revealed major projections to the: superior colliculus; inferior colliculus; midbrain, pontine, and medullary reticular formations; PPN; dorsal raphe; and thalamic nuclei VM, VA, MD, and Pf. To determine whether specific SNr cell types project to each target, retrograde tracers were injected into downstream structures, and following a 3-4 day survival, whole-cell patch-clamp recordings were targeted *in vitro* to labeled SNr neurons. All SNr neurons shared several features: spontaneous firing, sustained fast-firing (>50 Hz) capabilities, and linear firing rate responses to depolarizing currents. However, neurons projecting to brainstem targets differed significantly from each other and exhibited specialized intrinsic electrophysiological characteristics, including differential sensitivity to input currents, capacity to sustain firing, passive properties, and hyperpolarization-gated currents. Brainstem-projecting SNr neurons were topographically organized and, in some cases, morphologically distinct. In contrast, thalamus-

projecting SNr neurons exhibited heterogeneous electrophysiological and morphological properties and were distributed throughout the nucleus. Mapping of axonal collateralizations from specific SNr neurons revealed that projections to thalamus heavily comprised collaterals from specialized brainstem-projecting populations. These experiments define unique populations of SNr neurons, demonstrate specific and extensive collateralization of projections to thalamus and brainstem, and establish a framework for future investigations linking each SNr output channel to its behavioral functions.

Authors: *Y. MULLIE, I. ARTO, J. LEONARD, T. DREW;
GRSNC Groupe de recherche sur le systeme nerveux central, Dépt De Neurosciences, Univ. De Montréal, Montreal, QC, Canada

Abstract: One of the correlates of Parkinson's disease is a modified locomotor gait characterized by small, shuffling steps and a difficulty in turning. Later stages of the disease are frequently accompanied by freezing of gait. However, despite these effects on locomotion we have little information on the characteristics of neurones in different parts of the basal ganglia circuit during locomotion. In the current study we examined the activity patterns of neurons in the globus pallidus (equivalent to the external segment of the globus pallidus, GPe, of primates) of 2 cats during unobstructed locomotion and during visually guided locomotion, when cats stepped over obstacles attached to a moving belt. Most neurons showed relatively high discharge rates at rest (cat sitting or standing, average = 31Hz, range 10-72Hz) and during unobstructed locomotion. Only a small percentage of these cells (~20%) showed discharge activity that was modulated at the frequency of the step cycle during unobstructed locomotion. However, when the cats stepped over the obstacle, a larger percentage of cells (~50%) showed changes in discharge activity that were phase-locked to the modified cycle. In most cases, this discharge was related to the modified step in the contralateral forelimb but the discharge activity in a few cells was changed during the step over the obstacle by the contralateral hindlimb. Cells were related to

the contralateral forelimb both when this limb was the first to step over the obstacle (lead condition) and when it was the second (trail condition). In this respect the changes are similar to those observed in the motor cortex (Drew 1993). However, in all task-related cells, changes in discharge activity lasted throughout the swing period rather than being fractionated as in the motor cortex in the same task. The results suggest a function for the GPe in modulating the general features of the locomotor motor program rather than in regulating more specific details, such as intralimb coordination. Title: superior colliculus activation has opposing influence on parafascicular and medial posterior thalamic nuclei

Authors: *G. D. WATSON, K. D. ALLOWAY;
Ctr. for Neural Engin., Penn State Univ., University Park, PA

Abstract: The superior colliculus (SC) is known to be a part of a brainstem activating system that reorients attention to salient stimuli. Anatomically, SC sends dense projections to both the parafascicular (Pf) nucleus of the thalamus and to the zona incerta (ZI). The SC projections to ZI overlap with GABAergic neurons that project to the medial posterior (POm) nucleus of the thalamus. We have shown that microstimulating SC inhibits spontaneous activity in POm, putatively through ZI. Previous research has also shown that microstimulating SC activates neurons in the centromedian-parafascicular complex. However, the effect SC stimulation specifically has on Pf in rats has not been well characterized. Therefore we stimulated SC while simultaneously recording from whisker-sensitive regions of Pf and POm. We found that activating SC enhances activity in Pf, while activity in POm is attenuated. These findings support the hypothesis that during a salient stimulus, SC orchestrates Pf and POm in an opposing fashion to influence striatal activity.

Title: Basal ganglia output is not the determinant of movement-related activity in the pallidal-recipient thalamus

Authors: *A. ZIMNIK[1], R. S. TURNER[2];
[1]Neurobio., [2]Neurobio. and Systems Neurosci. Inst., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Most theories of basal ganglia-thalamo-cortical (BG-TC) function assume that this circuit operates by a "gating" mechanism in which movement-related activations of the BG recipient thalamus (the anterior ventrolateral nucleus, VLa) are produced primarily by disinhibitory decreases in firing in the globus pallidus internus (GPi, primary output nucleus of the BG). To test that theory, we recorded single unit activity and local field potentials (LFPs) from the GPi-VLa subcircuit interconnected with primary motor cortex (M1) as determined by the presence of orthodromic and antidromic responses to electrical stimulation in the proximal arm region of M1. We recorded simultaneously from connected regions in GPi and VLa (n=149 and 150 neurons, respectively) in a macaque monkey while the animal performed a choice reaction time reaching task. A comparison of the latencies of movement related changes in firing rate revealed that as a population, changes in VLa firing began earlier than changes in GPi firing (median 52ms lag, $p<0.05$). This temporal relationship was consistent for both sensory-cued and self-initiated movements. Additionally, large proportions of cells in both areas demonstrated peri-movement increases in firing (75% and 86%, respectively) rather than the inverse incidence predicted by the gating hypothesis. Both results are inconsistent with the idea that task-related activity in VLa is a product of GPi-mediated gating. Despite recording from a large number of GPi-VLa pairs (226 to date), only 4% of pairs showed significant spike-to-spike cross-correlations and all of those were of a form inconsistent with a direct driving of VLa activity by decreases in GPi activity. In agreement with our analysis of single-unit data, coherence between LFPs from GPi and VLa was often modulated around the time of movement onset, but the LFPs from VLa phase-led during those changes in coherence. Together, these results suggest that the relationship between GPi and VLa activity is more complicated than the gating model predicts. Our results are consistent with the idea proposed by others that cortico-thalamic inputs are the primary source of VLa task-related modulations in activity. During performance of a well-learned reaching task, the influence of GPi inputs on VLa activity is at most modulatory.

Title: Learning or not? Mechanisms underlying error correction in locomotion

Authors: *R. T. ROEMMICH[1,2], A. W. LONG[1,3], A. J. BASTIAN[1,2];
[1]Motion Analysis Lab., Kennedy Krieger Inst., Baltimore, MD; [2]Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [3]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: Multiple mechanisms are engaged during motor learning, yet it is not understood if and how they interact to improve performance and store new patterns. During walking, people adapt their locomotor pattern on a split-belt treadmill using intrinsic errors signaled by proprioceptive feedback. Yet, extrinsic visual feedback can accelerate error correction during learning. Here we studied how these two error correction processes interact. We collected kinematic data from young adults (n=28) as they walked on a split-belt treadmill. All participants adapted to a split-belt perturbation during which one belt moved twice as fast as the other (Adaptation, belt speeds 1.4 and 0.7 m/s, 10 min) and then underwent a washout period with the belts moving at tied speeds (Deadaptation, belt speeds 0.7 m/s, 10 min). In Experiment 1, the Feedback (FB) group was provided visual feedback of their step lengths at each heel-strike throughout Adaptation. The No Feedback (No FB) group watched a TV show during Adaptation. In Experiment 2, the Short Feedback group was provided similar feedback of their individual step lengths during the first 30 seconds of Adaptation, after which the participants watched TV for the remainder of Adaptation. All groups watched TV during Deadaptation. Participants used the feedback to match their step lengths bilaterally when the feedback was on and walked comfortably when the feedback was off. In Experiment 1, we observed that error correction occurred faster in the FB group than in the No FB group. However, both groups showed similar aftereffects during Deadaptation. We then asked whether faster error correction in the FB group driven by accelerated adaptation or by a different mechanism. In Experiment 2, we found that the removal of visual feedback during Adaptation caused a rapid drop in the amount of error corrected such that performance was similar to the No FB group from Experiment 1. These findings show that visual feedback drives a process characterized by rapid error correction and immediate forgetting whereas a slower, longer-lasting adaptive process builds similarly with or without extrinsic feedback. In sum, we found that intrinsic and extrinsic error feedback drive fundamentally different processes during split-belt treadmill walking. Intrinsic feedback facilitates adaptation, which occurred similarly across all groups. Conversely, extrinsic feedback drives an error correction process that is not adaptation; rather, this is a transient process that

responds to residual error from adaptation but shows no retention in the absence of extrinsic feedback. Supported by NIH grants NS090751 to RTR, NS092241 to AWL, and HD048741 to AJB.

Title: Variations in sensorimotor recalibration suggest multiple components of locomotor learning

Authors: *M. STATTON[1,4], A. VAZQUEZ[2,4], A. J. BASTIAN[3,4];
[2]Dept. of Biomed. Engin., [3]Dept. of Neurosci., [1]Johns Hopkins Univ., Baltimore, MD; [4]Motion Analysis Lab., Kennedy Krieger Inst., Baltimore, MD

Abstract: Recent work has shown that in addition to recalibrating movement, motor learning can lead to temporary changes in perception of limb position and movement. For example, perceived hand position and movement change after reaching adaptation, and perceived leg speed changes after split-belt walking adaptation. Here we discovered that specific perturbation conditions produce different perceptual aftereffects despite similar motor aftereffects following split-belt treadmill adaptation. Young, healthy adults walked on a split-belt treadmill with the “fast” and “slow” belt speeds set at 1.5 m/s and 0.5 m/s respectively. Subjects were randomly divided into three groups that experienced this perturbation either abruptly, gradually (where the belts both started at 0.5 m/s and the “fast” leg was gradually sped up to 1.5 m/s), or abruptly with an extended adaptation time (allowing for more time spent in the adapted state). Leg speed perception was assessed via a novel leg speed matching task, where subjects were asked to manually adjust the right belt speed while walking to match that of the left belt speed (which was held at a constant speed). Consistent with prior work, split-belt adaptation led to changes in leg speed perception such that the “fast” leg during adaptation feels slower afterward, and vice versa. We also found that different perturbation conditions led to similar amounts of motor adaptation, but gradual adaptation produced significantly larger changes in leg speed perception than abrupt adaptation. Additionally, extended abrupt adaptation tended to produce larger changes in leg speed perception compared to shorter abrupt adaptation. These results suggest that distinct mechanisms are involved in locomotor learning, and we hypothesize that one component alters the perception of leg speed similar to what might be expected from a forward model

computation. Importantly, this component responds to different perturbation schedules and is largest when small errors are experienced. Our results also suggest that at least one other learning mechanism is engaged to fully account for the motor learning. Supported by NIH HD048741.

Title: Dynamic postural control and associated attentional demands in contemporary dancers

Authors: G. SIROIS-LECLERC[1], A. REMAUD[3], *M. BILODEAU[1,3,2];
[1]Sch. of Rehabil. Sci., [2]Sch. of Human Kinetics, Univ. of Ottawa, Ottawa, ON, Canada; [3]Bruyère Res. Inst., Ottawa, ON, Canada

Abstract: Purpose: It has been suggested that attentional demands associated with postural control could be decreased if an individual becomes more proficient at performing a given postural task, such as in elite athletes. The aim of this study was to compare dynamic postural control and associated attentional demands between formally-trained contemporary dancers and controls. Methods: Twenty dancers and 16 non-dancers participated in the study. Dynamic postural control was assessed by having participants track a moving target on a screen (target speed = 1.9 cm/s) with the representation of their center of pressure (CoP) by shifting their weight, either side-to-side (ML) or front-to-back (AP), while standing on a force platform. In order to assess attentional demands associated with this postural task, AP and ML postural conditions were performed 1) with no concurrent task or while simultaneously performing 2) simple (SRT) or 3) choice (CRT) reaction time tasks (dual-task paradigm). The reaction time tasks consisted of responding verbally as fast as possible following the presentation of specific auditory tones (SRT: single tone; CRT: high- and low-pitch tones). Postural control was quantified by calculating 1) the average distance (in cm) between the CoP and the target (proximity) and 2) the average CoP velocity (in cm/s) in both the AP and ML directions for each trial. Mixed analysis of variance models were used to determine the effects of mainly: group (dancers/non-dancers), task (single/dual) and direction (AP/ML), as well as their potential interactions. Results: No differences or interactions were observed between dancers and non-dancers with regards to reaction time. For postural control variables, significant group interactions were found. In particular, the proximity value was smaller (closer) for the AP than

the ML direction for dancers, but only for the dual-task trials, whereas such AP/ML difference was present for all conditions in controls. Also, the average CoP velocity was higher in the ML compared with the AP direction in controls, but not in dancers. Discussion: The fact that dancers presented with lesser differences between AP and ML directions compared with controls, particularly for the single task condition, suggests that their training leads to improved dynamic balance control and potentially lesser associated attentional demands.

Title: Effects of auditory cues on sway during postural tasks of varying difficulty in young adults

Authors: *A. REMAUD[1], C. ALLARY[2], C. DESGAGNÉ[2], D. MURPHY[2], F. THIFFEAULT-GAGNÉ[2], V. VAILLANCOURT[2], C. GIGUÈRE[2], M. BILODEAU[1,2];
[1]Aging and Movement Res. Lab., Bruyere Res. Inst., Ottawa, ON, Canada; [2]Sch. of Rehabil. Sci., Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Background. Postural control is usually described as a multisensory process requiring the integration of somatosensory, vestibular and visual inputs. However, some studies have pointed out that the auditory system might also contribute to the control of balance, particularly when vision is removed. While some authors reported a decrease in postural sway when providing participants with auditory spatial cues, others have suggested that such cues could disturb the control of posture. The different postural conditions used in these studies may explain in part these discrepancies. The aim of this study was to examine how auditory spatial cues can influence postural sway during quiet standing tasks of various levels of difficulty. Methods. Twenty participants (11 women; 9 men) were first screened by audiometric testing to ensure they had normal hearing between 250-8000 Hz. They were then asked to stand as still as possible on a force platform during 30-s trials, in a soundproof room. Twelve postural conditions, presented randomly and performed three times, involved combinations of three bases of support (feet together, feet together on a foam surface, single-leg), two visual conditions (eyes opened and eyes closed), and the presence or absence of auditory spatial cues. The latter consisted of two independent sources of white noise delivered at 70 dB by two speakers located on the left and right sides, approximately 0.5 m away from the participant, at ear level. Postural control was

quantified by calculating: 1) the 95% confidence ellipse area (in cm²) of the center of pressure (CoP) displacements and 2) the average CoP velocity (in cm/s) in anterior-posterior (AP) and medial-lateral (ML) directions. Results. The values of the ellipse area did not differ between the silent and sound conditions, regardless of the base of support and visual condition ($p>0.05$). In contrast, higher CoP velocities in both AP and ML directions were observed when auditory spatial cues were added than when the trial was performed in silence, but only in the single-leg stance with eyes closed (AP: 4.89 ± 1.47 cm/s vs. 4.40 ± 0.91 cm/s, ML: 5.52 ± 1.36 cm/s vs. 5.03 ± 0.97 cm/s, respectively; $p<0.001$). Conclusion. This study showed that providing auditory cues (two independent sources of white noise) during postural tasks of easy-to-moderate difficulty does not improve nor disturb postural stability. However, the addition of auditory cues was shown to disturb postural stability during the more challenging postural task.

Title: The effect of cognitive manipulation and gender on the Timed Up and Go (TUG) test

Authors: R. ALMAJID, *E. A. KESHNER;
Dept. of Physical Therapy, Temple Univ., Philadelphia, PA

Abstract: Tasks that require memory and executive function have been shown to affect functional mobility [1,2]. The purpose of this study was to determine if the TUG test could be modified so that it presented attentional demands similar to real-world situations. Five cognitive tasks were performed while seated and during the TUG test to determine effect size and gender differences in 8 healthy male and 8 healthy female adults (25.8±4.9 yrs). Cognitive demands included verbal, mental, reaction, auditory Stroop, and memory tasks. MANOVA was used to compare cognitive performance across tasks, and repeated measures ANOVA was used to compare gait speed, cadence, number of steps, and time to completion. All subjects took significantly more time to complete the modified TUG ($p<0.001$) than the unmodified TUG except with the reaction time task. Gait speed was slower in the modified TUG tests ($p=0.003$) except during reaction time and auditory Stroop tasks. Subjects took significantly more steps ($p=0.01$) with all but reaction time and mental tasks. Results also suggest a gender difference in

cognitive performance both during sitting and the TUG. Women have faster response rates than men in a memory task during sitting (p=0.005) and men are faster than women in the mental task during the TUG test (p=0.01). Women had a significantly higher cadence than men (p=0.008). Although not significant, it was observed that men took greater time via a slower gait speed and fewer steps during modified TUG conditions. Results suggest that TUG combined with cognitive tasks would present a more functional measure of gait performance than the standard TUG test. Cognitive tasks that produce mental interference were more detrimental to spatiotemporal measures of gait. References 1.Al-Yahya E et al. (2011). Title: Neural correlates of attentional demands associated with dual-task walking

Authors: *S. SANGANI[1], T. KURAYAMA[2], J. FUNG[1,3];
[1]Feil/Oberfeld/CRIR Res. Ctr., Jewish Rehabil. Hosp., Laval, QC, Canada; [2]Chiba Univ., Chiba, Japan; [3]Sch. of Physical and Occup. Therapy, McGill Univ., Montreal, QC, Canada

Abstract: Walking while simultaneously performing another task requires divided attention, eg. holding a cup without spilling. Stability control during gait alone requires attention, which may be compromised as the cognitive demand increases. The impact of dual-tasking on biomechanical and neural components is yet to be explored. Our primary goal was to investigate gait pattern changes and the neural correlates of complex dual-task walking using functional near-infrared spectroscopy (fNIRS). Healthy young adults (n=11) and a stroke participant walked on a 3m long force-sensing treadmill (CMill, Motek-Forcelink). Cortical activation was acquired with a NIRScout system (NIRx) using a custom-built cap covering the frontal cortex. The protocol included repeated block trials consisting of four alternating blocks of standing (20s) and walking (25s) at a comfortable speed determined prior to the experiment. Five walking trials were performed, each consisting of four randomized conditions including holding a Styrofoam cup that was empty or filled with water, jelly or hot liquid. Participants held the cup in the dominant or non-paretic hand. Primary outcomes included stride length, step width, stride

duration, center of pressure displacements and gait variability (% coefficient of variation in stride duration). The cortical hemodynamic response was quantified by concentration changes of oxygenated hemoglobin (oxyHb) in the frontal cortex. Cortical response maps were determined based on the general linear model using SPM (nirsLAB). Walking with a cup filled with hot liquid was associated with a slight decrease in step width and gait variability in all healthy participants but not the stroke individual. The decrease in step width suggests that all subjects adapted to the back-and-forth slosh frequency of the fluid by adjusting their gait so as to suppress the resonant slosh frequency thereby preventing any spillage. In healthy controls, walking while holding jelly was associated with activation of the supplementary motor area (SMA), whereas holding hot liquid resulted in activation of the premotor cortex (PMC) and dorsolateral prefrontal cortex (DLPFC), which are associated with selective attention. Cortical activation in the stroke participant demonstrated increased activation in the contralesional DLPFC and medial SMA while walking and holding either jelly or water. Absence of significant changes in biomechanical gait parameters suggests that during complex dual-task locomotion, the brain can allocate the required cortical resources to account for increased attentional demands without modifying the inherent locomotor pattern.

Title: Effects of partially removed visual feedback on gait symmetry

Authors: ***S.-J. KIM**[1], K. GRAHAM[2];
[1]Mechanical & Bioengineering, [2]Bioengineering, California Baptist Univ., Riverside, CA

Abstract: Patients suffering from neurological disorders often receive treadmill training as part of their rehabilitation. Incorporating elements of visual feedback (VF) have been shown to increase the effectiveness of treadmill training. We have previously shown that the distortion of VF of step length entail unintentional modulations in gait symmetric pattern. In this paradigm, the VF consisted of two vertical bars representing the subject's right and left step lengths displayed on a computer screen and also distorted so that subjects perceived their step length as being asymmetric during treadmill walking. We found that a gradual distortion of VF systematically modulated gait step length away from symmetry. In this study, we explored the effect of a different paradigm of VF by investigating whether the absence of a portion of VF had any impact on gait patterns. In pilot experiment, ten healthy subjects were asked to watch the screen and walk comfortably on the treadmill for two 8-minute trials. The treadmill's speed was

changed during both trials. The first trial increased in speed from 1.3 mph to a peak speed of 2.7 mph midway through the trial, before decreasing in speed to 1.3 mph once more. The second trial began at 2.7 mph and decreased to 1.3 mph midway through the trial before increasing back to 2.7 mph. All the speeds were adjusted by 0.2 mph at 30 seconds intervals (the change in speed profile during the first half of the trial exactly mirrored the change in speed profile during the second half of the trial). After 4 minutes (midway through each subject's trial), only the left vertical bar continued to be displayed. This change in visual perception caused each subjects to modulate his or her gait symmetry. However, subjects displayed two different trends. The more prominent trend (64% of trials) was one in which subjects' right steps became longer than their left steps. The less prominent trend (36% of trials) was that subjects' right steps became shorter than their left steps. We also found that subjects had a greater response at lower walking speeds, which suggests that the observed gait asymmetry may not be simply an aftereffect produced in response to any change in VF since the slower speeds were conducted at different times between the two trials. This result suggests that when the method of VF is altered, such as in displaying step length information for only one leg rather than both legs, subjects respond by spontaneously modulating their gait. If this continues to be shown true, this technique could be used to alter patient's gait patterns by simply removing a portion of VF. The results of this study may contribute to more effective implementation of VF for treadmill rehabilitation.

Title: Cognitive factors influence postural alignment

Authors: *J. L. BAER, A. Q. JOHNSON, R. G. COHEN;
Univ. of Idaho, Moscow, ID

Abstract: BACKGROUND: Stooped posture with the head forward of the torso is associated with multiple health problems, including headaches and neck pain, reduced upper body strength and mobility, and impaired postural control. Neither physiological nor ergonomic factors are sufficient to explain the prevalence (two of three adults aged 65 or older) of stooped posture, so we are investigating the influence of cognitive factors. Previous research has linked postural control to cognitive factors (especially executive function and attention), but the link between

postural alignment and cognitive factors is almost unexplored. We recently found a correlation between inhibitory control and upright posture, in both healthy older and young subjects. HYPOTHESIS: Cognitive factors play causal role in maintaining upright posture, both (1) in ongoing tasks, and (2) at the onset of goal-directed action. APPROACH: Young, healthy subjects were presented with simple postural/motor tasks while the level of cognitive challenge was manipulated. 3D motion capture data were collected to analyze the influence of cognitive factors on postural alignment. Study 1: Subjects sat and played an easy and hard computer game for 5 minutes with no motivational instruction, then repeated the task with incentive to focus on either their posture or task performance. Study 2: Subjects walked to grasp a target at either a leisurely or hurried pace, with or without instruction to pay attention to their posture. Cognitive tests and questionnaires were also administered. RESULTS: Overall, subjects sat and stood more upright when given incentive to attend to their posture. Study 1: Instructing subjects to prioritize task performance caused stooped posture only during the difficult task. Stooped posture was positively correlated with both state and trait anxiety, and with neck pain. Study 2: When preparing to walk, stooped posture became evident, regardless of whether subjects were hurrying or not. Poor inhibitory control (false alarms in a go-nogo task) was correlated with stooped posture overall and with increased neck compression in the rushed condition. CONCLUSION: Cognitive factors affected postural alignment both when preparing for movement and during extended computer tasks. Anxiety, task difficulty, and inhibitory deficits were all associated with stooped posture, while attention to posture diminished the effects.

Title: Effects of attentional dispersion on event-related brain potentials and postural muscle activities during unilateral arm abduction with neck flexion

Authors: *C. YAGUCHI[1], K. FUJIWARA[2];
[1]Dept. of Physical Therapy, Fac. of Human Sci., Hokkaido Bunkyo Univ., Eniwa, Japan; [2]Fac. of Sports and Hlth., Kanazawa Gakuin Univ., Kanazawa, Japan

Abstract: A flexed neck position leads to non-specific activation of the brain. These effects were investigated only when attention was focused to the task. Attentional allocation has capacity limitation, and when attention is divided to multiple objects, the allocation to an object

decreases. Moreover, attentional function is affected by activation state. Thus, the brain activation by neck flexion would change according to attentional dispersion. We investigated the effects of attentional dispersion on event-related potentials and postural muscle activities during unilateral arm abduction with neck flexion. Subjects were 13 healthy adults. A visual cue signal (S1) was presented for 100 ms around the fixation point. At 1 s after S1 onset, a visual imperative stimulus (6°×6° checkerboard, S2) was presented for 150 ms at 9° to the left or right from the fixation point. Interval between S1s was 3.5 s. S2 comprised target and non-target stimuli presented at the position indicated by S1. If S1 simultaneously indicated two positions, S2 was presented unpredictably at one of the two positions with the equal probability. Subjects covertly focused attention on the position (attentional focusing) or divided attention to two positions (attentional dispersion). In response to the target S2, subjects abducted their right arm at maximum speed. This task was performed with the neck resting and flexion postures. The onset time of postural muscles with respect to middle deltoid onset and the following components of event-related brain potentials were measured. P1-N1, N2 and P3 components were analyzed as indices of the sensory, perceptual and cognitive processing of S2, respectively. The late component of contingent negative variation (CNV) was used to evaluate motor preparation before S2 and anticipatory attention directed to S2. With attentional focusing, CNV potential significantly increased, and N2 and P3 latencies shortened by neck flexion ($p < 0.05$). With attentional dispersion, P1-N1 amplitude significantly increased by neck flexion ($p < 0.05$). The onset time of postural muscles became earlier with both attentional focusing and dispersion ($p < 0.05$), but the earliness was significantly larger with attentional focusing than with attentional dispersion ($p < 0.05$). These results suggest that by neck flexion, the brain areas related to higher cognitive processing, anticipation of S2 and motor preparation were activated with attentional focusing, and that of sensory processing of S2 was activated with attentional dispersion. These changes of the sensory-motor processing by neck flexion would relate to the earliness of onset time of postural muscles.

Title: Coherence of center-of-mass and center-of-pressure velocities may reveal influence of increased attentional demand on postural control

Authors: *K. TERRY, J. TO-ALEMANJI, P. JO;
Rehabil. Sci., George Mason Univ., Fairfax, VA

Abstract: This study examined the interaction between postural control and attentional demand as quantified by the dynamics of the body's center of mass (COM) and each foot's center of pressure (COP). After screening 19 healthy participants (6 F/13 M, 24.4 ± 4.7 yrs.) for balance and mobility deficits , each individual stood quietly with eyes open (EO) or closed (EC) on either the floor (FL) or a 2-1/2" thick foam pad (FM). Additionally, attentional demand was increased by having each individual also maintain their standing balance while counting backward by 10 or 7. Each of the 12 condition combinations (2 vision x 2 surface x 3 counting) was repeated 3 times for 36 trials. COM displacement, velocity, acceleration were measured using an integrated measurement unit placed on the lumber spine (APDM, Inc.). COP locations were measured using a pair of pressure-mapping shoe insoles (Pedar, Inc.). COP velocity was calculated using a central difference derivative. To examine COM-COP interaction, COM-COP velocity coherence was calculated and sorted by each condition combination. Overall, group mean coherences for both feet were significantly lower for the EO-FL as compared to the EC-FM condition when no counting was performed. However, for both counting tasks, this difference was no longer present. For the right foot (the dominant foot for all but one participant), counting tasks produced significantly higher EO-FL COM-COP coherences that were also similar to those for the other three vision/support surface combinations. Likewise, there were significant regressions between COM-COP coherence and COM rms velocity ($R2=0.22-0.26$, $p<0.001$) for the EO-FL condition while counting. These findings indicate additional volitional postural control for the EO-FL condition may be required as attentional demand is increased. Conversely, the lack of significant differences for the other three vison/surface combinations indicates that the introduction of increased attentional demand did not significantly affect postural control and that postural control was prioritized over performance of the counting task. Also, despite the much slower counting rate for the count by 7 condition, there were no significant differences in coherence, which suggests that counting difficulty was not a moderator of attentional demand effects on postural control. Caution should be taken in interpreting these results, however, as comparison of each participant's mean coherences and bootstrapped confidence intervals revealed unique relationships between coherence and various standing balance conditions, suggesting that attentional demand effects on postural control are highly individual.

Title: Dissociation of parietal cortex contributions to obstacle memory in walking cats

Authors: *C. WONG[1], K. G. PEARSON[3], S. G. LOMBER[2];
[1]Grad. Program in Neurosci., [2]Brain and Mind Inst., The Univ. of Western Ontario, London, ON, Canada; [3]Univ. of Alberta, Edmonton, AB, Canada

Abstract: A working memory of environmental obstacles is essential for avoidance in walking mammals. In quadrupeds, vision is unavailable to guide hindleg stepping over an obstacle previously cleared by its forelegs. Instead, visual information about the obstacle and motor information about foreleg clearance are held in memory to modify hindleg movements. Previous studies suggest that this memory system relies on parietal areas associated with sensorimotor integration. To examine the role of parietal cortex in obstacle memory, cortical cooling was used to reversibly deactivate areas 5 or 7 in cats trained to step over an obstacle with their forelegs and pause for a variable delay period before resuming locomotion. While visual input of the obstacle was permitted to guide foreleg clearance in some trials, a tactile variation of the test relied on tactile input to the forelegs to guide hindleg stepping over the remembered obstacle in the absence of visual input. Hindleg step height and trajectory over the obstacle were measured to assess memory. In both visual and tactile variations, bilateral deactivation of area 5 resulted in significantly lower steps and altered trajectories, demonstrating a disregard for the obstacle. In contrast, hindleg stepping was unaffected when area 7 was bilaterally deactivated in both variations. When area 5 cooling was restricted to the delay phase when obstacle memory must be maintained, similar stepping deficits were observed regardless of sensory input type. In the tactile obstacle memory test, restricting area 5 cooling to the memory acquisition phase (approach and foreleg clearance) also produced similar memory deficits, demonstrating the necessity of area 5 to all phases of the tactile test. However, obstacle memory was restored when deactivation was limited to the memory acquisition phase of the visual test. Furthermore, when area 5 was deactivated and reactivated within the memory maintenance phase, stepping was demonstrative of intact obstacle memory. Inputs from other areas may be responsible for restoring obstacle memory if area 5 is reactivated during memory maintenance. Together, these results demonstrate that area 5 is necessary, but not sufficient for visually-guided obstacle memory.

Title: Effects of light-induced modulation of the neuronal activity in the lateral cerebellar nucleus on locomotor-related discharges of motor cortex neurons in the cat

Authors: *V. MARLINSKI, I. N. BELOOZEROVA;
Barrow Neurolog. Institute. Div. of Neurobio., Phoenix, AZ

Abstract: During locomotion, the activity of neurons in the lateral cerebellar nucleus (LCN) is modulated with the step cycle. The LCN gives rise to cerebello-thalamo-cortical pathways, which are hypothesized to convey locomotor-related signals to motor cortex (MC). The goal of this study was to elucidate impact of LCN activity on locomotor-related discharges of motor cortex neurons. A cat was trained to walk on the treadmill, and surgically prepared for chronic experiments. Using extracellular recordings, hindlimb-related areas in the LCN and MC were identified. The LCN area was infected with a 50/50 mixture of rAAV5-CAG-ArchT-tdTomato and rAAV5-CAG-ChR2-GFP (UNC Vector Core): 6 injections of 1 µL spaced 0.5 mm apart. Two months later, 6 fiber-optic cannulae (125 µm, Doric) were inserted into sites of injections. During recording experiments, cannulae were connected to lasers (MGL-FN-561nm-100mW and MBL-III-473nm-150mW, OptoEngine) via an optical cable (ThorLabs). During locomotion, the activity of MC neurons was recorded, while the LCN was transiently illuminated with yellow (1.3 s pulses, 10 mW) or blue light (1.3 s trains of 2 ms 50/s pulses, 10 mW). Illumination intensity was verified with the Optical Power Meter (ThorLabs). Postmortem histological examination revealed that, on each of 40 µm sections through the LCN, ~10 neurons located within 1 mm distance from the injection side expressed tdTomato, and a few neurons and glial cells expressed GFP. All labeled cells were located in the dorsal or dorso-lateral part of the LCN extending 1 mm anterio-posteriory, 1 mm medio-laterally, and 0.5 mm vertically. Effects of light-induced modulation of the activity of the LCN on the firing behavior of 19 MC neurons during locomotion were analyzed. Nine MC neurons (47%) responded to LCN stimulation. Six changed their activity during illumination with blue light and 6 with yellow light. Three neurons of each group responded to both lights. All neurons responding to blue light increased their firing rate. Changes in the activity of neurons responsive to yellow light were diverse. In 4 of these neurons the firing activity decreased, and in 2 of them increased. In all neurons, differences in the locomotor-related activity were expressed as moderate changes in the average firing rate and/or in the amplitude of stride-related modulation of the firing activity. Temporal patterns of the firing during the stride were not affected. The study shows that optogenetic technique can be successfully used for transient modulation of neuronal activity in the feline brain. The results suggest that even small groups of LCN neurons can effectively modulate the locomotor-related activity in the MC.

Title: Using reward to access the limits of locomotion in a rodent-robot interaction paradigm

Authors: *D. LOGAN, J. VANLOOZEN, R. ESPAÑA, S. F. GISZTER;
Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Measures of motor behavior such as number of lever presses or motion speed have been used to study tradeoffs of motivation for reward, effort and value in a neuroeconomic framework. Here we introduce a framework which uses reward-based learning to investigate how much an animal is willing to alter locomotion (i.e., central patterns with high spinal involvement) for reward. We investigated if animals consistently learn to increase the global variable of pelvis height during treadmill locomotion to receive electrical stimulation of the medial forebrain bundle (MFB), and the long term effects of such learning. SD rats (n=5) were implanted with a bipolar stimulating electrode aimed at the MFB and a pelvis orthosis. This pelvis orthosis connected to a gimbal attached to a phantom haptic robot so the pelvis height of the animal could be monitored in real time. Animals received reward (25 pulses at 60 Hz with 2 msec width) when their pelvis reached a specified offset height. Animals were given at least three weeks to recover from implant surgery and then completed 3 days (2x 10 min each day) of locomotor training on a treadmill with no reward given. Following this baseline training, animals began the shaping process of learning to walk with a higher pelvis for reward. This consisted of sessions (~2-3 per week) where a 3 minute baseline trial without reward was followed by 2 minute reward trials where offset height was progressively increased from trial to trial until the animal no longer received a single reward during a 2 minute trial. Offset heights were chosen as intervals (1.75, 2, 2.25, etc.) of each specific animal's standard deviation of pelvic height during the initial baseline trial. Significant change was determined from comparisons (dependent samples t-test, $p<.05$) of pelvis height during reward trials compared to the baseline trial of that session. All animals have shown the capability to successfully and progressively raise their pelvis in the majority (79% on average across animals) of these reward sessions. On average across subjects, animals were able to simultaneous raise pelvis significantly and receive reward at a maximum offset of 3.4 standard deviation units from initial baseline levels. Our long-term goal is to standardize this shaping procedure to investigate the interaction, and potentially effort-value trade-offs, among reward and energetic and coordinative changes in the locomotive behavior. Doing so may provide a model system for studying the neuroeconomics of locomotion, a more automatic component of movement, in relation to novel skills, and a novel way to evaluate the usefulness of reward-driven plasticity in locomotive rehabilitation.

Title: Goal-directed locomotion in post-stroke unilateral spatial neglect

Authors: *T. OGOURTSOVA[1], P. ARCHAMBAULT[2], A. LAMONTAGNE[2];
[1]McGill University, Sch. of Physical and Occupati, Montreal, QC, Canada; [2]Sch. of Physical and Occup. Therapy, McGill Univ., Montreal, QC, Canada

Abstract: Unilateral spatial neglect (USN), a highly prevalent post-stroke impairment, has been shown to affect the recovery of locomotion. Our current understanding of goal-directed locomotion control in post-stroke USN, however, is poor and existing literature lacks consensus on the expression of the deficits. Goal-directed reaching accuracy to remembered, as opposed to actual seen objects, is also more affected by USN. Whether such distinctions exists for goal-directed walking remains to be explored. We examined goal-directed locomotion abilities to different target locations in chronic stroke subjects with USN (USN+) and without (USN-). Sixteen individuals, aged 56.9 ± 8.1 (USN+, n=9), and 58.6 ± 12.8 (USN-, n=7) participated in the study. Subjects were asked to walk to actual targets and remembered target locations, represented by 3D spheres, located at 7m and at -15, 0, or 15° from the midline, while immersed in a richly-textured virtual room viewed though a head mounted display. Fifteen trials per target condition were performed. Endpoint heading errors (difference in orientation between actual and ideal trajectory) were examined at 5m of forward displacement. Heading errors for the USN- group ranged from 0.4 ± 1.9° to -2.4 ± 3.8° for the actual target condition, and from -0.3 ± 4.7° to -1.0 ± 4.5° for the remembered target condition. USN+ participants displayed heading errors that resembled those of the USN- group for the middle (-1.9 ± 4.3°/-1.9 ± 4.8°, actual/remembered) and right target locations (0.9 ± 5.7°/-1.4 ± 4.9°), both for the actual and remembered conditions. For the left target location, however, they showed larger heading errors (-4.8 ± 2.9° / -4.5 ± 4.8°, actual/remembered) than the USN- group. Findings indicate that the presence of post-stroke USN alters goal-directed locomotion abilities, especially when walking towards targets located in the left (neglected) hemispace. Results collected so far, however, do not support the presence of larger deficits in response to remembered target vs. actual targets, as reported previously for goal-directed reaching. Possible reasons for the latter finding include the use of a different spatial frame of reference in reaching and walking, as well as a different expression of USN in near (within arm reach) vs. far space.

Title: Does awareness of split-belt perturbation reduces the generalization of treadmill-learning to over ground walking?

Authors: D. M. MARISCAL, P. A. ITURRALDE, *G. TORRES-OVIEDO;
Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Previous studies have demonstrated that awareness of external perturbations affecting our movements results in faster motor adaptation to such perturbations (e.g., Malone and Bastian 2010). Here we ask whether awareness of external perturbations has an effect on the generalization of adapted movements to different situations. We reason that if we are aware of the source perturbing our movements we might be able to contextualize motor corrections to that situation and, thus, generalize less the adapted movements to other conditions. To test this hypothesis, we compared the generalization of movements adapted on a split-belt treadmill to natural over ground walking when awareness of the split-belt (external) perturbation was manipulated. Three groups (n=7 each) were tested with distinct awareness conditions: 1) an "awareness" group (24.0±2.6 yr.), 2) a "distracted" group (26.14± 3.0 yr.), and 3) a control group (24.29±2.7yr.). The "awareness" group walked on the split-belt treadmill while subjects looked at a screen displaying the speed at which each belt was moving. The "distracted" group walked on the split-belt treadmill while subjects performed a cognitive task requiring them to count the number of times they heard a stimulus that appeared at random instances. Finally, the control group walked on the split-belt condition without any visual feedback or distractor. All groups walked over ground and on the treadmill with both belts moving at the same speed for a baseline condition. Then, all groups experienced a gradual split-belt perturbation (i.e., gradual change from 1:1 to 2:1 speed ratio) because this type of adaptation induces generalization (Torres-Oviedo and Bastian 2012) and we tested if awareness of the perturbation would reduced it. Adaptation effects (i.e., after-effects) were assessed on the treadmill when the two belts moved at the same speed and over ground following split-belt walking. Kinematic data were recorded to characterize the after-effects of step symmetry, which is an inter-limb gait parameter known to adapt after split-belt walking (Reisman et al. 2005). One-way ANOVA was used to compare after-effects on the treadmill and over ground across groups. We found that all groups had similar after-effects on the treadmill ($p=0.84$) and over ground ($p=0.73$), regardless of the awareness condition they experienced. Our results indicate that the generalization of adapted movements across different contexts is not affected by awareness of the perturbation adapting our movements. Therefore, context-specificity of motor adaptation is not modulated consciously, but is implicitly regulated by the motor system.

Title: Dynamic entrainment of human walking to external mechanical perturbations

Authors: *J. OCHOA[1], D. STERNAD[3,4,5], N. HOGAN[1,2];
[1]Mechanical Engin., [2]Brain and Cognitive Sci., MIT, Cambridge, MA; [3]Biol., [4]Electrical and Computer Engin., [5]Physics, Northeastern Univ., Boston, MA

Abstract: The concept of a central pattern generator as a fundamental rhythmic movement primitive has found support in animal locomotion. Our recent research on human locomotion demonstrated dynamic entrainment to external periodic perturbations during treadmill walking, evidence of an underlying limit-cycle oscillator. To further explore that oscillator, this study tested the effect of periodic perturbations during overground as well as treadmill walking. Healthy subjects walked overground and on a treadmill while receiving periodic perturbations at the ankle joint via a wearable robot that was programmed to exert short square plantarflexion torque pulses. Prior to the experiment, subjects' preferred stride period was measured and the perturbation periods were set to be 50ms faster and slower than preferred. On each of 4 trials, subjects walked 15 strides without perturbation; 50 strides with perturbation; and continued walking for 20 further unperturbed strides. Subjects performed a distractor task to minimize voluntary adaptation. To assess entrainment and phase-locking, subjects' knee angles were measured. Entrainment to both slower and faster perturbations was observed during both overground and treadmill walking, evidenced by a near-constant phase of maximum knee flexion with respect to the perturbation pulse. Entrainment to faster perturbation periods occurred after 15-20 cycles and with little phase variability. Entrainment to slower perturbations only occurred after 35 perturbation cycles and showed greater phase variability. This pattern was also observed

during treadmill walking, although entrainment to faster perturbations was delayed and accompanied by more phase variability. In all trials phase-locking occurred with the perturbation pulse at 'push-off' (~50% of the gait cycle) suggesting that subjects assumed a phase relation such that the perturbation assisted propulsion. After perturbations were discontinued, the entrained walking period persisted for at least 20 strides in both overground and treadmill walking. These observations indicate the presence of a nonlinear limit-cycle attractor underlying human locomotion. They are consistent with a neuro-mechanical periphery that instantiates a dynamic primitive in the form of a semi-autonomous oscillator. That dynamic primitive appears to be capable of generating rhythmic locomotion with minimal intervention from higher centers of the nervous system. This subtle modification of walking period and its persistence suggests a new avenue for gait rehabilitation of patients with neurological impairments.

Title: Computer simulation of a brain-musculoskeletal dynamical model for bipedal walking towards personalized rehabilitation

Authors: *D. ICHIMURA[1,2], S. YANO[2], T. YAMAZAKI[1];
[1]Grad. Sch. of Informatics and Engin., The Univ. of Electro-Communications, Chofu/Tokyo, Japan; [2]Rehabil., Tamagawa hospital, Chofu/Tokyo, Japan

Abstract: Rehabilitation is repetition of trial-and-error. For each patient,physical therapists test different rehabilitation methods until they find an effective one for the specific patient. This process could be long and painful. If we can eliminate the trial-and-error process, this will be beneficial for the patients. A potential way is computer simulation of rehabilitation with a personalized computer model for each patient. It is possible to build a brain-musculoskeletal model that takes conditions of a specific patient into account, and test rehabilitation to the model on a computer by simulation. Thus, once estabilished, a personalized brain-musculoskeletal model will provide a means to reduce the cost and pain in rehabilitation, which would realize taylor-made rehabilitation for individual patients. In this study, we built a brain-musculoskeletal dynamical model, which is composed of simulated central pattern generators that generate a gait pattern for multiple joints, a cerebellar model that predicts timing of foot contact on the ground, and a musculoskeletal model of a body. We conducted computer simulation of bipedal walking

using the model. We introduced certain delay in proprioceptive feedback signals, especially from the foot to detect the ground contact. During the initial phase of walking, the cerebellum learned the timing of foot contact on the ground, and after that stable bipedal walking was realized. We observed that when one hemisphere of the cerebellum was removed, the foot at the damaged side was lifted larger than that at the other side. We also observed that increasing the torque at hip joints of both sides was effective for robust gait, which seems consistent with a traditional rehabilitation method. Finally, we observed similar abnormal foot lifting in cerebellar damaged patients. These results suggest that the cerebellum plays an essential role in smooth gait control, and that it is possible to build a brain-musculoskeletal model for an individual patient for taylor-made rehabilitation.

Title: Keeping in step: Entrainment of theta and low-gamma activity in the brain with gait rhythm

Authors: *J. WAGNER[1], S. MAKEIG[2], C. NEUPER[1], G. MUELLER-PUTZ[1];
[1]Inst. for Knowledge Discovery, Graz Univ. of Technol., Graz Univ. of Technol., Graz, Austria;
[2]Inst. for Neural Computation, Univ. of California San Diego, San Diego, CA

Abstract: Cortical processes occurring during upright human gait are not yet well studied. Source-resolved analysis of high-density electroencephalographic (EEG) data is a promising approach to monitoring brain activities supporting walking. In two recent studies, we investigated spectral patterns of high-density EEG data from able-bodied volunteers in a robot-assisted gait-training experiment. Using independent component analysis (ICA), we were able to show that lower gamma band modulations (24-40 Hz) in premotor cortex are timed to the gait cycle (Wagner et al., 2012; Wagner et al., 2014). It has been previously shown that oscillations in auditory and motor cortices may entrain to external rhythms, and this mechanism has been connected to the encoding of temporal information. Predictive timing is essential when performing rhythmic movements. We will present results from a third study in which we examined the EEG of participants attempting to step in time to an auditory pacing tone sequence. Subjects had to adapt their step length and rate to shifts in tempo of the pacing stimulus (e.g., following unforeseen shifts to a faster or slower tempo). The analysis revealed that during steady

state walking lower gamma (25-40 Hz) and theta (4-8 Hz) modulations entrain to the rhythm of walking in auditory and motor areas. Calculation of the modulation index (Canolty et al., 2006) shows that the gamma modulation is coupled to the phase of the theta rhythm. Unexpected shifts of tempo in the auditory pacing sequence perturbs these neural rhythms. It has been previously proposed that neural oscillations are hierarchically coupled, i.e. low-frequency cortical oscillations can phase-lock to rhythmic external events while high-frequency cortical activity is largest at phases crucial to processing of the attended event (Schroeder & Lakatos, 2009). We propose that entrainment of theta and low-gamma band modulations to gait rhytm could reflect the temporal processing of external (auditory pacing) and internal (step pacing) events. Coupling of these neural rhytms may be instrumental in step timekeeping.

Title: Destabilization of postural stability in young adults with minimal added load

Authors: *N. R. BIRCHFIELD, N. DOUNSKAIA;
Arizona State Univ., Phoenix, AZ

Abstract: Introduction: Humans often carry loads, either in the hands or on the upper trunk as a backpack. The representation of the body in the vertical position as an inverted pendulum and the complexity of neural and muscular control of balance predict that loads can substantially affect postural stability. This is especially true if the load is above the center of mass. It has been confirmed that loads equal to 10% of body weight and greater disturb postural stability in young adults; however, it is unknown if added loads less than 10% of body weight also destabilize postural control. **Purpose:** To investigate whether loads less than 10% of body weight produce a noticeable effect on postural stability in young adults. **Methods:** Participants included 21 young males and females. Four conditions of load were used, unloaded (baseline), and 1%, 3%, and 5% of body weight. In each loaded condition, half of the load was positioned on each shoulder. Postural stability was assessed by testing functional reach (forward and lateral) and by recording postural sway with the use of a HUMAC (CMSi, Stoughton, MA) balance board. The postural sway was recorded in two conditions: with eyes opened and closed. Following baseline (unloaded) measurements, the load and visual feedback (eyes open/closed) conditions were randomized. Functional reach scores were calculated as reach distance. Mean COP velocity was obtained using kinematic measures of COP in the anterior-posterior (COP_Y) and medio-lateral (COP_X) directions. **Results:** There was a significant effect of load on functional reach in the

forward ($p < .001$) and left medio-lateral ($p = .03$) directions. In the forward direction, pairwise comparisons revealed significant differences between baseline and 1% ($p < .001$), baseline and 3% ($p = .007$), and baseline and 5% ($p < .001$), but no significant differences between the loaded conditions. In the lateral direction, there were significant differences between baseline and 1% ($p = .02$) and baseline and 5% ($p = .03$), but no significant differences between the two. There were significant main effects for load ($p = .004$) and vision ($p < .001$) on mean velocity. No significant interactions were found. Within the loaded conditions, pairwise comparisons revealed significant differences between baseline and 1% ($p = .019$) and baseline and 5% ($p = .017$) but there were no differences between the loaded conditions. **Conclusions**: The obtained results suggest that even minimal loads of 1% perturb balance in young healthy adults. This result emphasizes the complexity of neural and muscular control that provides postural stability in humans and demonstrates its high sensitivity to the mechanical properties of the body.

Title: The integration of haptic information for balance support: effects of contact duration and hand dominance

Authors: *L. JOHANNSEN, D. KAULMANN;
Technische Univ. München, München, Germany

Abstract: Fingertip contact with an earth-fixed referent reduces body sway. Few studies addressed the time course of sway during contact transitions. Investigating intermittent touch with only short contact durations, Johannsen et al. (Gait and Posture, 2014) demonstrated that durations of more than 2 s cause slowed recovery of reduced sway to baseline levels. This aftereffect indicates that the sway reduction involves postural control strategies not dependent on concurrent tactile feedback. In the present study we aimed to replicate previous findings by testing not only short, intermittent contact durations but also longer durations resulting in postural steady states. In addition, we assessed the effect of hand dominance on steady-state sway and sway during contact transitions. 16 young adult participants stood with eyes closed on a force plate, were instructed to actively initiate light finger contact on an auditory signal and to keep contact in place until a second signal indicated to cease contact. 5 different contact durations were assessed in partly randomized order within a trial: 1.5, 3.5, 5, 10 and 20 s. The 20

s contact phase always occurred first to prime a steady-state reference postural set with light touch contact. 2 blocks of 6 trials each were conducted with either the dominant or non-dominant hand in random order. Body sway was recorded in terms of Centre of Pressure and trunk kinematics in addition to forces and torques at the contact point. We replicated aftereffects of light touch contact on body sway for contact phases lasting longer than 3.5 s. No difference was found between the 10 s and 20 s phases. Short contact durations (< 5 s) led to an overshoot in sway within 1 s after contact removal. In general, post-contact overshoot and return to baseline levels occurred quicker after contact with the non-dominant hand. Our findings show that contact durations longer than 3.5 s are required to instantiate a postural set for the utilization of light touch for sway control. Dominance of the contacting hand has a general influence on the post-contact sway time course with reduced overshoot and longer aftereffect, which might indicate subtle effects of hemispheric lateralization on sway control with light touch.

Title: Locomotor adaptation by visual feedback distortion among healthy adults and subjects with stroke

Authors: *J.-H. SHIN[1], W.-K. SONG[1], J. CHUNG[1], S. KIM[2], S.-J. KIM[3];
[1]Natl. Rehabil. Ctr., Seoul, Korea, Republic of; [2]Hanyang Univ., Seoul, Korea, Republic of; [3]California Baptist Univ., Riverside, CA

Abstract: Backgrounds: Various interventions have been tried to alter locomotion in human, and it is especially important among subjects with stroke. Recent studies showed visual feedback could change gait pattern. However, the optimal visual feedback has not been ascertained, and the possibility of locomotor adaptation by visual feedback among participants with stroke was not depicted. Methods: Seven healthy adults and five stroke patients participated in this study. Visual feedback was provided as bar graphs on the screen in front of subjects, which represents stride length of each limb. When participant walks on treadmill with comfortable walking speed, the graph of selected limb was gradually distorted, and they were not aware of the distortion.

Four different types of visual distortion were provided; the distortion gradually increased from 0% to 12% by 2%, 4%, and 6%, and decreased to 0% with the same ratio every minutes. The 2% distortion was also changed every 30 seconds. The visual distortion was given to dominant or non-dominant limb in healthy subject and unaffected limb in stroke patient. Locomotor adaptation was determined by change of bilateral stride length ratio. Results: All of the feedback induced change of bilateral stride length ratio according to the distortion. When the distortion was applied to dominant limb, the 2% distortion induced less change of stride length ratio between limbs compared to other visual distortion. With the distortion to nondominant limb, the 2% distortion which changed every minute induced relatively marked change of bilateral stride length ratio. Among participants with stroke, the stride length ratio was changed with 2% and 4% distortion according to the visual feedback, however 6% distortion did not lead to expected change. Conclusion: We found that a visual feedback with gradual distortion of stride length could induce locomotor adaptation. However, the adaptation differed according to the visual feedback. In addition, the difference was also found between healthy control and subjects with stroke.

Title: Human walking entrained by brain alternating current stimulation

Authors: S. KOGANEMARU[1], Y. MIKAMI[2], M. MATSUHASHI[2], H. FUKUYAMA[2], *T. MIMA[2];
[1]Kyoto univ., Kyoto, Japan; [2]Human Brain Res. Cntr, Kyoto, Japan

Abstract: Walking is one of the most fundamental movements in animals and human. It requires specific neurons coordinately activating to generatefor regularly patterned motor outputs for of walking. Cerebellum is one of brain locomotor regions as well as midbrain, subthalamus. It can evoke walking-like patterned activities of limb muschles in animal studies. In the present study, we investigated whether transcranial alternating current stimulation (tACS) simulating gait rhythm given over the cerebellum posterior head could alter locomotion rhythm in human. Fourteen healthy subjects participated in the study. They were given tACS over the left cerebellar cortexinion with frequency similar to individual gait cycle, given sham stimulation

and given tACS over skin of scalp during 10-minute walking in a randomized order. As a result, tACS given over the cerebellum posterior head showed a significant entrainment of gait rhythm, compared with sham and skin stimulation. It suggested that the effects of entrainment were probably due to rhythmical activation of brain locomotor region in cerebellum by tACS. Our findings suggest that patterned brain stimulation such as tACS might be a promising method to stimulate brain locomotion center. This is possibly a novel approach for recovery of locomotion function.

Title: Different effect of attentional focus conditions on postural sway parameters during quiet standing

Authors: *K. HAGIO[1], H. OBATA[2], S. SASAGAWA[3], M. SHINYA[2], A. YAMAMOTO[4], K. NAKAZAWA[2];
[1]Grad. Sch. and Col. of Arts and Sci., [2]Dept. of Life Science, Grad. Sch. and Col. of Arts and Sci., The Univ. of Tokyo, Tokyo, Japan; [3]Dept. of Human Sci., Kanagawa Univ., Kanagawa, Japan; [4]Dept. of Community Hlth. Sciences, Grad. Sch. of Hlth. Sci., Kobe Univ., Kobe, Japan

Abstract: Many studies have investigated the effect of cognitive tasks on postural stability. However, changes in postural sway reported in the previous studies remains controversial. The reasons include that parameters, represented by center-of-pressure (COP) based measures, to quantify the postural sway are different. The standard deviation of the COP (COPsd) and the mean velocity of COP (COPvel) has been suggested to represent overall postural stability and the amount of activity required to maintain stability, respectively. This study aimed to compare the effect of attentional focus conditions on different center-of-pressure based measures of postural steadiness during quiet standing. Fifty-one young adults participated in this study. They were required to stand on a force platform for 30s and asked to (1) maintain quiet standing (QSt), (2) minimize their postural sway (conscious standing, CSt) and perform a silent mental arithmetic task (calculation, Cal). From the measured ground reaction forces, we calculated the standard deviation (COPSD) and the mean velocity (COPvel) of the center-of-pressure in the anterior/posterior (AP) and the medio/lateral (ML) directions, respectively. The results demonstrated that an internal focus condition (i.e., CSt) and a cognitive task condition (i.e., Cal) on postural control had a different effect on the COPSD and the COPvel, respectively. The CSt

condition increased the COPvel in the AP and ML directions compared to the QSt and Cal conditions. On the other hand, the Cal condition reduced the COPSD in the AP and ML directions compared to the QSt and CSt conditions. These results indicate that postural control mechanisms interfering with a secondary task are different depending where subjects direct their attention.

Title: Effect of time pressure on attentional shift and anticipatory postural control during unilateral shoulder abduction reactions in an oddball-like paradigm

Authors: *K. ANAN[1], K. FUJIWARA[2], C. YAGUCHI[3], N. KIYOTA[4];
[1]Sapporo Intl. Univ., Sapporo, Japan; [2]Fac. of Sports and Hlth., Kanazawa Gakuin Univ., Kanazawa, Japan; [3]Dept. of Physical Therapy, Fac. of Human Sci., Hokkaido Bunkyo Univ., Eniwa, Japan; [4]Dept. of Rehabilitation, Fac. of Hlth. Sci., Japan Hlth. Care Col., Eniwa, Japan

Abstract: In a reaction task with high time pressure, the onset time of postural muscle activity with respect to the focal muscle of arm flexion is later than in low time pressure, and the latter part of P3 waveform varies in a transient choice-reaction task using a finger reaction. However, no studies have investigated the effects of time pressure on P3 waveform in a repeated arm movement task, using the simultaneous evaluation of the behavior and cognitive processing (especially from a viewpoint of attentional shift). Therefore, the effect of time pressure on attentional shift and anticipatory postural control was investigated during unilateral shoulder abduction reactions in an oddball-like paradigm. A visual cue signal (S1) was presented for 100 ms around the centrally located fixation point. At 1 s after S1 onset, a visual imperative stimulus (6°×6° checkerboard, S2) was presented for 150 ms at 9° to the left or right from the fixation point. This S1-S2 sequence was repeated for 100 s in each experimental block. The time interval from S2 to the subsequent S1 was 1.0, 1.5, or 2.0 s. S2 comprised target and non-target stimuli presented at the position (the left or the right) indicated by S1. Right shoulder abduction was performed only in response to target stimuli, which were presented with a 30% probability. The P1, N1, N2, and P3 components of event-related potentials were analyzed, and onset times of

postural muscles were quantified with respect to middle deltoid activation. There was no significant effect of S2-S1 interval on the latency or amplitude of P1, N1, or N2. The percentage of subjects with bimodal P3 peaks was significantly smaller and the slope of the P3 waveform in the 100 ms after the first peak was significantly steeper with a 1.0-s S2-S1 interval than with a 1.5- or 2.0-s S2-S1 interval. The onset of postural muscle activity was significantly later in the shorter interval conditions. These results suggest that with a shorter S2-S1 interval (higher time pressure), attention was allocated to hasten the latter part of cognitive processing that may relate to attentional shift from S2 to next S1, which led to insufficient postural preparation associated with arm movement and anticipatory attention directed to S2.

Title: Neuromechanics and neurogenetics: old questions and new tools targeted at the control of legged locomotion

Authors: *A. SPENCE;
Bioengineering, Temple Univ., Philadelphia, PA

Abstract: One of the grand challenges for modern science is to understand how animals move. Locomotion results from the dynamic interaction of many complex, nonlinear constituents: the nervous system, muscles, the body, and an often-unpredictable external environment. Yet animals can move quickly, stably, and economically through these challenging environments, relying on these interacting neural and mechanical mechanisms. Here we present an overview of three lines of research that seek to understand distinct but critical aspects of legged locomotion control: 1) comparative work in insects, dogs, and a six-legged robot (the XRL; X-Rhex Lite: Haynes et. al. Proc. SPIE 8387, 2012) aimed at understanding how and why locomotor control strategy (here choice of leg stiffness) varies with body size and leg number; 2) a nonlinear, phase-based approach to modeling gait, that seeks to explain how gait regulation reflects ultimate constraints such as quasi-static stability, and finally, 3) recent work towards bringing optogenetics to bear on problems such as these in intact, freely behaving mice. The

aforementioned lines of research will be used to highlight new avenues of investigation that are being opened up by a burgeoning genetic toolkit and closed-loop experimental designs; historically used to good effect by the flight neuroscience community but less so in terrestrial locomotion.

Title: Execution of reactionary control of posture during an ongoing volitional upper and lower limb task

Authors: *A. H. HUNTLEY[1], K. A. INKOL[1], L. VALLIS[1,2];
[1]Human Hlth. and Nutritional Sci., Univ. of Guelph, Guelph, ON, Canada; [2]Schlegel-UW Res. Inst. of Aging, Kitchener, ON, Canada

Abstract: Incorrect weight transfers during ongoing volitional movement is known to be one main cause of falls, especially in older adults. Previous literature in this area of study has been primarily limited to lower limb tasks, such as gait perturbation studies. Understanding how consistent reactionary control is executed during ongoing volitional tasks involving simultaneous upper and lower limb actions may have important fall prevention implications, as this may be a more representative scenario for activities of daily living that may lead to a fall. In this preliminary study, young adults (n=5) transported a 0.5kg cylindrical object between two, countertop height stands by executing a side step. Support surface perturbations (1m/s^2, 9cm displacement) occurred in 50% of trials (40/80), triggered upon initial touchdown of the subjects' lead laterally stepping foot. Trials involving a sidestep and perturbation in the same or congruent direction were considered SLIP trials, while trials involving a sidestep and perturbation in opposing or incongruent directions were considered TRIP trials. Participants transported the object under two instructed speeds, self-paced and as "quickly and efficiently" as possible. Variability of movement execution and peak velocity was examined based on whole-body kinematic data (OptiTrack, NaturalPoint, USA, 100Hz). Peak center of mass (COM) velocity significantly increased during fast-paced trials compared to self-paced trials ($p<0.001$), confirming that younger adults were able to increase the speed of their movement execution when instructed to, regardless of the challenging demands of the task. Peak COM velocity also

significantly increased from the SLIP condition to the TRIP condition ($p<0.001$), while a trend for coefficient of variation values to increase from SLIP to TRIP conditions was observed ($p=0.061$). This may be due to increased task complexity and level of motor control required by the central nervous system to arrest body motion safely and complete the volitional task, thereby avoiding a fall. Further analyses are underway to examine measures of whole-body stability throughout the volitional and reactionary phases of movement to help quantify variability changes in task execution. This will help elucidate how reactionary control strategies are executed during ongoing volitional tasks to prevent an individual from losing balance, and ultimately falling.

Title: Head movement predictability explains suppression of vestibular input during locomotion

Authors: *P. R. MACNEILAGE, S. GLASAUER;
Univ. Hosp. of Munich, Munich, Germany

Abstract: There is accumulating evidence that vestibular afferent signals are partially or fully suppressed during active movement in animals. During locomotion the suppressed vestibular signals are supplemented or even replaced by predictive signals based on efference copies of locomotor commands. Such a strategy is thought to improve estimates of head motion through space for compensatory behaviors such as gaze stabilization. But the value of this periodic and presumably deterministic efference copy for estimating head motion should depend critically on the stereotypy or predictability of the resulting head motion. Here we express this intuition quantitatively in the form of a statistically optimal model in which relative weight given to efference copy and sensory signals depends on motor predictability. We empirically quantify this predictability during human locomotion (running, walking, and walking stairs) by measuring head motion with an inertial measurement unit, and calculating the variance explained by the mean stride-cycle. Head motion predictability is greater during running than during walking, such that efference copy signals should be upweighted and vestibular signals downweighted during running compared to walking. This coincides with reports that impairment of patients with vestibular dysfunction and of normal subjects with vestibular perturbations is less during running than walking. Thus, we provide a theoretical and evidence-based explanation for

vestibular reliance which was previously explained by degree of automatization for different behaviors. The probabilistic model is general and applies to any situation in which achieved movement is estimated from both efference copy and a zero-mean sensory signal with signal-dependent noise.

Title: Neural mechanisms involved in mental imagery of slipping while walking: A preliminary fMRI study

Authors: *T. S. BHATT[1], P. PATEL[2], S. LANGENECKER[3], S. DELDONNO[3], K. SHARMA[3], L. JENKINS[3];
[1]Physical Therapy, Movt Sci., [2]Physical Therapy,, [3]Psychiatry, Univ. Illinois, Chicago, IL

Abstract: Background: Perturbation induced falls (from trips or slips) are responsible for ~60% of outdoor falls among community-living elderly. Compared with conventional balance training, perturbation training induced via support surface translations (i.e. repeated slips) has proven effective for longer-term falls prevention. While behavioral evidence of motor learning (adaptation & retention) induced via perturbation training is established, the neural correlates underlying such behavioral changes can only been speculated. As a first step this preliminary study *aimed to examine the neural mechanisms involved in reactive balance control for recovery from large-scale environmental perturbations such as slips using mental imagery.* **Method:** Seven healthy young participants after being exposed to one walking and one slip trial performed two mental imagery tasks in the MR scanner. During each MR run including 30s blocks for each condition, participants received verbal instructions to 1) imagine either walking on a treadmill (IW) or 2) imagine experiencing a slip while walking on a treadmill (IS) or 3) rest with vision fixated on a white cross on a black screen. T2* weighted images with echo planer imaging to measure BOLD signals and T1-weighted whole head structural images were acquired. After data pre-processing, level I analysis using GLM was performed to compare the hemodynamic response between conditions for each participant in SPM8. The following contrasts were analyzed: IW vs rest & IS vs IW. **Result:** Subjects received a median score of 4.5/5 on the vividness of visual imagery questionnaire. Results for IW vs rest indicated significant activation of the dominant superior frontal gyrus (premotor area), bilateral superior cerebellar peduncles,

bilateral parahippocampal gyrus, the basal ganglia, and thalamus. Comparing IS to IW, in addition to the dominant premotor area, bilateral superior cerebellar peduncles there was significant activation in the bilateral post central gyrus, posterior cingulate and palteral orbital frontal cortices. **Conclusion:** Results are in concurrence with previous findings examining mental imagery of walking. During mental imagery of an unexpected balance loss and fall from a support surface perturbation (i.e slip), the substrates involved in motor planning, coordination and postural stabilization of internally generated movements were significantly more active.There was also significantly greater activation of substrates involved with internal awareness of body movement and episodic memory retrieval. These findings support the involvement of higher cortical and subcortical structures in reactive balance control.

Title: Avoidance strategies in response to animate and inanimate obstacles in young healthy individuals walking in a virtual reality environment

Authors: *W. H. DE SOUZA SILVA[1,3], G. ARAVIND[2], S. SANGANI[4], A. LAMONTAGNE[2];
[2]Sch. of Physical and Occup. Therapy, [1]McGill Univ., Montreal, QC, Canada; [3]Integrated Program in Neurosciences, Montreal, QC, Canada; [4]Feil and Oberfeld Res. Ctr., Jewish Rehabil. Hosp., Laval, QC, Canada

Abstract: Many studies have described obstacle avoidance strategies while walking, either in physical or virtual environments. These studies, however, were limited to the avoidance of inanimate objects (e.g. cylinders) or failed to address the influence of the visual and auditory properties of the obstacle in shaping avoidance strategies. This study aims to describe the extent to which three different types of obstacles (cylinder, visual human-like avatar and visual human-like avatar with footsteps sounds) affect the inherent avoidance strategies in young healthy

individuals. Healthy young adults (n=4, 50% male, aged 24.7 ±3.5 years (mean ±1SD)) were tested while walking over ground and viewing a virtual environment (VE) displayed in a helmet mounted display (HMD) unit (nVisor SX60). The VE, controlled in Caren-3 (Motek medical), simulated a large room that included a target located 11m straight ahead. In addition, three identical obstacles were positioned 7m ahead in three locations facing the subject (40° right, 40° left, and straight ahead). As the subjects walked 0.5m, one of the three obstacles approached them by walking/moving towards a theoretical point of collision located 3.5m ahead at the midline. Meanwhile, the two remaining obstacles moved/walked away from the participants. The ability of the subjects to steer toward the target while avoiding the obstacles was characterized using the 3D position and orientation of the head recorded from reflective markers (Vicon) placed on the HMD. Preliminary findings show a trend towards smaller minimal distances in all directions when interacting with human-like avatars (left: 1.25±0.47**;** center: 1.22±0.20; right: 1.31±0.24) as compared to cylinders (left: 1.49±0.26**;** center: 1.29±0.12; right: 1.52±0.17). The addition of footstep sounds to human-like avatars did not modify minimal distance values compared to when no footstep sounds were provided (left: 1.20±0.39**;** center: 1.71±0.14; right: 1.31±0.28). Onset times of avoidance strategies were similar across all conditions. These findings suggest that participants had equivalent movement perception of the obstacles regardless of the condition displayed. They also indicate that smaller clearances in the presence of human-like entities may occur due to an inherent real life perception of the avatars resulting in actions that rely on strategies applied during daily locomotion. Finally, the similarity of results following the addition of footstep sounds to the visual human-like avatar condition suggests that avoidance strategies may primarily rely on visual cues. **Key Words:** Navigation; Vision; Walking.

Title: Movement-related cortical activities during self-paced and externally-cued gait initiation

Authors: *K. CHA[1], J. CHOI[1], J.-I. SONG[2], J.-H. PARK[2], H.-S. JEON[2], K. KIM[1];
[1]Yonsei Univ., Wonju City, Korea, Republic of; [2]Dept. of Physical Theraphy, Yonsei Univ., Wonju, Korea, Republic of

Abstract: Self-paced and externally-cued movement initiations are controlled by strategies in the central nervous system, but the mechanisms remain unknown. In order to compare control mechanisms between the two different movement initiations, we analyzed the movement-related electroencephalograms (EEGs) during self-paced and externally-cued gait initiations (GIs). The spatiotemporal characteristics of cortical sources were compared between the two GI conditions. 17 volunteers with no record of neuromuscular disorders were enrolled in this study. Subjects were requested to perform an immediate forward gait in response to a visual cue sign, or a self-paced forward gait after the visual cue. During the task performance, 32-channel EEGs and force platform signals were recorded. The EEG waveforms were segmented in -5000~6000 ms interval based on the gait onset determined by the force platform signal for each trial. In addition to the averaged movement-related (MP) waveform analysis, low resolution brain electromagnetic tomography (LORETA) analysis was performed to observe movement-related cortical activities. At -400~0 ms period, Bereitschaftspotential (BP) was observed at central areas for both initiation conditions. The BP amplitude was significantly higher for the self-paced GI than for the externally-cued GI. The LORETA results showed prominent cortical sources at paracentral lobule for both GI conditions. The source current density was significantly higher for the self-paced GI than for the externally-cued GI, especially at medial frontal gyrus. Considering that pre-movement activities in frontal and supplementary motor area are devoted to the preparation and planning of movement, the increased BP amplitude and frontal source current in self-paced GI may reflect the higher cognitive load required for determining the type and timing of movement.

Title: Behavioral effects of transcranial direct current stimulation to the supplementary motor area during motor tasks

Authors: K. E. HUPFELD[1], *C. J. KETCHAM[1], H. D. SCHNIEDER[2];
[1]Exercise Sci., Elon Univ., Elon, NC; [2]Yale Med. Ctr., New Haven, CT

Abstract: Low-cost, portable, and easy-to-use, a technique called transcranial direct current stimulation (tDCS) holds great promise as a novel therapy for treating motor impairments in neurological patients (Madhavan & Shah, 2012). tDCS passes low-intensity current between two electrode sponges_the anode and cathode_placed on the subject's head, which facilitates or inhibits neuronal activity by delivering weak electrical currents to specific brain regions, causing different behavioral outcomes depending on the area stimulated (Schestatsky, Quezada, & Fregni, 2013; Madhavan & Shah, 2012). tDCS has recently been investigated as a therapeutic intervention for treating conditions including aphasia, Parkinson's disease, and stroke_particularly as an augmentative treatment to incorporate into physical, occupational, and speech therapy programs to accelerate motor learning (Schestatsky et al., 2013; Brunoni, Boggio, Bikson, Bolognini, Nitsche, Fregni, & Priori, 2012). This study aimed to investigate the role of tDCS in facilitating motor planning. This study examined the effects of applying anodal tDCS to the supplementary motor area (SMA) on motor planning through administering a battery of motor planning tests, which included a simple reaction time test, balance task (Biodex mCTSIB test), and grooved pegboard task to a population of college students. Participants received either sham stimulation or between 20 and 25 mA•min of current to the SMA and performed each motor test before receiving tDCS at 20 minutes, 40 minutes, and 48 hours. Preliminary results showed college students improved on motor tasks following tDCS application to the SMA. This suggests that the SMA is involved in formulating and executing motor plans and that tDCS may be utilized to strengthen the neural pathways associated with the SMA for motor tasks. These findings have future implications for designing therapeutic interventions for individuals with movement decrements.

Title: Vestibular modulation of hand choice

Authors: *R. S. BAKKER, R. H. A. WEIJER, L. P. J. SELEN, W. P. MEDENDORP; Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: Our brain continuously decides which hand to use to perform an action. A critical factor in this competition between the hands is some assessment of the expected effort and expected task success associated with each hand (Schweighofer et al. 2015). These costs and

rewards may depend on the relative position of the hand to the target, biomechanical factors, accuracy demands or handedness (Cisek 2007; Oliveira et al. 2010; Schweighofer et al. 2015). If this competition is solely resolved based on biomechanical costs, hand choices should be symmetrically distributed around the body midline when the body is stationary. On the other hand, if the whole body is under acceleration, hand choices should be biased due to changes in biomechanical costs. Here, we set out to examine hand choices in a unimanual reaching task, both stationary and under whole body acceleration. The inertial forces induced by the whole body motion differ between the arms. This introduces differences in both the biomechanical cost (i.e. effort) and the accuracy (i.e. reward) associated with reaches of the individual arms. Right-handed subjects were seated on a vestibular sled that oscillated sinusoidally over 30 cm at a frequency of 0.71 Hz. Subjects made unimanual reaches to a body fixed target presented on a LED table mounted in front of them. One out of thirteen targets, organized in a semicircular array, was presented in a single trial. Once the target appeared, subjects had to reach as fast and accurate as possible with either hand. Targets were presented both at peak acceleration and peak velocity of the sinusoidal platform motion. Every target was presented 24 times for each condition, from which we calculated the PSE for that phase angle of the sled motion. These choice trials were interspersed with catch trials in which two targets were presented simultaneously and both arms had to move, as well as fixation catch trials in which subjects had to move both hands to the fixation light. The same experiment was also carried out while the subject was stationary, i.e. without acceleration induced inertial forces. Preliminary results of the stationary condition show a bias towards choosing the right hand, as shown by a mean PSE left of the body midline. While in motion, this PSE systematically shifts when the target is presented at peak acceleration, but remains unaffected at peak velocity. Currently, we are interpreting these findings in terms of the effects of whole body acceleration on the computation of the expected effort and expected task success.

Title: Stroke individuals have preserved multi-joint coordination during arm reaching movements in upright position

Authors: *S. M. FREITAS, C. A. LIMA, A. M. S. BALDAN, S. R. ALOUCHE;
Univ. Cidade De Sao Paulo, Sao Paulo, Brazil

Abstract: Individuals with mild post-stroke hemiparesis have several functional limitations in reaching objects during upright standing. It is unknown, however, whether such limitations are due to different patterns of joint coordination used to reach a target during the upright stance. Therefore, the aim of the present study was to investigate the joint coordination patterns used by stroke individuals to reach a target. Fifteen individuals with hemiparesis (eight on the right and seven on the left side) and eight healthy individuals stood in upright position and performed reaching movements towards a target shown in the center of a monitor. The monitor was placed at a distance of 115% of the upper limb's length. Stroke individuals used the arm ipsilateral to the brain lesion to perform the tasks. The patterns of joint coordination were evaluated in certain (target final position was known) and uncertain (target could move to an upper or lower position after the participant started to move) conditions. Each participant performed 5 trials for each target position and condition. Only the trials for the movements performed towards the center target were analyzed. Joint kinematics of the focal movement (shoulder, elbow and wrist) and postural adjustments (hip, knee and ankle) in the sagittal plane were recorded. Principal components (PC) analysis was carried out on the variance of joint angles to investigate the coordination patterns used 150 ms before (postural adjustments phase) and during the movement by stroke and healthy individuals. The uncertainty in target position increased the amplitude of focal joint excursions during both the postural adjustment and movement phases. Only the individuals with right hemiparesis reduced the amplitude of the ankle joint in the uncertain compared to certain condition. The first PC accounted for more than 90% of the total joint variance for all groups suggesting that two joint coordination patterns were implemented simultaneously, one related to the focal movement and other to the postural adjustments. The accounted variance of the first PC was greater during the uncertain compared to certain condition only for the postural adjustment phase. Before and during the movement, the joints of focal movement contributed most for the first PC compared to the other joints. Overall, the results suggest that uncertainty in target position during reaching in an upright position influences the amplitude of joint excursions for both focal and postural movements. However, it does not affect the multi-joint coordination patterns. Stroke individuals also have preserved multi-joint coordination during arm reaching movements in upright position.

Title: Muscle synergies and kinematic measures in subjects with multiple sclerosis during reaching and manipulation tasks

Authors: *L. PELLEGRINO[1], M. MARGIT[2], C. SOLARO[3], M. COSCIA[4], M. CASADIO[2];
[1]Dept. Informatics, Bioengineering, Robotics and Systems Engin., Univ. of Genoa, Ge, Italy;
[2]Dept. Informatics, Bioengineering, Robotics and Systems Engin., Univ. of Genoa, Genoa, Italy;
[3]ASL3 Genoa, Genoa, Italy; [4]Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

Abstract: According to several studies, muscles participate to the generation of movements in well-defined functional groups - called "synergies" - activated by descending cortical commands. A recent study has suggested that muscle synergies can be considered as physiological markers of motor cortical damage. The potential of this approach has not yet been exploited for understanding and describing the motor impairments caused by Multiple Sclerosis (MS). This study aimed at evaluating the muscle synergies and kinematic parameters of both upper limbs in MS subjects while they control their upper arm motion and/or forces under different environment conditions:(i) free space; (ii) rigid constrain; (iii) in presence of a spring that opposes the subjects' movement; (iv) in presence of a force field that attracts the hand of the subject toward the target. Subjects were seated on a chair grasping the handle of a planar manipulandum. The robot measured the end-effector position and provided the interactions forces. The subjects reached targets presented in random order in 8 directions equally spaced from a central target (distance: 14 cm or 10 N). The activities of the following 15 muscles of both arms were recorded: triceps brachii long and lateral, biceps brachii short and long head, brachialis, brachioradialis, pronator teres, infraspinatus, latissimus dorsi, upper trapezius, rhomboid major, pectoralis major, anterior deltoid, medial deltoid and posterior deltoid. Seven healthy subjects without neurological or muscular disorders (2 M- 5 F; 53±10 years) and seven subjects with clinically definite MS (2 M - 5 F; 54±8 years) according to McDonald criteria participated in the study. The inclusion criteria for SM were: (i) stable phase of the disease (no relapses in the last three months), (ii) relapsing - remitting (RR) form, (iii) Expanded Disability Status Scale (EDSS) ≤ 7, (iv) Ashworth scale< 2 and (v) 9-HPT >30. As expected control subjects generated straighter and smoother trajectories compared to the MS subjects. For both groups the most difficult task was the control of the isometric force against a rigid constraint. Muscle synergies analysis confirmed that the activity of the recorded 15 muscles could result from the combination of a limited number of basic modules, for both subjects' populations and for both arms. However, in MS subjects muscle synergies had a different structure in the two arms.

Title: Neurocomputational cost minimization accounts for the leading joint hypothesis

Authors: *N. DOUNSKAIA, Y. SHIMANSKY, W. WANG;
Arizona State Univ., Phoenix, AZ

Abstract: Although applications of the optimal control framework to human movements have been fruitful, the optimality criteria are still under debate. Minimization of muscle energy is considered most frequently. Surprisingly, the cost of information processing necessary for movement control [neurocomputational cost (NC)] has rarely been discussed. We propose that the tendency to reduce NC accounts for the empirically-derived leading joint hypothesis. Namely, experiments demonstrate a tendency to produce shoulder-elbow movements by rotating one (leading) joint actively and trail the other joint predominantly passively, with interaction and gravitational torques. We propose that the reason for using this trailing joint control pattern is that it reduces NC. This conclusion follows from NC estimation based on Shannon's theory of information, according to which, if a variable x is limited by an interval (xmin, xmax), and the maximum acceptable error in measurement (or production) of x is d, the amount of information required for encoding x value is I = ln(N), where N = (xmax - xmin)/d. We assume that information processing is described by a control law U = F(S), where S is the motor plant's state and U=(U1,⋯, Un) is a vector of control components. The amount of information I = I1 +⋯+ In required for encoding U can significantly depend on control strategy. During shoulder-elbow movements, coordinated contribution of muscle and passive torque to net torque is required, and therefore, U is represented by muscle torque contribution (MTC) to net torque at each joint. The trailing pattern reduces NC estimated as I by imposing low requirements on MTC error (d is high) at the leading joint and minimizing MTC magnitude [(xmax - xmin) is low] at the trailing joint. We hypothesize that NC is a dominant (as compared to muscle energy) cost function component for optimization of joint coordination and that the CNS decreases NC by using the trailing control pattern. We provide ample experimental support for this hypothesis.

Title: A test of dual drift-diffusion and independent-race models of reach target selection

Authors: *S. DUROCHER, J. BEAULAC, L. AIT ALI, J. F. KALASKA;
Neurosciences, Univ. De Montréal, Montreal, QC, Canada

Abstract: It is widely accepted that 2-choice decisions result from accumulation of net evidence favoring one choice over the other, but this assumption has rarely been tested rigorously with a range of stimuli that independently vary both the total evidence for each choice and the net evidence for one. Two studies with appropriate ranges of RDK stimuli support net evidence accumulation (Niwa & Ditterich 2008; Lam & Kalaska 2012). In contrast, a study with pairs of stimuli with many different levels of brightness supports a race model with 2 accumulators that each integrates the brightness evidence for their preferred choice (Liston & Stone 2013). Their critical finding was that the RTs for both chosen and rejected stimuli were positively correlated with the brightness of the corresponding stimuli. A net evidence model would predict RTs that are oppositely correlated to the brightness of the chosen and rejected stimuli. Given the fundamental importance of how sensory evidence is processed to reach a decision, it is essential to test this question across a wide range of task conditions. Coallier & Kalaska (2014, 2015) used a "choose and go" (CG) task in which subjects chose between two colored reach targets by deciding whether a multi-colored checkerboard-like Decision Cue (DC) contained more squares of the color of one target. Subjects' responses to a limited set of 10 DCs depended mainly on the difference in the numbers of squares of the 2 target colors. We tested this result more thoroughly with a set of 120 DCs with a wide range of total and relative numbers of colored squares, ranging from DCs with 30/0-100/0 squares of the two colors (evidence for only one target) to DCs with 30/30-100/100 squares (equal evidence for both targets). Five subjects each performed >6000 trials of the CG task over several sessions. Across all DCs, RTs were positively correlated with the total number of squares for the chosen target (mean r=+0.28, range +0.17 to +0.32) and negatively correlated with the number of squares for the rejected target (mean r = -0.46, range -0.23 to -0.61). Testing only DCs with squares of both target colors, positive correlations for chosen targets increased (mean r = +0.42, range +0.21 to +0.56) and correlations for rejected targets remained negative (mean r = -0.16, range -0.06 to -0.21). RTs for DCs with 0 net evidence (30/30 to 100/100) were uniformly long and weakly correlated to the numbers of squares (mean r = 0.04, range 0.12 to -0.05). The results suggest that subjects' decisions were strongly influenced by the difference in the numbers of task-relevant squares in the DCs, rather than a race between accumulators driven by the total number of colored squares supporting each target.

Title: Effects of movement duration on use of the affected limb in individuals post-stroke

Authors: *S. KIM[1], H. PARK[1], C. E. HAN[2], C. J. WINSTEIN[1], N. SCHWEIGHOFER[1]; [1]USC, Los Angeles, CA; [2]Korea Univ., Seoul, Korea, Republic of

Abstract: Patients with stroke often exhibit non-use of their more affected arm: Although capable of generating arm movements, they often chose not to. Here, we hypothesize that the slowness of movements with the more affected side is a significant factor underlying such non-use. Twelve individuals with chronic stroke (mild to moderate impairment; 46.1± 9.0 on Fugl-Meyer assessment) and six age-matched non-disabled participants performed the Bilateral Arm Reaching Test (BART; Han, Kim, et al. 2014) in the forced and free choice conditions with three different movement time constraints: no time constraint, medium (~1000 ms, depending on target location) and fast (~ 500 ms). Arm kinematics, movement time, and task success were recorded across conditions and amount of use in the free choice condition was computed and compared to normative data. Whereas the non-disabled group showed no differences in hand choice across conditions, the stroke group showed decreased affected hand use in the faster conditions. Further, individuals with left hemiplegia showed a dramatic decrease in use in the fast condition (68% decrease in paretic limb use compared to no time constraint condition), whereas individuals with right hemiplegia showed a only a 24% decrease in paretic limb use. We discuss our results in lights of the known right/left hand differences in arm control and in the framework of delayed rewards discounting.

Title: Challenging the modular control hypothesis: evidence for a functional space-by-time decomposition underlying the muscle activity of whole-body movements

Authors: ***P. HILT**[1], I. DELIS[2], T. POZZO[1,3], B. BERRET[4];
[1]INSERMU1093, Dijon, France; [2]Inst. of Neurosci. and Psychology, Glasgow, United Kingdom;
[3]Istitutio Italiano Di Tecnologia, Genova, Italy; [4]CIAMS, Paris, France

Abstract: Many studies have provided evidence that the muscle patterns underlying a wide variety of motor tasks can be approximated by combinations of a small number of invariant elements, also referred to as muscle synergies. In this study, we aimed at challenging the modular control hypothesis by using a very large data set with many motor tasks, many repetitions per task and bilateral muscle recording during 3D whole-body pointing movements. We asked 4 subjects to perform whole-body point-to-point movements in various directions when standing. The experimental protocol specified 9 targets on 3 vertical bars and subjects had to perform pointing movements between all pairs of targets (i.e. a total of 72 different pointing movements). Participants were asked to repeat each distinct task 15 times, for a total of 2160 movements recorded per participant. We recorded 30 muscles distributed on the whole body, and 22 retro reflective markers to track the motion of anatomical landmarks. To identify putative modules, we used a module extraction method that takes into account concurrently the spatial and temporal dimensions (space-by-time decomposition, Delis et al, 2014). To critically test the extracted modular decompositions, we examined whether tasks can be reliably inferred usinga single-trial decodingmethod described in a previous paper (single-trial task decoding approach, Delis et al, 2013). Overall, our results demonstrated that the 4subjects used a small number of modules (S1(4,4), S2 (6,4), S3(7,4), S4(5,4), spatial, temporalrespectively for each subject) to accomplish all 72 whole body pointing tasks. The extracted space-by-time decompositions consisted of highly similar temporal modules across subjects (average correlation coefficient between temporal modules across subjects: R=0.95) and slightly more variable spatial modules (R=0.6). Importantly, these representations not only accounted for the recorded muscle activity but also allowed highly reliable categorization of the executed tasks. Additionally, the modular structure was found to be especially relevant for task discrimination as compared to alternative methods that used the same number of task-dependent parameters but did not exploit the underlying modularity. In conclusion, we found a low-dimensional representation of muscle activity consisting of functional and consistent spatial and temporal modules to describe reliably a complex high-dimensional set of motor tasks.Thisfinding provides indirect yet strong evidence for the modular control hypothesis and suggests that motor modularity may rely on a separate but concurrent representation in the spatial and temporal domains.

Title: Influence of chronic stroke on functional arm reaching: Quantifying deficits in the ipsilesional arm

Authors: *R. VARGHESE[1], S. SUBRAMANIAM[2], T. BHATT[3];
[1]Univ. of Illinois At Chicago, Chicago, IL; [2]Univ. of Illinois at Chicago, University of Illinois at Chicago, IL; [3]Univ. of Illinois at Chicago, Chicago, IL

Abstract: ***Background***: Recent literature has found that following a stroke there may be considerable deficits in the motor control of the ipsilesional upper extremity. These deficits include impairments not only in movement execution, but movement planning as well, resulting in poorer overall quality of movement in the less-affected arm. For example, stroke-related postural problems will tend to further impact postural action preparation that precedes arm movements. Although past studies have evaluated seated reaching tasks, these tasks do not necessarily warrant postural preparation and movement planning as much as a stand-reaching task. Given that reaching while standing is relatively more functional in nature than seated reaching and used extensively in day-to-day activities, it may be valuable to study the impact of stroke on the performance of such a task. ***Purpose***: The purpose of this study was to quantify and compare reaching performance (kinematics and kinetics) of the ipsilesional arm in stroke survivors and age-similar healthy adults, using a reliable stand-reaching paradigm. ***Method***: Community dwelling chronic stroke survivors (n=10) and age-similar adults (n=10) performed two trials of flexion- and abduction-reaching tasks. Surface EMG and acceleration were sampled using wireless sensors from the prime movers, anterior and middle deltoid. Independent t-tests were performed between the two groups to compare response variables that were classified into performance-outcome (reaction time, burst duration and movement time) and performance-production (normalized EMG amplitude and peak acceleration) measures. ***Results***: Individuals with chronic stroke demonstrated a significant delay in performance outcomes (i.e. longer reaction time, burst duration and movement time) compared to their healthy counter parts ($p < 0.05$) for both flexion- and abduction- reaching movements. Likewise, they also exhibited poorer performance production ability (i.e. lower burst amplitude and smaller peak acceleration) ($p < 0.05$) in both reaching directions. ***Conclusion:*** Our results offers quantitative evidence that chronic stroke survivors demonstrate decreased arm movement control in both time (performance-outcome) and amplitude (performance-production) domains than age-similar adults while performing a relatively challenging, but considerably functional, stand reaching task. This may be suggestive of both planning- and execution-related deficits in ipsilesional motor function after stroke. Findings may have critical implications for rehabilitation, especially for interventions employing the ipsilesional arm for compensatory training purposes.

Title: Cortical representation of bimanual movements: patterns of interference

Authors: *P. THOMPSON, M. LEBEDEV, M. A. L. NICOLELIS;
Duke Univ., Durham, NC

Abstract: Independent movements by two arms, such as reaching simultaneously to two different targets, are prone to patterns of interference. For example, it is easier to move two arms in the same direction than to make different movements with the right and left arm. The underlying neural mechanisms are poorly understood. Here we show that cortical neuronal ensembles in the primary motor cortex (M1) and supplementary motor area (SMA) exhibit distinct patterns of activity that represent patterns of interference during bimanual reaching movements. Rhesus monkeys performed a bimanual joystick centerout task with four possible target locations for each hand. We found that clear patterns of movement interference existed during the task, and this was dependent on target configuration. Using bilateral, multielectrode implants, we recorded from several hundred neurons in M1 and SMA. We observed enhanced ensemble modulations during bimanual versus unimanual movements. Moreover, the degree of bimanual interference had a clear effect on neuronal patterns, particularly in SMA, where neurons were modulated more for more dissimilar movements with two arms. While the movements of each arm were represented by both cortical hemispheres, the distribution of activity across the hemispheres reflected the interference, as well. We suggest that both coordinated and independent bimanual movements are represented in a highly distributed fashion by cortical ensembles. This dynamic and highly plastic representation underlies what is usually called "cortical body schema".

Title: Characterizing movement initiation in primate motor cortex

Authors: *M. BEST[1], A. J. SUMINSKI[2], K. TAKAHASHI[1], N. G. HATSOPOULOS[1]; [1]Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL; [2]Dept. of Electrical Engin. and Computer Sci., Milwaukee Sch. of Engin., Milwaukee, WI

Abstract: Large ensembles of primary motor cortical (MI) neurons become activated when voluntary arm movements are initiated. The temporal dynamics of this activity have been studied extensively at multiple physiological scales including single cells, small ensembles, and in aggregate via the local field potential (LFP). And yet, how these temporal dynamics vary spatially across the cortical surface remains unknown. Here, we used 96-channel Utah multielectrode arrays to record unit spiking activity and LFPs from four rhesus macaques while they performed an instructed-delay, center-out reaching task. We identified a spatiotemporal sequence of neural activity that preceded movement onset. This spatiotemporal sequence propagated along the rostro-caudal axis of motor cortex and was reflected in unit spiking activity as well as in the beta frequency range (15-30 Hz) of the LFP. This spatiotemporal sequence was absent during motor planning, an epoch when the motor cortex is known to be transiently activated. The causal significance of this phenomenon has begun to be probed using spatiotemporal patterns of intracortical microstimulation. We speculate that movement initiation requires a spatiotemporal recruitment order in MI.

Title: The pre-dorsal premotor cortex (pre-PMd), dorsal premotor cortex (PMd), and primary motor cortex (M1) are differently involved in goal-directed behavior based on conditional visuomotor association

Authors: *Y. NAKAYAMA[1,2], T. YAMAGATA[1,2], J. TANJI[2,3], E. HOSHI[1,2,4];
[1]Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan; [2]Tamagawa Univ. Brain Sci. Inst., Tokyo, Japan; [3]Tohoku Univ. Brain Sci. Ctr., Sendai, Japan; [4]CREST, JST, Tokyo, Japan

Abstract: The dorsal premotor cortex residing in the dorsolateral aspect of area 6 is a rostrocaudally-elongated area, rostral to the primary motor cortex (M1) and caudal to the prefrontal cortex, and is thought to play a central role in the conditional visuomotor behavior. Functional and anatomical studies have revealed that the dorsal premotor cortex is subdivided into its rostral (pre-PMd, area F7) and caudal (PMd, area F2) subdivisions. In the present study, we attempted to examine functional specializations in the pre-PMd, PMd, and M1 with respect to a conditional visuomotor behavior. We examined neuronal activity while monkeys (*Macaca fuscata*) performed a conditional visuomotor task designed to include separate processes for the determination of a behavioral goal (selecting right or left of two potential targets) based on visual-object instructions, action specification based on the goal, and preparation and execution of an action. We found that pre-PMd and PMd neurons retrieve and maintain the behavioral-goal information without encoding the visual object features and, subsequently, specify the actions by multiplexing information for the goal with the spatial-target information. We further found that neurons in the PMd and M1 play a major role in representing the action during the periods of motor preparation and execution, whereas the contribution of the pre-PMd becomes progressively smaller toward the onset of movement execution. These findings revealed that the multiple processing stages underlying the conditional visuomotor behavior are implemented in an area-specific manner as a functional gradient from the pre-PMd to M1, with PMd intervening in between.

Title: Deficits in visual search following stroke contribute to impaired visuomotor processing and executive function

Authors: ***T. SINGH**[1], C. PERRY[1], A. ROSS[1], J. FRIDRIKSSON[2], S. FRITZ[1], T. M. HERTER[1];
[1]Exercise Sci., [2]Communication Sci. & Disorders, Univ. of South Carolina, Columbia, SC

Abstract: Introduction: Many activities of daily living, such as driving, require coordination of eye and limb movements to gather visual information and act on the environment. Executive function (mental processes that organize and regulate perception, cognition and action) is responsible for integrating visual information, working memory, and prior knowledge to organize eye movements (visual search) and limb movements (motor behavior). We know that visual search and motor behavior are commonly impaired following stroke, but our understanding of how impairments of visual search contribute to deficits in motor behavior is limited. Here we use a robotic version of a common neuropsychological assessment, the Trail Making Test (TMT), to examine the extent to which impairments of visual search contribute to deficits in visuomotor processing and executive function after stroke. Methods: We used the KINARM Endpoint Lab with integrated gaze tracking to examine 69 adults in 3 groups: Young (21-50 yrs, n = 37), Older (52-77, n=16), and Stroke Survivors (48-85, n=16). Subjects used the robotic device to perform the TMT, which involve connecting numbers (TMT-A: 1, 2, 3.), or numbers and letters (TMT-B: 1, A, 2, B.) in the shortest possible time. To minimize the contribution of motor impairments, controls performed the test with their dominant hand and stroke survivors with their less affected hand. We measured the total time (Total Time) to complete the test and the number of reaching errors. Total Time was further divided into the time spent when the hand stayed on a number/letter (Dwell Time) and moved between them (Movement Time). From the eye-tracking data, we measured the number of saccades and fixation duration at each number/letter. Results: Total Time increased progressively from young to older to stroke survivors. The numbers of errors were higher in TMT-B than in TMT-A. The average Dwell Time and Movement Time were longer for TMT-B than TMT-A and also increased progressively between the three groups. The count of saccades to numbers/letters for TMT-B were about ~63% higher than for TMT-A. Stroke survivors made more number of saccades and fixated longer at each number/letter than the healthy controls. During both the dwell and movement phases, stroke survivors made more saccades than the young and older controls. Conclusions: These results indicate that impairments of visual search contribute to decreases in TMT performance. Based on our results, we created a stochastic model of visual search that showed that the main determinant of deteriorated TMT performance in stroke survivors was their inability to combine working memory with topographic strategies during visual search.

Title: Reversible deactivation of motor cortex reveals functional connectivity with anterior and posterior parietal cortex in Old World monkeys (Macaca mulatta)

Authors: *D. F. COOKE[1,2], A. B. GOLDRING[1,2], M. K. L. BALDWIN[1], M. S. DONALDSON[1], L. KRUBITZER[1,2];
[1]Ctr. Neurosci, [2]Psychology, UC Davis, Davis, CA

Abstract: A complex network of connections between motor (M1), premotor (PM) and posterior parietal cortex (PPC) in primates plays an important role in voluntary movement. Long-train intracortical stimulation (ICMS) in all of these fields elicits complex movements, which are segregated into domains of ethologically relevant behaviors such as grasping, reaching or defense. Additionally, M1, PM and portions of PPC send direct projections to the spinal cord in primates. Recently, deactivation of M1 in prosimian galagos and tree shrews (a close primate cousin) has been shown to alter the movements evoked by stimulation of PPC, suggesting that inputs from M1 strongly modulate neurons in PPC. Deactivation of M1 generally affects movements evoked by stimulation in matched PPC domains, although in galagos there appear to be cross-domain effects - interactions between mismatched domains and even mismatched body parts to a degree not seen in tree shrews. For example, deactivating a specific domain in M1 (e.g. forelimb lift) resulted in loss of evoked movement in a different movement domain in PPCr (e.g. hand-to-mouth or eye-blink). The goal of the present investigation was to rapidly and reversibly deactivate forelimb (e.g. grasp) and orofacial domains (e.g. grimace) of M1 by cooling, and to examine the effect of such deactivation on movements evoked from parietal areas (area 1/2, area 5, area 7b) in anesthetized rhesus macaques. By using small (6.9 mm^2) microfluidic thermal regulators we could control both the spatial extent and duration of cooling deactivation and make minute-by-minute observations of the resulting effect. We demonstrate that deactivation of an M1 forelimb domain decreases the amplitude of or eliminates movements evoked by ICMS of matching domains in parietal cortex. We also observed effects on distinct but related movements as well as on very different movements involving other body parts. Such cross-domain effects observed in this investigation may be mediated by the dense intrinsic connectivity in PPC and divergent and convergent reciprocal connectivity between parietal and motor cortex. Through these connections, the activity of an M1 domain greatly impacts both related and unrelated parietal domains. Such functional connectivity of disparate movement representations may underlie coding of movement sequences or, through simultaneous activation, may produce a large number of possible combinatorial movements.

Title: Defining the contribution of the rubrospinal tract to forelimb behavior in rats

Authors: ***K. M. KEEFE**[1], I. SHEIKH[2], C. ENEANYA[2], G. SMITH[2];
[1]Neurosci., [2]Shriner's Pediatric Res. Ctr., Temple Univ., Philadelphia, PA

Abstract: The rubrospinal tract (RST) is an indirect neuronal pathway that contributes to the control of upper arm flexion in humans. Studies in primates show that when the corticospinal tract is damaged, compensatory circuits can form with the RST, allowing for recovery of gross movements of reaching and grasping. Though anatomically well-defined, the RST's involvement in behavioral function in the rat is not fully understood. This study focuses on the discovery of rubrospinal tract impact on forelimb function in a normally behaving rat. We use an inducible dual-vector system featuring the highly efficient retrograde gene transfer (HiRet) lentivirus combined with an adeno-associated TetOn virus (AAV-TetOn) and injection of doxycycline to induce synaptic shutdown of RST neurons in these animals. HiRet is injected unilaterally into the C5-C7 spinal cord to target RST synapses in the area of forelimb motor pools, and TetOn is injected into the contralateral red nucleus to target RST neurons. Doubly infected cells are unable to release neurotransmitter upon application of doxycycline. Behavioral measures include forepaw placement during exploratory rearing, food manipulation and digit movement assessment via the IBB scale, strength of forepaw grip, and coordination of forelimb, shoulder, wrist and paw pronation when reaching for a food pellet. We found that animals injected with this system have significant forelimb deficits on the treated side in the presence of doxycycline. These deficits illustrate the specific involvement of RST neurons in forelimb function.

Title: Relationships between high-density EEG and arm EMG dynamics

Authors: *S. MAKEIG, L. PION-TONACHINI;
Inst. of Neural Computation, UCSD/INC/SCCN, La Jolla, CA

Abstract: Electromyography (EMG) records electrical potentials created by muscle activity either using surface electrodes placed on the skin (sEMG) or needle electrodes inserted into a muscle body (iEMG). sEMG is typically assumed to assess the activities of superficial muscles only and is adversely affected by fatty tissue, while iEMG is invasive and requires expert knowledge (and some subject fortitude) to use safely. Both modalities suffer "crosstalk," the instantaneous linear mixing of volume-conducted electrical potentials that also degrades interpretation of both scalp and intracranial electroencephalographic data. In both EEG and EMG records, therefore, individual electrode channel signals sum the volume-projected activities of many spatially distinct brain and/or nearby muscle sources. Independent Component Analysis (ICA) can separate high-density EEG data into activities consistent with activity in a single cortical patch, and can also be meaningfully applied to EMG. Here we performed a pilot study using concurrent high-density whole-arm EMG and whole-head EEG recording to test a new way to analyze non-invasively recorded sEMG in which ICA decomposition of unrectified sEMG data learns a set of spatial filters that estimate the activity time courses and spatial projection patterns of spatially distinct and temporally maximally independent muscle sources. The spatial projection patterns were generally compatible with dipolar sources oriented parallel to and located at one or both ends of a single muscle, as expected from electrical modeling of muscle activity. Pairwise mutual information, computed between the effective muscle sources, showed that sources with overlapping arm surface projections (and, likely, adjacent muscle tissue sources) exhibited stronger interdependency. By exploiting the wealth of methods already developed for EEG analysis, source-resolved EEG/EMG analysis, should allow separation of specific muscle activities and more detailed analysis of EMG-EEG source interactions, while avoiding the need for invasive needle electrode recordings.

Title: Shared neural sensory signals for eye-hand coordination in humans

Authors: *L. LI[1], D. NIEHORSTER[1], L. NI[1], D. LISTON[2,3], L. STONE[2];
[1]The Univ. of Hong Kong, Pokfulam, Hong Kong; [2]NASA Ames Res. Ctr., Moffett Field, CA;
[3]San Jose State Univ., San Jose, CA

Abstract: Previous studies that examined eye and hand tracking using either a self-driven or a predictable moving target proposed that eye-hand coordination is realized by a coordination control system that uses both efferent and afferent information of hand movement to synchronize and couple eye and hand motor systems. In the current study, we examined the correlation between the noises of eye and hand tracking of an unpredictable moving target that made efferent and afferent information of hand movement unusable. In Experiment 1, two experimental conditions were tested: in the eye-hand condition, while participants used their eyes to track the movement of a Gaussian target (σ=0.6 deg) on a computer display (40 deg H x 30 deg V) as its horizontal position was perturbed by the sum of seven harmonically-unrelated sinusoids (0.1-2.19 Hz), they also used their dominant hand to control the horizontal position of a second vertically-offset Gaussian cursor (8 deg below) with a high-precision mouse to align it with the target. In the eye-alone condition, the target and cursor positions previously recorded in the eye-hand condition were played back, and participants were instructed to use only their eyes to track the movement of the target. In Experiment 2, the same two experimental conditions were tested except that there was no cursor to indicate hand tracking on the screen. Prior to computing the correlation between the noises of eye and hand tracking responses, for each 90-s trial, we subtracted best-fitting linear tracking responses at the seven input perturbation frequencies to remove direct correlation with the visual stimulus. For both experiments, trial-by-trial examination revealed that the correlation between the residual noises in eye and hand tracking in the eye-hand condition was both highly significant and much higher than the spurious correlation found when eye tracking was not accompanied by simultaneous hand tracking in the eye-alone condition. Our study provides the first behavioral evidence showing that common neural sensory signals drive both eye and hand motor systems and limit eye-hand coordination. This is consistent with the neurophysiological findings of common neural substrates that serve both eye and hand tracking.

Title: Outcome prediction of observed actions affects one's own outcome estimation but not action correction

Authors: *T. IKEGAMI[1], G. GANESH[2];
[1]Natl. Inst. of Information and Communications Technol., Suita City, Osaka, Japan; [2]CNRS-AIST JRL(Joint Robotics Laboratory), UMI3218/CRT, Intelligent Systems Res. Institute,, Natl. Inst. of Advanced Industrial Sci. and Technology(AIST), Ibaraki, Japan

Abstract: The ability to estimate and predict outcomes of self-generated actions and actions observed in others is fundamental for our social life. Previous motor studies have shown that estimation of self-generated actions is achieved by forward models. However, whether the same forward models that help us estimate the outcomes of our own actions are also used to predict the outcomes of actions observed in others remains controversial. Furthermore the structure of the forward model in the action prediction architecture has been a source of recent debate. The traditional view from motor control believes the core role of the forward model to be sensory estimation but not motor command generation, which in turn is handled by the Inverse model. On the hand, some recent models propose a single forward model to play an integrated role and contribute to both action prediction and motor command generation and thus regard a distinct inverse model as dispensable. The goal of this study is two-fold; to examine if a same forward model is involved in both observed outcome prediction and self outcome estimation by humans, and to examine whether the forward model is distinct from the inverse model in the brain. First, we use our novel observation learning paradigm (Ikegami & Ganesh, 2014) to show that a change induced in prediction ability of observed actions by a subject affects the subject's ability to self-estimate the outcome of his own actions. Next, we use model based analysis to distinguish and quantify the changes in the outcome forward model in our experiment. This enabled the critical exhibition that the changes in the subject's self-estimation accuracy were not due to errors in the input (i.e. efference copy of motor command) to the outcome forward model but due to changes in the outcome forward model itself. Our results thus exhibit a causal relation between change in outcome prediction of observed action and the change in one's own outcome forward model. Finally, we exhibit that while the outcome forward model of subjects changed with their outcome prediction ability of observed actions through our task, their outcome inverse

model remained unaffected, exhibiting a distinction between the forward and inverse model in the brain at least at the level of outcome prediction.

Title: Investigation of head and eye movements using the Oculus Riff and electrooculography

Authors: ***B. QUINLIVAN**[1], J. BUTLER[1], I. BIESER[2], N. FOLEY[1], M. HUTCHINSON[2], R. REILLY[1];
[1]Trinity Col. Dublin, Dublin, Ireland; [2]St. Vincent's Univ. Hosp., Dublin, Ireland

Abstract: It is well documented that the appearance of visual targets outside the central field of view usually elicit an eye saccade and a head movement resulting in an overall change in gaze. While saccades have been well characterized through electrooculography and eye tracking, head movements have been less widely investigated. This may be due, in part, to the relative difficultly involved in concurrently recording head and eye movements. Studies that have looked at head movements generally rely on motion capture systems and separate external stimulus such as eccentrically located LEDs. While these set-ups have produce robust and accurate objective measures of head movement, they also come with a number of unavoidable drawbacks. Motion capture systems require large open spaces, lack portability, are prohibitively expensive to smaller studies and are limited by the choice of stimulus and mode of stimulus presentation. Here, we utilize the capabilities of a Head Mounted Display (Oculus Rift Developer kit 2) to study head movements in a Posner paradigm that address many of the limitations of those paradigms built around motion capture systems. The Head Mounted Display is capable of simultaneously presenting an immersive 3D environment with precision while also collecting head turn trajectories in 3 axis (yaw, pitch and roll) at up to ~1000Hz. 15 participants (18-25yrs) performed a speeded head turn task while head rotations and eye movements were monitored. Participants were seated on a fixed upright chair in comfortable position. At the start of each trial, participants aligned their heads to a neutral central position and were presented with an arrow cue, indicating the direction of the target. Participants rotated and aligned to the target. The target disappeared after 1.2 seconds, and participants self-initiated a return movement, to the neutral central position. The cue indicated the valid target direction 80% of the time and invalid direction the remaining 20%. The results of this study indicate that participants take longer to

initiate movement for invalid trials. Furthermore, the speed and latency of the movements in the valid trials were highly similar to that previously reported in the literature using similar paradigms. Furthermore, these paradigms have shown abnormal head control in small groups of people with movement disorders.This portable set-up and paradigm holds particular promise for acquiring large normative datasets from controls for comparison with people with movement disorders, such as cervical dystonia.

Title: Design of an experimental platform for voluntary behavioral training and neurophysiological study of the common marmoset

Authors: *J. WALKER, N. HATSOPOULOS;
Committee on Computat. Neurosci., Univ. of Chicago, Chicago, IL

Abstract: The common marmoset is a promising non-human primate model species for behavioral and systems neuroscience. As is true of other non-human primates, it has a well-developed frontal cortex and has remarkable capacities for motor control and sensorimotor integration. Its lissencephalic cortex, small size, and rapid breeding cycle provide important advantages for neurophysiological study including optical imaging, multi-site electrophysiology, and transgenic manipulation. Yet it maintains a reputation for being difficult to train in traditional experimental tasks. We report a novel self-training approach that allows marmosets to voluntarily participate in training for neuroscience experiments studying the cortical contribution to upper limb motor control. We designed a training apparatus to be attached to the home-cage with ducting allowing the marmosets to move to and from the training apparatus at will. We demonstrate that marmosets are able to learn to voluntarily take a posture within the apparatus appropriate for recording of both neural activity and the kinematics of the upper limb, and that marmosets are willing to participate in training throughout their waking hours in a manner similar to that described for their natural foraging behavior in the wild. This work provides a foundation for the use of the common marmoset as a model system for studying the neural basis of upper limb motor control.

Title: Evaluating motor and cognitive performances of elderly people using their handwriting features

Authors: ***M. TABATA, IV**[1], M. MATSUBARA[1], K. WATANABE[2], T. WATANABE[2], E. TANAKA[2], T. ANME[2], H. KAWAGUCHI[1];

Abstract: We aimed to establish a simple quantitative method for evaluating motor and cognitive performances of elderly people by analyzing their handwriting characteristics using a "digital pen." This device, which digitizes handwriting with a spatial resolution of 0.3 mm and a temporal resolution of 13 ms, can easily and simultaneously acquire data from many users. Therefore, the digital pen is suitable for screening decreasing motor and cognitive performances. The participants were 219 elderly people (56-93 years old, 20 males, 199 females) from the Joso project (Elderly People Health Empowerment Project in Joso city, Ibaraki Prefecture, Japan), which was conducted in co-operation with Joso city, University of Tsukuba, and Toyo University. Participants were required to use the digital pen to draw a picture without lifting the pen from the paper (one-stroke sketch task) and to complete two questionnaires, the Motor Fitness Scale (MFS) and a questionnaire relating to cognitive performance. Their physical and motor functions (PMF), such as body height, body weight, abdominal girth, handgrip strength, timed up and go test (TUG), and skeletal muscle index (SMI) were also measured. We analyzed several handwriting characteristics such as stroke time, writing pressure, writing speed, and writing speed acceleration. Significant correlations were noted between some handwriting indices and the scores of some MFS or PMF parameters (level of significance, $p < 0.05$). We also found significant correlations between MFS scores and those of the questionnaire relating to cognitive performance. Thus, handwriting data could be used in the simple evaluation of the motor and cognitive performances of elderly people, which, in turn may help in developing strategies for maintaining their quality of life. The protocols used in this study were approved by the Ethics Committee at University of Tsukuba.

Title: Description of sensitive tactile and motor pattern in infants with down syndrome

Authors: *D. HERRERO;
Case Western Reserve Univ. Sch. of Med., Cleveland, OH

Abstract: INTRODUCTION: As important as knowing "what" changes during motor development is to know "how" and "when" these changes occur. The absence of such data prevents us from describing this process in a continuous and linear fashion in groups of individuals with motor dysfunction, such as infants with Down syndrome. For example, the main references to motor development that are still used in published studies only informs us about the duration of reflexes, but not their pattern. Such studies report on movement intensity, but not on how it can be differentiated from the typical pattern. They may also mention that there is a delay on the emergence of gait, but not whether there is a relation between gait and motor memory. These data would give us relevant information on which stage of motor development infants with Down syndrome may have an alteration in the typical pattern of movement. In addition, they would allow us to optimize specific strategies of intervention for this group. PURPOSE: To describe the pattern of motor development in infants with Down syndrome. METHODS: This is a cross sectional study that is being conducted from March to July, 2015, in the Follow-up Ambulatory Unit at Darcy Vargas Children's Hospital, São Paulo, Brazil, in a clinic specialized in the care of infants with Down syndrome. The following steps are being performed: (1) memory assessment, (2) General Movements, and (3) application of questionnaire. The invitation for parents to participate in the research occurs during routine medical follow-up visits. RESULTS: Currently in this study, we have observed infants from birth to five months with diagnosis of Down syndrome presenting spontaneous movements characterized by moderate abnormal speed and range, with abrupt initiation and termination of movement, and uneven motion flow. Regarding the memory assessment, compared with preterm and term infants groups from previous studies, the subjects of our study were more like the preterm group in relation to the timing of activity execution, displaying longer time to recognize an object. With the video of spontaneous movement, we have data indicating that the articular ends of the feet and toes present less flexion in kick movements and proximity to body trunk, which translate into less

muscular tension and movement range. CONCLUSION: Both assessment scales give us information on the effect of trisomy 21 on central nervous system. The unique feature of our study in relation to previous studies is that both assessments are being done simultaneously, which allows us to characterize motor pattern, memory and articular motion and hopefully inform future, more specific intervention to this group.

Title: Memory-guided force output is associated with ADHD symptomatology in young adults

Authors: *K. A. NEELY[1], A. YODER[1], A. CHENNAVASIN[1], G. K. R. WILLIAMS[3], C. L. HUANG-POLLOCK[2];
[1]Dept of Kinesiology, [2]Dept of Psychology, Pennsylvania State Univ., State College, PA;
[3]Anglia Ruskin Univ., Cambridge, United Kingdom

Abstract: Visual feedback is a rich source of information for guiding human motor performance and provides a basis for the formation of memory to guide performance in the absence of visual feedback. The goal of this study was twofold: (1) to examine visually and memory-guided precision grip force in young adults and (2) to examine the relationship between motor performance and scores on the Conners' Adult ADHD Rating Scale (CAARS). To create a large group with a range of CAARS scores, we recruited adults ages 18-25 in two categories, those who self-identified as having ADHD persisting into adulthood and those who self-identified as never having been given a diagnosis of ADHD. Participants (N = 40) completed 20-second trials of isometric force with their index finger and thumb, equal to 25 % of their maximum voluntary contraction. The visual display contained a movable force bar and a stationary target bar. Participants were instructed to move the force bar vertically to overlap the target bar indicating the target amplitude. Real-time visual feedback was provided for the first 8 seconds of the trial. In the remaining 12 seconds, participants were to maintain the same amount force in the absence of visual feedback. All participants completed CAARS-Self Report: Short Version and subscale scores were used as covariates. When participants had visual feedback to guide their force output, force was maintained at a constant level in the last 12 seconds of the trial. In other words, there was no effect of time on mean force output when visual feedback was available. In contrast, when visual feedback was removed, force output decreased as a function of time.

Moreover, the rate of decrease was associated with higher scores on the CAARS subscales for Inattention/Memory Problems, Impulsivity/Emotional Lability, and ADHD Index. This finding suggests that these cognitive domains are important for developing an accurate and stable representation from which to guide force production in the absence of visual feedback. Further, cognitive impairment in these domains may contribute to abnormalities in sensorimotor control in young adults with ADHD.

Title: Transferring experience of agency from voluntary to involuntary movement

Authors: *N. KHALIGHINEJAD, P. HAGGARD;
Univ. Col. London, London, United Kingdom

Abstract: Sense of agency refers to the capacity to control one's actions, and, through them, the external world. Internal signals within the basal-ganglia-thalamocortical loops are associated with a conscious sense of trying, or willing. Association between these signals with other events could be a basic mechanism for acquiring sense of agency. This presumably occurs during early human motor development, but is not remembered. We have investigated whether healthy adults could acquire new agency-like experiences with respect to involuntary movements, through such associative mechanisms. We used the perceived temporal relationship between an action and its sensory outcome as an implicit proxy measure of sense of agency. 34 healthy volunteers, 18-35 years of age were tested in two separate experiments. In the first experiment, self-paced voluntary actions of one hand were paired with involuntary twitches of the other hand, triggered by transcranial magnetic stimulation (TMS), followed by a tone 250ms later. These learning trials alternated with test trials containing only involuntary twitches followed by tones. Participants judged the time of the tone using a rotating clock display: a perceptual shift of tone towards preceding action is an established index of agency. In a control experiment, participants again judged the time of the tone following an involuntary twitch, but the twitch was never associated with any voluntary action. In the first experiment, participants perceived tones as shifted towards the test trials with TMS-induced twitches that caused them. This ‘intentional binding’ was absent in the control experiment. We showed, for the first time, that coupling an

involuntary movement to a voluntary action leads to acquiring an agency-like experience with respect to the involuntary movement. This finding suggests that we learn to be voluntary. This research could guide development of neuroprosthetic systems designed to augment voluntary motor control.

Title: Capacity of motor representation through the task of implicit motor imagery in patient with mild cognitive impairments

Authors: ***J. BOURRELIER**[1,2], A. KUBICKI[1,2], O. ROUAUD[3], F. MOUREY[1,2];
[1]INSERM U1093 Cognition Action Sensorimotor Plastic, Dijon, France; [2]Univ. of Burgundy, Dijon, France; [3]Memory Resources and Res., Univ. health Ctr., Dijon, France

Abstract: Mild cognitive impairment (MCI) is an early stage associated in Alzheimer's disease (AD). It is characterized by a cognitive decline greater than expected for age without a significant disruption in one's daily functionality (Albert, 2011). The investigations in motor control during early stage of AD are relatively scarce. This topic should raise a greater interest to allow the introduction of preventive action to maintain the functional physical capacity in aged people with cognitive impairments. In the present study, we wanted to assess the mental representation ability in patients with mild cognitive impairment related-AD through implicit motor imagery (IMI) task. Motor imagery is the ability to create a mental simulation of movement without a concomitant execution. We used an implicit task of hand laterality judgement (Parsons, 1987). To judge of the laterality, the participant imagines implicitly moving his own hand into the orientation and the view (e.g. palm) of the stimulus. These motor processes committed in the IMI task, are engaged also at the motor preparation of action and followed the common neurophysiological way (Jeannerod, 2001). 24 elderly participants aged between 65 and 90 years old (12 women, 73.4 ± 6 years, mean ± S.D.), 12 subjects whom have a Mild Cognitive Impairments related to AD (MCI group) and 12 healthy aged adults (HAA group), were included in the study. First, there is no difference of response time (RT) and accuracy (Acc, calculated though the rate of wrong responses) between the both groups on a simple reaction time task (SRT) and a discrimination task (DT) between two neutral stimuli (left or right arrows) (SRT: RT, $t20 = -1.54$, $p=0.138$; DT: RT, $t22 = -1.16$, $p=0.255$; Acc, $t22 = -1.54$ $p=0.137$). Comparatively, there is a significant difference of response time and the accuracy for the IMI task between the groups (RT, $t22 = -4.89$, $p < 0.001$; Acc, $t22 = -2.88$, $p = 0.008$). In fact, the

further analysis in IMI performance, revealed disparities between both groups in the hardest conditions of IMI task. These kinds of conditions correspond to mentally representation of the non-dominant hand (RT, hand (left-right)*group, $F(1.22)= 6.965$, $p= 0.014$; post hoc Tukey's test, RThand*MCI , $p< 0.001$), of complex orientation angles and of non-congruent view related to own posture. To conclude, the results showed that the patients with MCI are always able to achieve the IMI because duration of the mental rotation process is influenced by the stimuli orientations (RT-orientation ($F(7.154)=41.768$, $p<0.001$), which reflect different biomechanical constraints (Sauner, Bestmann, Siebner, & Rothwell, 2006).

Title: Immature motor control contributes to deficient reactive driving performance in adolescents

Authors: *C. KIM, H. MOON, N. LODHA, E. CHRISTOU;
Univ. of Florida, Gainesville, FL

Abstract: The highest car accident and fatality rates occur for adolescents around the minimum legal driving age (15 years in the US). Our purpose was to determine whether reactive driving in adolescents is impaired relative to young adults. Six adolescents from 13-16 years old (13.7 ± 1.4 years) and eleven young adults (20.3 ± 2.1 years) performed a simulated reactive driving task and an isolated visuomotor task with the ankle. In the reactive driving simulation task, participants controlled the gas pedal during a visuomotor task and responded to a sudden visual stimulus by moving their foot from the gas pedal to the brake pedal. Their goal was to apply 40 N force on the brake pedal as quickly and as accurately as possible. Gas pedal control was quantified with the gas pedal error. Brake pedal control was quantified with the brake force error and variability. The response to the visual stimulus was quantified with the pre-motor response time (from stimulus onset to tibialis anterior (TA) activity onset) and motor response time (onset of TA activity to onset of the brake pedal force). We quantified an overall reactive driving index by averaging the normalized scores from gas pedal control, pre-motor response time, motor response time, and brake force control. During the isolated visuomotor task, participants tracked a sinusoidal target at a frequency of 0.5 Hz by producing isometric ankle dorsiflexion forces. We quantified ankle force variability. We found that adolescents under 16 years of age exhibited

impaired motor control compared with young adults as quantified by greater force variability during the isolated visuomotor task ($t = 5.2$, $p < 0.001$) and greater brake force variability during the reactive driving task ($t = 4.42$, $p < 0.001$). The overall reactive driving index was also greater in adolescents than young adults ($t = 5.53$, $p < 0.001$) and the score was significantly related to age ($R2 = 0.58$, $p < 0.001$). Finally, the overall reactive driving index score was correlated with both measures of motor output variability (isolated visuomotor task force variability: $R2 = 0.37$, $p = 0.013$; brake force variability: $R2 = 0.61$, $p < 0.001$). In conclusion, these findings suggest that immature motor control in adolescents contributes to deficient reactive driving performance compared with young adults. The motor control deficiency in adolescents could contribute to higher car accident rates independent of other contributing factors, such as distraction.

Title: The effect of coordinate frame on motor learning in Alzheimer's disease and Parkinson's disease

Authors: K. A. CAULFIELD[1], Y. R. MIYAMOTO[2], J. M. BRETON[3], J. B. BRAYANOV[2], M. A. SMITH[2], *D. PRESS[1];
[1]Dept Neurol., Beth Israel Deaconess Med. Ctr., Boston, MA; [2]Sch. of Engin. and Applied Sci., Harvard Univ., Cambridge, MA; [3]Neurosci., Univ. of Calif., Berkeley, Berkeley, CA

Abstract: Alzheimer’s disease (AD) causes deficits in performing previously learned motor skills, but its effects on the acquisition of motor skills remains uncertain. Independent cortical networks allow for acquisition of motor skills in an intrinsic, body-based reference frame, as compared to an extrinsic, world-based reference frame. Previous studies did not disambiguate these reference frames, possibly explaining the mixed results. The neuropathology of AD shows substantial atrophy in parietal areas that may be crucial for acquisition of extrinsically-referenced skill, but relative sparing of motor cortical regions likely necessary for the acquisition of intrinsically-referenced skill. We therefore hypothesized that AD participants would display deficits in extrinsically-referenced learning, leading to a shift towards acquiring skill in a more intrinsic reference frame. We recently found that healthy participants learn a visuomotor rotation (VMR) task in a combination of intrinsic and extrinsic space. In this study, we tested AD participants (n=17) and age matched controls (n=20) on this task in which participants conducted

9cm point-to-point reaching arm movements to ±30° VMR. Movements in 10 directions were tested both in trained and novel workspaces. In the novel workspace, the arm posture was rotated by 90°. This change in arm posture resulted in a 90° shift in the correspondence between intrinsic and extrinsic representations of the movement direction. In the novel workspace, this allowed the degree to which the peak generalization shifts away from the trained target to quantify how much the learned adaptation is represented in intrinsic vs extrinsic reference frames; no shift would occur if adaptation were represented in a purely extrinsic frame, since the extrinsic movement direction corresponding to the trained target is maintained. In contrast, a 90° shift in generalization would be expected if adaptation were encoded in a purely intrinsic frame. In the novel workspace, we observed shifts in generalization that were significantly closer to 90° for the AD participants than for the healthy elderly controls (69.9° vs. 52.2°). These data indicate that AD patients have reduced extrinsically-referenced learning abilities, perhaps due to parietal lobe dysfunction, $p = .0012$. Lastly, we plan to test VMR shifts in generalization in Parkinson 's disease (PD) participants. Since PD patients have dysfunction in motor cortical regions that are implicated in the acquisition of intrinsically-referenced skill, PD participants may show deficits in intrinsically-referenced learning.

Title: Inter-subject coherence in frontal pole increases during better group walking

Authors: ***S. IKEDA**[1], T. NOZAWA[1,2], R. YOKOYAMA[3], A. MIYAZAKI[4], Y. SASAKI[4], K. SAKAKI[4], R. KAWASHIMA[1,2,4,5];

Abstract: A rhythm of sound (70 BPM) is known to promote walking flow during the group walking. This phenomenon can be intuitively understood because pedestrians can keep smooth flow of walking along to the rhythm sound. We had a simple question of how the rhythm sound changes pedestrians' cognitive processes. However, no studies have investigated changes of the cognitive processes during the group walking of the rhythm sound. Our hypothesis was that

inter-subject coherence in the frontal pole increases during better group walking. The frontal pole is known to be associated with a role for predicting the behaviors of others during cooperation action. We investigated the coherence between subjects' signals from the frontal pole while the subjects performed the group walking. The brain activities were measured by ultra-small NIRS that can simultaneously and wirelessly measure multi-subjects' signals. In the group walking, the subjects (24 or 25) were asked to walk on a circle with a radius of two meters, and to walk naturally, keeping smooth flow in mind. As a control condition for the group walking, the subjects performed stepping. The stepping is similar in movement to the group walking but the subjects can perform it without consideration for others' pace. Our experiment, therefore, consists of four conditions (i.e. rhythm walking, no-rhythm walking, rhythm stepping, and no-rhythm stepping). Using wavelet transform coherence which is a method of measuring the coherence between two signals as a function of frequency and time, we calculated inter-subject coherence for each frequency (0.01_0.1 Hz). We, then, calculated ΔW (walking) and ΔS (stepping) which showed the coherence difference between rhythm and no rhythm conditions, and evaluated whetherΔW was statistically larger than ΔS for each frequency. We observed that the walking flow increased in the rhythm condition compared to that in the no-rhythm condition. Furthermore, ΔW was larger than ΔS in frequencies from 0.03 to 0.04 Hz, which was interaction effect between the rhythm sound and the group walking. Our results suggested that rhythm sounds like that used in our experiment might promote inter-subject coherence during cooperation action by a group.

Title: Hand Blink Reflex modulation during a voluntary movement

Authors: *M. BOVE[1], M. BIGGIO[1], E. FALSINI[1], C. FOSSATARO[2], F. GARBARINI[2], A. BISIO[1];
[1]Univ. of Genoa, Genoa, Italy; [2]Univ. of Turin, Turin, Italy

Abstract: Defensive reflexes are primitive and involuntary motor responses to potentially dangerous stimuli, mediated by fast, subcortical pathways. It has been recently demonstrated that the Hand Blink Reflex (HBR), which is a subcortical response at the brainstem level elicited by the electrical stimulation of the wrist, is modulated by the proximity of the stimulated hand to the face, being dramatically increased when the hand is inside the peripersonal space surrounding the

face. The experimental paradigm used in this previous study was based on evaluating the HBR amplitude during different static positions of the hand. In our opinion, the defensive peripersonal space is not only modulated by the position of the hand but also by the intentional direction of the movement. To this aim we investigated the role of the voluntary movements in modulating this defensive physiological response. Here, we asked whether, on equal hand positions, the intentional direction of the hand movements (either close to the face or far from the face) can modulate the HBR. Electromyographic activity was recorded from the orbicularis oculi bilaterally in three different conditions, in which the subjects were asked a) to stay still ("static hand"), to move their arm close to the face ("far-near" movement direction) or far from the face ("near-far" movement direction). In each condition, the HBR was elicited by delivering electrical stimuli to the median nerve at the wrist in three hand positions, depending on the amplitude of the elbow angle: with the arm frontally extended at ~180° (α1; far from the face); tilted at ~90° (α2; intermediate position); tilted at ~45° (α3; close to the face). We extracted the area under the curve of each HBR average waveforms and we entered the obtained values in a RM-ANOVA with two between factors "condition" (three levels: static, up, down) and "angle" (three levels: α1, α2, α3). Our results showed a significant interaction angle*condition ($p = 0.0003$), suggesting that the same angle amplitude induces different HBR modulation, depending on the condition. In particular, in the "static hand" condition, we replicated the previously described HBR increase in α3 (near-position) with respect to the α1 (far-position). In the "far-near" condition, the HBR increase in α3 was found with respect to both α1 and α2. Crucially, in the "near-far" condition, no difference between the three angles was found. These findings suggest that, when the hand is close to the face but the subject is planning to go down, the motor system through a combination of a feedforward and feedback control is able to anticipate the final state of the movement: the "near" becomes "far".

Title: Kinematic description of handwriting movements during fMRI examination

Authors: ***A. BISIO**[1], L. BONZANO[1], L. PEDULLÀ[1], C. BRUNO[1], A. TACCHINO[2], G. BRICHETTO[2], M. BOVE[1];
[1]Univ. of Genoa, Genova, Italy; [2]Fondazione Italiana Sclerosi Multipla, Genoa, Italy

Abstract: Despite the widespread use of computers, handwriting represents an important form of communication among individuals that is acquired from childhood. Indeed, writing plays a crucial role in school performance, with important implications for motor and cognitive development. Due to neurological diseases as, for instance, multiple sclerosis, handwriting skills can deteriorate till interfering with daily life activities. Writing rehabilitation is one of the target of the occupational therapy treatments, which includes new techniques emphasizing the learning and practice of functional motor skills within a task-specific context. However, due to the low sample of scientific work at disposal, reliable quantitative data on the efficacy at behavioral level of this kind of interventions are lacking, as also it is not clear whether and what are their effects on brain networks. The aim of the present study was to define an evaluation methodology that allows to quantitatively characterize the kinematics of handwriting movements and to correlate the behavioral measures with structural and functional brain architecture using non-conventional magnetic resonance imaging (MRI) techniques. This represents the first part of a project whose ultimate goal is to assess the differences in movement planning and execution of handwriting movements between people affected by multiple sclerosis and healthy age-matched controls. As first step we tested the goodness of kinematics measurements inside the magnetic scanner, during a functional MRI (fMRI) session. To do that we compared the spatiotemporal kinematic data acquired by mean of a MRI-compatible tablet (E.M.S. srl, Bologna) during a fMRI test with those obtained in an ecological condition where the subject was seated at the table and wrote with an ink-jet pen over a paper positioned on the surface of the tablet. Twenty-two healthy participants were enrolled for the study. They were requested to write the Italian sentence “Il sole scalda” (i.e., “The sun warms”) for three times in each experimental condition. Kinematic analysis showed that, although spatiotemporal features (movement duration, amplitude and velocity) of the written trace augmented significantly during fMRI acquisition ($p<0.05$), significant correlations among the kinematic parameters acquired outside and inside the magnetic scanner were obtained (duration $p<0.05$, amplitude $p<0.05$, mean velocity $p<0.01$)) indicating a similar motor behavior in these two conditions. Therefore, we can suggest that this approach to evaluate the kinematic of handwriting during fMRI session provides reliable kinematic measurements.

Title: Electric and acoustic stimulation during movement preparation can facilitate movement execution in healthy participants and stroke survivors

Authors: *W. MARINOVIC, S. BRAUER, K. S. HAYWARD, T. CARROLL, S. RIEK;
The Univ. of Queensland, Brisbane, Australia

Abstract: The presentation of unexpected loud acoustic stimuli (LAS) during movement preparation has been used to investigate movement preparation and initiation in healthy participants. Recent studies have shown that LAS can also facilitate movement initiation and execution in chronic stroke survivors, motivating the examination of alternate methods of sensory stimulation that could be used in therapies for movement recovery. Here we sought to determine whether somatosensory (e.g. electric) stimulation could be used to facilitate movement execution and initiation in healthy participants and chronic stroke survivors. In Experiment 1, 15 healthy participants performed an arm supination action in response to a visual go-signal. In some trials, we presented either an auditory (50 ms white-noise, 114dBa) or electric stimulus (2 ms pulse) in synchrony with the presentation of the go-signal. In Experiment 2, 12 healthy participants performed the same task, but we delivered electric stimulation either to the ulnar styloid process or to the short-head of biceps brachii. In Experiment 3, 12 healthy participants attempted to perform finger abduction in synchrony with the predicted time of appearance of the last of a sequence of four flashes on a monitor screen. Occasionally, acoustic, electric or combined stimulation were presented 200 ms prior to the expected time of movement onset. In Experiment 4, five chronic stroke patients and 8 healthy adults performed a reaching task in response to a visual go-signal. Acoustic and electric stimuli were used as in Experiment 1. We found that electric stimulation was as effective as acoustic stimulation in facilitating motor actions in both reaction time and anticipatory timing tasks (Exp. 1 and 3), and that the site of electric stimulation made little difference in facilitating motor actions (Exp. 2). Simultaneous acoustic and electric stimulation caused faster release of anticipatory actions than unimodal stimulation of either modality (Exp. 3). Finally, the responses of both chronic stroke patients and healthy adults were faster and initiated earlier than normal in the presence of both types of sensory stimulation in a functional reaching task (Exp. 4). Our results suggest that electric and acoustic stimulation impact movement initiation and execution through arousal elicited by strong and unexpected sensory stimulation. They also demonstrate that cross-modal stimulation can be useful to boost the facilitatory effects of sensory stimulation on movement execution and initiation. These findings may lead to new avenues for experimental and clinical exploitation of the effects of sensory information on movement execution.

Title: Investigating the role of mIPS in movement planning using HD-tDCS

Authors: ***S. XU**[1], J. P. GALLIVAN[1], G. BLOHM[1,2,3];
[1]Queen's Univ., Kingston, ON, Canada; [2]Canadian Action and Perception Network (CAPnet), Toronto, ON, Canada; [3]Assn. for Canadian Neuroinformatics and Computat. Neurosci. (CNCN), Kingston, ON, Canada

Abstract: The medial part of the intraparietal sulcus (mIPS) has been traditionally viewed to be involved in the integration of target and effector to generate a motor plan. However, the precise contribution of the mIPS is unclear. Previous transcranial magnetic stimulation studies have suggested a role in performing motor vector calculations based on visual cues of initial hand position as well as in implementing the direction vector (Vesia et al 2010; Davare et al. 2011). Here we used high definition-transcranial direct current stimulation (HD-tDCS) to locally modulate neuronal excitability in a polarity-specific manner in the left mIPS to investigate the role of mIPS in movement planning during visually guided reaching. The left mIPS was functionally localized on an individual-basis using functional magnetic resonance imaging (fMRI) during performance of a center-out interleaved pointing and saccade task. We then used BrainSight to localize mIPS on the scalp of each participant and administered anodal and cathodal stimulation (2mA for 20min; 3cm radius 4x1 electrode placement) over the left mIPS in two separate sessions separated by a week within a randomized, single-blind design. Participants were asked to perform memory-guided reaching movements from one of 2 initial hand positions (5cm left/right of midline) to one of 4 randomly chosen briefly flashed targets (20cm distant, 5cm apart horizontally) while fixating on a straight-ahead cross located on the target line. Each participant completed a minimum of 200 control, stimulation and post-stimulation trials. We examined amplitude errors and direction errors for 3 participants. In general, anodal tDCS (during and post stimulation) resulted in over-reaching compared to pre-stimulation controls while under-reaching was observed during and after cathodal stimulation for both ipsilateral and contralateral reaches, and from all initial hand positions to all targets. Directional error analysis revealed that for all subjects, anodal stimulation induced directional gains, specifically under-reaching to all targets, while cathodal stimulation induced directional shifts, specifically, under-reaching to rightward targets, and over-reaching to leftward targets. These results are consistent with a role of mIPS in reach planning. Direction and amplitude modulations in our experiment

indicate that at the level of mIPS, initial hand position and target position have been integrated into a reach vector code. This validates the use of HD-tDCS as a tool to study the causal role of cortical areas in movement planning.

Title: Neuroanatomical basis of the intentional response deficits associated with unilateral neglect: an rTMS study in healthy subjects

Authors: M. GUTIERREZ-HERRERA[1], S. SAEVARSSON[2], T. HUBER[3], *J. HERMSDORFER[1], W. STADLER[1];
[1]Technische Univ. München, München, Germany; [2]Klinikum Bogenhausen, München, Germany; [3]Klinikum rechts der Isar, München, Germany

Abstract: Studies exploring the neuroanatomical basis of the intentional response deficits (IRD) associated with neglect have reported contrasting findings, with lesion sites ranging from right parietal to subcortical and frontal areas (e.g. Vossel et al, 2010; Ghacibeh et al, 2007; Husain et al, 2000). The present study assessed the occurrence of IRD following the application of repetitive transcranial magnetic stimulation (rTMS) to the right middle frontal (rMFG) and angular (rAG) gyri in healthy subjects. Sixteen participants underwent a 10-Hz rTMS protocol (600 ms duration) while performing a pointing task with the right hand to either of two lateral targets, under two task conditions (i.e. internally guided [IG; pointing side freely selected] vs. externally guided [EG; pointing side spatially cued]) and two visual feedback conditions (i.e. blindfolded vs. sighted). The experiment consisted of three counterbalanced blocks including rMFG stimulation, rAG stimulation and no-TMS (control condition). Three main variables were considered for the analysis (i.e. movement time, reaction times and frequency of leftward vs. rightward IG movements). A repeated measures analysis of variance (ANOVA) conducted on movement times revealed a significant interaction between stimulation site and movement direction, $F(2,32) = 10.55$, $p < .05$, with left directed movements showing longer movement times under parietal stimulation conditions compared to control ones. As to reaction times, a repeated measures ANOVA showed a significant interaction between task condition, movement direction and stimulation site, $F(1.44, 21.69) = 9.95$, $p < .05$. This interaction was given by the presence of longer reaction times for left compared to right directed movements under EG

conditions, when receiving frontal stimulation. Furthermore, a generalized linear model analysis with binary logistic regression conducted on the frequency of leftward vs. rightward IG movements, indicated movement direction to be significantly predicted by the interaction between visual feedback and stimulation site, b= -0.58, Wald $\chi 2(1) = 7.06$, $p < .05$. This interaction pointed to a reduced number of leftward movements under blindfolded conditions compared to sighted ones, when frontal stimulation was applied. Our findings suggest that rMFG and rAG have different roles in the manifestation of IRD, with the former related to planning and initiation difficulties and the latter affecting movement execution. Such evidence would be in line with the idea that neglect is a modular syndrome (Coulthard et al, 2007) and the variability of IRD may depend on the amount of damage to specific nodes in the visuomotor network.

Title: Associative sensorimotor learning of manipulation in humans: role of premotor dorsal area

Authors: *P. J. PARIKH, M. SANTELLO;
Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: Humans have an exquisite ability to learn motor behaviors through arbitrary sensory cues. Non-human primate work suggests that dorsal premotor area (PMd) is involved in building associations between arbitrary visual cues and movements. However, the role of PMd in arbitrary sensorimotor learning in humans is not well understood. In this study, we hypothesized that integrity of PMd is necessary for learning a sensorimotor task that required human subjects to manipulate, using two-digit precision grip, an object whose center of mass was cued by arbitrary colors. The manipulation task required participants to grasp and lift an inverted T-shaped grip device while balancing it. The center of mass (CM) of the device was pseudo-randomly changed across trials by adding a 400-g mass at the base of the object (right, center, or left location). Through trial and error, participants were required to learn the association between the arbitrary color cue and CM location, and exert the required torque on the object to balance it over 3 blocks of 20 trials each. For right and left CM locations, participants were required to exert compensatory counterclockwise and clockwise torque, respectively, on the object to balance it. For centered CM, participants were not required to exert any torque on the object. We found that right-handed young adults (n=11) learned to associate arbitrary color cues about CM location to balance the object. Specifically, we found a significantly greater torque error

averaged across trials (avTerr) for block 1 than block 2 ($p < 0.01$), whereas no difference was found between avTerr for blocks 2 and 3. Next, we used continuous theta burst transcranial magnetic stimulation (TMS) to disrupt contralateral PMd on separate group of participants (n=8) before they learned the same task. Following disruption of PMd, participants produced greater avTerr for block 1 as compared to participants that did not receive TMS ($p=0.008$). For block 2, there was a trend toward a statistically significant difference between avTerr produced by the TMS group versus No TMS group ($p=0.056$). No group difference was found on the manipulation performance during block 3. These results indicate that disruption of PMd interfered with participants' ability to associate arbitrary cues with anticipatory control of manipulation. Therefore, our study suggests that contralateral PMd plays an important role during acquisition of a sensorimotor task based on arbitrary visual cues.

Title: Sparse encoding of natural "in-the-wild" hand movements

Authors: *A. A. FAISAL[1], A. THOMIK[2];
[1]Imperial Col. London, London, United Kingdom; [2]Imperial Col. London, London, United Kingdom

Abstract: A fundamental problem in neuroscience is to understand how the brain translates a symbolic sequence of action descriptors, or high-level motor intention, into appropriate movement of the limbs. Starting from a large collection of hand movement data collected using an unobtrusive motion capture glove “in-the-wild” (i.e. in daily life) we develop a data-driven approach to seek a model of movement generation capable of capturing both spatial and temporal structure of natural behaviour. Drawing inspiration from findings in the sensory system, we assume that the brain generates hand movements by activating a temporally sparse sequence of sparse eigenmotions. These sparse eigenmotions - building blocks of natural movement - are characterised by very high correlation of the joints involved in the movement. To identify the set of sparse eigenmotions required for a parsimonious representation of the data, we developed a

new dictionary learning approach which determines the number and shape of sparse eigenmotions directly from the data in an unsupervised fashion. We show that the dictionaries of sparse eigenmotions learnt are consistent across subjects with some minor variations, likely due to individuality and differences in activities. We also find that the number of sparse eigenmotions identified in the data grows logarithmically with increasing amounts of data, not unlike the number of different words in an English language text. We thus postulate a "language of natural movement" where the brain composes meaningful behaviour by aligning sparse eigenmotions according to a yet to be determined rule set. In a first step towards understanding these rules, we determine the encoding of our data using the learnt dictionaries. Using orthogonal matching pursuit (OMP), we identify the temporal sequence of sparse eigenmotions required to represent the data in optimal fashion. Analysis of the structure of the encoding is currently ongoing. This work has multiple implications: (1) it offers a potential mechanism for movement generation by the brain which is richer and potentially more natural than previous work relying on dimensionality reduction by principal component analysis. Our sparse eigenmotions may thus reflect behaviour induced by neurons akin to grasp-type specific neurons found in the monkey premotor cortex. (2) The knowledge of the spatiotemporal structure of natural movement may contribute to the design of neural prostheses which are easier to control and contribute to a better quality of life for amputees.

Title: Effects of androgen on GnRH3 neurons in slice culture of the tilapia brain

Authors: ***Y. NARITA**[1], A. TSUTIYA[1], T. KANEKO[3], R. OHTANI-KANEKO[1,2];
[1]Grad. Sch. of Life Sci., Toyo Univ., Gunma, Japan; [2]Bio-Nano Electronics Res. Ctr., Toyo Univ., Saitama, Japan; [3]Grad. Sch. of Agr. and Life Sci., Tokyo Univ., Tokyo, Japan

Abstract: Gonadotropin-releasing hormone type III (GnRH3) neurons are reported to control male reproductive behaviors such as nest building and aggressive behaviors in tilapia. In our previous study, we found the sexual dimorphism of GnRH3 neurons in tilapia; males have a greater number of GnRH3 neurons in the terminal nerve (TN) than females. Treatment with 11-ketoteststeron (11-KT) and methyltestosterone, but not with 17β-estradiol (E2), increased the number of GnRH3 neurons in mature females to a level similar to that in males (Kuramochi et

al., 2011). In addition, our recent study revealed that androgen treatment increased proliferating (PCNA-positive) cells and Hu-positive neurons in the female TN. We also found that Hu-positive neurons with 5-bromo-2'-deoxy-uridine (BrdU) labeling were significantly increased after simultaneous injection of 11-KT and BrdU to females. Furthermore, about 20% of increased GnRH3 neurons were labeled with BrdU in females injected simultaneously with 11-KT and BrdU, while the rest of GnRH3 neurons were not labeled with BrdU. These results indicated that androgen induced adult neurogenesis in the female TN and that the androgen-induced increase of GnRH3 neurons in females is mediated partly through adult neurogenesis. The objective of the present study is to know from where new GnRH3 neurons originate after females were treated with 11-KT. Do they originate within the TN, or originate from other brain regions and migrate to the TN? To answer the question, we prepared female brain slices including the TN and cultured them with or without 11-KT. When slices were cultured in the medium containing 11-KT (11-KT-treated slices) or just solvent ethanol (control slices) for three days, GnRH3 neurons were significantly increased in 11-KT-treated slices, compared to those in control slices. However, when slices were cultured in the medium containing 11-KT and either BrdU or 5-ethynyl-2'-deoxyuridine (EdU) for three days, GnRH3 neurons with BrdU- or EdU-labeling in the nucleus were scarcely found in the slices. These results indicated that androgen is able to induce the differentiation of GnRH3 neurons and increase their number in the TN, although the new generation of GnRH3 neurons may not be induced within the TN. Therefore, it was suggested that the newly generated (BrdU-labeled) GnRH3 neurons observed in the TN *in vivo* after 11-KT- and BrdU-injections may arise outside the TN and then migrate to the TN.

Title: The effect of steroid hormones on neurogenesis in the green anole lizard brain

Authors: N. A. BOOKER[1], J. SON[1], N. D. HART[1], Y. LEE[1], *R. E. COHEN[2];
[1]Biol. Sci., Minnesota State Univ. Mankato, Mankato, MN; [2]Biol. Sci., Minnesota State University, Mankato, Mankato, MN

Abstract: Gonadal steroid hormones, such as testosterone (T) and its metabolites (dihydrotestosterone, DHT and estradiol, E2), are important for maintaining reproductive behaviors and brain morphology, including the survival of new adult-born neurons. These hormones change dramatically in seasonally breeding animals, including the green anole lizard (Anolis carolinensis). In addition to changing steroid hormone levels, anoles have altered brain morphology and reproductive behaviors in the breeding (BS) and non-breeding seasons. For example, the preoptic area (POA) is larger in volume and the medial amygdala (AMY) has fewer neurons in the BS. These structural changes may be related to seasonal differences in steroid hormone levels. To examine how steroid hormones alter brain morphology, we gonadectomized breeding adult male lizards and inserted subcutaneous capsules containing T, E2, or DHT, or capsules that were left empty. Animals were then injected with bromodeoxyuridine (BrdU) to mark new cells. Brains were collected 25 days after the last BrdU injection and an immunohistochemistry for BrdU and Hu C/D (a neuronal marker) was conducted. We found that new neurons (BrdU/Hu positive cells) were present in the AMY of this species and we are currently counting these cells to determine whether different hormone treatments impact the survival of new neurons in the anole AMY during the BS. In addition, we found that animals treated with androgens had a larger POA volume, as defined by Nissl staining, compared to those treated with empty or estradiol capsules, and are currently investigating the effects of steroid hormone treatment on cell number and soma size in both the AMY and POA. These preliminary results help to further determine how steroid hormones impact changes to brain morphology and neurogenesis during the breeding season in a non-avian reptile.

Title: The last hours before singing··· short-term dynamic transcriptomes after testosterone treatment in female canaries

Authors: *M.-C. KO[1,2], C. FRANKL-VILCHES[1], A. BAKKER[1], M. GAHR[1];
[1]Max Planck Inst. For Ornithology, Seewiesen, Germany; [2]IMPRS for Organismal Biol., Seewiesen, Germany

Abstract: Singing is a sexually dimorphic behaviour in domestic canary (Serinus canaria), given that female canary song is rarely observed in nature. Nonetheless, female song can be induced within 3-5 days and crystalized (fully differentiated) within 1 month by testosterone (T)

treatment. Such plasticity of female canary provides an excellent model to study hormone modulation in the brain hence stimulation of behavior. To investigate the dynamic expression of T-driven singing-related genes and their biological pathways of the emerging female singing, we analyzed female canaries treated with T for short (1, 3, 8 hours) or long duration (3, 7, 14 days), and untreated controls (n=6 in allgroups). Plasma T concentration and vocalization were monitored before and during implantation. Animals were sacrificed by decapitation after the desired implant duration, and brains were removed. Subsequently, we performed exon-level microarray analyses (Affymetrix) of the transcriptomes of microdissected HVC (a crucial area of the song control system) and entopallium (visual region). We detected singing activity from day 4, whereas the plasma T increased radically (>450 fold than baseline) after 1h, peaked at 3h (>550 fold), and gradually decreased until 14d (>130 fold). Correspondingly, HVC exhibited rapid and strong transcriptional response to T, as 684, 4990 and 4549 genes were up-regulated after 1, 3, and 8 hours, respectively; compared to the untreated controls. Further, we found long-lasting transcriptional responses given that 4022, 2594 and 5946 genes were up-regulated after 3, 7 and 14 days, respectively. Whereas about 18% of genes expressed in HVC were continuously up-regulated between 3h and 2 weeks of T-exposure, about half the transcriptional regulation was dynamic and progressive. Gene ontology analysis of the up-regulated genes at the various time-points revealed the following dominant pathways: histone modification (1h), angiogenesis, mitosis (3h), G-protein activities (8h), protein synthesis and cell signalling (3d), vascular system development, neuron projection development, neurogenesis and neuron-neuron synaptic transmission (7d), (regulation of) cell differentiation and cell migration (14d). Our results indicate that adult female canary HVC transcriptome is highly sensitive to T. Studying the dynamics of gene expression after T treatment can elucidate the sequence of cellular changes necessary to develop singing behaviour and fully-differentiated songs.

Title: Intraspecific variation in hormone modulated neuroplasticity in canaries

Authors: *F. N. MADISON[1], G. F. BALL[2,1];
[1]Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD; [2]Dept. of Psychology, Univ. of Maryland, College Park, MD

Abstract: Previous work in our lab has shown that male canaries of the American singer strain did not exhibit hormone-modulated plasticity in the song control nucleus HVC as can be readily observed in other strains such as the Border canary. In response to high exogenous testosterone (T), male American singers responded in a variable manner. For example, various doses of T did not consistently induce an increase in the volume of the song nucleus HVC. Our data suggests that domestication of the American Singer canary, via human selection perhaps to lock-in a certain level of song quality and quantity, has led to a decrease in neuroplasticity associated with changes in a hormonal action. In order to characterize hormone modulated neuroplasticity in the avian and mammalian brain, the microtubule-associated protein doublecortin (DCX) has been shown to facilitate neuronal migration and final positioning of newly born neurons and is densely expressed in the adult canary HVC thereby serving as a marker of adult neurogenesis. In this study, we investigate possible strain differences in response to T on HVC volume in adult male American singer and Border canaries exposed to identical environmental conditions. Fifteen male American singer (AM) and fifteen male Border canaries (BDR) were housed on a short day 8L:16D light cycle for at least eight weeks, rendering them photosensitive. Birds were then placed into groups of intact (INTACT), castrated (CX), and castrated implanted subcutaneously with one 12mm length Silastic implant filled with crystalline T (CX+T). Immediately after implantation, birds were individually housed in sound attenuated chambers on the 8L:16D light cycle for three weeks. After three weeks of treatment, brains were collected from male AM and BDR canaries, sectioned, and HVC volumes were measured based on Nissl stained sections. Brain sections were also analyzed via immunohistochemistry for DCX and immunopositive cells were counted in HVC. Consistent with our hypothesis, we found that HVC volumes were significantly larger in response to T in BDR than in AM. We also found a significantly higher number of both round and fusiform DCX positive cells in HVC in response to T in BDR than in AM. These data suggest that the process of selection for certain strain phenotypes is implemented by significant changes in hormone-regulated plasticity that reduce behavioral variability in preferred traits.

Title: Effects of testosterone on microglia in song control nucleus HVC in female canaries

Authors: *G. F. BALL[1,2], F. N. MADISON[2];
[1]Univ. of Maryland, College Park, MD; [2]Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Songbirds, such as the canary, demonstrate remarkable seasonal plasticity in the volume of telencephalic brain nuclei that control song behaviors, specifically in the key forebrain nucleus HVC. In the spring, male canary testosterone (T) concentrations increase, stimulating an increase in HVC volume. HVC exhibits a marked sex difference in that female canaries have a smaller HVC volume than males, yet it has been shown that exogenous T in adulthood can stimulate an increase in HVC volume in females. This volumetric increase in HVC induces male-typical songs in females who normally sing songs simpler than males. This hormone-modulated adult seasonal neuroplasticity associated with the increase in circulating T seems to be mediated at least in part by estrogens via the conversion of T to estradiol (E2). E2 is synthesized from T via the enzyme aromatase and is thought to promote the survival and differentiation of new neurons in HVC. Interestingly, mammalian studies have shown that T reduces the occurrence of apoptosis in the sexually dimorphic nucleus of the preoptic area in female and castrated male rats early in development. It has also been shown that microglia are required for the masculinization of brain and behavior during development and that E2 was sufficient in masculinizing the microglia number and morphology in female rats. In this study, we wanted to characterize the distribution of microglia positive cells in HVC in response to exogenous T in adults. Fifteen adult female American singer canaries were surgically implanted with one 12mm length Silastic implant filled with crystalline T for three weeks and then removed (T-REM) for three weeks, implanted with an empty implant (CONT), or implanted with a T-implant for the last three weeks of the study (T-IMP). Immediately after the first implantation, birds were individually housed in sound attenuated chambers on a short day 8L:16D light cycle for six weeks. Brains were collected, fixed, and sectioned for immunohistochemical analysis of the microglial specific marker Iba1. Preliminary results suggest that CONT females had a higher number of Iba1 positive cells in HVC compared to T-IMP females who had fewer immunopositive cells per unit tissue in both HVC and surrounding tissue. T-REM females had fewer Iba1 positive cells in HVC compared to CONT, but had a higher number of Iba1 positive cells bordering HVC. T treatment did result in a change in the morphology of the Iba1 positive cells so that they appear less ramified, which is consistent with them moving toward a more activated state. These data suggest that microglia may be playing a role in hormone-regulated plasticity in songbirds.

Title: Female rats liberated for inclusion in neuroscience research

Authors: *J. B. BECKER[1], J. W. LIANG[2], B. J. PRENDERGAST[3];
[1]Univ. Michigan, Ann Arbor, MI; [2]Psychology, Hunter College, City Univ. of New York, New York City, NY; [3]Psychology, Univ. of Chicago, Chicago, IL

Abstract: Not including female rats or mice in neuroscience research has been justified due to the variable nature of female data caused by hormonal fluctuations associated with the female's reproductive cycle. Prendergast et al., (2014 *Neurosci Biobehav Rev* 40:1-5) recently reported in a meta-analysis that female mice are not inherently more variable than male mice across diverse physiological traits. In this study we investigated whether this pattern of variability extends to neuroscience-related traits in rats. PubMed and Web of Science were searched for the period from 8/01/2010 to 7/31/2014 for articles that included (rat AND sex difference) AND (brain OR neuroscience OR neuron). This yielded 562 articles, which were manually reviewed. Only empirical articles using both male and female gonad-intact adult rats, written in English, and including the number of subjects (or a range) were included— resulting in 314 articles for analysis. Methods and data sections were examined and analyses were carried out as described in Prendergast et al. (2014). Data were only used if the mean and standard deviation (SD) or standard error (SEM) could be extracted from the article. Data were extracted from digital image files generated from high-resolution screenshots of article PDFs, and from manuscript tables and text. Vector graphics software was used to quantify the mean and SEM or SD values directly from figure images (in mm), which provided a relative measure of the mean and SD/SEM for each trait. In addition, the results were coded for the type of research being measured (behavior, electrophysiology, histology, neurochemistry, and non-brain measures) and for the strain of rat. Over 6000 data points were extracted for both males and females, and the coefficient of variation (CV; S.D./mean) was calculated for each data point. Data were analyzed by ANOVA followed by two-tailed t-tests. There were no sex differences in trait variability, as indicated by the CV, for any of the measures or overall. The distributions of CV ratios [CV-female/(CV-female+CV-male)] were also analyzed by trait. The CV ratio distribution ranges from 0.0 to 1.0, with CV ratios > 0.5 indicating greater trait-specific CVs in females, and CV ratios < 0.5 indicating greater trait CVs in males. There were significant differences among the CV ratios, driven primarily by the finding that only for the histology measures was the CV ratio > 0.5. For all other measures the CV ratio was < 0.5.

Title: Selective activation of estradiol receptors differentially modulates motivation for food in female rats

Authors: *K. YOEST[1], J. A. CUMMINGS[2], J. B. BECKER[1];
[1]Mol. and Behavioral Neurosci. Inst., [2]Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: In females, eating behavior and weight are strongly influenced by levels of circulating gonadal hormones. In normally cycling intact female rodents, ovulation is accompanied by a drop in food intake and overall body weight. Removal of gonadal hormones by ovariectomy results in a dramatic increase in body weight and administration of estradiol to ovariectomized rats results in a significant decrease in meal size and body weight (Asarian and Geary, 2006, Philos Trans R Soc Lond B Biol Sci 361:1251-1263). Recent work has focused on the role of two selective estradiol receptors, ERα and ERβ, in mediating this reduction in feeding behavior. Food intake in ovariectomized rats is decreased by the ERα selective agonist propylpyrazole triol (PPT), but not by the ERβ selective agonist diarylpropionitrile (DPN; Santollo et al, 2007, Am J Physiol Regul Integr Comp Physiol. 293:R2194-201). This study investigates whether the estradiol-mediated decrease in food consumption is accompanied by a decrease in motivation for food. These two aspects of behaviors are dissociable in a number of paradigms and so may be differentially affected by gonadal hormones. Ovariectomized female rats were trained to respond for a food reward on a fixed interval schedule. Females were then hormone primed with either estradiol benzoate (EB), PPT, or DPN for two days, followed by progesterone on the third day in a regimen that induces sexual receptivity (Cummings and Becker, 2012, J Neurosci Methods. 15;204:227-33). Administration of estradiol and progesterone reduced the total number of rewards the animals received as well as the number of responses animals made during each fixed interval. Administration of PPT and progesterone appeared to mimic this effect, while administration of DPN and progesterone resulted in an increase in the total number of rewards the animals received as well as the number of responses per fixed interval. These findings demonstrate that reduced food intake after administration of estradiol is accompanied by a decrease in motivation for food rewards. In addition, activation of ERα appears to be responsible for the effect of estradiol to decrease motivation for food. Interestingly, activation of ERβ had the opposite effect. We found enhanced responding for a palatable food pellet following treatment with DPN. For female rat sexual behavior ERα activates both lordosis and proceptivity, while ERβ modulates this action of ERα (Mazzucco et al, 2008, Behav Brain Res. 5;191:111-7). These results, together with the results reported here, suggest that ERα may play a

role in directing the activation of specific appetitive behaviors which are then modulated up or down by ERβ.

Title: Estrogen-mediated signaling regulates synaptic proteins in the arcuate nucleus of the hypothalamus

Authors: ***A. M. WONG**, L. M. RUDOLPH, P. E. MICEVYCH;
Neurobio., UCLA, Los Angeles, CA

Abstract: Lordosis, a measure of female sexual receptivity in rodents, is regulated by estradiol membrane-initiated signaling (EMS) in the arcuate nucleus of the hypothalamus (ARH). During EMS, membrane estrogen receptor-α (mERα) activates intracellular signaling pathways through the transactivation of metabotropic glutamate receptors (mGluRs). This EMS-initiated regulation of mGluRs promotes the development and maturation of dendritic spines in the ARH, which are required for estradiol-induced lordosis behavior. To better understand the molecular mechanisms of EMS-regulated spinogenesis in the ARH, we examined how estrogen regulated GAP-43 and PSD-95, measures of synaptic sprouting and synapse maturation, respectively. Following a systemic injection of estrogen benzoate (EB; 50 μg), GAP-43 mRNA in the ARH was rapidly induced (40% increase from oil-injected rats 30 min post-EB) and continued to increase until it peaked at 24 h (2.5-fold increase from oil-treated controls). EB-induced transcription of PSD-95 was more gradual, significantly increasing at 24 h post-EB treatment (60% increase from oil controls) with a 2-fold increase in mRNA levels 48 h post-EB, a time point when EB-induced lordosis is maximal. These transcriptional changes in markers of synapse sprouting and maturation are consistent with our previous findings demonstrating that estrogen rapidly induced the formation of immature, filapodial spines in the ARH (< 4 h), but the mature mushroom spines appear later (20-48 h). To support the hypothesis that these EB-induced changes in these synaptic markers are regulated by EMS activation of mGluRs, we injected 100 nmol of LY 367385, a selective mGluR1a antagonist, into the lateral ventricle 30 min prior to systemic EB treatment (50 μg) and measured GAP-43 and PSD-95 in the ARH 24 h later. We found that EB induced GAP-43 mRNA and protein (58% increase) 24 h after EB treatment. Inhibiting mGluR1a with LY367385 suppressed EB induction of GAP-43 (35% decrease) and PSD-95

(40% decrease) mRNAs in the ARH, demonstrating that EB-induced GAP-43 and PSD-95 mRNAs occur via EMS and require mGluRs. Together, these data are consistent with hypothesis that EB-induced synaptic changes required for exhibition of sexual receptivity require rapid spinogenesis in the ARH, and later, maturation of dendritic spines, processes both mediated by mGluR1a-dependent EMS.

Title: Different effects on calcium signaling during and following acute estrogen application in F344 rat basal forebrain neurons and involvement of L-type calcium channels

Authors: *D. A. MURCHISON, D. W. DUBOIS, A. S. FINCHER, W. H. GRIFFITH; Dept. of Neurosci. and Exptl. Therapeut., Texas A&M Hlth. Sci. Ctr., Bryan, TX

Abstract: Our lab has been investigating neuronal estrogenic signaling in a rat model of reproductive aging and has identified inhibitory synaptic transmission as an important target of acute estrogenic modulation. We attributed this modulation to the inhibitory effect of 17-β estradiol (17βE) on voltage-gated Na and Ca currents (~35%), as well as on the amplitude of evoked Ca signals (~25%). Here, we elaborate on these findings by using fura-2 microfluorimetry to examine evoked Ca responses before, during and after acute application of 17βE (200 nM) and L-type (CaV1) channel blocker nifedipine (NIF, 10 μM) in acutely dissociated neurons from the basal forebrain (BF) of young adult (2-4 mo) male F344 rats. We found previously that brief (2-10s) focal application of 17βE to BF neurons stimulated small transient Ca signals in a fraction of cells from female rats while being ineffective in males. Also, we observed that the amplitudes of Ca-transients evoked by focal application of elevated potassium solution (Hi K, 20-30 mM) were reduced in the presence of 17βE. We now report that more prolonged applications (3-5 min) of 17βE trigger spontaneous Ca-transients and a persistent elevation in baseline Ca concentration (66 ± 9 nM) in a majority (15/16) of BF neurons from young male rats. We found also that acute 17βE has only a small inhibitory effect on the amplitude of HI K evoked Ca-transients in NIF (12 ± 3 % in 11/20 cells). This result was supported by whole-cell voltage-clamp experiments showing that barium currents through high voltage activated (HVA) Ca-channels in NIF were inhibited by 17βE in 2/7 BF neurons (mean inhibition 15 ± 0.7%). Unexpectedly, after 5-10 minute washout of 17βE and NIF, the amplitude

of Hi K evoked Ca-transients was significantly increased (24 ± 5 %, n=15). We determined that this was partly due to an effect of repetitive stimulation, because neurons (n=12) subjected to repeated Hi K stimulation (13-22 stimuli, 0.3-0.5 s each) over 20 minutes had a 16 ± 44 % increase in Ca-transient amplitude. Tests for a persistent effect of acute 17βE revealed that Ca-transient amplitudes were increased 63 ± 20 % (n=10) over control 5-12 minutes following washout from a 3-5 min application of 17βE without intervening Hi K stimulation. Overall, our data suggest that L-type and other HVA Ca-channels are targets of acute estrogen signaling. Given the role of L-type channels in age-related calcium dysregulation and our earlier results showing that chronic estrogen therapy preserves youthful Ca-buffering properties in BF neurons from ovariectomized reproductively senescent female rats, these findings may help resolve some of the paradox surrounding estrogenic therapy.

Title: A Golgi study of the plasticity of dendritic spines in the hypothalamic ventromedial nucleus during the estrous cycle of female rats

Authors: *M. CERVANTES[1], D. A. VELÁZQUEZ-ZAMORA[2], D. GONZÁLEZ-TAPIA[2], I. GONZÁLEZ-BURGOS[3];
[1]Fac. C. Medicas y Biologicas, Morelia, Mexico; [2]Univ. Politécnica de la Zona Metropolitana de Guadalajara, Tlajomulco de Zúñiga, Mexico; [3]Inst. Mexicano del Seguro Social, Guadalajara, Mexico

Abstract: Estradiol-induced plasticity involves changes in dendritic spine density and in the relative proportions of the different dendritic spine types that influence neurons and neural circuits. Such events affect brain structures that control the timing of neuroendocrine and behavioral processes, influencing both reproductive and cognitive functions during the estrous cycle. Accordingly, to investigate the dendritic spine-related plastic changes that may affect the neural processes involved in mating, estradiol-mediated dendritic spine plasticity was studied in type II cells situated in the ventrolateral portion of the ventromedial hypothalamic nucleus (WMN) of female, adult rats. The rats were assigned to 4 different groups (n = 6) in function of

their stage in the estrous cycle: proestrus, estrus, metaestrus, and diestrus. Dendritic spine density and the proportions of the different spine types on type II neurons were analyzed in the ventrolateral region of the VMN of these animals. Dendritic spine density on primary dendrites of VMN type II neurons was significantly lower in metaestrus than in diestrus, proestrus and estrus (with no differences between these latter stages). However, a significant variation in the proportional density of the different spine types was found, with a higher proportion of thin spines in diestrus, proestrus and estrus than in metaestrus. Likewise, a higher proportion of mushroom spines was seen in diestrus and proestrus than in metaestrus, and a higher proportion of stubby spines in estrus than in diestrus and metaestrus. Very few branched spines were found during proestrus and they were not detected during estrus or metaestrus. The different types of dendritic spines in non-projection neurons of the VMN could serve to maintain greater synaptic excitatory activity when receptivity and estradiol levels are maximal. However, they may also fulfill an additional functional role when receptivity and estradiol decline. To date specific roles of the different types of spines in neural hypothalamic activity during the estrous cycle remain unknown and they clearly deserve further study.

Title: Glucocorticoids desensitize neurons to norepinephrine by enhancing ligand-dependent adrenergic receptor internalization

Authors: *G. L. WEISS, Z. JIANG, J. G. TASKER;
Tulane Univ., New Orleans, LA

Abstract: Glucocorticoids (GC's) are stress related hormones that are released by activation of the hypothalamic-pituitary-adrenal (HPA) axis. GC's regulate peripheral metabolism and feed back on the brain to act on several systems, including the feedback inhibition of the HPA axis. Canonically, GC's mediate transcription by binding to nuclear receptors, a process that can take several hours. Recent findings suggest that GC's have rapid, transcriptionally independent effects, which are likely required for HPA homeostasis. We have previously shown using acute slice electrophysiology that GC's rapidly inhibit the norepinephrine (NE) excitatory drive to

corticotropin releasing hormone (CRH) neurons in the hypothalamus. We hypothesize that CRH neurons are desensitized to NE in response to GC's due to changes in alpha-1 adrenergic receptor (ARα1) trafficking. The GC desensitization of the NE-induced excitation of CRH neurons was reversed when clathrin-mediated endocytosis was blocked, indicating that GC's could be increasing ARα1 internalization. Transfection of N42 immortalized hypothalamic cells with an ARα1b-eGFP construct allowed us to track ARα1b using confocal microscopy. Unexpectedly, GC's had no effect on ARα1b internalization in cultures grown in charcoal-stripped media. However, GC's caused a significant increase in ligand-dependent internalization of the ARα1b receptor in the presence of NE. Additionally, both NE-treated and GC and NE-cotreated cells recovered their membrane ARα1b membrane localization similarly after NE washout, indicating the increase in internalized receptors is not due to a decrease in receptor trafficking back to the membrane. Live-cell imaging revealed increased internalization after only a few minutes, which is consistent with the rapid NE desensitization in our electrophysiological findings. Our data suggest that GC's enhance the NE-induced internalization of ARα1, resulting in complete desensitization of the NE response.

Title: Estrogen and age interact to differentially regulate the hippocampal transcriptome in female rats

Authors: *E. M. WATERS[1], J. D. GRAY[2], W. YIN[3], B. S. MCEWEN[2], A. C. GORE[3]; [1]Sci. Outreach Program, [2]Rockefeller Univ., New York, NY; [3]UT-Austin, Austin, TX

Abstract: Estrogens have both direct and indirect effects on gene transcription via estrogen receptors. In the hippocampus, genomic actions of estradiol modulate plasticity in an estrogen receptor dependent manner. To identify the gene targets by which age and hormone status modify the hippocampus, we conducted RNA sequencing in young (4 month) and middle aged (11 months) female rats that were ovariectomized (OVX) and given estradiol or vehicle capsules for three months. At that time, brains were collected, sectioned and stored in RNALater (same animals as used by Yin et al 2015). The CA1, CA3 and dentate gyrus regions of the hippocampus were individually dissected and RNA extracted. Total RNA from 8-10 individuals was pooled and ribosomal RNA was depleted using the Illumina Ribo-Zero kit to enrich for

messenger RNA, and then preamplified prior to RNA sequencing. Using an Illumina Hi-Seq 2500, 100bp single end reads were collected at a depth of approximately 30M reads per pooled sample. Reads were trimmed and filtered to preserve only high quality reads prior to alignment to the rat genome (Rn5) using TopHat2. Analysis was carried out using Strand (Agilent) to identify differentially expressed genes, novel transcripts and transcript variants. We found that estradiol treatment induced a multitude of transcriptional changes in both young and middle aged OVX females and these effects occurred in an age- and region-specific manner. In both the CA1 and CA3 regions, estradiol treatment resulted in numerous transcriptional events but only 50% of these entities were shared by the young and middle age females. In addition, the results from the CA1 and CA3 were largely unique, suggesting that estradiol's actions in each region is distinct. These results also confirm previous work on synaptic proteins, growth factors, and steroid receptors as well as identified new gene targets related to estrogen-mediated plasticity in the hippocampus. Altogether, these results provide further insights into the ability of hormone replacement to reverse estrogen loss with increasing age.

Title: Estradiol robustly regulates the hippocampal transcriptome in middle-aged, ovariectomized female rats

Authors: *Z. LIPOSITS[1], I. KALLÓ[1], E. HRABOVSZKY[1], N. SOLYMOSI[2], A. RODOLOSSE[3], C. VASTAGH[1], H. AUER[4], M. SÁRVÁRI[1];

Abstract: The hippocampus plays indispensable roles in learning and memory. In this area, gonadal hormones including 17β-estradiol (E2) are powerful modulators of neurogenesis, neurotransmission, synaptic plasticity and neuroprotection. In women, menopause is associated with increased risk of memory disturbances which can be attenuated by timely estrogen replacement therapy (ERT). ERT's effects on hippocampus and memory are complex, and depend on responsiveness of the individual, chemical structure and dosage of the estrogen

compound and treatment initiation, among others. In middle-aged rat models of menopause, E2 replacement improves hippocampus-dependent spatial memory (Rodgers SP et al., Endocrinol 151:1194, 2010). In this model, we explored the effect of E2 replacement on hippocampal gene expression. Middle-aged ovariectomized female rats were treated continuously for 29 days with E2 and then, the hippocampal transcriptome was investigated with Affymetrix expression arrays. Microarray data were analyzed by Bioconductor packages and web-based softwares, and verified with quantitative PCR. At standard fold change (FC) selection criterion, 156 genes responded to E2. All alterations but four were transcriptional activation. Prime (FC>10) E2 target genes included transthyretin, klotho, claudin 2, prolactin receptor, ectodin, coagulation factor V, insulin-like growth factor 2, Igfbp2 and sodium/sulfate symporter. Classification of the 156 genes revealed major groups including signaling (35 genes), metabolism (31 genes), extracellular matrix (17 genes) and transcription (16 genes). We selected 33 genes for further studies and all changes were confirmed by real-time PCR. The results suggest that E2 promotes retinoid, growth factor, Otx2 homeoprotein, neurohormone and neurotransmitter signaling, changes metabolism, extracellular matrix composition, transcription, and induce protective mechanisms via genomic effects. We propose that these mechanisms contribute to the beneficial effects of E2 on memory performance. Our findings provide further support for the rationale to develop safe estrogen receptor ligands for the maintenance of cognitive performance in postmenopausal women.

Title: An Apiarian Mixture achieves to balance the neuron density in CA3 layer, Serum Estradiol Levels and improves the memory in ovariectomized rats

Authors: *D. A. VÁZQUEZ MATÍAS[1], R. MAYEN DIAZ[2], M. RAMIREZ ESCOTO[3], I. SÁNCHEZ CERVANTES[2], I. LOPEZ MARTINEZ[3], K. PINEDA ROMERO[2], R. GONZALEZ TREJO[2], A. SOLANA ROJAS[2], M. VELAZQUEZ PANIAGUA[2], P. VERGARA ARAGÓN[2]; [2]Dept. of Phisiology Fac. of Med., [3]Cell and Tissue Biol. Dept. Fac. of Med., [1]UNAM, Coyoacán, Mexico

Abstract: The aim for this study was to assess the effect of an Apiarian Mixture on the cognitive impairment and its relation with the CA3 neuron density in an induced menopause rat model.

Methods: 40 Wistar rats 600-800g were divided in four groups of 10 rats each one: a)Control; b)rats with Apiarian Mixture (AM), c) Rats underwent to Ovariectomy (OVX), and d) Ovariectomized rats with Apiarian Mixture (OVX+AM). The AM is made from apiarian derivates such as honey, propolis, royal jelly, pollen and queen-bee larvae. It was administrated vo 0.2 mg/kg/28 days. Short Term Memory (STM) and Long Term Memory (LTM) were evaluated with a passive avoidance test, 10 minutes after the training for STM, and 24 hours for LTM. Blood samples were obtained to determine serum 17β-estradiol levels (SE) by ELISA. Brains were obtained to assess the neuron density (ND) on CA3 layer by optical microscopy. Data were analyzed with One-Way ANOVA and Pearson´s test; p values < 0.001 were considered significant. Results: STM showed a significant decline in the OVX group compared to the other groups. OVX vs control: (280.0±83.0 vs 550.0±46.0), OVX vs AM: (280.0±83.0 vs 600.0±0.0), OVX vs OVX+AM (280.0±83.0 vs 509.9±63.9); the ovariectomized rats who got the AM displayed a recovery in their latency during the test. LTM showed a significant decrease in latency of OVX rats compared to the other groups: OVX vs Control: (190.6±69.3 vs 547.1±78.5), OVX vs AM: (190.6±69.3 vs 600.0±0.0), again, the ovariectomized rats who got the AM displayed a recovery in their latency OVX vs OVX+AM: (190.6±69.3 vs 496.2±61.0). SE showed significant differences, where OVX animals displayed lower SE than the rest of the groups. OVX vs Control: (25.7±9.1 vs 49.03±6.91 pg/ml), OVX vs AM: (25.7±9.1 vs 48.2±6.8 pg/ml) Comparing SE from OVX rats vs OVX+AM, the rats who received the AM improved their SE, similar to SE displayed by control rats: (25.7±9.1 vs 43.98±5.09 pg/ml). In CA3 ND analysis, OXV group displayed a significant increase compared to the other groups: OVX vs Control: (37.8±11.0 vs 22.3±4.6), OVX vs AM: (37.8±11.0 vs 19.9±2.8), while the comparison of OVX vs OVX+AM disclosed a normalization of the neuron density in CA3 in the rats who got the AM: (37.8±11.0 vs 15.1±4.6), showing a ND similar to the control rats. Pearson test, revealed negative association among neuron density and STM r=-0.8508, and LTM r=-0.8591. Conclusion: The components of the AM are able to raise SE in OVX rats up to normal levels, which promote a recovery of the citoprotective function of this hormone. Also we conclude that CA3 layer is sensitive to the elements of the AM, and its neuron density have a strong negative association with STM and LTM.

Title: Sex-specific role of PKA in acute estradiol-induced potentiation of excitatory synaptic transmission in the rat hippocampus

Authors: *A. JAIN, C. S. WOOLLEY;
Northwestern Univ., Evanston, IL

Abstract: 17-β estradiol (E2) is synthesized in the hippocampus and can acutely influence synaptic physiology through non-genomic mechanisms. One acute effect of E2 is to potentiate excitatory synaptic transmission, which occurs in the hippocampus of both males and females. For example, using whole cell voltage clamp recording in rat hippocampal slices, we found that a brief (10 min) bath application of E2 increased the amplitude of synaptically evoked excitatory postsynaptic currents (EPSCs) in ~60% of CA1 pyramidal neurons, by 73±7% in females (n=14) and 80±13% in males (n=13). The remaining E2-nonresponsive cells showed no effect on EPSC amplitude (1±7%, n=10 females, n=8 males). In both sexes, E2-responsive EPSCs remained high after E2 washout. The mechanisms underlying E2-induced EPSC potentiation are unknown, but may involve kinases that act rapidly and are known to regulate other forms of plasticity. Thus, using the same approach, we investigated whether cAMP-activated protein kinase (PKA) contributes to the initiation and/or maintenance of E2-induced EPSC potentiation. PKA activity was inhibited by bath application of H89 (1μM) or membrane-permeant PKI (0.5μM), which have different mechanisms of action. In females, PKA inhibitors completely blocked the E2-induced increase in EPSC amplitude (n=7 H89, n=7 PKI E2-responsive cells). Thus, PKA is required for the initiation of E2-induced EPSC potentiation in females. In contrast, in males, PKA inhibitors failed to block the E2-induced increase in EPSC amplitude (n=9 H89, n=4 PKI). This was true even with a higher dose of H89 (5μM, n=5). Thus, unlike in females, PKA is not required for the initiation of E2-induced EPSC potentiation in males. Further, the magnitude of E2-induced EPSC potentiation with PKA inhibition in males (117±17%) was significantly greater ($p<0.01$, unpaired t-test) compared to that with E2 alone (80±13%), suggesting that, in males, PKA constrains the initiation of E2-induced EPSC potentiation. In contrast to the effects of PKA inhibitors on initiation of E2-induced EPSC potentiation, H89 applied after E2-induced EPSC potentiation was established had no effect in either sex, demonstrating that PKA is not required for maintenance of E2-induced EPSC potentiation (n=7 females, n=6 males). Together, these results demonstrate that although E2 acutely potentiates excitatory synaptic transmission in the hippocampus of both males and females, the molecular mechanisms that underlie this potentiation differ between the sexes. This study adds to a small but growing literature showing sex-specific roles of kinases in neuromodulation, even in brain regions not directly involved in reproduction.

Title: Hippocampal excitatory synapses are acutely modulated by estradiol through distinct mechanisms in males and females

Authors: *J. G. OBERLANDER, C. S. WOOLLEY;
Neurobio., Northwestern Univ., Evanston, IL

Abstract: Estradiol (E2) acutely potentiates glutamatergic synaptic transmission in hippocampal CA1 pyramidal cells of both sexes. Separate studies have shown, in males, that E2-induced synaptic potentiation involves an estrogen receptor (ER)β-dependent increase in postsynaptic sensitivity to glutamate (Kramar et al., 2009) and, in females, that E2-induced synaptic potentiation involves an ERβ-dependent increase in presynaptic glutamate release probability (Smejkalova & Woolley, 2010). Whether these distinctions reflect sex differences or other factors has been unclear. In preliminary work, we used whole cell recording and two-photon (2p) uncaging of glutamate at individual dendritic spines to investigate pre- and postsynaptic effects of E2. We found that E2 increases miniature EPSC (mEPSC) frequency, mEPSC amplitude, and the amplitude of 2p glutamate uncaging evoked EPSCs (2pEPSCs) in both males and females, confirming pre- and postsynaptic effects of E2 in each sex. Consistent with other studies, E2 regulation of mEPSCs occurred in a subset of cells (55-60%). Interestingly, pre- and postsynaptic effects often occurred in separate cells suggesting distinct mechanisms. Here, we used the same approaches combined with ER-selective agonists to investigate which ERs mediate pre- and postsynaptic effects of E2, and we compared males and females. Agonists selective for ERα (PPT,100nM), ERβ (WAY200070,10nM), or GPER1(G1,100nM) were applied to hippocampal slices from adult female or male rats for 10 min, followed by E2 for 10 min. In females, WAY increased mEPSC frequency in 6 of 13 (46%) cells, with no effect on mEPSC or 2pEPSC amplitude. In males, WAY had no effect on mEPSC frequency, but increased mEPSC amplitude in 4 of 16 cells (25%) and increased 2pEPSC amplitude at 16 of 51 (31%) dendritic spines. PPT had no effect on mEPSCs or 2pEPSCs in females (n=10 cells, 33 spines), whereas in males, PPT increased mEPSC frequency in 9 of 16 (56%) cells, with no effect on mEPSC amplitude or the amplitude of 2pEPSCs (n = 54 spines). In females, G1 increased mEPSC amplitude in 7 of 18 (39%) cells with no effect on mEPSC frequency, and increased 2pEPSC amplitude at 13 of 52 (25%) dendritic spines. In males, G1 had no effect on mEPSCs (n=22) or 2pEPSCs (n= 67). Together, these results show that, in females, E2 increases glutamate release probability through ERβ and glutamate sensitivity through GPER1. In males, E2 increases glutamate sensitivity through ERβ and glutamate release probability through ERα.

Thus E2 acutely potentiates glutamatergic synapses in the hippocampus of both males and females, but works through different ER-dependent mechanisms in each sex.

Title: Progranulin deficiency attenuates estrogen-induced increase of adult neurogenesis in the hippocampus

Authors: *M. DOKE, T. MATSUWAKI, K. YAMANOUCHI, M. NISHIHARA;
Vet. Physiology, the Univ. of Tokyo, Tokyo, Japan

Abstract: Neurogenesis in the adult mammalian brain is known to occur in predominantly two regions, the subgranular zone (SGZ) of the dentate gyrus and the subventricular zone of the lateral ventricle. It is generally accepted that estrogen has a function to protect neurons by promoting neurogenesis as well as attenuating neuroinflammation and neurodegeneration. Estrogen also has a function to induce sex differences of the brain during the perinatal period in rodents, and we have suggested that progranulin (PGRN), a multifunctional growth factor, mediates this function of estrogen. In addition, we have recently demonstrated that PGRN is involved in voluntary exercise-induced neurogenesis and suppression of neuroinflammation after traumatic brain injury. Thus, in the present study, we hypothesized that the neuroprotective functions of estrogen might be also mediated by PGRN, focusing on the adult neurogenesis in the SGZ of the hippocampus. In all the experiments, female C57BL/6J wild-type (WT) mice or PGRN-deficient (KO) mice of the same background were used 1 week after ovariectomy. First, we investigated neurogenesis in WT mice 4 and 24 hours after injection of estradiol benzoate or 8 days after implanting silastic tubing containing 17β-estradiol. The brains were dissected out 2 hours after the injection of bromodeoxyuridine (BrdU), a thymidine analogue, and immunohistochemically analyzed. Estrogen increased the number of the BrdU-immunoreactive (ir) cells 4 hours after treatment, but thereafter no stimulatory effect of estrogen on neurogenesis was discernible. Subsequently, we compared the neurogenesis between WT and KO mice 4 hours after injection of estrogen. The estrogen-induced increase in the number of BrdU-ir cells seen in WT mice was not observed in KO mice. We also performed qPCR to evaluate gene expression of PGRN and other growth factors known to be related to neurogenesis, i.e., NGF, BDNF, IGF-1 and VEGFB, in the hippocampus 4 hours after estrogen injection. The results showed that neither genotypes nor estrogen treatment affected gene expression of these growth factors, implying the involvement of these growth factors in cooperative neuroprotective action

of estrogen and PGRN is unlikely. In summary, it is suggested that estrogen only acutely enhances hippocampal neurogenesis and that PGRN is prerequisite for this function of estrogen.

Title: Role of estrogen and tamoxifen in regulation of immune system and neuroprotection in female rat hippocampus

Authors: ***P. KUMAR**[1], P. DHAR[1], R. MEHRA[2];
[1]AIIMS, New Delhi, India; [2]Anat., HIMSR, New Delhi, India

Abstract: Background: Ever since the first demonstration of estrogen concentrating cells in the brain by Donald Pfaff in early 1960s, the role of this female sex hormone has been under immense scanning in different areas of brain. The effects of estrogen in the central nervous system extend far beyond its predominant role in reproduction. The two most widely acclaimed non-reproductive effects of estrogen are related to i) memory and cognition and ii) neuroprotection. Postmenopausal aging is accompanied with decline in estrogen levels in females, which predispose them to a multitude of age related pathophysiological events including the cognitive decline and Alzheimer's disease. A decent amount of evidence associates the estrogen (E2, 17β estradiol) with hippocampal and cerebellar activity. Presence of estrogen receptors (ERs) in the learning and memory related brain areas gives further evidence of them being a few of the target brain regions for the hormone activity. Existence of ERs in other brain areas further expands the view of pleotropic nature of this hormone. In our current research we have further explored the role which estrogen may have in crosstalk between the nervous, endocrine and immune systems in female brain regions like hippocampus in view of the reports of heightened inflammatory events in neurodegeneration. **Methods**: Ovariectomized rat model was used in the present investigations. Immunohistochemistry, western blot, qRT-PCR and ELISA techniques were used for proteomic and genomic analyses. Our findings have revealed that ovariectomy (OVX, hormone depletion) leads to decreased synaptic activity, degenerative cytoarchitectural changes, microglial activation, altered levels of ERs, anti-apoptotic and other key signalling proteins and concomitant changes in the expression of complement proteins (C1q,

C3 and C3aR) and pro- and anti-inflammatory cytokines (IL-6, TNF-α and IL-10) in these brain areas. We have further observed that long-term estrogen therapy to OVX rats maintains synaptic plasticity (synaptophysin) and regulates microglial activity, apoptotic molecules (Bax and Bcl2), complement proteins and pro-inflammatory cytokines. **Conclusion**: These findings put forth a new perspective on the neuroprotective and neuromodulatory effects of estrogen, which may also include anti-inflammatory response via regulating the neuro-immune response and levels of complement system and pro-inflammatory cytokines together with anti-apoptotic protein regulation. **Ethical Statement**: This study was performed in strict accordance and duly approved by the institutional animal ethics committee.

Title: Ethanol modulates CNS and systemic immune responses through HMGB1, IL-1β and HMGB1-containing microparticles

Authors: *L. G. COLEMAN, JR[1], J. ZHOU[2], C. LONERGAN[2], F. CREWS[3];
[1]Univ. of NC- Chapel Hill, Durham, NC; [2]UNC-Chapel Hill, Chapel Hill, NC; [3]UNC-Chapel Hill, Chapel HIll, NC

Abstract: Alcohol modulates innate immune signaling in the brain and periphery through the release of multiple signaling molecules, including the danger associated molecular pattern (DAMP) molecule HMGB1. Expression of brain HMGB1 protein has been found to be elevated in human alcoholics and correlates with lifetime drinking level and age of onset of drinking. Acutely, alcohol increases gut permeability leading to endotoxin released into the blood and DAMP receptor activation. We investigated the CNS and systemic effects of alcohol on innate immune activation. In mice, ethanol (6mg/kg, i.g.) caused a rapid increase in HMGB1 in the plasma that was sustained for 24 hours (2-fold maximum increase, $p<0.05$) and returned to control levels by 48 hours post-treatment. This was associated with an acute increase in plasma IL-1β, which peaked at 6 hours (20% increase, $p<0.002$). HMGB1 protein expression in the brain followed a similar expression pattern, peaking at 1 hour (96% increase, $p<0.05$). Brain expression on inflammasome component caspase-1 also peaked at 1h (62%, $p<0.007$) followed by a transient reduction in expression beyond 6 hours. BV2 microglia treated with of ethanol (0.5%) secreted HMGB1 into the media within 6 hours (37% increase, $p<0.002$) without any

increase in toxicity as measured by LDH. This secretion was enhanced by the addition of the autophagy promoting mTORC1 inhibitor rapamycin (84% increase above control, $p<0.0001$) and reduced by the autophagasome inhibitor Wortmannin to control levels indicating a role of autophagy machinery in secretion of HMGB1 by microglia. SH-SY5Y neurons showed no changes in intracellular or secreted HMGB1 at 6h. However, SH-SY5Y intracellular HMGB1 had increased by 12 hours post-ethanol washout (57%, $p<0.05$). Using a neonatal hippocampal slice culture model to assess a system containing both neurons and glia, we found that 96h ethanol treatment caused a dose dependent increase in cellular (EC50 67.1mM, maximum increase 73.8%) and released HMGB1 (media and microparticle fraction). Released HMGB1 expression had a maximum increase of 17% (EC50 37.2mM) in the media microparticle (MP) fraction and 27% (EC50 27.9) in MP-depleted media. Flow cytometric analysis of media MP revealed a 32% increase in HMGB1 + MP of neuronal origin ($p<0.05$) in response to ethanol (25-100mM). Thus, ethanol causes differential transient microglial and neuronal release of HMGB1 in response to ethanol. Further, ethanol causes the release of neuron-derived HMGB1+ microparticles that may participate in the systemic inflammatory response to ethanol.

Title: Activation of the suprachiasmatic nucleus following salmonella infection

Authors: *R. MÉNDEZ-HERNÁNDEZ, G. SUÁREZ-PÉREZ, R. M. BUIJS;
Inst. De Investigaciones Biomédicas, UNAM., México, Mexico

Abstract: The suprachiasmatic nucleus (SCN) is involved in maintaining circadian physiology. Recently, it has been suggested that it participates importantly in modulating the immune response to bacterial lipopolysaccharide. Moreover it has been shown that the degree of Salmonella infection depends on the time of inoculation, suggesting that as a master clock, the SCN might be also involved. In this study we evaluated the SCN response to Salmonella infection. Wistar rats were inoculated with Salmonella at two different time points (day and night) and brain activation 72 hours after inoculation was assessed by c-fos

inmunohistochemistry. The time of inoculation was shown to have an influence in the outcome of the infection. Activity in several brain regions including the SCN was changed in response to Salmonella in a time point-dependent manner. These findings support a role for the SCN in the outcome of the salmonella infection.

Mexicano del Seguro Social, Guadalajara, Mexico

Abstract: Multiple sclerosis (MS) is an immune-mediated demyelinating disease that affects the central nervous system. Relapsing-remitting (RRMS) is the most frequent form of MS and its defining feature comprises fluctuating disease activity, in which the patient undergoes clinical relapses separated by periods of clinical stability. The immune system plays an important role in axonal demyelination, involving T-cell subtypes such as Th1, Treg, and Th17, which characteristically produce Interferon gamma (IFN-γ), Interleukin-10 (IL-10), and Interleukin-17 (IL-17A), respectively. Glatiramer acetate (GA) and Interferon beta (IFN-β) are the first-line treatment for RRMS approved by U.S. Federal Drug Administration (FDA). The objective of this study was to explore for the possible existence of different subgroups of patients with MS according to treatment, gender, age, and disease evolution time. In the present work, we determined serum levels of IFN-γ, IL-10, and IL-17A in 82 samples of RRMS (50 females and 32 males) treated with GA and IFN-β. We stratified patients by treatment, gender, age, and disease evolution time. Subsequently we correlated these independent variables with the concentrations of the previously mentioned cytokines. Results showed that treatment exerted possible differential effects depending on disease evolution time and evidence of the existence of

different subgroups of patients with MS as follows: i) male or female under or over the age of 40 years; ii) disease duration according to treatment; and iii) classification according to fluctuating levels of IFN-γ, IL-10, and IL-17A in the following three stages of disease evolution: <5 years; between 5 and 10 years, and after 10 years. These subgroups must be taken into account for the clinical follow-up of patients with MS in order to provide them with a more personalized treatment, and also for a detailed analysis of the disease's progress, in an attempt to comprehend fluctuations and clinical variability by means of better understanding of the disease's intrinsically physiological variables.

Title: Reelin expression in endothelial cells: an electron microscopy study

Authors: *H. J. CARUNCHO[1], E. Y. FENTON[1], R. ROMAY-TALLON[1], L. E. KALYNCHUK[2], E. PEREZ-COSTAS[3];
[1]Col. of Pharm. and Nutr., [2]Col. of Med., Univ. of Saskatchewan, Saskatoon, SK, Canada; [3]Dept. of Psychology, Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Background*:* Reelin expression and function have been extensively studied in the brain, although its expression has been also reported in other tissues including blood. This raises the possibility that reelin might be able to cross the blood-brain barrier, which could be functionally relevant. Up-to-date no studies have been conducted to assess if reelin is present in the blood-brain barrier, which is mainly constituted by tightly packed endothelial cells. In this report we assessed the expression of reelin in brain capillaries using immunocytochemistry and electron microscopy. **Results**: At the light microscope, reelin immunolabeling appeared in specific endothelial cells in brain areas that presented abundant diffuse labeling for this protein (e.g., layer I of the cortex, or the *stratum lacunosum moleculare* of the hippocampus), while it was mostly absent from capillaries in other brain areas (e.g., deeper cortical layers, or the CA1 layer of the hippocampus). As expected, at the electron microscope reelin labeling was observed in neurons of the cortex, where most of the labeling was associated with the rough endoplasmic

reticulum. Importantly, reelin was also observed in some endothelial cells located in small capillaries, which confirmed the findings obtained at the light microscope. In these cells, reelin labeling was located primarily in caveolae (i.e., vesicles of transcytosis), and associated with the plasma membrane of the luminal side of endothelial cells. In addition, some scarce labeling was observed in the nuclear membrane. **Conclusions:** The presence of reelin immunolabeling in brain endothelial cells, and particularly in caveolar vesicles within these cells, suggests that reelin and/or reelin peptides may be able to cross the blood-brain barrier, which could have important physiological, pathological, and therapeutic implications.

Title: Role of toll-like receptor 4 in mediating oxidative stress-induced proinflammatory state in macrophages

Authors: *Y. ZHANG, O. J. IGWE;
Univ. of Missouri-Kansas City, Kansas City, MO

Abstract: **Background:** Disturbances in reduction-oxidation (redox) equilibrium of tissue can lead to inflammatory state, which is a mediating factor in many human diseases. However, the mechanism (s) by which oxidative stress can activate an inflammatory response have not been fully elucidated**.** Emerging evidence suggest that Toll-like receptor 4 (TLR4) activation is involved in mediating this response. **Objective:** This study will determine the role of TLR4 in mediating oxidative stress-induced proinflammatory state in macrophages **Methods:** SIN-1 and potassium peroxychromate (PPC) were used as prooxidant sources and a TLR4-specific agonist LPS-EK was used as the positive control. CLI-095, was used to block signal transduction following TLR4 activation. We used murine macrophage RAW-Blue cells chromosomally integrated with secreted embryonic alkaline phosphatase (SEAP) inducible by nuclear factor-κB (NF-κB). Intracellular reactive oxygen species (iROS) production was visualized and quantified by fluorescence imaging and flow cytometry, respectively. Lipid peroxidation were quantified by malondialdehyde (MDA) assay and 4-hydroxynonenal (4-HNE) ELISA. Total antioxidant capacity within cells was quantified by antioxidant assay kit. Activation of NF-κB was quantified by measuring DNA binding activity in the nuclear fraction by TransAM assay, and by measuring

the levels of SEAP release with QUANTI-Blue assay. Expression and phosphorylation of inhibitory κBα (IκBα) were determined by Western blot. Tumor necrosis factor α (TNFα) and Interleukin 10 (IL-10) released into the media were measured by ELISA. **Results:** We found that pro-oxidants treatment increased iROS production and lipid preoxidation, but decreased total antioxidant capacity. Consistent with TLR4 agonist LPS-EK, prooxidants evoked increased level of transcriptionally active form of NF-κB p65 and subsequent SEAP released, which were blocked by pretreatment with CLI-095. In addition, prooxidants treatment decreased protein expression of IκBα with enhanced phosphorylation at Tyr42. Finally, prooxidants and LPS-EK enhanced TNFα production but did not change IL-10 production causing imbalance between cytokines, which can be inhibited by CLI-095. **Conclusion:** Taken together, the results indicate that TLR4 mediated prooxidants induced inflammation response by inducing NF-κB activation in macrophages. Therefore, oxidant stress can serve as an initiator of inflammatory processes that maintain many chronic diseases.

Title: Microglia regulate cell proliferation in the neonatal hippocampus in a sex-dependent manner

Authors: *L. H. NELSON[1,2,3], A. GALAN[4], K. M. LENZ[4,3,2];
[2]Group in Behavioral Neuroendocrinology, [3]Dept. of Neurosci., [4]Dept. of Psychology, [1]Ohio State Univ., Columbus, OH

Abstract: Several neuropsychiatric disorders have been shown to involve altered immune signaling during development and also show a significant sex bias with prevalence toward males. We and others have shown that several regions of the male brain have significantly greater numbers of activated microglia, the innate immune cell in the CNS, during development than the female brain (Lenz et al., 2013, J Neurosci; Schwarz et al., 2012 J Neurochem). We hypothesize that microglia may contribute to sex differences in both normal and abnormal brain development. Microglia regulate the number of proliferating cells in the developing cortex by releasing diffusible factors and phagocytizing healthy progenitors (Cunningham et al., 2013, J Neurosci; Shigemoto-Mogami et al., 2014, J Neurosci). During development there is a basal sex difference in hippocampal neurogenesis in rats, with males having more neurogenesis than females (Zang et al., 2008, Eur J Neurosci). In these studies, we sought to determine whether microglia regulate the sex-specific rate of proliferation in the neonatal hippocampus. Rats were treated by bilateral

intracerebroventricular injection of minocycline or clodronate on postnatal days (PN) 1-2. Minocycline inhibits activated microglia, and clodronate ablates microglia. BrdU was injected on PN2 to label actively dividing cells. Brains were collected on PN3 for immunohistochemical analysis. Minocycline decreased proliferation in the dentate gyrus (DG) of males, but not females, as determined by the number of BrdU+ cells. Similarly, clodronate decreased proliferation in males to female-typical levels. Ongoing studies will determine the effect of clodronate in females. These results suggest that microglia support sex-specific rates of proliferation in the DG. We also analyzed microglial morphology by counting and categorizing Iba-1 positive cells in the DG. We found that females had more phagocytic microglia than males. There was a positive correlation between the number of amoeboid microglia and BrdU+ cells across groups, but no correlation between the number of phagocytic microglia and BrdU+ cells, suggesting that amoeboid microglia may be responsible for sex differences in proliferation, and that phagocytic microglia may be responsible for another sex-specific process in the hippocampus. Future studies will determine what cells are being phagocytized by microglia, and what microglial-factors may regulate proliferation. Examining the role of microglia in the developing brain is important for understanding how they contribute to the development of neuropsychiatric disorders following perinatal perturbations, such as stress or infection.

Title: Actin dynamics shape microglia effector functions

Authors: ***R. UHLEMANN**[1], K. GERTZ[2], W. BOEHMERLE[2], T. SCHWARZ[2], C. NOLTE[3], D. FREYER[2], H. KETTENMANN[3], M. ENDRES[2], G. KRONENBERG[2];

Abstract: Impaired actin filament dynamics have been associated with cellular senescence. Microglia, the resident immune cells of the brain, are emerging as a central pathophysiological player in neurodegeneration. Microglia activation, which ranges on a continuum between classical and alternative, may be of critical importance to brain disease. Using genetic and pharmacological manipulations, we studied the effects of alterations in actin dynamics on microglia effector functions. Disruption of actin dynamics did not affect transcription of genes

involved in the LPS-triggered classical inflammatory response. By contrast, in consequence of impaired nuclear translocation of phospho-STAT6, genes involved in IL-4 induced alternative activation were strongly downregulated. Functionally, impaired actin dynamics resulted in reduced NO secretion and reduced release of TNF and IL-6 from LPS-stimulated microglia and of IGF-1 from IL-4 stimulated microglia. However, pathological stabilization of the actin cytoskeleton increased LPS-induced release of IL-1beta and IL-18, which belong to an unconventional secretory pathway. Reduced NO release was associated with decreased cytoplasmic iNOS protein expression and decreased intracellular arginine uptake. Furthermore, disruption of actin dynamics resulted in reduced microglia migration, proliferation and phagocytosis. Finally, baseline and ATP-induced [Ca2+]int levels were significantly increased in microglia lacking gelsolin, a key actin-severing protein. Together, the dynamic state of the actin cytoskeleton profoundly and distinctly affects microglia behaviors. Disruption of actin dynamics attenuates M2 polarization by inhibiting transcription of alternative activation genes. In classical activation, the role of actin remodeling is complex, does not relate to gene transcription, and shows a major divergence between cytokines following conventional and unconventional secretion.

Title: Contraction regulates CCL5 secretion in C2C12 myotubes -Potential roles of myokines on peripheral nervous system-

Authors: *H. SATO, T. SHIBAGAKI, K. SATO, T. NEDACHI;
Life Sci., Toyo Univ., Gunma, Japan

Abstract: Microenvironment of peripheral nervous systems (PNS) that are regulated by neuron and glia surrounding PNS is not only important for maintaining normal neuronal activities, but also for protecting neurons from various deleterious stresses. Many researches focused on the neuron-glia and/or glia-glia interaction and several soluble factors secreted by these cells have been implicated in nervous system morphogenesis. However, the microenvironment of PNS could be not only regulated by neuron and glia, but also by the other cell types. Recently, secreted factors from skeletal muscle, also referred to as myokines, were identified and recognized as important mediators of physical exercise. In this study, by utilizing C2C12

contractile model, we attempted to identify novel myokines that potentially modified the microenvironment of PNS. Differentiated C2C12 myotubes were subjected to electrical pulse stimulation (EPS) to induce contraction, thereby analyzed secreted proteins by membrane antibody arrays (Proteome Profiler). Several novel myokines were successfully identified by this method, particularly, we found two myokines, including Chemokine (C-C motif) ligand 5 (CCL5), were significantly reduced by exercise. Quantitative PCR analysis revealed that the exercise-dependent reduction of CCL5 was regulated by gene expressional control. In addition, we found exercise-dependent AMP kinase activation was sufficient for reducing secreted CCL5 levels. Moreover, the inhibition of phosphatidylinositol 3-kinase activity by LY294002 diminished this exercise-dependent CCL5 reduction. In conclusion, we identified CCL5 as a novel myokine that secretion is reduced by skeletal cell contraction, and this reduction is mediated by AMP kinase pathway. It has been demonstrated that CCL5 is secreted from neurons following peripheral nerve injury and appears to be important factor for neuroprotection. Thus, exercise may modify microenvironment of PNS via regulating myokine production, thereby influence on these neuronal protective process.

Title: NLRP3 inflammasome activity demonstrates a diurnal pattern within the somatosensory cortex

Authors: ***M. R. ZIELINSKI**[1], D. GERASHCHENKO[2], S. A. KARPOVA[2], R. W. MCCARLEY[3], R. BASHEER[2];
[1]Harvard Univ. and Veterans Affairs Boston Healthcare Syst., West Roxbury, MA; [2]Harvard Med. Sch. and VA Boston Healthcare Syst., West Roxbury, MA; [3]Harvard Med. Sch. and VA Boston Healthcare Syst., Brockton, MA

Abstract: Inflammasomes are oligomeric protein complex assemblies found in cells throughout the body including neurons, astrocytes, and microglia. The nucleotide-binding domain of leucine-rich family pyrin-containing 3 (NLRP3) component of the inflammasome recognizes pathogen-associated molecular patterns (PAMPs), such as extracellular adenosine tri-phosphate (ATP). In turn, the assembly of a carboxyl-terminal caspase-recruitment domain (ASC)

component of the inflammasome is recruited into the complex. The recruitment of ASC is required for inflammasome activation. The NLRP3 inflammasome activates caspase-1, which converts the pro-form of interleukin-1 beta (IL-1β) into its mature active form. IL-1β is well-documented to be enhanced in the cortex during times of the day when sleep propensity is high. We examined the diurnal molecular activation of the NLRP3 inflammasome within the somatosensory cortex. Male NLRP3 knockout (KO) mice and C57BL/6 wild-type controls were sacrificed at the beginning of light onset [zeitgeber (ZT) 0; a time of high sleep propensity following the active dark period] and at the beginning of dark onset (ZT 12). Somatosensory cortex tissue was homogenized, RNA was extracted, and cDNA was made. The gene expression analysis of NLRP3, ASC, and IL1β mRNA levels was performed using real-time polymerase chain reaction analysis. Somatosensory cortex tissue was also homogenized and processed for caspase-1 activity using a kinetic enzyme-linked immunosorbent assay (ELISA) and the protein levels of IL-1β by ELISA. WT mice exhibited significant enhancements in NLRP3, ASC, and IL-1β mRNA levels, caspase-1 activity, and IL-1β protein levels during the beginning of the light period (ZT 0) compared to the beginning of the dark period (ZT 12). In contrast, NLRP3 KO mice showed no significant differences in NLRP3, ASC, or IL-1β mRNA levels, caspase-1 activity, or IL-1β protein levels between light (ZT 0) and dark periods (ZT 12). These data indicate that diurnal fluctuations in inflammasome activation occur within the somatosensory cortex that coincide with times of sleep propensity, which suggests that the NLRP3 inflammasome might be involved in sleep regulation, perhaps by enhanced ATP production induced by waking activity.

Title: IFN-beta is a master regulator of microglial phenotype in aging

Authors: *A. DECZKOWSKA[1], O. MATCOVITCH[1], K. BARUCH[1], I. AMIT[2], M. SCHWARTZ[1];
[1]Neurobio., [2]Immunol., Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Microglial activity is essential for brain maintenance and repair. Therefore, aging-related changes in microglial phenotype are viewed as a factor contributing to brain function decline in aging. Recently we found, in aged mice and human samples, that the choroid plexus (CP), an epithelial tissue that forms blood-cerebrospinal fluid-barrier (BCSFB), expresses type I interferon (IFN-I) response program, including IFN-β, a pleiotropic cytokine, which, depending on the context, can display both anti- and pro- inflammatory properties. Here, we hypothesized that CP-derived IFN-β is secreted to the CSF and contributes to the age-related changes in microglia, which hold a potential to robustly respond to IFNs-I. To challenge this hypothesis, we performed high throughput RNA-Sequencing of microglia of aged mice following transient blockage of IFN-I receptor (IFNAR) within the brain's territory. In these settings we found that IFNAR inhibition contributed to broad changes in aged microglia expression profile. Specifically, we found, that clusters of genes related to "antigen presentation" (e.g. B2M, CD74) and "defense response" (e.g Itgax, Oasl1 2'-5', Isg15), the expression of which was upregulated in aging, was down-regulated following IFNAR blockage. Conversely, a gene cluster related to "cognition", "learning and memory" and "behavior", the expression of which was down-regulated in aging, was up-regulated in aged mice microglia 7 days after IFNAR blockage, a time-point when the treated mice showed elevated cognitive ability. These results suggest that IFN-β is involved in shaping aged microglia pro-inflammatory phenotype, with possible consequences for cognitive decline and reduced brain plasticity.

Title: Sex differences in the microglial responses to cerebral ischemia

Authors: *M. M. GAUDIER-DIAZ, N. ZHANG, A. DEVRIES;
Neurosci., The Ohio State Univ., Columbus, OH

Abstract: Cerebral ischemia, caused by cardiac arrest and stroke, is a leading cause of death and disability worldwide. Thus, it is important to find ways to prevent it, facilitate recovery, and improve the quality of life of survivors. Previous research demonstrates that social isolation increases neuroinflammation, neuronal degeneration, and functional impairment following cerebral ischemia. We hypothesize that microglia, the innate immune cells of the central nervous system, modulate the detrimental effects of social isolation on ischemic outcomes. Environmental stressors can sensitize microglia to respond in an exaggerated manner upon

further immune stimulation; by triggering similar mechanisms, it is plausible that the psychological stressor of social isolation can also sensitize microglia. To study the effect of social environment on the microglial response to cerebral ischemia, mice were pair housed (n=24) or socially isolated (n=24), and then a week later exposed to cardiac arrest/cardiopulmonary resuscitation (CA/CPR; n=12/group) or the sham procedure (n=12/group). Samples were collected 24 h later. The brain was dissected, minced, homogenized and resuspended in a percoll gradient to provide an enriched sample of microglia. Then, gene expression of pro-inflamamtory (IL-1β, IL-6, TNFα) and anti-inflammatory (IL-10) cytokines was assessed. Among individually housed male mice that received the CA/CPR procedure, there was increased microglial gene expression of IL-1β and IL-6 relative to sham controls; in contrast, gene expression among pair housed males did not differ between CA/CPR and sham groups. This suggests that social isolation exacerbates ischemia-induced neuroinflammation through microglial production of pro-inflammatory cytokines. In contrast, among female mice there was increased microglial gene expression of pro-inflammatory cytokines following CA/CPR relative to sham, regardless of housing conditions. Additional studies are necessary to determine the mechanism underlying this sex-difference in the effects of social environment on ischemia-induced neuroinflammation. However, these data highlight the importance of including both sexes in cerebral ischemia research. In sum, social environment can have a substantial influence on the pathophysiological response to global cerebral ischemia.

Title: Development of microglia in germ free and conventionally colonized mice

Authors: *M. K. HOLDER, N. V. PETERS, A. CASTILLO-RUIZ, M. D. MOSLEY, B. CHASSAING, A. T. GEWIRTZ, N. G. FORGER, G. J. DEVRIES;
Georgia State Univ., Atlanta, GA

Abstract: The internal and external surfaces of all mammals are colonized by a diverse group of microorganisms, collectively called the microbiota. The microbiota contributes to a range of developmental processes, especially in the intestine and immune system, and the microbiota-gut-brain axis is known to influence brain development and social behavior. Furthermore, both the microbiota and microglia, the resident immune cells of the brain, have been implicated in the development of sex differences. Here, we sought to determine how rearing animals in the absence of a microbiota (i.e. germ-free; GF) would influence the microglia. As microglia

respond to signals from the peripheral immune system and GF mice often have a poorly developed immune system, there may be fewer or less activated microglia in GF mice. Alternatively, the development and maintenance of microglia may occur independently of the microbiota. To test these hypotheses, immunoreactivity (IR) of a protein constitutively expressed in microglia, ionized calcium binding adaptor molecule 1 (Iba1), was compared in neonatal (postnatal day 3; PN3), juvenile (PN21), and adult (PN56) male and female GF and conventionally colonized (CC) Swiss-Webster mice. Furthermore, we examined the effects of re-colonization of GF mice, by exposing them to gut microbiota from conventional mice at PN28. Preliminary analyses indicate that the presence of the microbiota does not influence Iba1 IR in neonatal or juvenile mice. However, we did observe some sex differences in Iba1 IR that depended on microbiota status. Juvenile female mice have greater Iba1 IR than males in the nucleus of the solitary tract (NTS), which receives visceral input via the vagus nerve, and this sex difference was also seen in CC adult females. Adult male CC mice have greater Iba1 IR than females in the paraventricular nucleus of the thalamus (PVT), which receives brainstem afferents and projects to the forebrain. Rearing animals in a GF environment prevented the sex differences in both the NTS and PVT; moreover, re-colonization did not reinstate these sex differences. These results suggest that the presence of the microbiota does not affect the expression of Iba1 neonatally, when microglial number increase markedly in many brain regions, or during the juvenile period, when microglial morphology matures. The effects of rearing in a GF environment emerge in adulthood and appear to be sex- and region-specific, indicating that early postnatal colonization by microbiota may contribute to sex differences in adulthood.

Title: Altered brain perfusion and structure accompany experimental sepsis-associated encephalopathy: a combined magnetic resonance imaging and histology study

Authors: *J. KONSMAN, I. DHAYA, M. GRITON, G. RAFFARD, B. HIBA;
CNRS UMR 5536 RMSB / Univ. Bordeaux, Bordeaux, France

Abstract: Sepsis-associated encephalopathy (SAE) refers to brain dysfunction during systemic inflammation, which can range from mild delirium to coma. Despite its clinical relevance and poor outcome, SAE remains poorly understood even though magnetic resonance imaging (MRI) in septic patients has provided indications of cerebral vasospasms and diffuse edema. In the

present work, we combined advanced MRI modalities and post mortem histology to study the brains of the same animals 24h after induction of sepsis by cecal ligature and puncture (CLP) in an attempt to better understand the pathophysiology of SAE. Sepsis was accompanied by the classical signs of sickness behaviour, but also by reduced reflexes indicating nervous system dysfunction. Assessment of cerebral perfusion with Arterial Spin Labeling (ASL) revealed that the cortex of animals that underwent CLP received less blood relative to the whole brain compared to sham surgery. T2 MRI indicated the presence of more water in the cerebral cortex after CLP than after sham surgery. Diffusion Tensor Imaging (DTI) showed increased water diffusion parallel to the fibers of the corpus callosum after CLP as compared to sham surgery. These imaging findings indicating both functional and structural CNS changes during experimental sepsis. We are currently studying to what extent these changes are linked to perivascular prostaglandin production, blood-brain barrier breakdown and glial responses affecting water diffusion on brain sections of the same animals.

Title: TLX, a regulator of neural stem cell self-renewal, is required for microglial integrity in the adult mouse dentate gyrus

Authors: D. A. KOZAREVA[1], C. M. HUESTON[1], C. S. Ó'LÉIME[1], J. F. CRYAN[1], *Y. M. NOLAN[2];
[1]Dept. of Anat. and Neurosci., [2]Univ. Col. Cork, Cork, Ireland

Abstract: Tailless homolog TLX (Nr2e1) is an orphan nuclear receptor expressed primarily in the neurogenic niches of the adult mouse brain. At present, the functions attributed to the receptor are the maintenance of the stem cell pool in a proliferative and undifferentiated state, as well as regulating hippocampal neurogenesis-associated tasks of spatial learning and memory. Extracellular stimulation of both embryonic and adult hippocampal neural stem cells with pro-inflammatory cytokine IL-1β has recently been shown to detrimentally affect TLX expression. Hippocampal inflammation has been implicated in the pathology of many neurodegenerative and psychiatric disorders including Alzheimer's disease and stress-induced depression. Alterations in adult hippocampal neurogenesis have also been implicated in these disorders. Our aim is to

understand the relationship between inflammation, TLX expression and adult hippocampal neurogenesis in order to position TLX as a novel therapeutic target for hippocampal-dependent neurodegenerative disorders that have an inflammatory component. In order to explore the interaction between TLX and inflammation, we assessed microglial morphology and hippocampal architecture in mice which have a spontaneous deletion of Nr2e1 (Nr2e1-/-). Immunohistochemistry on coronal sections through the dentate gyrus of the hippocampus of BrdU-injected mice (Nr2e1-/-; Nr2e1+/-; Nr2e1+/+) was performed to compare the number of microglia (Iba1+ cells) and number of newborn neurons (DCX+ cells), across groups. The activation status of microglial cells in the dentate gyrus of these mice was also established. To determine gene expression levels of pro- and anti- inflammatory cytokines, qrtPCR analyses was carried out on hippocampal tissue of mice from each genotype. We observed a marked discrepancy in the integrity of the dentate gyri in Nr2e1-/- mice compared to wild type. Furthermore, lack of TLX expression led to reduced numbers of newly born neurons in the adult mouse dentate gyrus as well as altered microglial morphology. We are currently establishing the pro- and anti-inflammatory cytokine profile in the hippocampus of mice from each genotype. Our current findings suggest that TLX is necessary for intact neurogenic cells as well as microglial activation.

Title: The role of estradiol in microglial phagocytosis in the developing rat cerebellum

Authors: *M. PEREZ-POUCHOULEN, M. M. MCCARTHY;
Dept. of Pharmacol., Univ. of Maryland, SOM, Baltimore, MD

Abstract: Microglia are the resident immune cells of the central nervous system and play important roles during normal development and under injury or infectious conditions in adulthood. We recently showed microglia are non-uniformly distributed in the developing cerebellum and execute phagocytosis in an age and region dependent manner that peaks during the third postnatal week of development from postnatal day (PN) 17 to 19 in the granular layer, but not in the molecular layer of the cerebellar cortex. Aromatase is the estradiol synthesizing

enzyme and we found its expression increases around PN10 in the rat cerebellum. In order to determine if endogenous estradiol synthesis is critical for microglia function we injected the aromatase inhibitor formestane (Form, 5 µg / 0.05 ml s.c.) from PN8 to PN12 and estradiol benzoate (EB, 5 µg / 0.05 ml) from PN10 to PN14 in male and female rat pups and quantified microglial morphology and the number of phagocytic cups in the cerebellar cortex at PN17. Form treatment significantly decreased by ~ 24 % the number of phagocytic cups as well as ~ 36 % the number of phagocytic microglia with thin processes. Phagocytic microglia with thick processes decreased ~ 14 % when treated with Form compared to control; however, this decrease was not significant. No regional or sex differences were found in the cerebellar cortex between the control and Form treated groups. These data indicate endogenous estradiol regulates microglial phagocytosis in the developing cerebellum and that microglial phagocytosis at PN17 might be established during the second week of postnatal development. In contrast, treatment with EB did not effect the number of phagocytic cups or phagocytic microglia with thick or thin processes in the immature cerebellum. Nonetheless, EB slightly increased the density of overall microglia (1.1-fold) compared to control. This may be an indication of: 1) a sensitive period regulating microglial phagocytosis before PN10, or 2) the EB dose used in this experiment was too low to impact phagocytosis by microglia, although it was sufficient to modify the overall microglial population. We also analyzed mRNA by qRT-PCR for both estrogen receptors (ERs) α and β during the microglial phagocytosis window. While ERα decreased (~ 66 %) by PN19 compared to PN15, only a small change was detected for ERβ (~ 14 %) indicating estradiol may regulate microglial phagocytosis via ERα. Title: Lithium stimulates complement component C3 production via GSK-3 inhibition in monocytic cells

Authors: *Z. YU[1], C. ONO[2], S. AIBA[3], Y. KIKUCHI[2], I. SORA[4], H. MATSUOKA[5], H. TOMITA[2];

Abstract: Lithium (Li), a direct inhibitor of glycogen synthase kinase 3 (GSK-3), has been widely prescribed mood stabilizer in treatment of bipolar disorder. Evidence suggests that Li

affects monocytic cells, which play pivotal roles in the innate immune systems in both the brain and peripheral tissues. Although majority of the studies into the mechanism of action of Li has been focused on neuron, astrocyte and oligodendrocyte, recent studies indicate that Li and GSK-3 inhibition also affect immune cells, such as peripheral monocytes, macrophages, monocyte-derived dendritic cells (MoDCs) and microglia. Li and GSK-3 inhibition are shown to mediate inflammation, microglial migration, monocyte-derived dendritic cells differentiation and reverse monocytic malfunction observed in neuropsychiatric diseases. Here, we surveyed molecules which take major roles in regulating these monocytic cellular functions. MoDCs treated with 1 and 5 mM Li, and microglia separated from Li-treated mice were subjected to microarray-based comprehensive gene expression analyses. Findings were validated using multiple experiments, including quantitative PCR, ELISA and immunostaining studies. We found the Li significantly increased the complement component C3 production via GSK-3 inhibition in the mouse and human monocytic cells, which suggest a potential involvement of complement system induction into neuroprotective and mood stabilizing effects, as well as non-neurologic diseases of Li treatment.

Title: The effects of voluntary exercise on neuroinflammatory status: role of monocyte chemoattractant protein 1

Authors: *A. KLEGERIS, L. J. SPIELMAN, M. ESTAKI, C. B. POINTER, S. GHOSH, D. L. GIBSON;
Dept. of Biol., Univ. of British Columbia Okanagan Campus, Kelowna, BC, Canada

Abstract: The health benefits of exercise have been well studied, and it is universally accepted that physical activity is crucial for maintaining a healthy body. One of the proposed mechanisms for these beneficial effects involve modified peripheral immune adaptations in response to exercise. Several whole-body anti-inflammatory effects have been attributed to exercise including: decrease in circulating levels of pro-inflammatory cytokines, elevation of anti-inflammatory cytokines, reduction in the number of macrophages infiltrating adipose tissue,

switching of adipose tissue macrophages from a pro-inflammatory (M1) phenotype to an anti-inflammatory (M2) phenotype, and a decrease in the expression of toll-like receptor 4 in several peripheral tissues. To date, very few studies have looked for the anti-inflammatory effects of exercise behind the blood brain barrier. We sought to bridge this information gap by testing whether physical activity has an effect on the inflammatory status of the brain. We measured the effect of voluntary wheel running on pro- and anti-inflammatory cytokine levels in the brains of female C57BL/6 mice. A key inflammatory chemokine, monocyte chemoattractant protein (MCP)-1 is upregulated during inflammatory events in the central nervous system, and it is also critically involved in the cross talk between the peripheral immune system and the immune system of the brain. Therefore, we used MCP-1 knock-out mice to investigate the role of this inflammatory mediator in regulating the immune effects of physical activity in the periphery and in the brain. We demonstrated that mice exposed to six weeks of voluntary physical activity had modified profiles of both pro- and anti-inflammatory cytokines and glial markers in the brain, compared to their sedentary counterparts. Measurement of serum cytokine concentrations showed that the changes in brain cytokine levels could not be attributed to the peripheral effects of physical activity. We propose that this modified neuroimmune response in the physically active group represents a primed immune system, as opposed to a suppressed immune system in the sedentary group. Comparison of brain cytokine profiles between sedentary and physically active MCP-1 knock-out mice revealed the key role that MCP-1 may play in physical activity-induced modulation of neuroimmune reactions. We concluded that in addition to its peripheral effects, voluntary wheel running modifies neuroimmune reactions in a MCP-1-dependent manner. The identified mechanisms could be responsible for the observed negative relationship between physically active lifestyles and risk for a number of neurodegenerative diseases.

Title: Expression and lipopolysaccharide-induced shedding of polysialylated proteins by NCAM-negative microglia and human THP-1 cell-derived macrophages

Authors: ***S. WERNEBURG**[1], F. BUETTNER[1], H. NEUMANN[2], M. MÜHLENHOFF[1], H. HILDEBRANDT[1];
[1]Hannover Med. Sch., Hannover, Germany; [2]Univ. of Bonn, Bonn, Germany

Abstract: Microglia are the innate immune cells of the brain that adopt distinct reactive phenotypes in response to brain injury or infection. The glycan polysialic acid (polySia) has been implicated in the regulation of microglia activation. Recently, we detected polySia in microglia obtained from mice negative for NCAM, the major polySia protein carrier (Werneburg et al. 2015, Glia 63:1240). PolySia was strictly confined to the Golgi of these cells and a glycoproteomic approach revealed the presence of polysialylated neuropilin-2, which first has been identified in dendritic cells. Now, we demonstrate Golgi-confined polySia in stem cell-derived microglia and human THP-1 cell-derived macrophages. Western blot analysis corroborates the expression of polySia-NRP2 but glycoproteomic analysis indicates the presence of a second Golgi-confined polySia protein carrier in both cell types. Activation by lipopolysaccharide (LPS), but not interleukin-4, causes cell surface translocation and a rapid release of the two polysialylated proteins in microglia and THP-1 cell-derived macrophages. Addition of metalloproteinase inhibitors prevents polySia depletion, indicating that the release is mediated by protein ectodomain shedding. Furthermore we demonstrate that polySia inhibits LPS-induced activation of nitric oxide (NO) release. Together these data suggest that shedding of polysialylated proteins contributes to a negative feedback regulation of LPS-induced activation of microglia and possibly macrophages.

Title: Identification of macrophage projections in the organ of Corti of the cochlea

Authors: *B. HU, W. YANG, R. R. VETHANAYAGAM;
Ctr. Hearing & Deafness, State Univ. Buffalo, Buffalo, NY

Abstract: The cochlea was traditionally considered as an immune privileged organ due to the presence of the blood-labyrinth barrier. However, recent studies have documented strong immune activities under both steady-state and disease conditions. In the cochlea, the organ of Corti houses sensory cells, which are vulnerable to stresses. Sensory cell damage is known to provoke the immune activity of cochlear macrophages. However, cochlear macrophages are commonly absent in the organ of Corti. At present, it not clear how macrophages in other anatomic sites of the cochlea detect immune signals from the organ of Corti. Here, we report the

finding of immune cell projections in the organ of Corti. The cochleae of C57BL/6J mice were immunolabeled for CD45, a receptor tyrosine phosphatase presenting on all hematopoietic/bone marrow derived leukocytes. We found CD45 positive cells in the spiral ligament, the spiral limbus, and the scala tympani side of the basilar membrane. In addition, we found CD45 positive structures in the scala media side of the basilar membrane. These structures had an irregular shape. They were located along the junction between Claudiu's cells and Hensen's cells, and were more visible in the apical and middle cochlear turns. High magnification view of confocal images showed that these structures had macrophage phenotypes including small projections on the surface and vacuoles in the cytoplasm. To provide further evidence for the nature of macrophages, we stained the tissues for F4/80, a macrophage marker protein, and found strong immunoreactivity in these structures. Surprisingly, we did not find nuclei within these structures, suggesting that these structures are not individual macrophages, but macrophage projections from neighboring tissues. We revealed two possible sources of the projections: one from the macrophages beneath the basilar membrane and the other from the macrophages in the lateral wall. We suspect that these projections enable neighboring macrophages to detect immune signals and participate in the immune activity in the organ of Corti.

Title: Protection of acute kidney injury by electrical vagal nerve stimulation: pathways and potential mechanisms

Authors: *C. ABE[1], T. INOUE[2], D. L. ROSIN[2], M. D. OKUSA[2], P. G. GUYENET[1]; [1]Pharmacol., [2]Nephrology, Univ. of Virginia, Charlottesville, VA

Abstract: The vagal nerve (VN) regulates the immune system (Cholinergic Anti-inflammatory Pathway). For example, electrical stimulation of VN efferents suppresses lipopolysaccharide (LPS)-induced tumor necrosis factor-alpha (TNF-α) release from macrophages. Here we show that VN stimulation reduces kidney ischemia/reperfusion injury (IRI) in mice and rats and we explore some of the mechanisms responsible for this protective effect. Electrical stimulation of

VN efferents or afferents in mice (50 μA, 1 ms, 5 Hz, 10 min) was performed 24 h before induction of renal ischemia (clamping both renal artery and vein for 26 min). Stimulation of VN efferents or afferents equally suppressed plasma creatinine 24 hours after kidney IRI. The C1 neurons are lower brainstem neurons that activate both sympathetic and VN efferents (Abbott et al., Eur J Neurosci, 2014). C1 neurons were unilaterally transduced to express ChR2 in dopamine-beta-hydroxylase Cre mice using a Cre-dependent AAV2. Selective optogenetic stimulation of the C1 neurons in conscious mice attenuate the rise in creatinine elicited by kidney IRI to the same extent as VN nerve stimulation. In rats, selective stimulation of VN efferents (150 μA, 1 ms, 5 Hz, delivered under anesthesia 24 hs before kidney IRI) also reduced the rise in creatinine present 24 h after kidney ischemia (45 min). VN efferents stimulation had no effect on the splenic sympathetic nerve mass activity whereas VN afferents stimulation (150 μA, 1 ms, 1 Hz) evoked a robust response in this nerve consisting of two distinct activation peaks. This evidence suggests that the protective effect of VN efferents stimulation might not be mediated by splenic sympathetic nerve activation but via other immune organs innervated by the VN e.g. the thymus. We confirmed that the thymus receives VN efferents via a collateral branch of the recurrent nerve and we showed that thymectomy (7 days before VN stimulation) prevented the beneficial effect of efferent VN stimulation on kidney IRI as judged by the creatinine level 24 hs after renal ischemia. In conclusion, stimulation of either VN efferents or afferents protects the acute kidney injury. C1 cell stimulation is equally effective, probably because these neurons activate both VN and sympathetic efferents. The immunosuppressive effect of VN efferent stimulation may be mediated by the thymus and this organ may provide a humoral link to the spleen and the previously described Cholinergic Anti-inflammatory Pathway.

Title: Microglia polarization: a common paradigm spanning from neuro-oncology to infectious diseases

Authors: *L. LISI[1], E. LAUDATI[2], C. DELLO RUSSO[3], P. NAVARRA[1];
[1]Catholic Univ. Med. Sch., Rome, Italy; [2]Catholoic Univ. Med. Sch., Roma, Italy; [3]catholic Univ. Med. Sch., Roma, Italy

Abstract: We have investigated microglia polarization in the framework of microglia interactions with primary brain tumors. In a series of *in vitro* experiments, we have characterized

the influence of glioma-soluble factors on microglial function, comparing the effects of media harvested under basal conditions with those of media obtained after inducing a pro-inflammatory activation state in glioma cells. Microglia exposed to basal glioma-derived factors (a condition resembling the early stage of pathology), shows increased M2b polarization status and up-regulation of IL-10 only. At variance, when exposed to activated glioma-derived factors (a condition mimicking the late stage of pathology), microglia presents as a mixture of polarization phenotypes (M1 and M2a/b), with up-regulation of iNOS, arginase and IL-10. In this paradigm, the inhibition of mTOR polarizes glioma-activated microglial cells towards the M1 phenotype, thus preventing the induction of the M2 status that would promote tumor growth. Investigations are currently underway on 54 surgical specimens of glioblastoma multiforme to confirm the influence of brain tumor exposure on microglia polarization. An apparently unrelated line of research in our lab was addressed to investigate the effects of antiretroviral drugs (ARVs) exposure on microglia cultures, seeking for putative mechanism of drug neurotoxicity. We found that certain RRTIs and PIs increased NO production with a mechanism independent from iNOS induction. Rather, these agents increased the availability of the iNOS substrate L-arginine by blocking arginase, a well-established marker of M2 polarization. Thus, the investigation of microglia polarization markers turned out to be a common background linking studies on the most different patho-physiological conditions involving the CNS.

Title: CCL2-CCR2 mediated monocyte trafficking into the VSV-infected brain is under circadian control

Authors: ***K. GAGNIDZE**, K. H. HAJDAROVIC, K. BULLOCH;
Neuroimmunology and Inflammation Program, Lab. of Neuroendocrinology, Rockefeller Univ., New York, NY

Abstract: In the mammalian organism many immune functions are under circadian control. We have recently shown that circadian time of infection has a profound effect on the survival of mice in a vesicular stomatitis virus (VSV) induced encephalitis model. Specifically, mice infected at zeitgeber time 0 (ZT0) were more susceptible to LD_{50} dose of the virus than mice infected at ZT12. The poor survival of ZT0 mice was accompanied by higher accumulation of

$CD45^{hi}/CD11b^{hi}$ cell to the site of infection, the olfactory bulb (OB), 4 days post-infection (dpi). Further analysis revealed that this cell population comprises inflammatory monocytes, bone marrow-derived cells characterized by the expression of $Ly6c^{hi}/CCR2^{+}$, which egress into the bloodstream and migrate to the site of infection where they can differentiate into macrophages and dendritic cells (DC). Signaling through chemokine receptor, CCR2, is known to be essential for the migration of monocytes to the site of infection where they help clear pathogens. However, if left unregulated, monocytes can also contribute to the damage in chronic inflammatory diseases. In the current study we tested the hypothesis that *CCL2-CCR2 mediated migration of inflammatory monocytes is under circadian control and contributes to poor survival in ZT0 mice in VSV-induced encephalitis model*. Analysis of CCL2 mRNA in steady-state mouse OB revealed the rhythmic pattern of expression with higher levels observed at ZT0 compared to ZT12. To identify the cellular source of CCL2 in the OB, we measured mRNA in sorted microglia (MG, $CD45b^{int}/CD11b^{+}/CD11c^{-}$), brain DC ($CD45^{int}/CD11b^{+}/CD11c^{+}$) and monocytes ($CD45^{hi}/CD11b^{+}/CD11c^{+}$), and found that at 4 dpi VSV, brain-resident MG express significantly higher levels of CCL2 at ZT0, whereas bDC and monocytes display higher levels of CCL2 at ZT12. Next we examined whether egress of monocytes into the bloodstream, which depends on CCL2-CCR2 signaling, is also under circadian regulation. We found a higher number of $Ly6c^{hi}/CCR2^{+}$ monocytes present in the blood at ZT0 compared to ZT12 in non-infected animals. To test whether CCR2-mediated trafficking of inflammatory monocytes into the brain contributes to VSV neuropathology, we blocked CCR2 using systemic injections of antagonist (RS504393) in VSV-infected mice 0, 1 and 2 dpi. Blocking CCR2 signaling within the first three days of VSV infection improves survival in both, ZT0 and ZT12 groups, and nullifies circadian effect on survival. In summary, this data demonstrates circadian regulation of CCL2-CCR2 mediated monocyte trafficking to the brain, thus contributing to VSV-induced neuropathology and mortality.

Title: Chronic unpredictable mild stress alters the metabolism of carbohydrates and lipids in rats by oxidative stress and systemic inflammation

Authors: A. L. LÒPEZ-LÒPEZ[1], *M. ARTEAGA-SILVA[2], F. J. ALARCÓN-AGUILAR[1], M. C. ESCOBAR-VILLANUEVA[1], H. BONILLA-JAIME[1];

[1]Univ. Autonoma Metropolitana, Mexico, D.F, Mexico; [2]Univ. Autónoma Metropolitana-Iztapalapa, Méxcio, Mexico

Abstract: Physiological stress is a risk factor for many pathologies that are considered priority health problems. It has been suggested that chronic glucocorticoid and catecholamine circulation, released during stress response, activate damage mechanisms, which at long term producing metabolic alterations that can be associated to oxidative stress and inflammation. However, the consequences of stress in animal models in periods longer than 40 days not been explored. The goal of this work was determining if the chronic unpredictable mild stress (CUMS) induces metabolic alterations due to modifications in the redox state and the inflammatory profile of rats at 20, 40, and 60 days of stress. CUMS consisted in randomly exposing the animals to different stressors. The effects of CUMS on corticosterone, body weight, glucose tolerance, triglyceride, cholesterol levels and insulin were evaluated. In liver and pancreas was determined reduced glutathione (GSH), lipid peroxidation (LPO), superoxide dismutase (SOD), catalase (CAT), total antioxidant capacity (TAC) and protein oxidation. Likewise, cytokine serum levels (IL-6, TNF-α, IL-1β, and IL-10) were determined. Results show that CUMS decreased weight gain after of 40 days of stress, while at 60 days the rats presented glucose intolerance. A reduction was observed in cholesterol levels at 40 and 60 days, and triglycerides decreased at 60 days. Insulin levels were elevated only at 20 days. In liver and pancreas, GHS levels were decreased from day 40, while protein lipid peroxidation and protein oxidation were increased. This is the first work where pancreas redox state under chronic stress conditions is reported. Liver TAC was constant while in pancreas it was reduced. Regarding inflammation markers, an increase in TNF-α, IL-1β, and IL-6 levels was observed, while IL-10 levels were reduced due to CUMS, generating a systemic inflammation state. Corticosterone levels remained high and constant up to the end of the experimental period at 60 days. These data suggest an association between chronic stress and metabolic alterations that may gradually alter carbohydrate and lipid metabolism. CUMS consequences at day 60 suggest that oxidative stress and inflammation can contribute the development of chronic degenerative diseases, like cardiovascular disease and diabetes mellitus. CUMS is an animal model that in addition to avoiding habituation, it activates damage mechanisms, like oxidative stress and low-grade chronic inflammation, which allows the study of physio-pathological stress aspects in prolonged time periods, of at least 60 days.

Title: Apobec1 ko mice manifest neuropsychological defects

Authors: *D. C. COLE[1,2], K. H. HAJDAROVIC[2], F. PAPAVASILIOU[3], K. BULLOCH[2]; [1]Neuroimmunology, [2]Neuroimmunology and Inflammation Program, Lab. of Neuroendocrinology, [3]Lymphocyte Biol., The Rockefeller Univ., New York, NY

Abstract: Apolipoprotein B mRNA editing enzyme, catalytic polypeptide 1 (Apobec1) is an mRNA editing enzyme that induces C to U transitions in specific mRNAs. It has been implicated in the host immune response, the regulation of cell identity, the development of cancer, and lipid metabolism regulation. Apobec1 and its cofactors have also been found to be differentially expressed in certain cell types including monocytic cells of the CNS. The cell type specific regulation of Apobec1 and its cofactors in the brain indicates that it could be a potent regulator of immune function. Our analysis of immune mediators in the steady state Apobec1 KO mouse showed that several markers of inflammation were up-regulated in the cortex and hippocampus, areas associated with memory and learning, by three months of age. Given that chronic inflammation is thought to underlie many cognitive and neurological dysfunctions we examined the behavior of male Apobec1 KO mice at one year old, 9 months old, and 3 months old. When tested for anxiety using an open field test or elevated plus maze, we found that Apobec1 KO mice are far more anxious than their male wild type litter mates. This effect is seen to increase with age: one year old mice spent less time in the open arms of the plus maze and the center of the open field as compared to younger mice. When tested for depression using the splash test, the KO mice were found to have a severe depressive phenotype, but were not found to be anhedonic. This effect did not exhibit age related increases in severity, unlike the anxiety phenotype. When assayed for memory deficits using novel object recognition the KO mice displayed significant memory impairment that progressed with age. These findings demonstrate that Apobec1 mediated mRNA editing plays a regulatory role on inflammatory mediators in the brain; and that loss of Apobec1 mediated RNA editing as seen in the KO animals can contribute to neuropsychological and degenerative brain diseases.

Title: Sphingosine 1-phosphate (S1P) dependent c-IAP2 mediated ubiquitination of IRF-1 is essential for IL-1 induced CCL5 and IP-10 production

Authors: *K. HARIKUMAR[1], J. YESTER[2], M. SURACE[2], C. OYENIRAN[2], M. PRICE[2], W.-C. HUANG[2], N. HAIT[2], J. C. ALLEGOOD[2], A. YAMADA[2], R. BHARDWAJ[2], K. TAKABE[2], S. MILSTIEN[2], S. SPIEGEL[2], T. KORDULA[2];
[1]Cancer Res., Rajiv Gandhi Ctr. For Biotech., Thiruvananthapuram, India; [2]Virginia commonwealth Univ., Richmond, VA

Abstract: Sphingosine-1-phosphate (S1P) and sphingosine kinase 1, one of the isoenzymes that produce the potent bioactive lipid mediator S1P, have long been implicated in the actions of pro-inflammatory cytokines. Interleukin 1 (IL-1), a quintessential pro-inflammatory cytokine that plays a major role in many inflammatory diseases, enhances the production of various chemokines, including RANTES (CCL5) and IP-10 (CXCL10), which exacerbate inflammation. However, the regulatory mechanisms regulating production of these chemokines have largely remained unclear. Here, we show that IL-1-mediated effects require activation of yet another transcription factor, IRF-1 (interferon regulatory factor-1). Interestingly, IL-1-induced IRF-1 activation required its K63-linked polyubiquitination that was mediated by cIAP2 and depended on the presence of S1P that acted as a co-factor for cIAP2 E3 ligase activity. The IL-1-mediated RANTES and IP-10 production was abolished in IRF1-/- and cIAP2-/- MEFs as well as IRF1-/- mice. In addition, RANTES and IP-10 levels were markedly diminished in the serum of IL-1-treated SphK1-/- mice. This study provides a mechanistic explanation for the key role of SphK1 and intracellular S1P in IL-1-mediated chemokine production and identifies cIAP2 as a novel intracellular target of S1P. Further our findings may in part explain the diminished susceptibility of Irf1-/- mice to autoimmune diseases, such as collagen-induced arthritis and mouse models of multiple sclerosis that are in part IL-1-dependent. Title: Chondroitin sulfate proteoglycans in multiple sclerosis

Authors: *E. STEPHENSON, J. A. ROGERS, M. B. KEOUGH, M. MISHRA, V. W. YONG; Univ. of Calgary, Calgary, AB, Canada

Abstract: Multiple sclerosis (MS) is a chronic inflammatory and degenerative disease of the central nervous system, presenting with profound destruction of myelin and axons that form focal areas of demyelination. MS also presents with changes in the extracellular matrix, a network of molecules involved in maintaining brain architecture. The extracellular matrix molecules observed at the border of active demyelinating lesions in MS are the chondroitin sulfate proteoglycans (CSPGs) (Sobel and Ahmed J Neuropathol Exp Neurol 2001). CSPGs may have the ability to promote activation of immune cell subsets, migration of immune cells into the CNS, and killing of neurons. Thus, we hypothesize that interfering with CSPG production in MS and in an animal model of MS, experimental autoimmune encephalomyelitis (EAE), will improve outcomes. The purpose of this work was to investigate the ability of CSPGs to influence the immune system, and characterize changes in CSPGs over the course of EAE and MS. We also tested whether a CSPG-targeting glucosamine derivative can affect inflammation, neuropathology, and clinical disease scores in EAE. To study the role of CSPGs in T cell proliferation we used *in vitro* proliferation assays, where T cells were exposed to CSPGs with or without anti-CD3/anti-CD28 co-stimulation. Cell survival was assessed by propidium iodide staining and flow cytometry. EAE was induced by immunization with the immunogenic portion of the myelin protein myelin oligodendrocyte glycoprotein (MOG35-55) in C57Bl6 mice. Immunohistochemistry and real-time polymerase chain reaction were used to determine changes in CSPG protein and transcript levels, respectively. MS tissues were also investigated for CSPG expression with immunohistochemistry. Current results show that CSPGs promoted proliferation of T cells in culture in an activation-dependent manner. At peak severity of EAE in mice, we observed an upregulation of transcripts and protein of the CSPG member versican. Other CSPG members were not significantly altered. Versican was also upregulated in MS tissue, particularly in the vicinity of inflammatory perivascular cuffs. EAE mice treated at onset or peak with a CSPG-lowering glucosamine derivative had reduced EAE severity and reduction of inflammatory transcripts. Thus, CSPGs, such as versican, may promote inflammatory disease in MS and EAE. These results emphasize that reducing CSPGs may prove useful in pathologies such as MS, where the immune system plays a role in central nervous system damage.

Title: Strategic utilization of SGs by VSV for replication and survival in cultured microglia but not neurons

Authors: *Y. CHUNG[1], D. C. COLE[1], N. F. PAPAVASILIOU[2], K. BULLOCH[1]; [1]Rockefeller Univ., New York, NY; [2]Lab. of Lymphocyte Biol., The Rockefeller Univ., The Rockefeller University, NY

Abstract: Stress granules (SGs) are dynamic non-membranous cellular structures composed of proteins and translationally silenced mRNA that are formed under stress conditions. Emerging evidence shows that certain viruses can subvert RNA granule function and co-opt SGs to increase their survival and proliferation. In the present study, we examined how the maintenance and function of SGs is regulated by vesicular stomatitis virus (VSV) infection in different neural cell types. Our *in vitro* studies show that VSV infection induces the formation of distinct SG types (TIA-1, G3BP and TDP-43 positive SG vs TIA-1, G3BP positive and TDP-43 negative SG) in E^tC cerebellar granule neuronal cells and BV2 microglial cells, respectively. In the BV2 microglia which form noncanonical SGs, viral replication and cell death are increased. Whereas, in the E^tC neuronal cell line that form canonical SGs viral replication is diminished and survival is high compared to the microglia. Moreover, the formation of these compositionally different types of SG is mediated by cytoplasmic localization of TDP-43 and cell-type specific regulation of TIA-1 and TDP-43. We also show that decreased TIA-1 expression induces up regulation of Apolipoprotein B mRNA editing enzyme complex (Apobec1) and its cofactors (A1CF and RBM47) in VSV-infected BV2 microglial cells, but not in E^tC neuronal cells. This increase in Apobec1 correlates with the dampening of the BV2 intracellular viral protection mechanism. These results suggest that VSV infection can manipulate the stress response mechanism and RNA metabolism of specific neural cell types to promote viral replication. Title: Cytochrome P450 2J3 and 2C11 regulation in a LPS-induced model of neuroinflammation in astrocytes

Authors: *C. NAVARRO-MABARAK, R. CAMACHO-CARRANZA, J. J. ESPINOSA-AGUIRRE;
Medicina Genómica y Toxicología Ambiental, Inst. de Investigaciones Biomédicas, UNAM, DF, Mexico

Abstract: Introduction: The development and progression of several neurodegenerative and neuropsychiatric illnesses have been related to inflammatory processes in the Central Nervous System (CNS). The cytochrome P450 (CYP) epoxygenases and its metabolites, the epoxyeicosatrienoic acids (EET) have been proposed as important therapeutic targets for the treatment of both systemic and organ specific inflammatory processes, due in part to its potent anti-inflammatory activity. However, little has been described about the regulation of these enzymes during inflammation in the CNS. It has been reported that the expression of some CYP can be modified by pro-inflammatory cytokines such as IL-6, IL-1b and TNF-a. Cytokine-mediated down regulation of some CYP has been related to NF-kB binding to the promoter region of its genes. Our goal is to elucidate whether an inflammatory process developed in astrocytes is able to modify CYP2J3 and 2C11 expression and the mechanism by which this process is carried out. **Materials and methods:** Rat brain primary astroglial cultures were obtained from the cortex of newborn Wistar rats. Immunocytochemical identification of astrocytes was performed. Cultures were treated with 100 ng/ml LPS, 5 ng/ml TNF-a, 100 ng/ml LPS + 1 ng/ml IMD-0354 (selective NF-kB inhibitor) or 5 ng/ml TNF-a + 1 ng/ml IMD-0354. CYP2J3 and 2C11 mRNA expression was determined by qRT-PCR. CYP2J3 protein levels were determined by Western blot. **Results:** The addition of LPS and TNF-a to astrocytes cultures caused a decrease in CYP2J3 and 2C11 mRNA expression. Concurrent addition of IMD-0354 to the cultures caused an inhibition of the observed effect on mRNA expression. CYP2J3 protein levels were also decreased after LPS treatment. **Conclusions:** The inflammatory process triggered by the addition of LPS to astrocytes cultures is able to down-regulate CYP2J3 and CYP2C11 mRNA expression and CYP2J3 protein levels. LPS mediated down-regulation of CYP2J3 and 2C11 expression may be due in part to the production of pro-inflammatory cytokines like TNF-a, since this cytokine is also able to down-regulate CYPs mRNA independently of LPS addition. Transcription factor NF-kB may play an important role in LPS/TNF-a mediated down-regulation of CYP2J3 and 2C11 since its inhibition by IMD-0354 reversed the observed effects.

Title: Effects of intravitreal treatment with IL-4 or IL-6 recruits different signaling molecules to modulate retinal afferent distribution within superior colliculus

Authors: *P. CAMPELLO-COSTA[1], G. MENEZES[2], V. G. GOULART[2], A. C. F. MELIBEU[2], C. A. SERFATY[2];
[1]Federal Fluminense Univ., Niterói, Brazil; [2]Federal Fluminense Univ., Niteroi, Brazil

Abstract: Interleukins, classical immune molecules, can induce many effects in different areas of the central nervous system (CNS), including retina. Interleukin- 4 (IL-4) and interkeukin-6 (IL-6), are classically known as anti-inflammatory and pro-inflammatory cytokines, respectively. Some studies have demonstrated effects of both cytokines in different aspects of CNS development such as survival of neurons, proliferation, differentiation and synaptic plasticity among others. The aim of the present research is to investigate the signaling pathway activated after intravitreal injection of IL4 or IL6 in the retina. We also analyse the effect of exogenous application of IL-4 or IL-6 upon the development of visual circuits, using the retinotectal pathways of rodents as a model. Lister Hooded rats were injected with either IL-6 or IL-4 in the right eye at PND10. Control matched-group received a PBS injection. At PND11 or PND14, animals were euthanized. Retinas were prepared for western blot or immunohistochemistry procedures to analyze both different intracellular mediators and glial markers. Nissl staining was performed in order to evaluate retinal cytoarchitecture after intraocular injection. Alternatively, a group of animals treated at PND11, received HRP injection in the left eye at PND14 to assess the distribution of retinal afferents into the superior colliculus after cytokines treatment. The thickness of retinal layers was similar between PBS- and cytokines treated groups and no pyknotic nuclei or inflammatory profile cells were detected with Nissl staining. Also, no difference was observed in Iba1 levels in all groups. Concerning astrocyte marker, IL-4 treated animals presented a lower level of GFAP content compared to control (PBS-treated rats) while IL-6 produced no change in the level of GFAP. The data from biochemical analysis revealed that IL-4 treated animals presented a transient increase in pSTAT6 24h after injection and a more sustained increase in pERK levels which was detected at PND11 through PND14. IL-6 treated animals presented an increase in pSTAT3 levels. No difference was observed in pAKT content

in any group. Both cytokines lead to a disruption in the uncrossed retinotectal connections of the intact eye. Our data show that exogenous *in vivo* treatments with IL-4 or IL-6 modulate different intracellular pathways in the retina, without inducing an inflammatory response. Moreover these modifications seem to trigger a different pattern of retinal activity, which in turns could be responsible for the reorganization of retinal afferent in the target.

Title: Neurotoxic kynurenine metabolism modulates microglial activity following lipopolysaccharide challenge

Authors: *A. M. DUGAN[1,2], J. M. PARROTT[1,2], J. N. DELGADO[1], J. C. O'CONNOR[1,2,3]; [1]Pharmacol., Univ. of Texas Hlth. Sci. Ctr. At San A, San Antonio, TX; [2]Sch. of Med., Ctr. for Biomed. Neurosci., San Antonio, TX; [3]South Texas Veterans Hlth. Syst., Audie L. Murphy VA Hosp., San Antonio, TX

Abstract: The kynurenine pathway (KP) of tryptophan metabolism is the major tryptophan degradation pathway in the body, and disruption of KP metabolic balance within the brain has been implicated in both neurodegenerative and neuropsychiatric disease. Inflammation in the brain skews KP metabolism toward increased production of oxidative and excitatory metabolites, but the role of microglia in this process remains poorly understood. To investigate this further, BV-2 murine microglia were challenged *in vitro* with lipopolysaccharide (LPS), a component of gram-negative bacteria cell wall. LPS treatment up-regulated pro-inflammatory cytokine and inducible nitric oxide synthase mRNA expression. Extracellular accumulation of nitrite, an indirect index of nitric oxide production, was significantly increased 24 hours following LPS challenge. Additionally, mRNA expression of the rate limiting enzymes for the formation of oxidative/excitatory KP metabolites, indoleamine-2,3-dioxygenase (IDO)-1 and kynurenine monooxygenase (KMO), was significantly increased 6 hours after LPS. Accumulation of kynurenine and the excitotoxic metabolite quinolinic acid was also increased in the media of

microglia 24 hours after LPS. To determine whether synthesis of oxidative/excitatory KP metabolites contributes to microglial activation, BV-2 cells were treated with the KMO inhibitor Ro 61-8048 at the same time as LPS challenge. Ro 61-8048 attenuated the production of extracellular nitrite and up-regulation of KMO and tumor necrosis factor-α, but not other pro-inflammatory gene targets following LPS challenge. Further, this experiment was repeated in primary microglia isolated from neonatal C57BL6/J wild type (WT) and KMO knockout (KMO-/-) mice. The KMO-/- genotype was sufficient to reduce nitrite accumulation with or without LPS treatment. There was also a main effect of LPS in both WT and KMO-/- microglia. These data indicate that microglia are likely playing an important role in skewing KP metabolism in the brain during inflammatory conditions, and oxidative/excitatory KP metabolites modulate microglial activity during immune challenge.

Title: Characterization of the role of the cannabinoid receptors on dendritic cell antigen presenting function

Authors: *J. SUAREZ MARTINEZ[1], R. B. CRAWFORD[2], N. E. KAMISNKI[2];
[1]Michigan State Universirty, East Lansing, MI; [2]Pharmacol. and Toxicology, Michigan State Univ., East Lansing, MI

Abstract: Cannabis is the most commonly used illicit drug in the United States. Δ9-Tetrahydrocannabinol (THC) is the principle psychoactive component in cannabis sativa causing well-known analgesic and behavioral effects. Additionally, THC has immunosuppressive effects, in part, mediated through cannabinoid receptor 1 (CB1) and 2 (CB2) ligation. Simultaneous deletion of CB1 and CB2 resulted in exacerbated immune reactivity to influenza infection. Dendritic cells (DCs) were identified to play a role in influenza induced immunopathology in cannabinoid receptor null mice (CB1-/-/CB2-/-). The objective of the present study is to characterize the role of the cannabinoid receptors (CBRs) on bone marrow DC development and function. Bone marrow cells extracted from femurs and tibias of C57Bl/6 (wild type, WT) and CB1-/-/CB2-/- mice were stimulated with lipopolysaccharide (LPS) and stained for DC by expression of CD11c and CD11b. Our results indicate that the percent of DC populations,

determined by CD11c expression, composes ~38% of freshly isolated bone marrow cells in WT mice and ~48% in CB1-/-/CB2-/- mice. We also found MHC I expression in CD11c+ DCs was not significantly different between WT and CB1-/-/CB2-/- mice. Interestingly, bone marrow cells isolated from CB1-/-/CB2-/- mice elicited a CD8+ T cell response in the absence of LPS stimulation. The expression of antigen-bound MHC I complexes on the surface of DCs was determined.. After 24 hours of incubation in the presence or absence of LPS, cells were washed thoroughly, pulsed with SIINFEKL peptide for two hours, washed and stained with an MHC I-SIINFEKL complex antibody. A significant increase in antigen-MHC I complexes in the surface of DCs from CB1-/-/CB2-/- mice was not observed in comparison with WT. The process of naïve T cell activation by DCs encompasses three signals. The first signal is the ligation of the T cell receptor to peptide-bound MHC molecules on DCs. The second signal can be either co-stimulatory that leads to T cell proliferation or co-inhibitory that debilitates the T cell response. The third signal, usually mediated by DC-derived cytokines, promotes the development into a specific effector or toloregenic T cell (1,2). Our results have demonstrate that the enhanced CD8+ T cell response observed is not due to an increase in MHC I expression or antigen loading to the molecule. Future studies will explore whether there is enhanced co-stimulation or soluble factor secretion in the bone marrow DCs of CB1-/-/CB2-/- mice.

Title: Pathologic T cell cytokines have both beneficial and deleterious effects on oligodendrocyte lineage cells

Authors: *A. P. ROBINSON[1], K. LYMAN[2], Y. HWANG[1], W. LINDSTROM[1], J. RODGERS[1], S. D. MILLER[1];
[1]Microbiology-Immunology, [2]1.Davee Dept. of Neurol. and Clin. Neurosciences and the Dept. of Physiol., Northwestern Univ., Chicago, IL

Abstract: The acute multiple sclerosis (MS) lesion is a highly inflammatory environment characterized by demyelination and oligodendrocyte loss. A clear pathologic role for inflammatory T cell subsets (Th1 and Th17) and cytokines (IFNγ, IL-17, GM-CSF) in MS and the animal model EAE have been demonstrated. Evidence for direct cytokine-induced effects on oligodendrocyte progenitor cells (OPCs) that undertake the reparative process of remyelination

has been less forthcoming. We stimulated OPCs in culture with IFNγ, IL-17, or GM-CSF and assessed their viability, proliferation, and maturation by histological and molecular techniques. The prototypical Th1 cytokine IFNγ had a deleterious effect directly inducing cell death in pure cultures of OPCs. Surprisingly the more recently identified Th17 cytokines IL-17 and GM-CSF had mixed effects: IL-17 stimulated OPC maturation without a loss in cell viability, whereas GM-CSF inhibited OPC maturation *in vitro* also without affecting viability. Additionally IL-17 and GM-CSF induced unique chemokine and receptor expression changes suggesting varied roles in OPC migration as well. These results suggest that inflammatory cytokines despite contributing to aberrant immune function in the lesion can have unique effects on remyelination and repair. A full characterization of pro- and anti-inflammatory cytokine effects on oligodendrocytes and remyelination may provide clues for more targeted therapeutic strategies for MS.

Title: RNA editing enzyme Complex APOBEC1 and its cofactor in monocytes/microglia linked to the sexually dimorphic response to VSV encephalitis

Authors: *K. HAJDAROVIC[1,2], K. GAGNIDZE[1], D. C. COLE[1], K. BULLOCH[1]; [1]McEwen, [2]Neuroimmunology and Inflammation Program, The Rockefeller Univ., New York, NY

Abstract: Sex affects outcomes of viral infection both in the brain and in the periphery, with females often surviving better than males, who have less robust responses or suffer more damage from inflammation. However, the increased resistance to infection comes at a cost, as females are more likely to be affected by autoimmune disease than males. In mice, the response to vesicular stomatitis virus (VSV) has been known to be sexually dimorphic. However, a mechanism for phenomenon has not yet been elucidated. Survival studies on sexually immature and sexually mature mice intranasally infected with an LD50 dose of VSV show that the sex effect may be related to the production of female gonadal hormones, as there is no difference in survival between male and female mice at 4 weeks of age. Flow cytometry analysis done on the olfactory bulbs of mice infected in the same manner show that females in proestrus have higher

number of microglia (MG, CD45int/ CD11bhi/CD11c-) than males. Additionally, the numbers of this cell population fluctuate significantly when female mice are infected at different points in their cycle, with mice infected during metestrus having higher proportion of microglia compared to mice infected during estrus or proestrus, further indicating a role of female gonadal hormones in the immune response. Furthermore, we assessed differences between males and females in expression of various genes known to be involved in the antiviral response in monocytes/microglia. Interestingly, we found sex differences in the expression of Apolipoprotein B mRNA editing enzyme, catalytic polypeptide 1 (APOBEC1) and its cofactor RNA binding motif protein 47 (RBM47), factors which have previously been shown to be involved in the attenuation of viral-induced encephalitis. At steady state, both males and females show similar expression levels of both APOBEC1 and RBM47 in the olfactory bulb. At four days post infection, however, females show significantly higher expression levels of both factors than both infected males and steady state females. We will discuss the role of RNA editing enzyme APOBEC1 in microglia in the sexually dimorphic response to VSV infection

Title: Gestational bisphenol-A exposure increases susceptibility of adult mice to development of EAE through the innate immune system

Authors: *J. ROGERS[1], M. MISHRA[1], C. SILVA[1], O. KOVALCUK[2], L. METZ[1], V. YONG[1]; [1]Univ. of Calgary - Hotchkiss Brain Inst., Calgary, AB, Canada; [2]Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Multiple Sclerosis (MS) is a debilitating disease of the central nervous system (CNS) with pathology that includes inflammatory lesions, demyelination and axonal loss. This damage in caused by inflammatory lymphocytes and monocytes crossing the blood-brain barrier into the CNS parenchyma. Several lines of evidence suggest that environmental factors play an important role in shaping immune responses including the immune system of MS patients. Bisphenol-A (BPA) is a persistent environmental contaminant and an endocrine disrupting chemical. Studies have shown that BPA can be detected in up to 90% of human serum samples in various regions of the world. This suggests significant and widespread human exposure. Furthermore, it has been

shown that BPA can act on multiple systems and derail homeostasis. Specifically, studies have shown that during early life animals are more susceptible to lasting effects of BPA. To investigate a possible role for BPA in MS we used the Experimental Autoimmune Encephalomyelitis (EAE) model in C57BL/6 mice. During gestation pregnant mice were treated daily with either BPA or vehicle. Pups were then allowed to grow for 8-10 weeks undisturbed. EAE was induced using myelin oligodendrocyte glycoprotein (MOG) in complete Freund's adjuvant without the use of pertussis toxin (PTx). In agreement with incidence reported in the literature, few control mice (no gestational exposure) or gestationally-exposed vehicle mice developed EAE when PTx was not used in the disease-inducing immunization procedure; in contrast, males who had been gestationally-exposed to BPA showed a significant increase in disease incidence. Examination of blood from gestationally-exposed mice when these were young adults showed a significant change in miRNA profile that is linked in the literature to dysregulation of the innate immune system. Moreover macrophages from gestational BPA-exposed mice appeared to have greater propensity to be activated in culture along a pro-inflammatory pathway. These results suggest that animals gestationally exposed to BPA may have increased susceptibility to EAE in adulthood through dysregulation of innate immunity. Gestational exposure to environmental factors that alter the immune system in later life may constitute a mechanism that predisposes an individual to MS.

Title: 17Beta-estradiol (E2) suppresses neuronal cyclooxygenase 2 gene expression

Authors: *W. STACEY[1], R. M. UHT[1,2];
[1]Pharmacol. and Neurosci., [2]Inst. for Aging and Alzheimer's Dis. Res., Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: Histological analyses of postmortem human brains suggest that neuronal cyclooxygenase-2 (COX-2) is upregulated in early stages of Alzheimer's disease (AD) (Ho, 2001). COX-2 is selectively expressed in a subset of neurons in the hippocampus, cerebral cortex, and amygdala (Yamagata, 1993). Although the suppressive effects of E2 on

cyclooxygenase-2 gene (cox-2) expression in the periphery are known, E2 effects on neuronal cox-2 remain uncharacterized. Data indicate that E2 and ERβ agonist Diarylpropionitrile (DPN) suppress COX-2 pre-mRNA and mRNA levels to the same extent. Furthermore, PHTPP a selective ERβ antagonist reversed the effect of both E2 and DPN. Because the cox-2 promoter lacks palindromic estrogen response elements, we targeted a proximal promoter region with a NF-κB response element implicated in cox-2 regulation. Using chromatin immunoprecipitation (ChIP), we analyzed changes with respect to promoter occupancy in the cox-2 proximal promoter region in response to E2 or DPN. Both ligands decreased NF-κB-p65 occupancy. Given that histone deacetylases (HDACs) may inhibit NF-κB activity, we sought to determine whether or not E2 repression of NF-κB-p65 occupancy involves HDACs. Treatment with the HDAC inhibitor trichostatin A (TSA) abrogated E2 and DPN suppression of COX-2 pre-mRNA. In keeping with the effect of TSA, E2 and DPN increased HDAC1 promoter occupancy; however recruitment of HDAC3 was unchanged. HDAC1 is known to form a complex with Sin3A, and E2 and DPN increased Sin3A occupancy. Interestingly, E2 and DPN both increased CBP occupancy. The recruitment of HDAC1 seems to correlate with decreased acetylation of histone 4 and not histone 3. Taken together, these data suggest that E2 suppresses neuronal cox-2 expression through ERβ-mediated recruitment of HDAC1 and Sin3A and a concomitant reduction of H4 acetylation. The role of CBP in this mechanism will be discussed.

Title: Acute onset inflammatory demyelinating polyradiculoneuritis in an infant affected by severe combined immunodeficiency (SCID) due to RAG-1 hypomorfic mutation

Authors: *A. LOGOTETA[1], S. GALASSI[2], S. PRO[3], M. DI CAPUA[3], R. GRADINI[4], B. BERNARDI[2], D. LONGO[2];
[1]Dip. di Neuroscienze, Facoltà di Medicina e Chirurgia, Univ. La Sapienza, Azienda Ospedaliera Sant'Andrea, U.O.C. Neurologia, Roma, Italy; [2]Dept. Immagini, Ospedale Pediatrico Bambino Gesù, IRCCS, U.O. Neuroradiologia, Roma, Italy; [3]Dept. di Neuroscienze e Neuroriabilitazione, Ospedale Pediatrico Bambino Gesù, IRCCS, Roma, Italy; [4]Dept. di Medicina Sperimentale, Univ. di Roma "La Sapienza", Roma, Italy

Abstract: An infant of 11 months suffering from SCID and polyradiculoneuritis was followed for two years from June 2012 to May 2013. Five days after the onset of clinical symptoms, the patient showed absence of reflexes, weakness of the limbs and bilateral ptosis. Lab. Data showed

hypergammaglobulinemia, CD4 + penia, PCR blood with CMV +, absence of both anti GQ1B-1 Ab and GM1- IgG/IgM. CSF examination showed increased proteins and IgG oligoclonal bands. Genetic analysis showed hypomorphic mutations of the RAG-1 gene. Electroneurography (ENG) was normal. MRI showed enhancement of roots of the cauda equina, III, IV, and VI cranial nerves and optic chiasm. IVIG treatment (2gr/kg in five days) + methylprednisolone was started. ENG at day 10 showed a demyelinating polyneuropathy. The patient continued the treatment with IVIG + methylprednisolone + ganciclovir. At day 21 the patient showed clinical worsening with ophthalmoplegia and respiratory failure and underwent plasmapheresis (8 cycles) combined with anti-CD20 (4 cycles) treatment. This therapy led to a mild symptomatological improvement. A further ENG evaluation at 70 day confirmed F-wave chronodispersion. On February 2013, MRI analysis showed unmodified neuroradiological lesions but the patient was still presenting a severe disability and underwent allogenic hematopoietic stem cells transplantation. After the transplantation the patient showed fair resistance to forced eyelid opening, good control of the head and trunk, spontaneous movements of both the upper and lower limbs with antigravitary contractions. Given the variety of symptoms, it was not easy to link the clinical data to the genetic mutation. MRI analysis was essential in the early stages of the disease to guide the diagnosis. This case is to our knowledge the first patient with a phenotype characterized by RAG-1 deficiency SCID-related polyradiculoneuritis.

Title: Brain region specificity of inflammation-associated kynurenine metabolism

Authors: ***J. M. PARROTT**, L. REDUS, A. M. DUGAN, J. C. O'CONNOR;
Pharmacol., Univ. of Texas Hlth. Sci. Ctr. At San Antonio, San Antonio, TX

Abstract: Clinical and preclinical studies have established an association between the kynurenine pathway of tryptophan metabolism and the development of depression symptoms or depressive-like behaviors. During neuroinflammation, kynurenine metabolism is up-regulated and results in the production of neurotoxic metabolites which are hypothesized to contribute to depressive-like behaviors. Though recent analysis characterized the specific changes of whole

brain kynurenine metabolites in response to peripheral immune challenge, it is unknown if this metabolic response exhibits any regional specificity. Symptoms of depression and distinct depressive-like behaviors can be facilitated by different brain circuitry. Therefore, regional characterization of kynurenine metabolism might allow for better understanding of the potential mechanisms that mediate inflammation-associated behavior changes. To directly address this gap in understanding, four microdissected brain regions relevant to depression-related symptoms (dorsal and ventral hippocampus, central nucleus of the amygdala, nucleus accumbens) were analyzed. Kynurenine metabolites were measured by LC/MS 24h after peripheral (i.p.) administration of either lipopolysaccharide (LPS, 0.5mg/kg) or saline. In all regions assessed, LPS administration resulted in an increase in kynurenine and the kynurenine/tryptophan ratio. Interestingly, downstream metabolism following LPS injections varied between the four regions assessed. Neurotoxic 3-hydroxykynurenine was elevated in all regions except the ventral hippocampus and 3-hydroxyanthranillic acid increased in the dorsal hippocampus but was decreased in the nucleus accumbens. Kynurenic acid and xanthurenic acid, both previously demonstrated to not respond to neuroinflammation, was increased in the nucleus accumbens. Xanthurenic acid was also elevated in both the dorsal and ventral hippocampus. Together these data suggest inflammation-induced changes in kynurenine metabolism are brain region specific which has therapeutic implications for a number of neuropsychiatric disease populations.

Abstract: Peripheral administration of gram-negative bacteria endotoxin - lipopolisaccharide (LPS) is known to activate the hypothalamo-pituitary adrenal axis (HPAA) and brain noradrenergic systems. We studied responses to peripherally administered LPS using the HPLC-ED to measure the concentration of noradrenaline and its metabolite MHPG in various brain regions of vagotomized rats. Rats were submitted to subdiaphragmatic vagotomy and after 30 days were used for experiments. They were injected with saline and LPS (10 μg ip) in random order, and two hours after the injections they were euthanized. The brains where removed from the skull and the hypothalamus, amygdala, prefrontal medial cortex, hippocampus, periaqueductal gray matter, and the brainstem were isolated. HPLC analysis indicated that subdiaphragmatic vagotomy did not protect against increase of noradrenaline concentration in analyzed brain regions. In case of LPS injected control animals we observed increased noradrenaline concentration versus saline injected ones. These results were comparable with those observed in sham operated rats. There results suggest that there may be compensatory mechanisms responsible for transferring of immune signal to the brain that develop during a relatively long time of recovery after subdiaphragmatic vagotomy.

Title: *In vivo* measurement of retinal ganglion cell health following optic nerve injury or demyelination in preclinical models of multiple sclerosis

Authors: *K. MIRCHIA[1], C. HOWE[2];
[1]Neurol., [2]Mayo Clin., Rochester, MN

Abstract: Optic neuritis (ON) is the leading cause of disability in multiple sclerosis and neuromyelitis optica. Clinically, retinal nerve fiber layer (RNFL) thickness assessed via optical coherence tomography (OCT) is used as a diagnostic tool for optic neuritis. However, diagnostic potential in early disease is limited due to acute RNFL swelling. Recent reports indicate that retinal ganglion cell (RGC) loss precedes thinning of the RNFL, suggesting that sensitive measurement of the ganglion cell layer alone or in conjunction with the RNFL may provide earlier diagnostic utility. However, the mechanisms involved in RGC dropout during ON are not well established and detailed relative kinetics are lacking. Therefore, we sought to provide a

more detailed characterization of acute RGC responses in experimental models of ON. The unique transparency of ocular tissues coupled with the multitude of available intraoptic imaging techniques allows for robust and efficient *in vivo* analysis of neuronal responses to inflammation and demyelination. Using both the cuprizone model of chemically-induced optic nerve demyelination and the experimental autoimmune encephalomyelitis model of neuroinflammatory demyelination, we report *in vivo* measurements of pathophysiological changes in retinal tissue. Specifically, we have combined conventional bright-field fundus imaging and OCT with fluorescent imaging to synchronously study how optic nerve demyelination contributes to: 1) RGC dropout and morphological changes, using an adeno-associated viral vector to drive eGFP expression in neurons; 2) alterations in retinal vasculature, using intravenous delivery of TRITC-labeled dextran; and 3) retrograde axonal transport defects in the optic nerve following stereotactic delivery of Fluorogold tracer to the superior colliculus. These findings will inform future studies investigating the role of T cell-mediated injury of optic nerve axons during chemical or neuroinflammatory demyelination.

Title: Arsenic exposure downregulates LPS or IL-4/IL-13 induced M1/M2 immune factors

Authors: *G. J. HARRY, R. ORIHUELA, C. A. MCPHERSON;
Natl. Toxicology Program Lab., Natl. Inst. Enviro Hlth. Sci., Durham, NC

Abstract: One primary health effect of inorganic arsenic (iAs) exposure relates to altered immune system function often resulting in a decreased ability of the system to mount an adequate response to infection, decreased T cell activation, and macrophage phagocytosis. Effects of arsenic exposure on the developing brain involve aspects of neuronal circuitry and connectivity. Given the link between microglia and synapses we examined the potential immune-dysregulatory effects of iAs exposure on microglia as a potential underlying mechanism for neurological effects. In BV-2 microglia cells, 24 hr exposure to iAs (1uM) decreased basal IL-4 and IL-1beta mRNA levels yet increased levels of LPS induced IL-1b. At 2.5 uM iAs, LPS induction of IL-1alpha, IL-1beta, IL-6, and iNOS mRNA levels was blunted. By 3 weeks of exposure, basal mRNA levels for M1 and M2 related cytokines were slightly elevated and levels

following LPS or IL4/IL13 induction significantly blunted. In primary microglia, 1uM iAs lowered basal levels of IL-1beta, IL-6, Arg-1 and IL-1RA mRNA and elevated LPS induction of IL-6. CD1 male mice exposed to 42.5 ppm iAs in the drinking water for 6 weeks produced comparable arsenic levels in the brain as those used *in vitro*. Under these conditions, iAs did not alter basal levels of M1 or M2 cytokines however, responses to LPS or IL4/IL13 were significantly blunted. Phagocytic actions of BV-2 cells exposed to arsenic did not appear to be compromised as measured by fluorescent bead-uptake and Image-Stream flow cytometry however, with increasing demand cells displayed a diminished level of bead uptake. Our data suggests that chronic exposure to arsenic significantly alters the brain immune system with a blunting of the normal protective response to challenge. Such alterations can have implications for brain development and for repair capabilities and plasticity later in life.

Title: Corticosteroids promote indoleamine/tryptophan-2,3-dioxygenase expression concomitantly with suppressing pro-inflammatory cytokines in the mouse brain

Authors: A. KELLY[1], M. A. LAWSON[2], K. W. KELLEY[2], *R. H. MCCUSKER[2];
[1]Neurosci. Program, [2]Animal Sci., Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: An association between an activated immune system, sickness behaviors, and major depressive disorder (MDD) is well established. Frequently, MDD is associated with elevated corticosteroid levels and an elevation in tryptophan metabolism towards the production of kynurenine via the action of indoleamine/tryptophan-2,3-dioxygenase's (DO's: Ido1, Ido2 and Tdo2). A direct or interactive role of elevated corticosteroids on cytokine and DO expression within the brain relative to sickness or MDD is poorly defined. Here, we investigated the interaction between corticosteroid receptor agonists and inflammatory signals within the brain using an *ex vivo* model to quantify changes in pro-inflammatory cytokine and DO mRNA expression. Organotypic hippocampal slice cultures were prepared from 7-9 day old C57BL/6J mice and treated on day 7 under serum-free conditions with either dexamethasone (Dex, a

glucocorticoid receptor agonist) or aldosterone (Aldo, a mineralocorticoid receptor agonist) with or without pro-inflammatory mediators (LPS, poly I:C, IFNγ, IFNα). Both LPS and poly I:C increased expression of pro-inflammatory cytokines, TNFα and IL-6. This inflammatory response was attenuated in the presence of Dex, but not Aldo, which characterizes a prototypical anti-inflammatory glucocorticoid receptor-mediated response. Dex and Aldo had no effect on Ido1 expression when added alone. Only IFNγ induced the expression of Ido1, but surprisingly both Dex and Aldo interacted with IFNγ to accentuate expression of specific Ido1 transcripts. Ido2 expression was increased by LPS, poly I:C and IFNγ. Aldo also induced expression of Ido2 transcripts, both alone and in the presence of inflammatory mediators, while Dex had no effect. Tdo2 expression was increased only by Dex, a response unaltered by inflammatory mediators and not mimicked by Aldo. These results advance an emerging hypothesis that corticosteroids play a dichotomous role in the brain via interaction with the central innate immune system. In one role, glucocorticoids elicit an anti-inflammatory response, an action well established to be related to sickness recovery. In another role, corticosteroids may act through glucocorticoid and mineralocorticoid receptors to differentially enhance the expression of Ido1, Ido2, and Tdo2 within the brain. It is now necessary to characterize these newly discovered interactions *in vivo* to define the mechanism by which pro-inflammatory cytokines and stress hormones synergize relative to MDD.

Title: Participation of the inflammatory process in the treatment of patients with extraparenchymal neurocysticercosis

Authors: *Y. MARTINEZ LOPEZ, O. HERRERA VAZQUEZ, H. JUNG, R. CARRILLO, E. GARCÍA, L. ADALID, A. TOLEDO, À. FLEURY;
Inst. Nacional De Neurología Y Neurocirugía, Mexico, Mexico

Abstract: Neurocysticercosis (NCC) is the most common helminth infection of the central nervous system; remains endemic in developing countries. The extraparenchymal forms continue presenting high morbidity, because a 30-40 % of patients do not respond to cysticidal treatment. Objective: Evaluate the relationship between demographic, immunological and response to treatment in patients with cysticidal extraparenchymal neurocysticercosis. Material and Methods: Prospective, longitudinal, comparative and analytical study. Patients with definitive diagnosis of

vesicular extraparenchymal neurocysticercosis were included . Lymphoproliferation assays were performed on peripheral blood pre and post treatment (4-6 months) using antigens of Taenia solium. Clinically and radiologically patients were evaluated before and after treatment, determining the response to it. One sample was taken for measurement of plasma albendazole sulfoxide at the end of treatment Results: The study included 20 patients (7 women, 13 men) with a mean age of 45 ± 10 years; 17 of them had multiple parasites and 3 only one. It was found that 6 patients did not respond to treatment, in two cases were found association with gender or the number of parasites (P = 0.2, P = 0.24), but no association with age (P = 0.003) was found. The most common symptoms were headache and intracranial hypertension in 75% (15/20). The intensity of the pre and postreatment specific lymphoproliferative response were similar in patients with and without response to treatment (P = 0.70). Patients with response to treatment had a higher increase in cerebrospinal fluid cellularity evaluated before treatment (P = 0.02). Discussion:The lack of response to treatment in patients with extraparenchymal neurocysticercosis is currently one of the biggest problem in the management of patients. Preliminary results of this study show that intensity of the inflammatory reaction is associated with a better response to treatment. Also results show that lymphocyte proliferation index could predict clinical and radiological outcome in patients with extraparenchymal neurocysticercosis. This results, which will be completed with the measurement of inflammatory proteins, are of interest because it could indicate that the use of corticosteroids to prevent inflammatory complications should be done individually by patients.

Title: Primary and BV-2 murine microglia can be pharmacologically manipulated by epigenetic modifiers to mimic microglial senescence

Authors: ***S. MATT**, R. W. JOHNSON;
Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: The progressive decline in maintaining homeostatic function during aging can lead to genomic instability and cellular senescence that are primary risk factors for age-related pathologies such as autoimmune disorders and neurodegenerative diseases. This aging phenotype

can partially be explained by the imbalance between pro-inflammatory and anti-inflammatory states. Microglia, the brain's resident immune cells, play a major role in the age-associated shift of the inflammatory profile of the central nervous system (CNS). During aging, microglia develop a more inflammatory phenotype and have increased gene and protein expression of pro-inflammatory cytokines such as interleukin (IL)-1β. Further, when the immune system is challenged with a pro-inflammatory agent such as lipopolysaccharide (LPS), microglial activation is amplified and prolonged in the aged brain compared with adults, leading to exaggerated neuroinflammation, sickness behavior, and cognitive deficits. What causes these impairments and brings about a "primed" microglial population remains to be elucidated. Significant associations between aging and epigenetic alterations have recently been identified, notably that global DNA methylation decreases with age leading to a loss of phenotypic plasticity. We have previously demonstrated that aging-induced exaggerated pro-inflammatory cytokine gene expression in microglia was associated with DNA hypomethylation of the Il1b promoter, so we sought to determine whether adult primary microglia or the microglial BV-2 cell line could be modulated by epigenetic drugs similar to senescent microglia. We investigated whether the demethylating agent 5-azacytidine (5-aza) increased mRNA expression and decreased methylation of Il1b. Novel findings indicate that both 5-aza and/or LPS altered Il1b mRNA expression and DNA methylation of BV-2 and primary microglia as well as mRNA expression of epigenetic regulators including histone deacetylases and DNA methyltransferases. Manipulating the epigenetic landscape has enormous potential for improving our understanding of age-related neuroinflammatory complications and the role of microglial hyperactivity in the aged brain.

Title: Dynamic changes in dendritic spine numbers in an animal model of Multiple Sclerosis

Authors: *K. MILLOY[1], M. VERBEEK[1], S. ACHARJEE[2,1], Q. J. PITTMAN[2], A. BENEDIKTSSON[1];

Abstract: Multiple sclerosis (MS), a demyelinating disease with sensory and motor deficits, is also associated with behavioural co-morbidities such as neuropsychiatric and cognitive impairments, affecting around 50% of patients. The mechanisms underlying these changes are poorly understood. However, inflammation occurring even in the early stages of the disease can alter brain structure and function, leading to these abnormalities. We investigated if there were any changes in dendritic spines using in an animal model of MS, called experimental autoimmune encephalomyelitis (EAE). We focused on the amygdala and hippocampus, brain regions involved in emotion processing and memory, respectively. Methodology: EAE was induced in C57/BL6 mice with MOG33-55/CFA and pertussis toxin (PTX). Control mice received only CFA and PTX. Neurons were labeled using Golgi staining at two timepoints: day (d7), when behavioral changes can be seen, and at d17, where motor deficits are evident. Neurons were imaged with confocal microscopy and analyzed using Imaris software to examine dendritic spines, which form the postsynaptic structure of the synapse. A minimum of 34 neurons was analyzed in each condition. Results: Spine number was increased by 22% ($p<0.05$) in the principal neurons of the basolateral amygdala at d7, a stage when the animals do not show any sign of paralysis but have increased levels of cytokines in the brain. At d17, the difference in the spine count between the EAE and controls disappeared, indicating there was most likely increased spine loss in EAE. We did not observe any change in the spine density in the hippocampus at d7 or 17. Conclusion: There appears to be a temporal and region specific alteration in the spine density in the brains of EAE mice. Further functional analysis, with electrophysiology, and further characterization of spines will shed light on how spine density influences synaptic function and circuit dynamics that lead to behavioural changes.

Title: Suppression of microglial activation with PPAR-gamma agonists and anti-histamines: relevance to multiple sclerosis

Authors: *P. D. STORER, K. E. ROHR, C. S. MILLER, B. L. WADSWORTH;
Biol., Coe Col., Cedar Rapids, IA

Abstract: Multiple sclerosis (MS) is a chronic, progressive disease involving immunological damage to myelin sheaths and nerve cells in the brain and spinal cord. Microglial cells are thought to play a key role in the immune response of the central nervous system and are thus implicated in the pathology of MS. Once activated, microglia function to eliminate pathogens and secrete cytokines to promote further pro-inflammatory responses. However, chronically activated microglia fuel a self-renewing cycle of activation that results in the observed oligodendrocyte and neuron damage. In this study, a microglial cell line (N9) was used to study the potential anti-inflammatory properties of H1R-specific anti-histamine compounds following immunologically-relevant activation. The rationale for these studies is based on the clinical relevance of anti-histamines and their ability to control various aspects of the immune system in other disease models. Experimental comparisons were made to the anti-inflammatory properties of other known compounds including the PPAR-gamma agonists rosiglitazone and 15d-PGJ2. Results from epPCR, qPCR, ELISA and IHC studies confirmed the ability of PPAR-gamma agonists and demonstrated the ability of anti-histamines, namely clemastine, to attenuate nitric oxide production and cytokine/chemokine expression in N9 cells. These results suggest a potentially new combinatorial avenue at controlling inflammation in the CNS by targeting the inflammatory mechanisms of microglia cells.

Title: Homeostatic role of neuronal L1 cell adhesion molecule during inflammatory processes in the central nervous system

Authors: *L. MENZEL[1], M. PATERKA[2], R. WHITE[3], M. SCHACHNER[5], F. ZIPP[2], M. SCHÄFER[4];
[2]Neurol., [3]Inst. of Physiol., [4]Anesthesiol., [1]Univ. Med. Ctr. Mainz, Mainz, Germany; [5]Ctr. for Mol. Neurobio., Hamburg, Germany

Abstract: Neuroinflammatory diseases such as multiple sclerosis (MS) are associated with infiltration of peripheral immune cells into the CNS. It remains unclear how the CNS adapts to the presence of peripheral immune cells and autoimmune-directed inflammatory attacks.

Sustained contacts between immune cells and neurons have been reported in Experimental Autoimmune Encephalomyelitis (EAE), a rodent model of MS. This finding implies the existence of molecules mediating cell adhesion and recognition as well as reciprocal signaling between neurons and immune cells. In this study, we investigated a role of the neuronal L1 cell adhesion molecule (L1CAM) in neuroinflammation using EAE in mice as a model. L1CAM protein expression in spinal cord was downregulated at the peak of disease. In order to examine the relevance of reduced neuronal L1CAM expression in EAE, neuron-specific L1CAM knockout mice were analyzed. Severity progression of EAE was significantly attenuated in these mice compared to control. *In vitro* experiments further demonstrated a rapid downregulation of neuronal L1CAM mRNA expression in primary neurons when co-cultured with activated $CD4^+$ T cells. These results suggests that neuronal downregulation of L1CAM is triggered by T cell signaling and thereby ameliorates neuroinflammatory disease in a preclinical model of MS. Our results further support a role of L1CAM for CNS homeostasis in response to inflammatory processes.

Title: Early biomarkers for demyelination and neuroinflammation in the Experimental Allergic Encephalomyelitis (EAE), an animal model for Multiple Sclerosis

Authors: ***N. BORJINI**[1,2,4], M. FERNANDEZ[2], S. SIVILIA[3], L. GIARDINO[4,3], L. CALZÀ[4,2]; [1]Chiesi Farmaceutici Spa, Parma, Italy; [2]Hlth. Sci. and Technologies Interdepartmental Ctr. for Industrial Res. (HST-ICIR), [3]Dept. of Vet. Med. Sci., Univ. of Bologna, Ozzano Emilia (BO), Italy; [4]IRET Fndn., Ozzano Emilia (BO), Italy

Abstract: Inflammation and demyelination are the primary pathologies in multiple sclerosis (MS) lesions and in the EAE (experimental allergic encephalomyelitis), a widely used experimental animal model for this human disease. Despite the prevailing efforts made in the field of biomarkers to determine prognostic factors and predict the clinical disease course, a correlation between tissue neuroinflammation, demyelination, neurodegeneration and potential biomarkers in biological fluids remain to be defined. In this study, we perform a time-course investigation based on a discovery strategy of myelination and inflammation biomarkers in

cerebrospinal fluid (CSF) and spinal cord (SC), using high-throughput technologies in order to highlight the potential of novel early biomarkers for MS. Female Dark-Agouti rats were immunized using an emulsion of guinea pig spinal cord, heat-inactivated Mycobacterium tuberculosis and complete Freund's adjuvant and were daily weighed and examined for clinical score. At 1, 5, 8, 11 and 18 day post-immunization (DPI), EAE rats were sacrificed, CSF was collected and total SC was dissected. We performed multiparametric quantification of inflammatory mediators in the CSF through xMAP technology and Luminex platform. We used the SC for investigating inflammation and myelination markers by real-time PCR array and immunohistochemistry. Several proteins significantly changed in the CSF of EAE animals compared with control. In particular, the pro-inflammatory cytokines/chemokines IL1b, CCL5, TNFa and the anti-inflammatory such as IL5, IL10, VEGFA are upregulated starting from 8 DPI. Regarding gene expression, myelination genes were highly down-regulated starting from 5 DPI, especially MAL, MBP, PMP22 while an opposite expression profile was observed for inflammation related genes, for instance CXCL11, CXCL9 and LTA were the most upregulated genes showing 100 fold change at 8 DPI, around 300 at 11 DPI and 125 at 18 DPI. SC inflammatory infiltrates were identified in EAE animals and double staining with antibodies markers of microglia and myeloid (CD11b) M1 (CD86), M2 (CD163) phenotypes, T cells (CD44), astroglia (GFAP) oligodendrocyte precursor cells at different maturation stages (PDGFaR, NG2, CNPase, MBP) and neurons (b-tubulin, NSE) was performed in order to identify the producing cell type. This early biomarkers regulation reflects the immunological response and the demyelination process taking part as soon as 5 DPI, before the clinical onset of EAE. Most regulated genes/proteins will be processed through pathway databases in order to figure out possible mechanisms regulating inflammation/demyelination events during EAE.

Title: Role of miR-142-3p in inflammation-dependent synaptic dysfunctions affecting a mouse model of multiple sclerosis

Authors: **F. DE VITO**[1,2], *G. MANDOLESI[1], A. MUSELLA[1], A. GENTILE[2,1], D. FRESEGNA[2,1], S. BULLITTA[1], H. SEPMAN[2], N. HAJI[1], C. DI SANZA[1], E. HORNSTEIN[3], I. BOZZONI[4], C. PRESUTTI[4], D. CENTONZE[1,2];

[1]IRCCS-Santa Lucia Fdtn, Rome, Italy; [2]Tor Vergata Univ. of Rome, Rome, Italy; [3]Weizmann Inst. of Sci., Rehovot, Israel; [4]Sapienza Univ. of Rome, Rome, Italy

Abstract: MicroRNAs (miRs) are small non-coding RNAs, which regulate several physiological and pathological processes by repressing post-transcriptionally target mRNAs. Recently, the involvement of miRs emerged also in multiple sclerosis (MS), a chronic inflammatory and degenerative disease of the central nervous system. Although their role is mainly related to the immune system, little is known about miRs in MS grey matter pathology, in particular in the inflammatory-dependent synaptopathy, which affects MS and its mouse model experimental autoimmune encephalomyelitis (EAE). Aims: We asked whether a miR dysregulation is implicated in the interleukin1-β (IL1-β) dependent synaptic alterations, which affect the EAE cerebellum, leading to excitotoxic damage. Methods: MOG(35-55)-EAE was induced in female C57BL/6 mice. miR expression was analyzed by microarray and qRT-PCR in EAE cerebellum and by qRT-PCR in cerebrospinal fluids (CSFs) of MS patients (gadolinum-positive, Gd+ vs gadolinum-negative, Gd-). The role of miR deregulation in EAE cerebellar dysfunction was explored by miR over-dosage or inhibition *in vitro* (report assays), *ex vivo* or *in vivo* (lentiviral approach, miR KO mice or LNA anti-miR by intracerebroventricular infusion, ICV), followed by immunofluorescence and electrophysiological analyses. Results: We identified miR-142-3p as the most increased miR in the EAE cerebellum during the acute phase of the disease and demonstrated that it down-regulates GLAST/EAAT1, a glial glutamate-aspartate transporter important for synaptic glutamate uptake and strongly compromised in EAE in an IL1-β-dependent way. In support of an IL1-β-miR-142-3p-GLAST regulatory axis, we showed that incubation of IL1-β on normal cerebellar slices induced miR-142-3p up-regulation, GLAST down-regulation and an enhancement of the glutamatergic transmission as in EAE. Of note, the IL1-β synaptic effect failed in miR-142 KO slices as well as a recovery of the glutamatergic transmission was observed in EAE miR-142-3p KO mice or in a group of EAE mice preventively treated by ICV infusion with a miR-142-3p inhibitor. Finally, we provide evidence of an involvement of miR-142-3p in MS disease not only by detecting elevated miR levels in the CSF of Gd+ MS patients but also by reproducing the EAE synaptic alterations in cerebellar slices incubated with the Gd+ CSF. Interestingly, pre-incubation of the Gd+ MS CSF with a miR-142-3p inhibitor was protective. Conclusions: Our findings highlight miR-142-3p as key molecular player in IL1-β-mediated synaptic dysfunction and excitotoxic damage in both EAE and MS pathophysiology, with potential therapeutic implications.

Abstract: We previously demonstrated that herpes simplex virus-1 (HSV-1) infection in neurons causes marked changes in their excitability and intracellular Ca2+ content, together with the phosphorylation and amyloidogenic processing of amyloid precursor protein (APP), (De Chiara et al, 2010, Piacentini et al, 2011, Civitelli et al 2015). These data support the hypothesis that recurrent HSV-1 reactivations may contribute to neurodegeneration typical of Alzheimer's disease (AD), causing repeated cycles of viral infection into the brain. To further explore such an hypothesis, we established a murine model of recurrent HSV-1 infection, closely resembling those occurring in humans: 1 month old female BALB/c mice were inoculated via snout abrasion with a sublethal doses of HSV-1 (F strain, 1x10e6 plaque forming unit), or a mock solution as control. Viral reactivation was periodically induced by thermal stress. HSV-1 spreading to the brain, as well as AD-like neuropathological hallmarks were analyzed in mice during the course of aging. Following virus reactivations we found: 1) viral TK and ICP4 genes (markers of viral infection and active replication, respectively) in cortex and hippocampal tissues, indicating that HSV-1 is able to reach and actively replicate in those brain regions mostly affected during AD; 2) accumulation of β-amyloid peptides (Aβs) and other APP proteolytic fragments, together with altered tau phosphorylation and signs of neuroinflammation in hippocampus and cortex of aged animals; 3) significant impairments in mouse performance in the novel object recognition and Y Maze behavioral tests. Overall, these results strongly support the hypothesis that recurrent HSV-1 infections may contribute to neurodegeneration typical of AD.

Title: Herpes simplex virus type-1 infection promotes inflammation in mouse derived DRG explants and primary neuronal cell culture model

Authors: *H. SHARTHIYA[1], C. SENG[2], V. TIWARI[3], M. FORNARO[1];
[1]Anat., [2]Biomed. Sci., [3]Microbiology & Immunol., Midwestern Univ., Downers Grove, IL

Abstract: The hallmark of herpes simplex virus (HSV) infection is to establish lifelong latency in dorsal root ganglion (DRG) explants. A multi-step based interactions between HSV and cell surface receptor leads to the viral entry and cell-to-cell spread. Interestingly the major players involved in promoting viral entry and inflammation in sensory nervous system remains poorly understood. In this study we established a mouse derived dorsal root ganglion (DRG) explants and DRG-explants derived neuronal cell culture model in order to study the significance of HSV glycoprotein D (gD) interactions to 3-O sulfated heparan sulfate (3-OS HS) entry receptor and associated inflammation. Our results indicates that both DRG-explants and explant derived neuronal cells were susceptible to HSV-1 entry and spread as positive ONPG, ×-gal staining and plaque formation were recorded using reporter HSV-1-expressing reporter gene (β-galactosidase) and replication competent HSV-1 (KOS 804) virus. Using confocal imaging, we also provide a visual evidence for cell surface 3-O sulfated heparan sulfate (3-OS HS) expression followed by HSV-1 glycoprotein D (gD) interaction to 3-OS HS receptor during viral entry. Our screening for a panel of pro-inflammatory cytokines upon HSV-1 infection provided an interesting link between upregulated cytokines and heparan sulfate (HS) implicating potential role of HS and associated neuroinflammation. Taken together, our results highlight a novel approach to study gD-3-OS HS interactions in order to develop therapeutics HSV mediated neuroinflammation.

Title: Neurotrophins affect the number and distribution of two macrophage subtypes after optic nerve injury

Authors: *G. S. VEGA MELÉNDEZ[1,2], M. V. DUPREY-DIAZ[1,2], J. M. BLAGBURN[1], R. E. BLANCO[1,2];

Abstract: We have shown that ciliary neurotrophic factor (CNTF) and fibroblast growth factor (FGF-2) have strong enhancing effects on axonal regeneration in the adult frog optic nerve after injury. In these nerves, bundles of regenerating axons are associated with astrocytes and macrophage-like cells. The objective of the present study is to characterize and identify these cells, and to determine the changes that occur in them after axotomy and CNTF or FGF-2 application. We performed optic nerve crush and applied either saline solution or neurotrophic factors to the nerve. We examined the optic nerves at 48h, one week, and two weeks after axotomy. Ultrastructure studies of the macrophages/microglia after injury and neurotrophic treatment were carried out with electron microscopy of the proximal, injury, and distal sites. Immunocytochemistry for various macrophage subtypes was performed and confocal images of the different regions were taken. Ultrastructural examination of the nerves showed a large number of macrophage-like cells at the lesion site, and distally in close proximity to regenerating axons in CNTF and FGF-2 treated nerves. Significantly fewer cells were present proximal to the lesion. The vast majority of cells were ED-1-positive in saline-, CNTF-, and FGF-2-treated nerves. The distribution of these cells was quantitatively analyzed with antibodies against specific macrophage subtypes. Both pro-inflammatory M1 macrophages (CD-86-positive) and anti-inflammatory M2 macrophages (arginase-positive) were identified at the injury and distal sites. A small but significant increase in CD-86-positive cells (M1 subtype) was observed at 48h and one week after CNTF and FGF-2 application, when compared to saline-treated animals. In saline-treated nerves arginase-positive cells (M2 subtype) were present at one and two weeks after axotomy; treatment of the nerves with CNTF and FGF-2 significantly increased the number of labeled cells. We are also studying the secretions of different cytokines relevant to the presence of these macrophage subtypes. In conclusion, the application of CNTF and FGF-2 affects the number and the distribution of macrophage subtypes after optic nerve injury and it may play an important role in the success of optic nerve regeneration.

Title: Brimonidine suppresses loss of retinal neurons and visual function in a murine model of optic neuritis

Authors: *X. GUO, K. NAMEKATA, A. KIMURA, T. NORO, C. HARADA, T. HARADA; Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan

Abstract: Brimonidine (BMD) is a selective α2-adrenergic receptor agonist that is used clinically for the treatment of glaucoma, one of the leading causes of irreversible blindness that is characterized by progressive degeneration of optic nerves and retinal ganglion cells (RGCs). BMD lowers intraocular pressure, but recent evidence suggests that its therapeutic efficacy may also mediate through mechanisms independent of modulation of intraocular pressure (IOP). We show that BMD prevented retinal degeneration in excitatory amino-acid carrier 1 (EAAC1)-deficient mice, a murine model of normal tension glaucoma (NTG), probably by suppressing the phosphorylation of the N-methyl-D-aspartate receptor 2B (NR2B) subunit in RGCs and by stimulating the production of several neurotrophic factors that enhance RGC survival in Müller glial cells. Optic neuritis is inflammation of the optic nerve and is strongly associated with multiple sclerosis (MS), an inflammatory demyelinating syndrome of the central nervous system. It leads to RGC death and can cause severe vision loss. To further elucidate the neuroprotective role of BMD, we examined the effects of BMD on optic neuritis during experimental autoimmune encephalomyelitis (EAE), an animal model of MS. EAE was induced with MOG35-55 in female C57BL/6J mice and BMD eyedrops were applied daily. In the EAE retina, the number of RGCs was significantly decreased and this effect was suppressed with BMD treatment. Consistent with histological analyses, the visual impairment observed in EAE mice, as assessed by multifocal electroretinograms (mfERGs), an established noninvasive method for reliably measuring visual function, was inhibited with BMD treatment, indicating the functional significance of the neuroprotective effect of BMD. Furthermore, BMD increased the expression level of the basic fibroblast growth factor in the EAE retina, particularly in Müller glial cells and RGCs. Our findings suggest that topical administration of BMD may be available for RGC protection during optic neuritis, as well as for glaucoma.

Title: An application of a novel method to study cerebrospinal fluid dynamics in rats

Authors: ***J. K. KARIMY**[1], K. T. KAHLE[2], D. B. KURLAND[1], V. GERZANICH[1], J. M. SIMARD[1];

Abstract: Cerebrospinal fluid (CSF) flow dynamics play critical roles in both the immature and adult brain, with implications for neurodevelopment and disease processes such as hydrocephalus and neurodegeneration. Intracerebroventricular hemorrhage (IVH) is a deleterious CNS injury that affects thousands of people each year and often results in the formation of hydrocephalus. Unchecked, hydrocephalus can result in increased intracranial pressure, resulting in motor deficits and even death. Historically, hydrocephalus following IVH has been attributed to impaired reabsorption of CSF due to blockages in arachnoid granulations, however the contribution of injury-induced overproduction of CSF by the choroid plexus epithelium has been overlooked. Available tracer dilution methods do not permit ongoing real-time determination of the rate of CSF formation and are not readily amenable to pharmacological interventions, thus accurate characterization of CSF dynamics following CNS injury has been difficult. We recently published a simple method that permits the real-time measurement of the rate of formation of CSF in laboratory rats *in vivo* under near-physiological conditions. We hypothesized that this technique would be useful to study CSF production in a rodent model of IVH. To evaluate this, autologous blood (50 µl) was infused into the right lateral ventricle 48 hours prior to CSF measurements. Our results show a striking 3-fold increase in the rate of CSF production following IVH compared to age matched controls, 1.5 µl/min versus 0.5 µl/min, respectively. Overproduction of CSF following IVH correlated strongly with ventriculomegaly, a hallmark of hydrocephalus. To our knowledge, this is the first direct evidence that CSF overproduction may contribute to hydrocephalus following IVH. This observation has important clinical implications.

Title: Anatomic relationship between the ovaries and the autonomic and sensory ganglia during the estrous cycle in rats

Authors: *P. A. CRUZ MARTÍNEZ[1], Y. CRUZ GOMEZ[2], C. PASTELIN[3], A. HANDAL[3], C. MORAN[3];
[1]Univ. Autonoma De Tlaxcala, Puebla, Mexico; [2]Univ. Autonoma de Tlaxcala, Tlaxcala, Mexico; [3]Benemerita Univ. Autonoma de Puebla, Puebla, Mexico

Abstract: The ovaries innervation involves two nerves: the superior ovarian nerve (SON) and the ovarian plexus nerve (OPN), which connects the ovaries with the prevertebral [celiac ganglia (CG), superior mesenteric ganglion (SMG), suprarenal ganglion (SG)], paravertebral, sympathetic chain ganglia (SCG) and T12-L2 dorsal root ganglia (DRG). The aims of the present study were to localize the postganglionic neurons innervating the right and left ovaries, and describe the fluctuations of the neurons in the different ganglia during the estrous cycle. The study was conducted in virgin adult CII-ZV female rats. The estrous cycle was monitored by daily vaginal smears and only cyclic rats were used. The retrograde tracer true blue (TB) was injected into the right or left ovarian bursa. Four days later, the rats were transcardially perfused and the prevertebral, paravertebral and dorsal root ganglia (T12-L2) were collected and analyzed for positive true blue neurons. In the animals injected in the left ovarian bursa in the estrous, the ipsilateral CG had the higher number of positive true blue neurons (43±10 vs. SCG 24.7±7, SG 15.5±5 $p<0.05$). Moreover the CG in diestrus 1 had the lowest number of positive neurons (7.5±2.1). In the animals injected in the right ovarian bursa, the ipsilateral CG had the highest number of positive true blue neurons (50±8.0 vs. SCG 12±2, SG 15±2.8, SMG 10±2 $p<0.05$). The positive neurons in the ipsilateral sensory ganglia in the animals injected in the left ovarian bursa was higher during the estrous phase, meanwhile in animals injected in the right bursa the higher number of positive neurons was during proestrus day. We conclude that postganglionic neurons controlling the ovarian functions are located in several ganglia and most of the posganglionic neurons are in the CG and sensorial ganglia. We confirm the changes in the pathways that connect the ovaries to the nervous system during the estrous cycle of the rat and their asymmetry.

Autónoma de Tlaxcala, Tlaxcala, Mexico; [6]Inst. de Investigaciones Biomédicas, Dept. de Biología Celular y Fisiología, México, Mexico

Abstract: Pelvic and perineal floor muscles are crucial for the function of the urogenital system in female mammals. In women during childbirth these muscles and its innervation can be compressed or overstretched, and can be cause urinary and sexual dysfunction. The pudendal and perineal nerves are vulnerable to trauma during delivery. We showed that in multiparous rabitts does uncoordinated pattern of activity of the pelvic (pubococcygeus) and perineal (bulboesponjoso,Bsm) muscles and urinary dysfunctions. To discriminate if these changes are caused by damage to the innervation, specifically the of Bsm, to evaluate changes in the bladder and urethral function in a model of bulbospongiosus nerve crush. For experiments virgin rabbits (12 + 2 months n = 5) anesthetized with urethane 20%, which was underwent simultaneous cystometrograms, urethral and electromyogram records before and after of the crushing bulbospongiosus nerve. The results suggest that the nerve crushing produced voiding dysfunctions and inefficiency of the bladder contraction, a significant increase of the residual volume and urethral resistance similar at multiparous rabbits. It is possible that during the childbirth the perineal nerves, specifically the bulbospongiosus nerve, were compressed and postpartum, the women would develop sexual and urinary dysfunction.

Title: Modeling the spinal pudendo-vesical reflex for bladder control by pudendal afferent stimulation

Authors: *M. J. MCGEE[1], W. M. GRILL[1,2,3,4];
[1]Biomed. Engin., [2]Electrical and Computer Engin., Duke Univ., Durham, NC; [3]Neurobio., [4]Surgery, Duke Univ. Med. Ctr., Durham, NC

Abstract: Electrical stimulation of afferents in the pudendal nerve (PN) is a promising approach to restore continence and micturition following bladder dysfunction resulting from neurological disease or injury. Although the pudendo-vesical reflex and its physiological properties are well established, there is limited understanding of the underlying neural network mechanisms that mediate the reflexes governing the effects of PN stimulation on bladder function. The objective of this work was to develop a biophysically-motivated model of the neural network underlying the pudendo-vesical reflex. We implemented and validated a neural network architecture based on previous neuroanatomical and electrophysiological studies. Using synaptically-connected integrate and fire model neurons, we created a network model with realistic spiking behavior. Our model reproduced the hallmarks of the pudendo-vesical reflex: volume-dependence of stimulation-evoked bladder contractions and stimulation frequency-dependent bladder activation. Further, the model reproduced the effects of pudendal afferent stimulation frequency and stimulation pattern measured experimentally, and allowed for exploration of the mechanisms underlying the strong stimulation frequency-dependent effects. The model produced expected sacral parasympathetic nucleus (SPN) neuron firing rates from prescribed neural inputs and predicted bladder activation and inhibition with different frequencies of pudendal afferent stimulation. In particular, the model matched experimental results from previous studies of temporal patterns of pudendal afferent stimulation and selective pharmacological blockade of inhibitory neurons. Although the model included descending supraspinal control of the SPN, the frequency and pattern-dependent effects of pudendal afferent stimulation were determined by changes in firing rate of spinal interneurons, suggesting that neural network interactions at the sacral level can mediate the bladder response to different frequencies and temporal patterns of pudendal afferent stimulation. The anatomical structure of excitatory and inhibitory interneurons in the network model was necessary and sufficient to produce the critical features of the pudendo-vesical reflex and may prove useful to guide development of novel, more effective electrical stimulation techniques for bladder control.

Title: Pelvic nerve stimulation restores bladder capacity and voiding efficiency in rat prostaglandin E2 overactive bladder model

Authors: *C. L. LANGDALE[1], J. A. HOKANSON[1], A. SRIDHAR[5], W. M. GRILL[1,2,3,4]; [1]Biomed. Engin., [2]Electrical and Computer Engin., [3]Neurobio., [4]Surgery, Duke Univ., Durham, NC; [5]Bioelectronics R&D, GlaxoSmithKline, Stevenage, United Kingdom

Abstract: Overactive bladder (OAB), resulting in urgency, frequency, and incontinence, is a highly prevalent condition that leads to medical complications and decreased quality of life. Treatments for OAB include behavioral therapy, exercise therapy, pharmacotherapy, and electrical stimulation. Behavioral and exercise therapy have limited efficacy, and pharmacotherapy has dose-limiting side effects. The Medtronic Interstim device targets the S3 sacral spinal nerve, but sacral stimulation is relatively non-selective due to the convergence of parasympathetic, sympathetic, and somatic innervation of lower urinary tract and other pelvic systems. Electrical stimulation of peripheral nerves for OAB may provide greater selectivity thereby increasing efficacy and reducing side effects. We hypothesized that electrical stimulation of pelvic nerve (PEL) can restore bladder capacity (BC) and voiding efficiency (VE) in the rat prostaglandin E2 (PGE2) OAB model. The aims of this study were: (1) quantify and compare functional (BC and VE) and neural (PEL and external urethral sphincter (EUS) activity) changes after intravesical installation of control (saline) and PGE2; and (2) measure the effects of pelvic stimulation on BC and VE post PGE2. Acute urethane (1.2 g/kg) anesthetized female Wistar rats (Charles Rivers Laboratories) were studied using *in vivo* cystometry (CMG). A PE-90 catheter was placed to measure bladder pressure and for intravesical infusion of saline and PGE2 (30, 60, and 100 μM). Bipolar electrodes were placed on EUS and PEL to record electromyogram (EMG) and electroneurogram (ENG) activity during CMGs. In a subset of trials, continuous PEL stimulation was delivered after PGE2 infusion at different amplitudes (0.8 and 2 times threshold to evoke PEL-EUS reflex) and frequencies (1 and 10 Hz). 100 μM intravesical PGE2 reduced both BC and VE compared to control. 100 μM intravesical PGE2 also reduced PEL ENG activity and increased EUS EMG activity. Low amplitude (0.8 times threshold) 10 Hz PEL stimulation restored both BC and VE to control levels. These findings suggest that PGE2 associated deficits in BC and VE may be due to a loss of coordinated control of both pelvic and pudendal nerves, and that PEL stimulation is a promising approach for treatment of OAB.

Title: Contributions of pituitary adenylate cyclase-activating polypeptide (PACAP)/receptor signaling to increased voiding frequency and somatic sensitivity in mice with urothelium-specific overexpression (OE) of nerve growth factor (NGF) in the urinary bladder

Authors: *B. M. GIRARD, S. MALLEY, M. E. MATHEWS, M. A. VIZZARD;
Anat. and Neurobio., Univ. Vermont col Med., Burlington, VT

Abstract: NGF-OE in the urothelium stimulates neuronal sprouting or proliferation in the urinary bladder, produces increased voiding frequency and non-voiding contractions, and results in increased referred somatic sensitivity. Additional NGF-mediated changes might contribute to the urinary bladder hyperreflexia and pelvic hypersensitivity observed in these transgenic mice such as upregulation of neuropeptide/receptor systems. NGF-OE in the urothelium was achieved through the use of a highly urothelium-specific, uroplakin II promoter. We examined PACAP, vasoactive intestinal polypeptide (VIP), and associated receptor (PAC1, VPAC1, VPAC2) transcripts or protein expression in urothelium and detrusor smooth muscle and lumbosacral dorsal root ganglia in NGF-OE and littermate wildtype (WT) mice using real-time quantitative reverse transcription-polymerase chain reaction and immunohistochemical approaches. Results demonstrate upregulation of PAC1 receptor transcript and PAC1-immunoreactivity (IR) in urothelium of NGF-OE mice whereas PACAP transcript and IR were decreased in urothelium. In contrast, VPAC1 receptor transcript was decreased in both urothelium and detrusor smooth muscle of NGF-OE mice. VIP transcript expression and IR was not altered in urinary bladder of NGF-OE mice. Given the presence of PAC1-IR fibers, the expression of PAC1 receptor expression in bladder tissues, and the abilities of PACAP to facilitate detrusor contractility, whether PACAP/receptor signaling contributes to bladder hyperreflexia and somatic sensitivity was evaluated. Intravesical administration of PACAP6-38 (300 nM) significantly ($p \leq 0.01$) increased bladder capacity (2.0-fold), intercontraction interval and void volume in NGF-OE mice. Intravesical instillation of PACAP6-38 also decreased filling pressure and peak micturition pressure in NGF-OE mice. PACAP6-38 had no effects on WT mice. Intravesical administration of PACAP6-38 (300 nM) significantly ($p \leq 0.01$) reduced pelvic sensitivity in NGF-OE mice but was without effect in WT mice. These studies demonstrate that additional NGF-mediated pleiotropic changes, such as modulation of neuropeptide/receptor systems, contribute to the increased voiding frequency and pelvic sensitivity observed in NGF-OE mice.

Title: Pituitary adenylate cyclase-activating polypeptide (PACAP) expression in lower urinary tract pathways (LUT) with cyclophosphamide (CYP)-induced cystitis in PACAP promoter-dependent EGFP BAC transgenic mice

Authors: *M. A. VIZZARD[1], M. E. MATHEWS[1], S. MALLEY[1], B. M. GIRARD[1], K. M. BRAAS[1], J. A. WASCHEK[2], V. MAY[1];
[1]Neurolog. Sci., Univ. Vermont Col. Med., Burlington, VT; [2]Dept. of Psychiatry and Behavioral Sci., David Geffen Sch. of Med., Los Angeles, CA

Abstract: PACAP and associated receptors exist in rodent lower urinary tract (LUT); the majority derived from sensory neurons. PACAP expression in sensory neurons following nerve injury is changed; however, few studies have examined PACAP expression following inflammation. We have previously demonstrated an upregulation of PACAP expression in rodent micturition pathways following CYP-induced cystitis. We now examined the effects of CYP-induced cystitis (4 h, 48 h, chronic) in PACAP promoter-dependent EGFP BAC transgenic mice. We induced bladder inflammation in adult mice by injecting CYP intraperitoneally to produce acute (150 mg/kg; 4 h), intermediate (150 mg/kg; 48 h), and chronic (75 mg/kg; every third day for 10 days) cystitis. In control (no inflammation) animals, low basal expression of PACAP-EGFP+ fibers was present in the superficial DH at all segmental levels examined (L1, L2, L4-S1). Dorsal root ganglia (DRG; L1, L2, L6, S1) from control animals also exhibited PACAP-EGFP+ cells. After CYP-induced cystitis, PACAP-EGFP+ cells increased dramatically in spinal segments and DRG (L1, L2, L6, and S1) involved in micturition reflexes. Small diameter, PACAP-EGFP+ DRG cells co-localized with TRPV1- and TRPV4-IR. The density of PACAP-EGFP+ nerve fibers was increased in the superficial laminae (I-II) of the L1, L2, L6, and S1 DH. No changes in PACAP-EGFP+ nerve fibers were observed in the L4-L5 segments. PACAP-EGFP+ nerve fibers also increased in the lateral collateral pathway in L6-S1 spinal cord. Following CYP-induced cystitis, PACAP-EGFP+ urothelial cells were observed and the number of PACAP-EGFP+ urothelial cells increased with duration of cystitis. PACAP-EGFP+ urothelial cells were co-localized with TRPV4-IR. Changes in PACAP expression in LUT pathways after cystitis may play a role in altered visceral sensation (allodynia) and/or increased voiding frequency in the chronic inflammatory pain syndrome, interstitial cystitis/bladder pain syndrome.

Title: Cell therapy for neurogenic detrusor overactivity: proof of concept using intramural implantation of adrenal medullary chromaffin cells following chronic suprasacral spinal cord injury

Authors: ***M. O. FRASER**[1], J. M. BROOKS[2], D. J. DEGOSKI[2], P. C. DOLBER[3]; [1]Dept. of Surgery, Duke Univ. and Durham VA Med. Centers, Durham, NC; [2]Inst. for Med. Res., Durham, NC; [3]Univ. of Texas Med. Br., Galveston, TX

Abstract: Objectives: Suprasacral spinal cord injury (SCI) is often occasioned by the development of high pressure non-voiding contractions (NVC). NVC may result in significant morbidities, such as ureteral reflux, incontinence and autonomic dysreflexia. Previous work from our laboratory has demonstrated that β3-adrenergic receptor agonists are effective in reducing NVC number and amplitude in chronic SCI rats. To test whether stimulation of β-adrenergic receptors (BAR) by endogenous catecholamines as a result of cell therapy would similarly inhibit NVC, we transplanted adrenal medullary chromaffin cells (AMCC) into the bladder walls of SCI rats and examined their survival and function. Methods: Recipient female Lewis rats underwent SCI at T9-10 and their bladders were manually expressed 2X daily for 4-6 weeks prior to AMCC or Media bladder wall injections. On the day of bladder wall injections, adrenal medullas were harvested and AMCC isolated from donors. AMCC were injected in 4-6 bladder wall sites for total cell loads of 10.9 ±1.6 x 10^5 cells/bladder (n=10). Media animals (C) received 50 µl of culture medium (n=9). The animals recovered for 1-2 weeks prior to cystometric evaluation. On the day of cystometry, rats received jugular and transvesical catheters. Following 1 hour recovery, saline infusion (0.1 ml/min) into the bladder was initiated. One hour later, the animals received injections of vehicle and, 30 min later, a cocktail of BAR

antagonists (0.5 mg/ml propranolol + 1 mg/ml SR-59230A). Perfusion fixed bladders were harvested and processed for tyrosine hydroxylase (TH) immunofluorescence. Results: Treatment with BAR antagonists resulted in a ~2.5 fold increase in the number of NVC events in AMCC rats ($P<0.0001$; 2-Way ANOVA), while no effect was seen in C. Mean values for the AMCC rats were ~40% lower and higher during the vehicle control and the BAR blockade periods than C, respectively. Finally, numerous TH+ AMCC cells were detected in bladders from AMCC rats. Conclusions: Cell therapy using catecholamine (norepinephrine and epinephrine) producing cells holds promise for the treatment of NVC due to suprasacral SCI. AMCC may be harvested from the patients' own adrenal medullae, or autologous stem/progenitor cells may be converted into catecholamine producing cells for this purpose.

Title: Early-life dysbiosis and its effects on anxiety-like behaviors in the infant rat

Authors: *J. A. BRAVO[1], E. PONCE-GUEQUEN[2], C. BARRERA-BUGEÑO[2], J. ESCOBAR-LUNA[2], M. GOTTELAND[3], M. JULIO-PIEPER[2];
[1]Pontificia Univ. Catolica de Valparaiso, VALPARAISO, Chile; [2]Inst. de Química, Facultad de Ciencias, Pontificia Univ. Católica de Valparaíso, Valparaíso, Chile; [3]Dept. de Nutrición, Facultad de Medicina, Univ. de Chile, Santiago, Chile

Abstract: Intestinal colonization of the neonatal gut begins at the birth canal and continues as the newborn comes in contact with the mother (e.g.: breastfeeding). Therefore, interventions in the maternal gut microbiota, like the use of antibiotics in the perinatal period can modify the infant's microbiota as well. On the other hand, intestinal dysbiosis has been shown to affect human and animal behavior, thus establishing what is now recognized as the microbiota-gut-brain axis. Evidence shows that acquisition of a balanced gut microbiota in early-life is important for the adequate development of behavioral and physiological responses to stress. For instance, germ-free mice have reduced anxiety-like behaviors despite producing an exaggerated release of corticosterone upon a stressful stimuli. In addition, non-absorbable wide-spectrum antibiotics reduce anxiety-like behaviors in adult rodents. Notably, all these observations have been made in adult animals, and very little is known about the effects of gut dysbiosis in the behaviour at

young age. Thus, in order to test this we administered a mixture of non-absorbable wide spectrum antibiotics (neomycin 5 mg/ml, bacitracin 5 mg/ml, pimaricin 1.25microg/ml and vancomycin 0.5 mg/ml) in the drinking water of pregnant Sprague-Dawley dams, starting at three days before parturition and maintained until post-natal day (PND) 7, while control dams were given water alone. On PND 21 pups were weaned and behavioral testing begun on PND 22. Open field test revealed that male, but not female pups whose mother was exposed to antibiotics spent more time in the central area of the apparatus in comparison to control rats. On day 23, elevated plus maze test revealed that both female and male pups from dams exposed to antibiotics spent more time in the open arms (OA) and had an increased number of entries into the OA too, in comparison to control rats. On PND24 rats were subjected to the forced swim test, however there were no differences between treatments. These findings suggest that alterations in the bacteria colonizing the gastrointestinal tract during early-life (PND1-7) affect anxiety-like behaviors in infant rodents, but do not induce depression-like behaviors. These findings strongly support the notion that acquisition of a balanced microbiota is important for the development of adequate stress-related behaviors. Moreover, these changes are observable during infancy suggesting a potential timeframe when interventions can be made in order to prevent the occurrence of psychiatric-related disorders later in life.

Title: *Ex vivo* effects of fluoxetine on the rat intestinal barrier: relevance to disorders of the brain-gut axis

Authors: *M. JULIO-PIEPER, C. GONZALEZ-ARANCIBIA, M. P. GONZALEZ-TORO, J. A. BRAVO;
Instituto De Quimica, Pontificia Universidad Catolica De Valparaiso, Valparaiso, Chile

Abstract: Psychological stress is frequently associated with gastrointestinal (GI) symptoms including dysmotility and increased pain perception. The term “brain-gut axis disorder” has been used to describe a number of pathological situations where comorbidity of both systems has been well established. One classic example is irritable bowel syndrome, highly comorbid with

depression and anxiety. However, it is still unknown whether one condition leads to the other, or if they are both unrelated consequences of a primary event. Interestingly, one GI alteration that may be induced by acute or chronic psychological stress is increased intestinal permeability. In a healthy organism, the gut barrier prevents translocation of noxious luminal substances and microorganisms. Incorporation of luminal contents to the endothelial compartment may lead to local or systemic inflammatory disorders and possibly alterations in enteric nerve function, potentially worsening the patient's condition. During the last few years, antidepressant treatment has been used to provide relief to patients suffering from brain-gut axis disorders, with the main focus in the GI side of these conditions being restoration of normal motility and reduction in abdominal pain. However, little is known about the potential actions of antidepressant drugs on intestinal barrier function. Selective serotonin reuptake inhibitors (SSRIs) have anti-inflammatory effects and can inhibit toll-like receptor activity. Because inflammatory and immune mediators are important modulators of epithelial permeability, we aimed to investigate whether the SSRI fluoxetine is able to improve intestinal barrier function by acting directly on the intestinal tissue. We applied fluoxetine (0, 0.5, 5 or 50 microg/mL) on rat ileal and colonic preparations and examined tissue permeability *ex vivo*. The drug did not affect the permeation of macromolecules (4.4 and 40 kD dextrans) on either tissue along the three-hour experiment. However, the highest dose of fluoxetine significantly reduced transepithelial electrical resistance of both ileum and colon by 1 hour of treatment, indicating an increase of tissue permeability to electrolytes and/or small molecules. Our results show that a short-term *ex vivo* fluoxetine treatment does not strengthen intestinal barrier function; moreover the highest dose (50 microg/mL) induced barrier disruption. Although patients with major depression treated with fluoxetine have lower plasma levels than the doses tested here, the effects of long-term *in vivo* fluoxetine administration on intestinal permeability remain to be investigated.

Title: Serial Cystometry Measurements- a novel method for evaluation of lower urinary tract function in adult female sprague-dawley rats

Authors: F. QURESHI[1], P. KUNG[2], *S. A. SISTO[3], W. F. COLLINS, III[2];
[1]Hlth. and Rehabil. Science, Sch. of Hlth. Technol. and Mgmt., [2]Neurobio. and Behavior, [3]PhD in Hlth. & Rehab Sci., Stony Brook Univ., Stony Brook, NY

Abstract: Lower urinary tract (LUT) dysfunction is a common sequelae to many neurological disorders including spinal cord injury (SCI). The aim of the present study was to develop a method for reliable serial measurements of LUT function, including simultaneous bladder pressure and external urethral sphincter (EUS) activity over 12-16 weeks. Cystometry, combined with EUS EMG recording, was performed weekly on adult female Sprague-Dawley rats (225-250 g, n=8) under Ketamine/Xylazine anesthesia (90/10 mg/kg, i.p.). For each session, a sterile catheter (PE50) was inserted transurethrally into the bladder and connected in series to a pressure transducer to record bladder pressure and to a 60cc syringe attached to a syringe pump. EUS EMG recordings were made by inserting two sterile fine wire electrodes (A-M Systems; 50 μm insulated stainless steel) percutaneously into or near the EUS muscle using a 30 gauge hypodermic needle. Repetitive micturition events were elicited by continuous infusion of saline into the bladder (5-8 ml/hr, room temperature) and recordings of bladder pressure and EUS EMG activity were acquired. Each rat underwent simultaneous measurements of bladder and EUS once a week for three consecutive weeks where threshold bladder pressure (TBP), peak bladder pressure during contraction (PBP), duration of bladder contraction, average EUS peak amplitude, sustained EUS contraction after bursting, area under EUS EMG normalized by average peak (NAEUS), burst duration, and number of bursts per EUS contraction were captured. Reliability testing using intra-class correlation coefficient (ICC) test showed significant PBP (ICC=0.46, p=0.001), TBP (ICC=0.423, p=0.0001) and NAEUS (ICC=0.37,p=0.001) across days and rats. Our results show that this novel method of repeated measurements of LUT over several weeks is reliable producing consistent data for PBP, TBP and NAEUS, especially if detrusor sphincter dysynergia (DSD) is expected. We propose that this method can be used to follow changes in recovery of LUT function after chronic SCI, particularly for quantitative evaluation of DSD.

Title: Urethral sensory neuron activation by flow: electrophysiological quantification and modeling

Authors: *Z. C. DANZIGER, W. M. GRILL;
Biomed. Engin., Duke Univ., Durham, NC

Abstract: It is necessary to understand the neural encoding of sensation in the urethra to diagnose better, clarify etiology, and develop treatments for neuropathy-induced voiding dysfunction. We quantified the response of the sensory branch of the pudendal nerve (which densely innervates the urethra) to urethral pressure and flow. Physiological saline was passed through the urethra of urethane anesthetized Sprague-Dawley rats (without filling the bladder) via a suprapubic catheter to control directly flow through the urethra, which allowed us to expose the urethra to a wide range of flow rates and pressures to characterize the sensory response. We found that the primary stimulus driving urethral afferents was large, positive changes in intraurethral pressure. Constant pressures produced elevated levels of sensory activation, but these responses were of much lower magnitude and of greater variability than responses to changes in the pressure, indicating that pressure derivatives are the critical stimulus for these afferents. Notably, only increases (not decreases) in urethral pressure caused these large afferent responses. We also systematically mapped the time courses of the sensory responses and show, for the first time, that there is a significant long term (minutes) neural accommodation to changes in urethral pressure. The reduction of the pudendal sensory response caused by accommodation is of similar magnitude to the effect of changing the applied flow rate, indicating that this accommodation is of a physiologically relevant magnitude. We hypothesize that the phasic contraction of the external urethral sphincter observed during voiding in some rats may be linked to the fact that urethral afferents are selectively responsive to pressure derivatives because phasic bursting generates large and frequent pressure changes that amplify pudendal sensory activation. We present evidence for this from experiments where the pudendal motor branch, contralateral to the pudendal recording site, was stimulated to elicit controlled urethral sphincter contractions during applied flow, which resulted in pressure oscillations and increases sensory response. Further, experiments using the paralytics phentolamine and propranolol confirm that the neural responses and their accommodation are neurally mediated, rather than the result of an active reflex modulating the intraurethral pressure. Finally, we developed a compact mathematical model that predictively maps measured pressure into pudendal afferent response. This description of sensory signaling in the urethra provides a foundation to understand disruptions that may occur following trauma or disease.

Title: Chronic monitoring of lower urinary tract neurophysiology via sacral dorsal root ganglia

Authors: A. KHURRAM, S. E. ROSS, A. A. A. JIMAN, Z. J. SPERRY, C. M. MAHAR, *T. M. BRUNS;
Univ. of Michigan, Ann Arbor, MI

Abstract: Understanding lower urinary tract (LUT) neurophysiology is important for developing a closed-loop bladder neuroprosthesis in which information about the bladder state can be used to control and improve stimulation. However, literature on long-term recordings of afferent neurophysiology of the LUT is lacking. In contrast to previous studies in which spinal electrodes or nerve cuffs have been individually implanted to monitor and stimulate the LUT in short-term studies, we are developing an integrated approach of chronically recording afferent activity of the LUT at dorsal root ganglia (DRG) in a feline model. Two 32-channel microelectrode arrays were implanted in sacral DRG after a laminectomy for recording afferent activity while a nerve cuff was implanted on the pudendal nerve for stimulation. A dual-lumen supra-pubic bladder catheter was implanted to provide access for controlling bladder volume and monitoring pressure. The array connectors and cuff wires were contained in an external housing that was mounted percutaneously to the iliac crests. Periodic data collection sessions were held after implant surgery while the cat was sedated with dexmedetomidine. Bladder filling and emptying trials were done where the bladder was infused with saline or emptied through the bladder catheter. We have identified and tracked unique bladder sensory neurons across sessions (average firing rate of 2.6 spikes/s, range 1-12 spikes/s; bladder pressure correlation coefficients of 0.6 and higher). We also performed stimulation-driven bladder voiding trials in which the pudendal cuff was stimulated at 5-30 Hz. During these trials, effective bladder emptying (75-85% efficiency; up to 16 mL in 20 s) has occurred in which bladder and urethra flow afferents were identifiable. The urethra flow afferents fired at 3 spikes/s during initial leakage and up to 48 spikes/s during maximal urine flow. Our setup allows us to track LUT neurons over time and examine their characteristics. From these data, we hope to gain a better understanding of the LUT afferent neurophysiology, which can be used as a control signal for driving stimulation in a closed-loop bladder neuroprosthesis.

Title: Assessing gastrointestinal actions of commonly prescribed pharmacologic compounds using the gastrointestinal motility monitor (gimm) *in vitro* assay

Authors: *M. KLINGER, M. M. MCGILL, N. M. WIGHTON, S. R. BRUNO, G. M. HERRERA;
Catamount Res. and Development, Inc., Saint Albans, VT

Abstract: Functional gastrointestinal disorders such as irritable bowel syndrome, colitis, and chronic constipation affect millions of people. In addition to these disorders, many patients report adverse gastrointestinal affects from the use of commonly prescribed medications, including anti-hypertensives, opiate-based pain medications, and anti-depressants. These side effects cause many patients to discontinue treatment. Constipation is a persistent problem in human health, and still requires further investigation. Using the Gastrointestinal Motility Monitor (GIMM) *in vitro* pellet propulsion assay, we measured the effects of four compounds known to affect colonic function and motility in the human. These are the calcium channel blocker verapamil (0.1 - 10 uM), the opioid receptor agonist morphine (0.01 - 1 uM), the selective serotonin reuptake inhibitor fluoxetine (10-40 uM), and the norepinephrine/dopamine reuptake inhibitor bupropion (20-100 uM). Distal colons were isolated from guinea pigs following euthanasia, and were immersed in physiological saline solution (PSS, 37 °C). In each segment of colon, three baseline motility trials were completed by placing a fecal pellet inside the oral end, followed by three trials in the presence of test compounds. Through natural peristaltic motion, the pellet moved through the colon and its velocity was recorded by the GIMM. Colon segments with an average baseline motility below 1 mm/s were excluded from the study. Verapamil (1 μM) significantly increased pellet velocity by 50% as compared with baseline, while verapamil at 10 μM completely abolished motility. Morphine (1 μM) significantly reduced pellet velocity by 30%, and morphine at a concentration of 10 μM reduced motility by 90%. Fluoxetine (20 and 30 μM) reduced pellet propulsion velocity by 50%, and velocity was reduced by 60% with fluoxetine at 40 μM. Bupropion (100 μM) reduced pellet velocity by 90%. In conclusion, the velocity of fecal pellet propulsion in guinea pig distal colon is a useful *in vitro* assay to assess actions of pharmacological compounds on the gut, and this may be useful for drug development.

Title: A functional analysis of the influence of pelvic nerve on the micturition reflex in rats with acetic acid induced cystitis

Authors: *X. SU, J. E. AGRAN, D. E. NELSON;
Medtronic, Minneapolis, MN

Abstract: Bladder hypersensitivity is associated with the over excitation of the pelvic nerve (PN) including both the afferent-ascending pathway, which triggers urgency and the parasympathetic efferent-descending pathway, which induces the detrusor contraction. In this study we did a functional analysis of cystometric parameters with or without PN injury in rats with acetic acid (a.a.) induced cystitis. Male rats were anesthetized (urethane, IP 1.2 g/Kg) and cannulated with a bladder catheter via the bladder dome for 0.3% a.a. infusion (3 ml/hr). The cystometric parameters were compared in 3 groups of cystitis rats that received different levels of PN manipulation, 1) rats that received no PN manipulations (n=7), 2) rats that received partial PN injury using 4-6 gentle longitudinal stretches of the nerve bilaterally with a cotton tipped applicator (n=7), and 3) rats that received complete successive PN transection (unilaterally, followed by bilaterally) using preplaced silk threads (n=11). Intravesical a.a. infusion induced a hypersensitive bladder; the inter-contraction interval (ICI) was 197 ± 41 s (mean ± SEM). Partial PN injury significantly increased ICI to 404 ± 90 s (P=0.03, unpaired t-test), which was observed for up to 3 hrs. The increased ICI (or infused volume) was accompanied by an increase in both void volume and void duration. The maximal pressure was unchanged indicating the void functions were not impacted by partial PN injury. Unilateral PN transection produced total incontinence in 1/11 rat and partial incontinence in 3/11 rats. In addition, unilateral PN transection produced an immediate inhibition on bladder afferent function, increasing the ICI, from 497 ± 59 s to 892 ± 93 s (p=0.002, paired t-test) and threshold pressure, from 28 ± 2 mmHg to 30 ± 2 mmHg (p=0.008, paired t-test). However the efferent voiding function was decreased as reflected by mismatch of the void volume (0.43 ± 0.1 ml) and infused volume (0.74 ± 0.1 ml, p=0.03, paired t-test). Bilateral PN transection abolished voiding in all rats. In the rat cystitis model, the bladder hyperactivity was used to mimic the human condition of detrusor overactivity. This excitatory effect was significantly attenuated by partial PN injury when both PNs were intact. Intact PNs are critical for maintenance of normal voiding functions and an unilateral injury of the PN may significantly affect the micturition function. These results emphasize the important role that PNs play in normal bladder functions and their potential involvement in bladder dysfunction such as overactivity.

Title: "Evaluation of the mechanism involved in the gastro protective effect of DHA (docosahexaenoic acid) in the indomethacin-induced gastric injury model in mice"

Authors: *E. A. PINEDA[1], A. E. CHÁVEZ-PIÑA[2];
[1]Lab. de Farmacología de la Sección de estudios de posgrado e investigacio, Escuela Nacional De Medicina Y Homeopatía Del Inst., México, Mexico; [2]ENMyH, Natl. Polytechnic Inst. (IPN), México, Mexico

Abstract: Introduction. Nonsteroidal anti-inflammatory drugs (NSAIDs) such as indomethacin are widely used as analgesic and anti- inflammatory drugs for treatment of a variety of diseases characterized by inflammatory conditions; however, it has been reported that the use of NSAIDs causes severe adverse effects including erosions, bleeding and perforation with blood and protein loss in the gastrointestinal tract (GI), these side-effects limit their use. Besides the prostaglandin inhibition, gastric tissue damage by indomethacin is generated by others prostaglandin-independent mechanisms including induction of proinflammatory TNF-α expression, ICAM-1 expression, neutrophil infiltration and microvascular injury. Previous studies reported the gastroprotective effect of DHA (docosahexaenoic acid), but the mechanism and molecules involves in this effect have not been fully explained. The aim of this study was to examine the molecules and mechanism implicated in the gastroprotective effect of DHA. **Methods.** Balb/c mice received oral administration of DHA (3, 10, 30 and 100 mg/kg), and 2 h later, gastric damage was induced by a single oral dose of indomethacin (30 mg/kg). Five hours later, mice were anesthetized and euthanized by cardiac puncture. The stomach was removed and fully extended, then a macroscopic analysis of the total gastric lesion area (mm2) for each mouse was performed; a sample of gastric mucosa was taken and the leukocyte infiltration (by measuring Myeloperoxidase, Leukotriene B4 and histology study) and TNF-α levels were assessed. **Results and Discussion.** Our results showed that DHA treatment induces a gastroprotective effect in a dose-dependent manner against indomethacin-induced gastric injury. DHA pre-treatment

exhibits the ability to reduce the leukocyte infiltration in gastric tissue through the modulation of myeloperoxidase (MPO), LTB4 and the decreasing of TNF-α molecule. Our results suggest that DHA modulates the molecules involved in neutrophil infiltration induced by indomethacin administration and some pro-inflammatory molecules. In conclusion, DHA pre-treatment showed a gastroprotective effect against indomethacin-induced gastric injury effect through the modulation of leukocyte infiltration and others molecules implicated in inflammation process, therefore it may be a therapeutic resource to limit NSAIDS side-effects in gastrointestinal tract.

Title: Anti-inflammatory effects of acupuncture stimulation via the vagus nerve

Authors: *H. LIM[1], I. CHANG[2], J. LEE[2], K. KIM[2], C.-Y. LEE[3], U. NAMGUNG[2];
[2]Oriental Med., [3]Microbiology and Biotech., [1]Daejeon Univ., Daejeon, Korea, Republic of

Abstract: Although acupuncture therapy is widely used in traditional Asian medicine for the treatment of diverse internal organ disorders, its underlying biological mechanisms are largely unknown. Here, we investigated the functional involvement of acupuncture stimulation (AS) in the regulation of inflammatory responses. TNF-α production in mouse serum, which was induced by lipopolysaccharide (LPS) administration, was decreased by AS at the zusanli acupoint (stomach36, ST36). In the spleen, TNF-α mRNA and protein levels were also downregulated by AS and were recovered by using a splenic neurectomy. c-Fos, which was induced in neurons in the nucleus tractus solitarius (NTS) and dorsal motor nucleus of the vagus nerve (DMV) by LPS and acupuncture given manually and electrically, was further increased by focal administration of the AMPA receptor blocker CNQX and the purinergic receptor antagonist PPADS in the area of the dorsal vagal complex (DVC). TNF-α levels in the spleen were decreased by CNQX and PPADS treatments, implying the involvement of inhibitory neuronal

activity in the DVC. AS in unanesthetized animals generated similar patterns of c-Fos induction in the DVC neurons and of splenic TNF-α production. Thus, our data suggest that the therapeutic effects of acupuncture may be mediated through vagal modulation of inflammatory responses in internal organs.

Title: Quantification of hysteresis in bladder afferent neurons in response to changes in bladder pressure

Authors: ***S. E. ROSS**[1], Z. J. SPERRY[1], C. M. MAHAR[2], T. M. BRUNS[1];
[1]Biomed. Engin., [2]Nuclear Engin. and Radiological Sci., Univ. of Michigan, Ann Arbor, MI

Abstract: For patients with bladder dysfunction refractory to standard treatments, electrical stimulation of lower urinary tract nerves may be an alternative approach for controlling bladder function. A closed-loop system that provides feedback on the bladder state and delivers stimulation when needed may be advantageous over currently available devices. We are evaluating an interface with sacral dorsal root ganglia (DRG), at which we can monitor bladder afferent signals from the pelvic nerve and stimulate pudendal nerve pathways that drive bladder control spinal circuits. A key challenge is developing a robust model to estimate bladder pressure from the firing rate activity of bladder afferent neurons. Though linear regression can give estimates of the bladder pressure from bladder afferent firing rates, these linear models often yield lower quality fits during subsequent time periods. A major factor in this model inadequacy is that the firing rate of a bladder afferent neuron is typically different during the rising and falling phases of a bladder contraction. Previous studies have noted this firing rate-pressure hysteresis, but it has not been quantified (as far as we know). Our goal here is to examine bladder afferent neuron hysteresis, towards developing a model that takes into account this dynamic relationship. Bladder afferent activity was recorded with microelectrode arrays inserted into the first and second sacral DRG of intact male cats. In four acute experiments, 59 bladder afferents were identified based on their characteristic responses to pressure (correlation coefficient > 0.20) during infusion under alpha-chloralose anesthesia. We calculated maximum (Hmax) and mean (Hmean) hysteresis values for each afferent as the maximum and mean ratio between the firing

rate difference at each pressure (in 5 cmH2O bins) and the overall firing rate range. The hysteresis value range of 0 - 1 represents zero to maximal hysteresis. Across afferents we observed a mean Hmax of 0.78 ± 0.24 (mean ± standard deviation), with 28 neurons greater than 0.80, and a Hmean of 0.37 ± 0.31. These results indicate that correlated bladder afferents show moderate to high hysteresis. Advanced state models, such as neural networks, that can incorporate this non-linear relationship may lead to consistent estimates of bladder pressure.

Title: Developmental analysis of MET-EGFP transgene cell phenotypes and projection targets in the brainstem Vagal Motor Complex

Authors: *A. K. KAMITAKAHARA, H.-H. WU, P. LEVITT;
Children's Hosp. Los Angeles, Los Angeles, CA

Abstract: Recent meta-analysis data suggests that children with Autism Spectrum Disorder (ASD) are more than four times as likely to have comorbid gastrointestinal dysfunction (GID). One genetic point of convergence for both ASD and GID is a common promoter variant in the human *MET* receptor tyrosine kinase (*MET*) gene, which reduces MET expression, and is highly enriched in families of children with both ASD and co-occurring gastrointestinal symptoms. MET signaling has been demonstrated to be critically important for mouse neocortical and hippocampal dendritic elaboration and synaptogenesis; however it is unknown whether MET is also required for the development of autonomic brainstem circuits that modulate gastrointestinal function. To this end, we are characterizing the expression of MET in developing vagal visceromotor neurons in the dorsal motor nucleus of the vagus (DMV) and nucleus ambiguus (nA) in Met^{EGFP} mice using immunohistochemistry for both EGFP and MET protein. MET is highly expressed by a subset of neurons in the lateral DMV and the vast majority of nA neurons beginning around E11.5, shortly after these neurons are generated. Vagal MET^{EGFP} expression is sustained into the first two postnatal weeks, after which it is expressed only at moderate levels. All MET^{EGFP} neurons of the DMV and nA are cholinergic by analysis of choline-acetyltransferase (ChAT) co-expression. In addition, MET^{EGFP} neurons in the DMV are immunoreactive for the neuropeptide, cocaine- and amphetamine related transcript (CART). *In situ* hybridization further revealed that the MET ligand, hepatocyte growth factor (HGF), is

expressed prenatally in both the esophagus and intestinal submucosa, suggesting that target-derived HGF may impact the innervation of these regions of the gastrointestinal tract by MET-expressing neurons from the brainstem. Experiments are currently underway using whole mount immunostaining in conjunction with tissue clearing to determine the innervation patterns of MET-expressing neuronal projections to the gastrointestinal tract. Additionally, RNA sequencing of sorted vagal MET^{EGFP} expressing neurons will identify novel gene targets involved in the development of the circuits controlling gastrointestinal function.

Title: "Fast and slow": bowel dysfunction in spinal cord injured animals

Authors: *B. FRIAS[1], S. GOLBIDI[2], I. LAHER[2], A. KRASSIOUKOV[1];
[1]ICORD, Vancouver, BC, Canada; [2]Dept. of Anaesthesiology, Pharmacol. and Therapeut., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Introduction: Bowel dysfunction is among a broad range of autonomic abnormalities following spinal cord injury (SCI). SCI-patients experience symptoms, such as constipation, fecal incontinence and pain, which have a profound impact on their quality of life. These symptoms vary based on the type and level of SCI. Autonomic dysreflexia (AD), a life-threatning condition characterized by sudden increases in blood pressure and bradycardia, often occurs in patients with injuries above T6 level. AD can be triggered by non-noxious and noxious stimuli, such colon or bladder distention. Therefore, this study aimed to unravel the contribution of cardiovascular system impairment for bowel dysfunction. For that, an animal model of colorectal distention (CRD) will be used for induction of clinically relevant AD-symptoms. Methods: Male Wistar rats were assigned to groups (n=6/group): Sham, T3-SCI, T3-SCI+CRD, T10-SCI and T10-SCI+CRD. The assessment of induced-AD was performed by implanting a telemetry device in the carotid artery followed by CRD. For evaluation of colonic motility, the total number of fecal pellets and total gastrointestinal transit time (TGTT) were assessed at baseline and weekly after SCI for 4weeks. Animals were then sacrificed and 1cm of the proximal and distal colon was collected for wire-myography. Results: Chronic T10-SCI+CRD animals did not develop AD, in contrast to T3-SCI+CRD. The number of fecal pellets was decreased post-SCI ($p<0.05$ vs. Sham) but remained unchaged with CRD. TGTT was increased in following SCI

($p<0.05$ vs. Sham) and CRD caused early increase of TGTT at 1week ($p<0.05$ vs. T3-SCI/T10-SCI).At 4wks post-SCI, decreased contractility was registered in distal colon of T3-SCI ($p<0.0001$ vs. Sham/T10-SCI) and T10-SCI animals ($p<0.0107$ vs. Sham). CRD caused different effects in contractility depending on level of injury. In the proximal colon, contraction was decreased after SCI. T10-SCI+CRD animals presented decreased contraction. Conclusion: The data demonstrates that the level of SCI plus autonomic stress of CRD can contribute to the severity and early onset of bowel dysfunction.

Title: Characterization of cholinergic neurotransmission of bladder-innervating postganglionic neurons in mouse major pelvic ganglia through molecular, pharmacological and physiological measures

Authors: *C. KYI[1], D. J. SCHULZ[2];
[1]Biol. Sci., Univ. of Missouri-Columbia, Columbia, MO; [2]Biol. Sci., Univ. of Missouri, Columbia, MO

Abstract: Major pelvic ganglia (MPG) of mouse contain postganglionic neurons innervating pelvic organs such as urinary bladder, colon and the genitals. Pelvic ganglia receive cholinergic parasympathetic inputs from the preganglionic neurons in the sacral cord through pelvic nerve, and sympathetic cholinergic inputs from those in the lumbosacral cord through hypogastric nerve via inferior mesenteric ganglion. The storage function of micturition is mostly under tonic inhibitory control of sympathetic nervous system and voiding function is mostly under the control of parasympathetic nervous system. The axons from the pelvic ganglion synapse onto postganglionic neurons on the bladder detrusor, releasing acetylcholine from parasympathetic axons and noradrenaline from sympathetic axons. Data from our previous study showed pairwise correlated decrease in mRNA expressions among α3&β2 as well as α3 &β4 cholinergic receptor subunits throughout postnatal development suggesting changes cholinergic transmission in the postganglionic MPG neurons. We characterized the cholinergic ganglionic transmission at bladder-innervating MPG neurons in normal adult mice. We retrograde-labelled populations of bladder-innervating neurons in the MPG. Then, we performed absolute quantitation of multiple

receptor transcript copy number for each sample, and employed multiple correlation analyses to detect patterns in mRNA levels across all genes of interest. With these data, we sought to determine whether there are underlying relationships among cholinergic receptor mRNA levels in the bladder-innervating neurons at the MPG. We also performed pelvic nerve stimulations and recorded EPSPs from the neuronal cell bodies using intracellular sharp electrodes and characterized the Ach-activated currents using agonists and subunit-specific receptor antagonists. These data will subsequently provide a baseline of comparison to examine changes cholinergic transmission in injury models such as spinal cord injury.

Title: Characterization of neuroendocrine cell subpopulations in the digestive tract of the echinoderm Holothuria glaberrima

Authors: *M. A. LEFEBRE[1], J. E. GARCIA-ARRARAS[2];
[1]Inter American Univ. of Puerto Rico - Bayamon, Corozal, PR; [2]Dept. of Natural Sci., Univ. of Puerto Rico - Rio Piedras Campus, Rio Piedras, Puerto Rico

Abstract: Echinodermata is a phylum of marine animals that lie at the basal branch of the deuterostome evolutionary branch. Their nervous system has a radial symmetry that includes five radial nerve cords that join anteriorly in a nerve ring. Recent work by our laboratory and others has explored the different echinoderm nervous components. Here we evidence the neurosecretory component of their digestive system. Immunohistological techniques, were used to identify the neuroendocrine cells of Holothuria glaberrima in four digestive tract regions: the esophagus, descending small intestine, ascending small intestine, and the large intestine. Antibodies that recognize the STARD10 protein, Calbindin, the neuropeptide GFSKLYFamide, GABA and the transcription factor Nurr1 were used to observe, describe and quantify the neuroendocrine cells. Our results show that there are at least two different subpopulations of neuroendocrine type cells associated with the luminal tissue and one more neuron-like subpopulation in the connective tissue of the gastrointestinal tract of H. glaberrima. The

neuroendocrine cells found in the luminal epithelium, were labeled with anti-Calbindin and anti-GFSKLYFamide. The calbindin expressing population accounted for about 4% of the luminal cells while those expressing the neuropeptide accounted for 25 of the luminal cells. These cells also differed in other properties. The cells labeled with anti-GFSKLYFamide extended fibers into the connective tissue, while those labeled with anti-calbindin had limited accounted for about 2.5% of the luminal cells and had projections that were contained within the luminal epithelium. Moreover, the cells also differed in the localization of their nuclei; the nuclei of anti-Calbindin labeled cells were found to be closer to the apical end of the cells while those of anti-GFSKLYFamide labeled cells were closer to the basal end. The results obtained through these studies will provide important information on echinoderm anatomy, nervous system connectivity and evolution, and for future studies of cellular differentiation during intestinal regeneration.

Title: Spinal transection alters dependence of void size on intra-burst EMG timing during spontaneous voiding in unanesthetized freely-moving rats

Authors: *J. S. CARP[1,2], B. K. LAPALLO[1], X. CHEN[1,2], J. R. WOLPAW[1,2,3];
[1]Lab. Neural Injury and Repair, Wadsworth Ctr, NY State Dept Hlth., Albany, NY; [2]Natl. Ctr. for Adaptive Neurotechnologies, Albany, NY; [3]Dept. Neurol., Stratton VA Med. Ctr., Albany, NY

Abstract: During voiding in rats, the external urethral sphincter (EUS) exhibits “bursting,” a phasic pattern of short periods of activity alternating with periods of inactivity (silent periods (SPs)). Urine flow during bursting is thought to occur during the SPs. In anesthetized rats, spinal cord transection (TX) decreases SP duration and voiding efficiency. The contribution of the SP to spontaneous voiding in unanesthetized rats is unknown. In the present study, we recorded EUS

electromyographic activity (EMG) and urine output in unanesthetized rats to assess the contribution of SP duration to void size during spontaneous micturition in freely-moving rats before and after TX. Female Sprague-Dawley rats (n=22) were implanted with fine stainless steel wires running subcutaneously from a skull-mounted pedestal to the dorsal surface of the pubic bone, where the free wire ends were secured by sutures adjacent to the ventral aspect of the EUS muscle. Rats were housed in metabolic cages for 24-hr epochs while EUS EMG (conducted by a flexible tether to a commutator) and voided urine weight (measured by force transducer) were recorded. After 2-8 weeks of recordings (Intact), 14 rats received mid-thoracic TX (MidT-TX; T8-T9; n=7) or thoraco-lumbar TX (TL-TX; T12-L2; n=7) and recordings were repeated over 4 weeks. Bursting was variably expressed in Intact rats, such that SPs could only be quantified in 17 of 22 animals. Bursting was strongly and consistently expressed after TX; SPs were quantified in all 14 TX rats. SP decreased after TX (mean SP±SE= 121±10 ms, 60±9 ms, and 68±10 ms for Intact, TL-TX, and MidT-TX rats, respectively). In Intact rats, void size was positively correlated with SP on a void-by-void basis. After TX at either level there was no correlation between void size and SP. Void size was significantly larger in TX rats than in Intact rats when SP was restricted to a matched narrow range of short SP values. No differences were found in SP between the two TX levels. Total bursting time was significantly longer in TX rats than in Intact rats; a significant positive correlation was found between void size and cumulative SP in Intact, MidT-TX, and TL-TX rats. The bursting efficacy (void size/duration of bursting) decreased after TX at either level. These results suggest that during spontaneous voiding in rats with intact neuraxes, intermittent EUS relaxation during bursting facilitates urine production. After spinal TX, bursting is still important for voiding, but the contribution of the SP is reduced due to a TX-induced decrease in the intrinsic ability of bursting to void urine.

Title: Pudendal nerve stimulation restores bladder capacity in rat prostaglandin E2 overactive bladder model

Authors: ***J. A. HOKANSON**[1], C. LANGDALE[2], A. SRIDHAR[3], W. GRILL[2];
[1]Bioengineering, Duke University, Dept Biomed. Engin., Durham, NC; [2]Biomed. Engin., Duke Univ., Durham, NC; [3]GlaxoSmithKline, Stevenage, United Kingdom

Abstract: Overactive bladder (OAB), resulting in urgency, frequency, and incontinence, is a highly prevalent condition that leads to medical complications and decreased quality of life. Treatments for OAB include behavioral therapy, exercise therapy, pharmacotherapy, and electrical stimulation. Behavioral and exercise therapy have limited efficacy, and pharmacotherapy has dose-limiting side effects. The Medtronic Interstim device targets the S3 sacral spinal nerve, but is considered relatively non-selective. Electrical stimulation of peripheral nerves may provide greater selectivity thereby increasing efficacy and reducing side effects. We hypothesized that electrical stimulation of the "sensory" branch of the pudendal (SBPudN) nerve would restore bladder capacity (BC) and voiding efficiency (VE) in the rat prostaglandin E2 (PGE2) model of OAB. The aims of this study were to quantify functional changes (BC and VE) after intravesical installation of PGE2 and to measure the effects of SBPudN stimulation on BC and VE. Acute experiments were conducted in urethane (1.2 g/kg, SC) anesthetized female Wistar rats using *in vivo* cystometry (CMG). A PE-90 catheter was placed to measure bladder pressure and for intravesical infusion of saline and PGE2 (100 μM). Bipolar electrodes were placed on the external urethral sphincter (EUS) to measure electromyographic (EMG) activity and a bipolar nerve cuff was placed on the SBPudN for stimulation. In a subset of trials after PGE2 infusion, continuous SBPudN stimulation was delivered at different amplitudes (0.5 - 10x EUS reflex threshold) and frequencies (1, 10, 20, and 30 Hz). With rats prone with their abdomens lying on a heating pad, PGE2 administration quickly (within 50 minutes, on average) disrupted coordinated contraction of the bladder, decreased BC (53% of original, on average), and led to overflow incontinence. With rats in a supine position (abdomen closed), with a heating pad on their backs, PGE2 infusion decreased BC (62% of original) and increased VE (210% of original), but did not disrupt coordinated bladder contraction or cause overflow incontinence. Additional testing in the prone position with a heating pad on their backs confirmed that the overflow incontinence was likely due to increased heat delivered to the abdomen and/or catheter during PGE2 administration. In both prone and supine positons, SBPudN stimulation returned BC to control levels (105% of original). Stimulation decreased VE relative to the PGE2 condition (65% relative to PGE2), but still was higher than in the control case (138% of original). These findings suggest that SBPudN stimulation is a promising approach for treatment of OAB.

Title: Mechanism(s) of transforming growth factor-beta (TGF-β) mediated bladder afferent nerve hyperexcitability

Authors: *E. J. GONZALEZ, M. A. VIZZARD;
Neurolog. Sci., Univ. of Vermont, Burlington, VT

Abstract: The neural circuitry underlying the micturition reflex is often compromised following neural diseases, injuries and inflammatory conditions. We have previously demonstrated that TGF-β1 contributes to afferent nerve hyperexcitability in an experimental cystitis model of Bladder Pain Syndrome (BPS)/Interstitial Cystitis (IC). We hypothesize that afferent hyperexcitability may result from urothelial cells secreting neuroactive molecules, including adenosine triphosphate (ATP), that signal to the suburothelial nervous network. We used whole bladder preparations (n=4-8) isolated from C57BL6 mice (3-6 month old, male) to determine the role of TGF-β1 in urothelial mucosal ATP release. Intravesical instillation of recombinant TGF-β1 (10 ng/ml) significantly ($p \leq 0.01$) increased mucosal ATP release. The release of ATP was attenuated with the co-administration of a TβR-1 inhibitor, SB505124 (5 μM), suggesting the response was specific to TGF-β1 instillation. TGF-β-mediated ATP release was also reduced by either carbenoxolone (100 μM) or brefeldin A (10 μM) suggesting TGF-β1 stimulates ATP release via hemichannel and vesicular mechanisms. Taken together, these results demonstrate a role for TGF-β in urothelial signaling that may contribute to afferent nerve hyperexcitability and underlie peripheral and central sensitization. Targeting TGF-β within the sensory components of the micturition reflex may be a therapeutic approach to improve bladder function.

Title: Differences in the mechanisms of extinction and medial prefrontal cortex plasticity in the adult and post-weanling animals

Authors: *M. MAROUN[1], R. SCHAYEK[2];
[2]Sagol Dept. of Neurobio., [1]Univ. of Haifa, Haifa, Israel

Abstract: The neural circuit linking the medial prefrontal cortex (mPFC) and the basolateral amygdala (BLA) is a part of the limbic system known to mediate emotional learning, and it has crucial roles in both the acquisition and the extinction of fear conditioning. Exposure to behavioral stress is a major factor known to impair extinction, enhance fear responses and to severely affect memory processes. Exposure to behavioral stress is widely assumed as a major factor to enhance the development of anxiety disorders.We recently addressed the effects of exposure to stress in a form of exposure of 30 minutes to the elevated platform, on extinction and plasticity in the mPFC in the post-weanling pup. (Schayek and Maroun, Biological Psychiatry, 2014. Surprisingly, our results show that exposure to stress is associated with enhanced ability to extinguish fear responses in the post-weanling pup. Similarly, stress was associated with enhanced LTP in the mPFC. When recording in the BLA, stress results in enhanced LTP in the adult animal without leading to any potentiation in the post-weanling pup.Furthermore, we also show that systemic injections of the D1 receptors agonist, SKF38393 enhanced BLA-LTP in the post-weanling animal without affecting the induction of LTP in the adult animal. These results show that stress deferentially modulates extinction and plasticity in the post-weanling pup as compared to the adult animal and point that the mechanisms of extinction and stress-induced changes in extinction and plasticity are not similar across development.

Title: Autobiographical memory functioning in maltreated children and the theory of Latent Vulnerability

Authors: *V. PUETZ[1], E. VIDING[1], A. PALMER[1], P. KELLY[1], E. A. MAGUIRE[2], A. MECHELLI[3], E. MCCRORY[1];
[1]Dept. of Psychology and Language Sci., Univ. Col. London, London, United Kingdom; [2]Inst. of Neurol., Wellcome Trust Ctr. for Neuroimaging, Univ. Col. London, London, United Kingdom; [3]Dept. of Psychosis Studies, Inst. of Psychiatry, Psychology & Neuroscience, King's Col. London, London, United Kingdom

Abstract: Objective: Childhood maltreatment has been associated with alterations in autobiographical memory (ABM) functioning. A pattern of over-general ABM has also been associated with child psychopathology, and may represent a cognitive risk factor for psychiatric

disorder. The current study aimed to investigate the neural systems supporting ABM in children exposed to maltreatment and matched controls. Methods: 34 children with a documented history of maltreatment (age=12.53±1.6; n=17 boys) and 33 control children (age=12.66±1.3; n=15 boys) matched on age, gender, IQ, SES, ethnicity and pubertal status were recruited. Participants underwent fMRI, recalling ABMs in response to positively and negatively emotionally valenced cue words. Whole-brain and a-priori ROI analyses were conducted to investigate differential neural activation between the groups (Monte-Carlo-corrected at p .05). All participants and their caregivers gave written informed assent and consent respectively. Results: Greater valence-dependent neural differences in the control group to positive relative to negative stimuli were observed in the bilateral hippocampus, comparable to previous findings reported for adults. Between-group comparisons indicated significantly heightened neural activation in the right hippocampus in children exposed to maltreatment relative to controls, during ABM recall to negative versus positive cues. Post-task debriefing indicated that memories were comparable in terms of difficulty to recall, vividness and remoteness (all $p>0.1$). Conclusions: In line with previous research in adults, control children showed robust activations in memory and arousal related brain areas in response to positive autobiographical memory recall. The significantly heightened activity in the right hippocampus during negative recall may indicate greater salience of negative personal memories in children exposed to maltreatment, a pattern consistent with a cognitive strategy of functional avoidance. According to the theory of Latent Vulnerability (McCrory & Viding, in press), childhood maltreatment calibrates and sensitizes a number of neurocognitive systems in line with early at-risk environments, with potentially adaptive benefits in the short term but with longer-term costs. It is suggested that ABM functioning may represent a neurocognitive system that is altered as a consequence of maltreatment exposure, embedding latent vulnerability to future stressors, thereby increasing risk of later psychiatric disorder.

Title: Implications of maternal stress during pregnancy for neonatal amygdala connectivity and development of fear

Authors: *A. GRAHAM[1], D. A. FAIR[1], J. RASMUSSEN[2], M. RUDOLPH[1], J. H. GILMORE[3], M. A. STYNER[3], S. ENTRINGER[4,2], P. WADHWA[2], C. BUSS[4,2];

[1]Oregon Hlth. & Sci. Univ., Portland, OR; [2]Univ. of California, Irvine, Irvine, CA; [3]UNC, Chapel Hill, NC; [4]Charité Univ. of Med., Berlin, Germany

Abstract: Human infants exhibit multiple fear-related behaviors beginning in the first year of life. Animal models indicate that prenatal stress shapes development of fear via effects on underlying amygdala circuitry. However, the influence of prenatal stress on brain systems involved in the emergence of fear in humans remains poorly understood. Moreover, despite the understanding that emotion and cognition are inextricably linked at the level of brain and behavior, development of fear during infancy is not often considered in the context of cognitive development. This is important because the implications of early fearfulness for long-term outcomes likely depend on cognitive development. Data from an ongoing prospective longitudinal study of maternal-fetal/infant dyads (N=36 infants;15 females) were analyzed. Ambulatory momentary assessments of maternal stress were conducted in each trimester of pregnancy over 4 days. Resting state functional connectivity of the amygdala was examined in neonates (M=25.8 days, SD=12.9). Infant fear (Infant Behavior Questionnaire) and cognitive development (Bayley Scales of Infant Development) were assessed at 6-months-of-age (M=196 days, SD=13.5). Stronger, positive amygdala connectivity to anterior insula, ventral striatum (VS), parahippocampal gyrus, premotor cortex and temporoparietal junction predicted higher fear. Stronger amygdala connectivity to anterior medial prefrontal cortex (aMPFC) predicted a specific phenotype of higher fear and advanced cognitive development. This highlights the importance of considering fear in the context of cognition, and may shed light on a pattern of early amygdala connectivity that facilitates advanced emotional development balanced by parallel cognitive development. We then examined maternal stress during pregnancy as a predictor of these connectivity patterns. An increase in stress from early to late pregnancy (adjusting for stress in early pregnancy) predicted weaker amygdala-VS (β=-.522, p=.000) and amygdala-aMPFC (β=-.546, p=.000) connectivity in neonates. These findings suggest that maternal stress during pregnancy is associated with “slowed” development of these emotion-cognition circuits. Amygdala functional connections evident by the time of birth predict the early emergence of specific fear-cognition phenotypes. These functional connections are in turn influenced by levels of maternal stress during pregnancy. The findings highlight that high fear is not always associated with reduced cognitive skills, particularly in this early developmental period. The neural underpinnings of fear should be considered in the context of cognitive domains.

Title: Early life stress is associated with decreased reward-related activity and intrinsic functional connectivity of the ventral striatum as well as symptoms of depression in adulthood

Authors: *J. L. HANSON[1,3], A. KNODT[1], K. A. DODGE[1,2], A. R. HARIRI[1];
[1]Psychology & Neurosci., [2]Publ. Policy, Duke Univ., Durham, NC; [3]Ctr. for Developmental Sci., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC

Abstract: Studies of neural mechanisms through which early life stress (ELS) is associated with later psychopathology including depression have focused on dysfunction of a corticolimbic circuit supporting threat processing and stress responsiveness. However, emerging research further implicates dysfunction of a corticostriatal circuit supporting motivation and reward learning in stress-related psychopathology including depression. Here, we present results from two complementary studies examining associations between ELS, reward-related corticostriatal circuit function, and symptoms of depression. First, using a simple card-guessing task and fMRI, we examined reward-related activity of the ventral striatum (VS) in relation to ELS in a cohort of adults followed continuously since kindergarten (n=72). We found that greater levels of ELS during childhood and adolescence were related to lower reward-related VS activity in adulthood (Right VS, β=-0.248, p=0.03). Extending these results, we then examined the relation between ELS and intrinsic connectivity of the VS derived from resting-state fMRI in a large independent cohort of adults (n=598). We found that higher ELS was related to increased negative connectivity between the right VS and ventromedial prefrontal cortex (β=-0.202, p<.005). Moreover, individual differences in this intrinsic connectivity were associated with self-reported symptoms of depression (β=-0.13, p<.005). These converging patterns suggest that altered corticostriatal circuit activity and intrinsic connectivity represent mechanisms through which ELS can affect the later emergence of psychopathology.

Title: Development of dopamine functional pathways during infancy: normal trajectory and disruptions due to genetic and environmental risks

Authors: A. SALZWEDEL, W. LIN, K. GREWEN, J. GILMORE, *W. GAO;
Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: Dopamine (DA) is expressed prior to synaptogenesis and DA-mediated signaling plays a fundamental neurodevelopmental role in the brain's initial functional circuit formation. Therefore, delineation of the normal developmental time-line of the DA systems during early infancy_when the brain is dynamically developing, plastic, and susceptible to disruptions induced by either genetic or environmental risk factors_is crucial for both improved scientific understanding and better clinical intervention. In this study, the developmental time-lines of two fundamental DA pathways originated from the ventral tegmental area (VTA) and substantia nigra (SN) were delineated during infancy. A large sample of healthy infants underwent resting-state connectivity fMRI; 234 (118 Females) neonates, 150 (71 F) one-year olds, and 116 (56 F) two-year olds. Seed-regions were based on an a priori parcellation of the VTA and SN warped into infant space. Genetic and environmental influences on DA-pathway connectivity were characterized in infants at high risk of developing schizophrenia (i.e., mothers diagnosed with schizophrenia; 14 (8 F) neonate, 15 (8 F) one year olds, 16 (7 F) two-year olds) and in neonates with prenatal drug exposure (68 (33 F) healthy controls, 32 (16 F) with poly-drug exposure [NCOC, i.e., nicotine, alcohol, marijuana, etc] and 42 (22 F) with poly-drug exposure + Cocaine [PCE]). In the normative sample, our results indicated that functional circuits anchored by the VTA and SN are already differentiated at birth with the VTA circuit extending into ventromedial striatum and SN connectivity projecting to dorsal striatum and motor-related central parietal regions. With development, the SN connectivity remains largely constant but the VTA circuit shows extension into medial prefrontal areas in both 1- and 2-year olds. Compared with normal controls, infants at high risk for schizophrenia (HR) show significantly more decline of SN-motor connectivity and more enhancement of VTA-cortical-area connectivity with age. Finally, neonates with prenatal drug exposures (both NCOC and PCE) show region-specific disruption profiles (4 significant clusters detected) within both the VTA and SN circuits. Our results indicate that the SN-centered DA pathway mature earlier than the VTA however the VTA circuit shows more substantial postnatal development in normal infants. Importantly, this normal developmental process is disrupted by both genetic risks for schizophrenia and environmental risks from prenatal drug exposure as early as in the neonatal period. These results call for more attention and potentially early intervention to these at-risk infants.

Title: Effects of early life stress on amygdala, prefrontal cortex, and raphe GABA levels and its relatation to depressive-like behavior

Authors: ***S. L. ANDERSEN**[1], J. L. LUKKES[1], S. MEDA[2], B. THOMPSON[2], N. FREUND[3]; [1]Dept Psychiatry, McLean Hosp, Belmont, MA; [2]McLean Hosp., Belmont, MA; [3]Univ. of Tubingen, Tubingen, Germany

Abstract: Clinical and preclinical studies show that early life stress (ELS) is associated with greater affective dysfunction. In depression-vulnerable subjects with a history of ELS, imaging studies reveal that the ventral medial prefrontal cortex (vmPFC) can only transiently inhibit amygdala activation to repeated stress and then amygdala activity is elevated; depression-resilient individuals show greater vmPFC activity and less amygdala activity in response to stress. Increased amygdala responses to an acute stress in ELS may be due to low GABA inhibition or decreased regulation by the mPFC, or both. Here, we wanted to determine the relationships between ELS, GABA (e.g., parvalbumin cells; PVB), and depressive behavior, and whether behavior and PVB changes are preventable with the anti-inflammatory agent, COX-2. Separation of rat pups from the mother leads to a cascade of maladaptive behaviors, including depressive-like behavior. Sprague-Dawley female rats were exposed to ELS between 2 and 20 days of age or raised under typical animal facility rearing conditions (AFR). Subjects were tested for helplessness during adolescence. The effects of an acute stressor of witnessing their peers in distress for ~2 hours the day before testing were also determined. Latency to escape footshock and escape failures were higher in ELS than AFR subjects, as we have shown previously. The second stressor elevated latency to escape in AFR controls, but reduced latency in ELS subjects. These data suggest that ELS subjects may be better able to cope with an acute stressor than AFR subjects, but overall, their functioning is worse than AFR subjects. COX-2 inhibition prevented depressive effects in ELS subjects. Regional brain dissections coupled with Western immuoblot for PVB protein allowed us to specifically relate mPFC PVB changes to depressive-like behavior. The basolateral amygdala (BLA) and the dorsal raphe nucleus are involved in

regulating emotion and depression. PVB decreased in the mPFC and the dorsal raphe nucleus, but not the BLA in ELS relative to AFR subjects. Exposure to an acute stressor before testing, however, reduced PVB levels in the BLA and increased PFC levels to AFR control levels. In addition, we show for the first time that PFC levels of PVB inversely correlate with the latency to escape a footshock. These data suggest that elevated reactivity of the amygdala in individuals with a history of ELS may be partially mediated by reduced GABAergic inhibition that leads to increased activity when provoked. Finally, an acute stressor in ELS rats is also able to increase PVB levels, which may further explain a dampening down of mPFC function in these individuals.

Title: Impact of preterm birth on structural and functional connectivity in neonates

Authors: *C. ROGERS[1], C. HERZMANN[1], T. SMYSER[1], J. SHIMONY[1], J. ACKERMAN, Jr.[1], J. NEIL[2], C. SMYSER[1];
[1]Washington Univ. Sch. of Med., Saint Louis, MO; [2]Boston Children's Hosp., Boston, MA

Abstract: Premature birth is a deleterious early life stressor associated with altered cerebral gray matter and white matter development. It is also associated with developmental deficits and increased rates of psychopathology including ADHD, Autism Spectrum Disorder and anxiety disorders. There is increasing evidence these developmental deficits may be subsequent to altered cerebral development, particularly in those children born at the earliest gestational ages. However, few studies have applied multimodal imaging techniques to concomitantly assess structural and functional connectivity in this population. This study compared structural and functional connectivity in very preterm infants (VPT; gestational age<30 weeks; N=76) without

significant brain injury to that of healthy, full term infants (FT; gestational age≥37 weeks; N=58). All infants underwent MRI at term-equivalent age (36-42 weeks postmenstrual age), including acquisition of diffusion tensor imaging (DTI) and resting state fMRI (rs-fMRI) sequences. DTI data was analyzed using tract based spatial statistics (TBSS), assessing group differences in fractional anisotropy (FA). rs-fMRI data was analyzed to determine measures of correlation and covariance within and between seven canonical resting state networks (RSNs). TBSS results demonstrated widespread reductions in white matter tract FA in VPT versus FT infants (Figure 1A). VPT infants also demonstrated reduced correlation and covariance within and between all RSNs (Figure 1B). Among RSNs involved in attentional, social-communicative and affective processing, the default mode (DMN; p=.001) and frontoparietal (FPC; p<.001) networks were notably affected. White matter tracts connecting hubs of these RSNs (*e.g.,* cingulum, anterior limb internal capsule) were among those demonstrating greater between group differences. These results suggest preterm birth causes widespread disruption of functional and structural connectivity of the developing brain, including regions linked to the psychiatric disorders that occur commonly in preterm children.

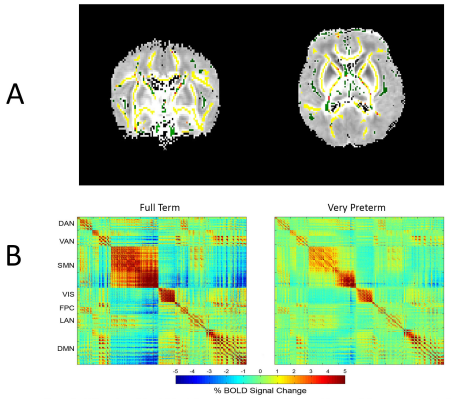

Figure 1. A) Tract Based Spatial Statistics analysis comparing Term and Preterm infants at term equivalent. Tracts are overlaid on FA maps of the neonates. Red and yellow note regions of significantly lower FA in preterm infants. B) Group mean covariance matrices generated using 1065 cortical gray matter regions of interest. The block structure corresponds to RSNs to which each region is assigned, including the dorsal attention (DAN), ventral attention (VAN), somatomotor (SMN), visual (VIS), frontoparietal control (FPC), language (LAN) and default mode (DMN) networks. (A) Term infants; (B) Preterm infants at term equivalent PMA. Note similarity of block structure in (A) and (B). This similarity reflects down-scaling of positive and negative rs-fMRI covariance values in the preterm subjects relative to the term subjects.

Title: Frontal EEG asymmetry and childhood maltreatment history predict systemic inflammation in middle-aged adults

Authors: *C. E. HOSTINAR[1], R. J. DAVIDSON[2], T. E. SEEMAN[3], D. K. MROCZEK[1], M. E. LACHMAN[4], G. E. MILLER[1];
[1]Northwestern Univ., Evanston, IL; [2]Univ. of Wisconsin, Madison, WI; [3]UCLA, Los Angeles, CA; [4]Brandeis Univ., Waltham, MA

Abstract: Frontal EEG asymmetry is thought to reflect temperamental variations in affective style, with studies showing that greater right frontal activity at rest predicts enhanced emotional responding to threatening or negative stimuli. A diathesis-stress model has been proposed to explain how this neuro-affective style might predispose to psychopathology, such that greater right frontal activity would constitute a vulnerability factor under stressful conditions, but would not predict symptomatology in the absence of circumstances that elicit an emotional response. Much less is known about the extent to which greater right frontal activity might also serve as a diathesis for physical illness in individuals exposed to an environmental stressor that elicits negative emotions. The present study examined the hypothesis that greater resting right frontal EEG activity might exacerbate the effects of childhood maltreatment on levels of adult systemic low-grade inflammation, a risk factor for several chronic diseases of aging (e.g., coronary heart disease). Resting EEG, serum inflammatory biomarkers, and self-report psychological measures were drawn from a group of 313 middle-aged adults from the national MIDUS study. Log alpha power in the right hemisphere was subtracted from log alpha power in the left hemisphere to create an index of laterality, considering both the lower (8-10 Hz) and upper (10-13 Hz) ranges of the alpha band. A composite measure of inflammation was derived from five biomarkers, including serum levels of interleukin-6, C-reactive protein, fibrinogen, E-selectin, and ICAM-1. Higher levels of right frontal neural activity and of childhood maltreatment exposure both independently predicted greater systemic inflammation ($\beta = .12$, $p = .03$ and $\beta = .11$, $p = .04$, respectively). There was also a significant interaction ($\beta = .16$, $p = .005$) such that individuals who had both greater right frontal activity and exposure to more types of maltreatment exhibited the greatest levels of inflammation. The interaction remained significant after adjustment for demographic and biomedical covariates. These results suggest that greater right frontal neural activity might amplify the health risks associated with a history of childhood maltreatment.

Title: Infant maltreatment alters limbic white matter tracts: support for the match/mismatch hypothesis?

Authors: *B. R. HOWELL[1], M. AHN[2], J. R. GODFREY[3], Y. SHI[5], G. NAIR[7], X. HU[8], M. A. STYNER[5,6], M. M. SANCHEZ[3,4];

Disorders and Stroke, NIH, Bethesda, MD; [8]Biomed. Engin., Emory Univ. and Georgia Inst. of Technol., Atlant, GA

Abstract: Early social experiences, such as maternal care, are important for socioemotional development in primates. Victims of childhood maltreatment are at higher risk for psychopathology including depression and anxiety. These alterations in socioemotional behaviors are related to neurobiological alterations in specific brain circuits. Utilizing a naturalistic nonhuman primate model of infant maltreatment we investigated how the neurodevelopmental effects of early experience unfold in white matter (WM) tracts involved in emotion and social behavior. Our model includes comorbid physical abuse and neglect during infancy, often interspersed with competent care much like in humans. In previous studies using this model we have reported long-term effects on social behavior and emotional reactivity, as well as alterations in WM integrity. The current study expands these findings by following a cohort of rhesus monkeys randomly assigned at birth to either competent or maltreating maternal care longitudinally, from 2 weeks through 18 months of age. Using this crossfostering design we are able to disentangle the effects of heritable factors from those of the experience itself. We used a longitudinal diffusion tensor imaging (DTI) rhesus brain atlas to gather DTI metrics (e.g. fractional anisotropy, FA, an indicator of structural integrity) along WM tracts and applied

sophisticated longitudinal statistical models to examine the effects of experience versus heritable factors (and their interactions) throughout this developmental period. We found that FA in the inferior longitudinal fasciculus and the middle longitudinal fasciculus, long association tracts involved in visual processing and possibly auditory processing, respectively, with both playing a role in socioemotional behavior, were affected by experience, but also influenced by heritable factors. Animals born to competent mothers and fostered to competent mothers had significantly higher FA than those in the 3 other foster groups. These results may support the environmental match/mismatch hypothesis that suggests that early life adversity leads to changes that are adaptive to the challenging environment, and that these adaptions may be passed from one generation to the next to prepare offspring to adapt to that environment. Another possibility is that there is a cumulative effect of maltreatment experience and the heritable factors passed from maltreating mothers to their offspring. Ongoing studies are aimed at better defining success within each environmental context and at integrating the current neurobiological findings with behavioral outcomes in the crossfostered offspring.

Title: Corticolimbic activation and functional connectivity in adults who experienced child maltreatment

Authors: *K. JEDD[1], R. H. HUNT[1], D. CICCHETTI[1], E. HUNT[2], F. ROGOSCH[2], S. TOTH[2], R. A. COWELL[3], K. M. THOMAS[1];
[1]Inst. of Child Develop., Univ. of Minnesota, Minneapolis, MN; [2]Univ. of Rochester, Rochester, Minnesota, NY; [3]St. Norbert Col., De Pere, WI

Abstract: Introduction. Child maltreatment is related to a host of problems with emotion perception and regulation, often manifesting as depression, conduct disorder, and substance abuse (Cicchetti & Valentino, 2006; DeBellis, 2001). Children with a history of maltreatment show altered emotion perception and emotional processing (Pollak & Tolley-Schell, 2003, Pollak

et al., 2000, Cicchetti & Curtis, 2005). Limbic structures in the brain may be especially sensitive to early life stress (Tottenham, 2012). The few functional studies that exist with maltreated samples point to hyperactivity in the amygdala following childhood maltreatment (e.g. Dannlowski et al., 2012). However, little is known about the lasting impact of childhood maltreatment on functional connectivity of the limbic system in adulthood. **Methods**. Participants included 71 adults from high-risk, low socio-economic backgrounds. 33 participants experienced documented cases of child maltreatment including emotional maltreatment, physical neglect, physical abuse, and/or sexual abuse; 38 participants had no history of maltreatment. All participants were recruited from a longitudinal sample of children who participated in a summer camp research program designed for low-income children. In the scanner, participants were asked to match a target face with one of two other faces based on emotional expression (Hariri et al., 1999). Whole brain analyses were conducted to examine group differences in task activation. In addition, a psychophysiological interaction (PPI) analysis assessed group differences in task based functional connectivity using a bilateral amygdala seed. **Results.** The maltreated group had greater activation than the comparison group in bilateral putamen/caudate and in right dorsolateral prefrontal cortex (dlPFC). Later onset of maltreatment was associated with increased activity in right dlPFC. Additionally, participants who experienced maltreatment in fewer developmental periods had greater activity in right dlPFC, left nucleus accumbens/putamen, and right amygdala. In the PPI analysis, the maltreated group showed increased connectivity of the amygdala with left hippocampus, bilateral parahippocampal gyrus, dorsal medial PFC, right inferior frontal gyrus, and right dlPFC. **Discussion.** These results indicate that childhood maltreatment is associated with lasting functional alterations in limbic circuitry. Altered neural processing in the limbic system could be a contributing factor in the development of psychopathology, however more research is necessary to understand how limbic structures respond to the intense stress of childhood maltreatment.

Title: Rescue of neurobehavioral deficits following infant abuse: The role of maternal odor

Authors: *R. E. PERRY, R. M. SULLIVAN;
Emotional Brain Inst., Nathan Kline Inst., Orangeburg, NY

Abstract: Experiencing infant abuse alters the expression of fear and aggression throughout development, with a heightened sensitivity to threat and an increased incidence of aggressive behaviors emerging by adolescence in humans. Here we use a rodent model of infant abuse to assess the expression of fear and aggression throughout the lifespan, explore possible modes of rescuing the neurobehavioral deficits that emerge following abuse, and investigate the neurobiological underpinnings mediating the effects of abuse. Infant rat pups were raised with a normal or abusive mother from postnatal days (PN) 8-12, and tested in a novel Threat Response Selection Test (TRST) at post-weaning (PN26-30), adolescence (PN40-45), and adulthood. In the TRST, individuals were placed in the center of a tri-sectioned arena and given the option to approach a predator odor (fox urine), or hide in a provided hut. Active (i.e. rearing, exploration) and passive (i.e. freezing, hiding) defensive responses were scored. Additionally, aggression was assessed in a Resident Intruder Test (RIT). In the RIT, animals were single housed for a week, before introducing a smaller, same sex intruder into their home cage for 10 minutes. Offensive and defensive behaviors were assessed. Lastly, the effects of infusing maternal odor into the testing arenas during the TRST and RIT were assessed on the adult response to threat following abuse. Activation of the prefrontal cortex (PFC), amygdala, hypothalamus, and periacqueductal gray (PAG) was scored following the TRST, via assessment of c-Fos activity. Post-weaning rats that experienced infant abuse showed heightened avoidance of fox urine and increased hiding in the provided hut in the TRST. However, in adulthood, previously abused rats displayed decreased hiding, increased approach and interaction with the predator odor, and decreased amygdala activation, relative to typically-reared rats. Additionally, infant abused rats showed increased offensive behaviors in the RIT, including lateral/dorsal attacks, pinning, boxing, and chasing the intruder. Importantly, the presentation of maternal odor at the time of testing for the RIT and TRST normalized the behavior of previously abused rats in adulthood, seemingly through a circuit involving the prefrontal cortex. Infant abuse alters responses to threatening stimuli throughout development, and decreases amygdala activation to threat by adulthood, making it more likely for one to place itself in harm's way. Understanding the neurobiology of threat responding and its modulation by early-life experience will provide insight for treatment of fear and aggression-related disorders that occur after abuse.

Title: Experimental manipulation of prefrontal cortex differentially affects amygdala reactivity and connectivity following early-life stress

Authors: *D. G. GEE[1], B. GOFF[2], L. GABARD-DURNAM[3], C. CALDERA[2], D. FARERI[3], D. LUMIAN[4], J. FLANNERY[5], N. TOTTENHAM[3];
[1]Psychology Dept, Weill Cornell Med. Col., New York, NY; [2]UCLA, Los Angeles, CA; [3]Columbia Univ., New York, NY; [4]Univ. of Denver, Denver, CO; [5]Univ. of Oregon, Eugene, OR

Abstract: Early-life stress can have profound and lasting effects on affective development and behavior. Humans rely on their caregivers longer than any other species, making parental deprivation one of the most potent stressors for an infant. Prior correlational studies suggest that parental deprivation alters the development of amygdala-prefrontal circuitry and related anxiety. However, the functional nature of these abnormalities is unknown. Experimental manipulation of prefrontal cortex (PFC) via cognitive load has been shown to have sustained and lasting effects on amygdala reactivity during adulthood (e.g., Wagner & Heatherton, 2012). The current study took advantage of PFC-mediated effects to investigate the nature of the amygdala-PFC relationship during development in children (8-11 years old) who experienced parental deprivation via previous institutionalization (PI) during infancy and typically developing comparison children (8-11 years old) and adolescents (12-17 years old). Participants completed a novel fMRI task that manipulates cognitive load on subsequent brain activation to emotional stimuli. Conditions of high cognitive load (relative to low cognitive load) induced inverse amygdala-medial PFC functional connectivity and reduced amygdala reactivity in comparison adolescents, but not comparison children, who showed positive amygdala-medial PFC functional connectivity and increased amygdala reactivity. PI children showed the more mature pattern of inverse amygdala-medial PFC functional connectivity, and despite heightened amygdala reactivity at baseline (low cognitive load), they also showed reduced amygdala reactivity during high cognitive load. Thus, the nature of amygdala-PFC recruitment and interactions differ qualitatively between typically developing and PI children, particularly under conditions that demand more cognitive resources. The finding that PI children resemble comparison adolescents suggests that early-life stress may accelerate amygdala-prefrontal development. Amygdala-prefrontal phenotypes following parental deprivation may be ontogenetic adaptations that the developing system makes in order to meet the demands of an adverse environment but are likely to have long-term consequences on emotional behavior.

Title: Exercise induces age-dependent neuroplastic changes in limbic regions responsible for learning, memory and emotional behavior

Authors: *K. HULEN[1,2], A. MIKA[2,3], N. L. RUMIAN[2], A. K. HILLS[2], S. O. MCCONNELL[2], A. L. INGALLS-WILLIAMS[2], M. R. FLESHNER[2,3];
[1]Univ. of Colorado Boulder, Boulder, CO; [2]Dept. of Integrative Physiol., [3]Ctr. for Neurosci., Univ. of Colorado, Boulder, CO

Abstract: Voluntary wheel running exercise produces a milieu of adaptive plastic changes in rodent brains, including elevated levels of brain-derived neurotrophic factor (BDNF), increased transcription of synaptic proteins, epigenetic changes in genes involved in neuroplasticity, and structural changes such as increased spine and dendritic growth. These adaptations are abundant in the prefrontal cortex, amygdala, and hippocampus, which are regions involved in cognition and emotional behavior. These neuroplastic and behavioral enhancements occur rapidly after exercise onset; however, they are transient in adults and last only as long as exercise is continued. Interestingly, the brain is more plastic and sensitive to environmental influence during early life. Recent work from our lab, as well as others, demonstrates that exercise, when initiated during critical developmental periods, can produce neuroplastic changes that last well beyond exercise cessation. These previous studies, however, utilized exercise time courses that spanned multiple developmental stages. Therefore, the precise period during which exercise capitalizes on the plasticity of circuits that promote these long lasting changes is unclear. The current study tested exercise time courses that were brief enough to allow us to isolate and compare the impact of exercise on increases in plasticity proteins and neuronal structure within brain regions involved in cognition and behavior during discrete developmental periods. Male F344 rats (n=8 per group) at three distinct ages, juvenile (PND 24), adolescent (PND 40), and adult (PND 70), ran for one week, after which the wheels were immobilized and half of each cohort was sacrificed while the other half remained sedentary for two weeks. Brains were removed and processed for either *in situ* hybridization of mRNA for plasticity markers, or for Golgi staining of neuronal structure. Preliminary analyses demonstrated that increased levels of BDNF mRNA persist for 2 weeks after exercise cessation only when exercise was initiated during the juvenile period. Quantifications are currently in progress for dendritic complexity, spine density, and mRNA for plasticity proteins, including cyclic-AMP binding protein (CREB), tyrosine receptor

kinase B (TrkB), synapsin-I, and synaptophysin. These data suggest that exercise during critical periods may produce persistent improvements in neural plasticity and brain function.

Title: Early life exercise produces persistent alterations in serotonergic circuits and long-lasting stress resistance

Authors: ***A. MIKA**[1,2], N. L. RUMIAN[1], A. K. HILLS[1], S. O. MCCONNELL[1], C. A. BOUCHET[3], B. N. GREENWOOD[3], M. R. FLESHNER[1,2];

Abstract: Voluntary exercise protects against the anxiety and depressive-like behaviors produced by inescapable stress (IS), including exaggerated fear and deficits in shuttle box escape learning. When exercise is initiated in adulthood, however, the protective effects are transient and the organism is once again vulnerable to the behavioral consequences of IS shortly after exercise cessation. We have demonstrated that early life exercise produces lasting protection against IS-induced exaggerated fear and shuttle box escape deficits that persist despite termination of exercise. The underlying neural mechanisms for this persistent effect are unknown. In adults, the stress protective effects of exercise are dependent upon plastic changes within serotonergic (5-HT) circuits. Specifically, hyperactivation and sensitization of 5-HT neurons within the dorsal raphe nucleus (DRN) are necessary and sufficient to produce exaggerated fear and shuttle box escape deficits. In sedentary rats, IS-induced sensitization of these neurons leads to exaggerated 5-HT release in brain regions regulating anxiety during later behavioral testing. 6 weeks of exercise prior to IS can constrain the hyperactivation and sensitization of these neurons, thereby protecting against exaggerated 5-HT release and resulting behavioral deficits. Exercise in adulthood regulates 5-HT neuronal activity by increasing mRNA for 5-HT_{1a} inhibitory autoreceptors (5-HT_{1a}R) within the DRN, and decreases postsynaptic 5-HT_{2C} receptors (5-HT_{2C}R) within DRN projection regions important for anxiety and depressive-like behavior. The persistent stress protection produced by early life exercise could involve stable adaptations within 5-HT receptors and/or adaptive alterations within circuits involved in

regulating DRN 5-HT neuron activity. To test this, adult (PND 70) and juvenile (PND 24) male, Fisher (F344) rats were allowed access to a running wheel or remained sedentary for 6 weeks. Following cessation of exercise, rats were sacrificed and brains were collected either immediately or following 25 days to examine gene expression using *in situ* hybridization. Preliminary analyses revealed that early life exercise produces persistent increases in 5-HT_{1a}R mRNA expression within the DRN. Analysis of 5-HT_{2C}R receptors and plasticity markers in brain regions involved in regulating DRN 5-HT neuron activity is currently underway. These data suggest that early life exercise produces long lasting, adaptive alterations in stress responsive brain circuits, perhaps by capitalizing upon the pervasive plasticity of the developing brain.

Title: Early life stress alters the development of the fear circuit and fear learning in mice

Authors: *G. MANZANO-NIEVES[1], K. G. BATH[2];
[1]Dept. of Neuroscience, Brown Univ., Providence, RI; [2]Dept. of Cognitive, Linguistic and Psychological Sci., Brown Univ., Providence, RI

Abstract: Acute traumatic events and/or prolonged stress incurred early in life increase the risk of developing anxiety and depressive-like behaviors in both humans and animal models. In addition, recent work has suggested that early life stress can accelerate the development of the fear circuit in rats (Cowan CS et al., 2013; Moriceau S et al., 2009). However, the effect of early life stress (ELS) on neural development, and their consequences on circuit activation are not well known. To investigate the effect of ELS on the development of the conditioned fear circuit we took advantage of an ELS paradigm that consisted of reducing maternal access to bedding and nesting materials from postnatal days 4 to 11 (Rice CJ et al., 2008). Subsequently, we investigated the development of fear learning and expression in control reared and ELS mice using a standard cued fear conditioning paradigm. Briefly, mice were exposed to six tones, each of which co-terminated with a foot-shock (0.57mA) on postnatal day (P) 21, 28, or 50. Consistent with previous work, we observed no effect of age on tone fear memory recall in control mice (Den ML and Richardson R, 2013). However, at postnatal day 21 both ELS reared

male and female mice showed significantly diminished levels of freezing during recall testing at 6 hrs. (Freezing: 45% Controls vs. 17% ELS; $P < 0.01$) and 24 hrs. (Freezing: 65% Controls vs. 22% ELS; $P < 0.01$) post conditioning. We hypothesized that ELS alters the timing of development of key regions involved in fear consolidation and recall, impairing performance at P21. Ongoing experiments are aimed at understanding the neural structures involved in the observed ELS phenotype.

Title: Predictable chronic mild stress during adolescence promotes fear memory erasure in adulthood

Authors: *J. DENG[1,2], C. CHEN[1,2], S. MENG[1,2], C. SUN[1,2], L. XU[1,2], Y. XUE[2], X. GAO[1,2], W. YAN[1,2], N. CHEN[2], J. SHI[2], L. LU[1,2,3];

Abstract: Objective: Numerous studies confirmed that early-life stress is a predisposing factor for mental illness, such as anxiety and posttraumatic stress disorder. However, our recent findings indicated that adolescent predictable chronic mild stress (PCMS) promotes resilience to depression- and anxiety-like behaviors in adulthood, indicating that PCMS in early life may improve the ability to cope with stressful experiences in adulthood. In the present study, we investigated whether PCMS during adolescence promotes the extinction-induced inhibition of conditioned fear responses in adulthood. Methods: During PCMS procedure, the rats were restrained for 5 min each day for 28 days (postnatal days 28-55). Contextual fear conditioning was used to investigate the effects of PCMS in adolescence on fear memory acquisition and

extinction. Protein levels of brain-derived neurotrophic factor (BDNF)-extracellular signal-regulated kinase 1/2 (ERK1/2) signaling and Bdnf DNA methylation were detected after PCMS. Intra- prefrontal cortex infusion of BDNF antibody or ERK1/2 inhibitor U0126 was conducted to investigate the relationship between BDNF-ERK1/2 signaling and the enhancement of fear extinction induced by PCMS exposure during adolescence. Results: We found that PCMS during adolescence facilitated the extinction and inhibited the reinstatement and spontaneous recovery of fear memory in adult rats, and this effect was still present 1 week after PCMS exposure. Moreover, PCMS in adolescence increased the activity of BDNF-ERK1/2 signaling in the infralimbic cortex (IL) but not prelimbic cortex in adulthood. Intra-IL infusion of BDNF antibody and the ERK1/2 inhibitor U0126 reversed the PCMS-induced enhancement of fear extinction. Lastly, we found that PCMS decreased DNA methylation of the Bdnf gene at exons IV and VI and elevated the mRNA levels of Bdnf in the IL. Conclusion: Our findings demonstrated that adolescent PCMS exposure promoted fear memory erasure in adulthood, and this effect may be achieved through methylation modification of the Bdnf gene in the medial prefrontal cortex.

Title: Hyper-excitability and epilepsy generated by chronic early-life stress

Authors: ***A. SINGH**[1], C. M. DUBÉ[2], J. MOLET[2], A. IVY[2], P. M. MARAS[1], T. Z. BARAM[3]; [1]Pediatrics, [2]Anatomy/Neurobiology, [3]Pediatrics, Anatomy/Neurobiology, Neurol., Univ. of Calfornia-Irvine, Irvine, CA

Abstract: Rationale: Epilepsy is more prevalent in populations with high measures of stress, but the neurobiological mechanisms are unclear. Stress is a common precipitant of seizures in individuals with epilepsy, and may provoke seizures by several mechanisms including changes in neurotransmitter and hormone levels in the brain. Previous studies have shown that stress during sensitive periods early in life contributes to ‘brain programming’, influencing neuronal function and networks. However, it remains unclear if early-life stress influences limbic excitability and promotes epilepsy. Methods: Here, we employed an established, naturalistic

rodent model of chronic early-life stress (CES). The rat pups were stressed by the unpredictable and fragmented nurturing behavior of the dams resulting from the limited bedding and nesting material in the cages from postnatal day (P) 2-9 (controls were housed under standard conditions). From P11-15, animals were implanted with bipolar electrodes in both hippocampi, or bilaterally in amygdala, as well as with one electrode over the right fronto-parietal cortex. Chronic cortical and limbic video-EEGs were used to examine the contributions of stress to age-specific epilepsies and network hyper-excitability. To probe the underlying molecular mechanisms, we utilized *in situ* hybridization and qRT-PCR to measure mRNA levels of Corticotropin-releasing hormone (CRH). Immunocytochemistry was used to determine CRH peptide levels. Results: EEGs obtained from the control animals throughout development were normal and no seizures were observed. EEGs from the majority of rats experiencing CES demonstrated epileptic spikes and spike series, and 57% of CES rats developed seizures. Behavioral events resembling the human age-specific epilepsy infantile spasms occurred in 48% of the animals, accompanied by EEG spikes and/or electrodecrements. 9% of the animals developed limbic seizures that involved the amygdala. Probing for stress-dependent, endogenous convulsant molecules within amygdala, we examined the expression of the pro-convulsant neuropeptide CRH, and found a significant increase of amygdalar, but not cortical, CRH expression in adolescent CES rats. Conclusions: These data suggest that CES has long-lasting effects on brain excitability and may promote age-specific seizures and epilepsy. Whereas the mechanisms involved require further study, these findings provide important insights into environmental contributions to early-life seizures.

Title: Stress during a critical postnatal period induces region-specific structural abnormalities and dysfunction of the prefrontal cortex via CRF1

Authors: X.-D. YANG[1], X.-M. LIAO[1], A. URIBE-MARIÑO[2], R. LIU[1], X.-M. XIE[1], Y.-A. SU[1], J.-T. LI[1], M. V. SCHMIDT[2], T.-M. SI[1], *X.-D. WANG[3];

Abstract: During the early postnatal period, environmental influences play a pivotal role in shaping the development of the neocortex, including the prefrontal cortex (PFC) that is crucial for working memory and goal-directed actions. Exposure to stressful experiences during this critical period may disrupt the development of PFC pyramidal neurons and impair the wiring and function of related neural circuits. However, the molecular mechanisms of the impact of early-life stress on PFC development and function are not well understood. In this study, we found that repeated stress exposure during the first postnatal week hampered dendritic branching and spine formation in layers II/III and V pyramidal neurons in the dorsal agranular cingulate cortex (ACd) of neonatal mice. In adulthood, postnatally stressed mice exhibited impaired structural plasticity in layer V, but not layer II/III, neurons in the ACd. Most importantly, concurrent blockade of corticotropin-releasing factor receptor 1 (CRF1) by systemic antalarmin administration during the stress exposure attenuated the region-specific effects of early-life stress and rescued stress-induced cognitive impairments. Moreover, the reduced length of apical dendrites of ACd layer V pyramidal neurons correlated with the degree of cognitive deficits in stressed mice. Our data highlight the importance of the time window of stress exposure on the development of subpopulations of PFC pyramidal neurons, and suggest that CRF1 modulates the adverse effects of early-life stress on structural plasticity and function of PFC.

Title: Early life stress impairs Parvalbumin networks in mouse prefrontal cortex

Authors: *Z. YE[1], K. SCHAEFER[3], H. S. KNOBLOCH-BOLLMANN[2], T. K. HENSCH[2,4];
[1]Neurobio., [2]MCB, Harvard Univ., Cambridge, MA; [3]Harvard Col., Cambridge, MA;

Abstract: Neuronal circuits controlling our perception and behaviors are radically shaped by early life experiences. In humans, early life stress (ELS) has been linked to negative behavioral consequences throughout life and compromised structure/function of the prefrontal cortex (PFC). However, the underlying cellular mechanisms of ELS have not been fully elucidated. Inhibitory parvalbumin (PV) expressing interneurons are particularly vulnerable to genetic or environmental insults associated with cognitive disorders. Whether and how PV networks in the medial PFC are affected by ELS, or if they mediate the behavioral consequences, remains unclear. Here, we first adapted a parental separation protocol in *Peromyscus Polionotus* (PO), a monogamous wild mouse species that provides bi-parental care to offspring. Female PO offspring subjected to ELS exhibited significantly increased anxiety-like behaviors in adulthood as compared to control (CTL) POs (n=9 for CTL, n=13 for ELS, $p<0.01$). Moreover, PV expression in the medial PFC was negatively correlated with their anxious behaviors (slope=-0.5814 ± 0.2436, p=0.027). No changes in anxiety behavior or PV expression were detected in male POs (n=7 for CTL, n=12 for ELS). To further examine a role for PV networks in the medial PFC following ELS, we characterized the developmental profile of PV+ interneurons in the C57Bl6/J laboratory mouse strain. Consistent with our findings in PO mice, after experiencing an ELS paradigm of fragmented care induced by limited nesting material, female (but not male) offspring exhibited increased anxiety (n=11 for CTL, n=6 for ELS, $p<0.05$) and impaired PV networks in the mPFC, as measured by both qPCR and immunohistochemistry. Notably, this sex-specific effect of ELS on anxiety behaviors may have been mediated by differential expression of BDNF in female and male mice after ELS. Taken together, our data reveal increased anxiety and impaired inhibitory prefrontal PV circuits in female animals across mouse species and stress paradigms.

Title: Chronic stress enhances the hyperthermia in response to acute restraint stress

Authors: *T. MIYAMOTO[1,2], Y. FUNAKAMI[1], E. KAWASHITA[1], A. NOMURA[1], N. SUGIMOTO[1], S. ICHIDA[1], A. KAWABATA[1];

Abstract: Stress responses are important biological reactions to maintain homeostasis particularly through the autonomic nervous system. Acute mental stress is known to raise body temperature through excitation of the sympathetic nervous system which regulates non-shivering thermogenesis in the brown adipose tissue (BAT). The mechanism of the acute stress-induced hyperthermia still remains unknown. Here, we investigated the effect of chronic stress on acute stress-induced hyperthermia, using the specific alternation of rhythm in temperature (SART)-stressed mice that show various chronic stress symptoms and are now considered a model for autonomic imbalance. Male ddY mice weighing 20-25 g were kept at room temperature (24 ± 1 °C) under a 12 h-light and dark cycle (lights on at 8:00 am) and allowed to access food and tap water freely. Mice were exposed to restraint for 1 hour as acute stress, and loaded with SART stress as chronic stress, as follows. The mice were transferred hourly between two cages maintained at 24°C and 4°C from 9:00 to 16:00 and housed in the 4°C cage from l6:00 to 09:00 overnight. These procedures were repeated for 8 days and stopped at 11:30 on the final day. Each mice was deeply anesthetized with isoflurane for blood collection, and serum corticosterone (CORT), noradrenaline (NA) and adrenaline (Ad) levels were measured. Rectal temperature was monitored during the 1-hour restraint stress. Serum NA and Ad, but not CORT, levels elevated in SART-stressed mice. Acute restraint increased serum CORT, but not NA or Ad, levels, a response being greater in SART-stressed mice than unstressed mice. SART stress did not change the body temperature, whereas the restraint stress-induced hyperthermia was greater in SART-stressed mice than unstressed mice. The selective β3 adrenoceptor antagonist, SR59230A, improved the increased hyperthermia in response to restraint stress in the SART-stressed mice, while diazepam, an anxiolytic drug, and indomethacin, a cyclooxygenase inhibitor, had no such inhibitory effect. These results suggest that chronic stress enhances the acute stress-induced responses including hyperthermia, and the underlying mechanism might involve the non-shivering thermogenesis in BAT via β3 adrenoceptor stimulation.

Title: Early life stress induces rapid and persistent alterations in limbic endocannabinoid system

Authors: ***P. ATSAK**[1,2], M. MORENA[3], C. A. OOMEN[1,2], M. N. HILL[3], B. ROOZENDAAL[1,2];

Abstract: Early life stress (ELS), such as childhood neglect, creates life-long vulnerability to stress-related anxiety disorders. Recent evidence has underscored endocannabinoid dysregulations in anxiety disorders; nevertheless, the endocannabinoid system has received very little attention in the context of ELS. Here, we examined the immediate and delayed effects of ELS on the endocannabinoid system in limbic brain regions in male rats. We employed a limited-nesting-induced maternal neglect paradigm that took place between postnatal day 2 and 9 that resulted in a robust disturbance in maternal care and induced stress in pups as evidenced by higher plasma corticosterone levels. We determined the immediate effects of ELS in pups at postnatal day 9 and found significant reductions in 2-arachidonoylglycerol (2-AG) levels in the amygdala, hippocampus and prefrontal cortex (PFC) as well as in anandamide levels in the amygdala. Moreover, ELS decreased 2-AG levels in the hippocampus and amygdala while augmenting anandamide levels in the amygdala and PFC in adult animals. Further, to investigate the residual effects of ELS on endocannabinoid recruitment during stress, we exposed adult animals to an acute swim stress challenge for 15 minutes and subsequently determined endocannabinoid levels in limbic brain regions. We found that forced swim stress significantly reduces anandamide levels in the amygdala and PFC. Stress, as expected, induced a dramatic increase in 2-AG levels in the hippocampus; however, this was absent in rats with ELS history. To gain insight into the mechanism underlying the ELS-induced endocannabinoid alterations, we assessed the activity of major endocannabinoid catalyzing enzymes in the same brain regions. Moreover, to examine whether the changes in endocannabinoid ligand levels drive a permanent effect on the receptor type 1 (CB1), we evaluated CB1 sensitivity and expression in all these brain regions. We did not find any alterations in these parameters except elevated CB1 expression. These findings show that ELS induces endocannabinoid alterations in brain region- and time-dependent fashion under baseline conditions. Moreover, ELS history significantly disturbs the stress-induced recruitment of hippocampal endocannabinoid signaling in adults. These findings may carry important implications for understanding the mechanisms that mediate the life-long effects of ELS. Early 2-AG alterations could affect the cortical wiring of the brain whereas delayed alterations can lead to cognitive deficits or enhanced emotional memory that might predispose individuals to vulnerability to psychopathology such as post-traumatic stress disorder.

Title: Early life stress accelerates behavioral and neural maturation of the hippocampus

Authors: *K. G. BATH[1], G. MANZANO-NIEVES[2], H. GOODWILL[2];
[1]CLPS, [2]Neurosci., Brown Univ., Providence, RI

Abstract: Early Life Stress (ELS) increases risk for cognitive and emotional dysfunction. ELS suppresses proliferation and increases cell death in postnatal hippocampus, leading to the prevailing hypothesis that ELS retards brain development. Recently, ELS has been associated with activating effects on behavioral and functional brain development, indicating potential consequences for the timing of brain development. However, the effect of ELS on measures of neural maturation have not been assessed. Here we used a mouse model of ELS, fragmented maternal care, and a cross-sectional dense sampling approach focusing on the hippocampus to directly measure the effects of ELS on the expression of genetic markers of neural maturation as well as the ontogeny of behavioral development. In a contextual fear-conditioning task, ELS accelerated the timed developmental suppression of contextual fear responding. Using RT-qPCR, we found that ELS led to a precocious switch in NMDA receptor subunit expression (marker of synaptic maturity), an earlier rise in parvalbumin expression (a late developing class of interneurons), and earlier expression of myelin basic protein (a key component of the myelin sheath). ELS led to a more rapid decline in expression of markers of cell proliferation and differentiation (Ki-67 and doublecortin). Together, these data are the first direct evidence to support the hypothesis that ELS serves to switch neurodevelopment from processes of growth to maturation. This represents a paradigm shift in our thinking regarding ELS effects on neurobehavioral development, and indicate that ELS may serve to promote earlier maturation of some circuits to cope with early adversity.

Title: Hippocampal cytogenesis on stress-exposed senile rats: effects of previous early-life exposure to environmental stress

Authors: *T. P. MARTÍNEZ[1], D. RUESGA-BARCENAS[2], J. GARCÍA-ESTRADA[3], S. LUQUÍN[2], Y. RUVALCABA-DELGADILLO[2];
[1]Neurosci., Univ. De Guadalajara, Guadalajara, Mexico; [2]Neurosci., Univ. de Guadalajara, Guadalajara, Mexico; [3]Neurosci., Ctr. de Investigación Biomédica de Occidente, Guadalajara, Mexico

Abstract: The hippocampus is one of the few areas of the rodent brain that has the ability to continue producing new cells postnatally; also this area is closely related to stress effects. Changes in hippocampal proliferation have been discussed based on volumetric variations reported in chronically stressed subjects; however, it is unclear whether proliferative changes may affect senile subjects with a history of stress. In the present study, hippocampal cytogenesis in stress-exposed senile rats was assessed as a function of whether or not the rats were exposed to stress at early stages of life. The thymidine analog BrdU was administered to senile male wistar rats in order to evaluate DG, CA3, CA2 and CA1 proliferative changes. We found statistically significant elevations in the number of BrdU marked cells among the hippocampus of rats of stressed rats that were also exposed at early stages of life. Then, we provide evidence that early exposure to stress may change the way that older subjects respond to new stressing conditions.

Title: Sex-dependent effects of early life inflammatory pain on energy homeostasis in adult rats

Authors: *M. B. PARENT[1,2], Y. O. HENDERSON[1], R. NALLOOR[3], A. VAZDARJANOVA[5,4], A. Z. MURPHY[1];
[1]Neurosci. Inst., [2]Dept. of Psychology, Georgia State Univ., Atlanta, GA; [3]Augusta Biomed. Res. Corp., [4]VA Res. Service, Charlie Norwood VA Med. Ctr., Augusta, GA; [5]Dept. of Pharmacol. and Toxicology, Georgia Regents Univ., Augusta, GA

Abstract: We hypothesize that dorsal hippocampal (dHC) neurons, which are critical for episodic memory, form a memory of a meal and inhibit meal onset during the postprandial period. In support, we showed previously that 1) consumption of a sucrose meal induces expression of the synaptic plasticity marker activity-regulated cytoskeleton-associated protein (*Arc*) in dHC neurons and 2) reversible inactivation of these neurons immediately following sucrose meal accelerates the onset of the next meal and increases the volume of intake. We have also previously reported that early life pain produces long-lasting dHC-dependent memory impairments in adult rats. The present study determined whether these memory deficits are accompanied by impaired energy homeostasis. Male and female Sprague-Dawley rats were given an intraplantar injection of the inflammatory agent carrageenan (1%) on the day of birth and their meal patterning and body mass were measured in adulthood. We found that neonatal inflammatory pain increased meal size in female and male rats, increased meal frequency in female rats, and prevented sucrose-induced *Arc* expression in dHC neurons in female rats, but not in male rats. Morphine administration at the time of injury attenuated the effects of injury. Injury also increased body mass at different ages in male and female rats; these sex- and age-dependent increases in body mass occurred concurrently with dHC-dependent memory deficits in the spatial water maze. Collectively, these findings indicate that one brief episode of neonatal inflammatory pain has a long long-lasting impact on energy homeostasis that is age- and sex-dependent and parallels dHC-dependent memory deficits.

Title: Elucidating central mechanisms of the anorexigenic effect of neuropeptide K in broilers (Gallus gallus)

Authors: *J. YI, E. R. GILBERT, M. A. CLINE;
Virginia Tech., Blacksburg, VA

Abstract: The central mechanisms mediating anorexigenic effects of neuropeptide K (NPK) are poorly understood in chickens. Herein, we demonstrated the anorexigenic effect of NPK and central mechanisms associated with the hypothalamus. Intracerebroventricular (ICV) injection of NPK decreased food intake but had no effect on water intake in 4 day-old chicks. The c-Fos immunoreactivity was increased in the paraventricular nucleus (PVN) and arcuate nucleus in NPK-treated chicks, while no effect of treatment was observed in the lateral hypothalamus, ventromedial hypothalamus, dorsomedial hypothalamus, paraventricular nucleus, or the suprachiasmatic nucleus of the hypothalamus. Microinjection of NPK into the PVN of 14 day-old chicks also induced anorexia, demonstrating a primary site of action. Additionally, treatment with corticotropin releasing factor (CRF) receptor antagonists did not affect NPK-induced anorexia, which may indicate that CRF was not involved in NPK's anorexigenic effect. Gene expression of appetite-associated factors was measured in the hypothalamus after ICV injection and there was decreased agouti gene-related peptide (AgRP) mRNA abundance but no change in proopiomelanocortin, neuropeptide Y and oxytocin mRNA in NPK compared with vehicle-injected chicks. A comprehensive behavior analysis revealed a decreased number of feed pecks, exploratory pecks, jumps, escape attempts, and distance moved and increased time spent standing for chicks that were ICV injected with NPK. In conclusion, NPK is associated with appetite regulation in chickens and its anorexigenic effects may be mediated by the paraventricular nucleus and arcuate nucleus in the hypothalamus and involve AgRP.

Title: Elucidating the anorexigenic mechanism of central oxytocin in birds

Authors: *B. MCCONN, E. R. GILBERT, P. B. SIEGEL, M. A. CLINE;
Virginia Tech., Blacksburg, VA

Abstract: Oxytocin (OT) is a well characterized neurotransmitter that participates in a wide range of physiological effects such as inhibition of food intake, although the mechanism mediating this response is poorly understood in any species, especially in non-mammalian vertebrates. Thus, this study was designed to determine the effects of central OT injection on food intake in 4 day-old 3-h-fasted chicks (Gallus gallus). Intracerebroventricular (ICV) injection of 0.625, 2.5, 5.0, and 10.0 nmol OT decreased food and water intake during the 180 min observation period. Drink was not prandial as chicks that were food-restricted after ICV OT still reduced their water intake. There was increased c-Fos immunoreactivity in several appetite-

associated hypothalamic nuclei after ICV OT, including the arcuate (ARC), dorsomedial nucleus (DMN), lateral hypothalamus (LH), paraventricular nucleus (PVN), and ventromedial hypothalamus (VMH). We then investigated appetite-associated effects of OT in chicks from lines that have been genetically selected for either low (anorexic-containing) or high (all obese) body weight. Central OT decreased food intake in both lines with the magnitude of response greater in the high than low weight line. In conclusion, ICV OT induced anorexia, reduced water intake, and was associated with activation of the ARC, DMN, LH, PVN, and VMH in the hypothalamus. Chicks from the line selected for high body weight were more responsive to the anorexigenic effects of OT.

Title: Expression patterns of BDNF with central anorexigenic signaling pathways involving PACAP in the hypothalamic ventromedial nuclei

Authors: *B. MAUNZE, M. HURLEY, J. M. RESCH, M. J. REILLEY, E. M. WASSMANN, S. CHOI;
Marquette Univ., Milwaukee, WI

Abstract: Pituitary adenylate cyclase-activating polypeptide (PACAP) is a 38-amino acid polypeptide belonging to the secretin super family of peptides. PACAP binds to its type 1 receptor (PAC1R) with greater affinity than for the receptors for vasoactive intestinal polypeptides (VIP), VPAC1 and VPAC2. Although mRNA for PACAP and its receptor PAC1R are found throughout the central nervous system, they are abundantly expressed in the hypothalamic ventromedial nuclei (VMN). In male Sprague Dawley rats, infusions of PACAP into the VMN produce a robust decrease in food intake with concomitant increased energy expenditure, decreased body weight, and significantly elevated brain-derived neurotrophic factor (BDNF) mRNA expression in the VMN. This latter effect of PACAP on BDNF mRNA expression has been shown to occur in other brain regions. Exogenous BDNF in the VMN regulates energy homeostasis in a manner similar to that of PACAP with decreased feeding and increased metabolism. Although the physiological responses to individual PACAP and BDNF infusions in the VMN lead to decreased feeding behavior and body weight loss, the anatomical distribution of these two cell signals in the VMN has not been established. PACAP-induced

changes in BDNF mRNA expression in the VMN may reveal an important interaction with PACAP signaling in the control of feeding behavior. In the present study, we have employed double-labeled fluorescent in-situ hybridization (FISH) to examine the expression patterns of PACAP, PAC1R and BDNF mRNA containing neuronal cells. In the VMN, PACAP mRNA expressing cells co-express BDNF, PAC1R, and VGLUT2. BDNF mRNA expressing cells co-express PAC1R and PACAP. Coupled with previous behavioral data demonstrating PACAP- and BDNF-induced changes in feeding behavior, the co-expression of BDNF with PACAP and PAC1R mRNA in the VMN suggest a potential functional relationship between the two signaling peptides in the regulation of energy homeostasis. The specific and integrated contributions of PACAP and BDNF in the VMN towards regulating energy homeostasis and feeding behavior still remain to be studied.

Title: Peripheral administration of glucagon-like peptide-1 and cholecystokinin-8 activates nesfatin-1-containing neurons in the hypothalamus and brainstem of rats

Authors: *Y. YAMAMOTO[1], R. SAITO[1], M. SO[2], Y. MOTOJIMA[2], T. MATSUURA[2], M. YOSHIMURA[2], H. HASHIMOTO[2], K. KUSUHARA[1], Y. UETA[2];
[1]Univ. Occupat & Environ Hlth., Kitakyushu city, Japan; [2]Dept. of Physiol., Univ. of Occup. and Envrn. Hlth., Kitakyushyu, Japan

Abstract: Peripheral anorectic hormones,glucagon-like peptide-1 (GLP-1), cholecystokinin (CCK)-8 and leptin suppress food intake. Newly identified anorectic neuropeptide, nesfatin-1 is synthesized not only in the peripheral tissue but also in the central nervous system, in particular various nuclei in the hypothalamus and brainstem. In the present study, we examined the effects of intraperitoneal (ip) administration of GLP-1, CCK-8 and serial ip administrations of GLP-1 and leptin at subthreshold dose against feeding in each on nesfatin-1-immunoreactive (ir) neurons in the hypothalamus and brainstem of rats, using immunohistochemistry for Fos. Ip administration of GLP-1 (100 μg/kg) caused significant increases of nesfatin-1-ir neurons expressing Fos-ir in the supraoptic nucleus (SON), the area postrema (AP) and the nucleus tractus solitarii (NTS) but not in the paraventricular nucleus (PVN), the arcuate nucleus (ARC) and the lateral hypothalamic area (LHA). On the other hand, marked increases of nesfatin-1-ir neurons expressing Fos-ir were observed in the SON, PVN, AP and NTS but not the ARC and

LHA after ip administration of CCK-8 (50 μg/kg). There were no differences in percentage of nesfatin-1-ir neurons expressing Fos-ir in above nuclei of the hypothalamus and brainstem among saline-, GLP-1 (33 μg/kg)- and leptin (300 μg/kg)-treated rats. However, serial administrations 37 of GLP-1 (33 μg/kg) and leptin (300 μg/kg) caused significant increases of nesfatin-1-ir neurons expressing Fos-ir in the AP and NTS. These results suggest that nesfatin-1-containing neurons in the brainstem may have an important role to sense peripheral levels of GLP-1 and leptin as well as CCK-8.

Title: Deletion of melanin-concentrating hormone receptor 1 from GABAergic neurons increases locomotor activity

Authors: *M. J. CHEE, S. E. FLAHERTY, III, N. BRIANCON, J. S. FLIER, E. MARATOS-FLIER;
Endocrinol., BIDMC, Harvard Med. Sch., Boston, MA

Abstract: Melanin-concentrating hormone (MCH) is an orexigenic neuropeptide produced exclusively in the lateral hypothalamus. It is a critical regulator of energy balance and acutely stimulates food intake, leading to increased body weight gain. Transgenic mouse models targeting the MCH system revealed that the loss of MCH or its receptor MCHR1 increased energy expenditure and locomotor activity. MCHR1 expression is widespread but the function and contribution of first-order MCH-responsive neurons is not known. We recently showed that the highest density of MCHR1-expressing cells is GABAergic, especially in the accumbens nucleus. Furthermore, the accumbens partly mediates MCH locomotor actions. By selectively deleting MCHR1 from cells expressing the vesicular GABA transporter (vGAT), we tested if GABAergic neurons mediate MCH effects on body weight, energy expenditure or locomotor activity. We first generated the *MCHR1-flox* mouse and crossed it to the *vGAT-cre* mouse; the resulting conditional knockout is designated as *vGAT-MCHR1-KO*. *In situ* hybridization showed the absence of MCHR1 from GABAergic regions, most notably in the caudate putamen, accumbens and arcuate nucleus. MCHR1 hybridization was unaffected in glutamatergic regions, including the pyramidal cells in the cerebral cortex and hippocampus and paraventricular

hypothalamic nucleus. We next compared differences in body weight and locomotor activity of female *vGAT-MCHR1-KO* mice to their *vGAT-cre* controls. *vGAT-MCHR1-KO* mice were 11% leaner, with 20% less body fat, and had 70% greater total energy expenditure. However the most impressive difference was their 93% increase in total baseline ambulation. Blocking dopamine reuptake with GBR12909 systemically induces hyperactivity. Consistent with our previous report that increased dopaminergic tone underlies the hyperactivity of MCH-deficient mice, we found that *vGAT-MCHR1-KO* mice had an enhanced and prolonged response to GBR12909, which produced a two-fold increase in cumulative activity lasting more than 5 hours. In aggregate, these results indicate that MCH acts partly via inhibitory GABAergic neurons to regulate body weight and energy expenditure. Furthermore, these findings indicate that MCHR1 activation on GABAergic neurons regulate dopaminergic tone that underlie MCH-mediated ambulatory activity. The identity of the specific GABAergic neurons underlying MCH-mediated ambulatory activity is not known. However we may infer that those critical GABAergic cells will receive strong dopaminergic projections. We speculate that MCH-mediated GABAergic signaling from accumbens neurons inhibits mesolimbic dopamine transmission.

Title: MANF is a neurotrophic factor involved in the regulation of feeding behavior and energy homeostasis

Authors: ***S. YANG**, S. LI, X.-J. LI;
Human Genet., Emory Univ., Atlanta, GA

Abstract: MANF is a newly identified, ubiquitously expressed neutrophic factor that is found to be neuro-protective in several disease models, including Parkinson's Disease, stroke and Spinocerebellar Ataxia 17. Emerging evidence suggests that MANF is an ER stress inducible protein, and possesses anti-apoptotic properties. However, the exact cellular functions of MANF, especially in the central nervous system, remain poorly understood. We have generated a

transgenic mouse model, which overexpresses MANF in the central nervous system via mouse prion promoter. Western blotting and immunohistochemistry confirmed that transgenic MANF is expressed in various brain regions. Interestingly, MANF transgenic mice developed significant obesity at the age of 4-month. By examining food intake, we found that the increased adiposity in transgenic MANF mice is due to hyperphagia, suggesting that MANF may be important for regulating feeding behavior. We are currently in the process of studying molecular mechanisms underlying MANF-mediated feeding behavior.

Title: Energy homeostasis and food intake alterations in mice lacking central serotonin

Authors: ***M. ANGOA-PEREZ**[1,2], J. G. GRANNEMAN[2,3], R. G. MACKENZIE[1], D. M. KUHN[1,2];
[1]Dept. of Psychiatry and Behavioral Neuroscien, Detroit, MI; [2]Res., Res. & Develop. Service (11R), John D. Dingell VA Med. Ctr., Detroit, MI; [3]Pathology, Wayne State Univ., Detroit, MI

Abstract: Energy homeostasis and feeding regulation are important adaptive responses critical for survival. Neuropeptide Y (NPY) is an important central regulator of food consumption and energy expenditure. This 36-aminoacid peptide is highly expressed in the hypothalamus but also can be found in other areas including the hippocampus and thalamus. Mammalian studies have shown a link between serotonin and NPY in the acute regulation of feeding and energy balance and central serotonin is considered a powerful anorexic agent. Therefore, we aimed to investigate the effects of the lack of brain serotonin on NPY expression and food intake. For this, we used mice genetically depleted of tryptophan hydroxylase-2 (TPH-2), the rate limiting enzyme in the synthesis of brain serotonin. We assessed body weight and food intake under ad libitum conditions and after periods of fasting in TPH-2 knockout (KO) and wild type (WT) control mice. Expression of NPY in the hypothalamus, hippocampus and thalamus was also evaluated in both genotypes. The results showed a significant decrease in expression of NPY in hippocampus, thalamus and hypothalamus in KO animals compared to WT controls. KO mice showed an increase in food intake under normal conditions but body weight was not significantly increased in these mice. KO mice showed a greater drop in body weight after fasting compared to WT mice. In addition, food consumption of KO mice was higher after being allowed to eat for 4

hours after fasting but normalized by 24 h. These results indicate that central serotonin is involved in the expression of NPY and consequently in the modulation of food intake and energy homeostasis.

Title: Changes in the immunoreactivity of c-Fos and α-MSH in the arcuate nucleus by activation of MC3 receptors

Authors: *D. DIAZ-URBINA, F. CORTES-SALAZAR, J. O. SUAREZ-ORTIZ, R. E. ESCARTÍN-PEREZ, V. E. LOPÉZ-ALONSO, J. M. MANCILLA-DÍAZ;
Facultad De Estudios Superiores Iztacala- UNAM, Tlalnepantla, Mexico

Abstract: The aim of the present work was evaluate the effects of the activation of cerebral MC3 melanocortin receptors (MC3r) on food intake (high-fat, HF) and the behavioral satiety sequence (BSS), as well as on c-Fos and α-MSH immunoreactivity in the arcuate nucleus of the hypothalamus (ARC). METHODS: Forty male Wistar rats (200-230g) were feed with a HF diet (45% kcal from fat), and after 2 days of habituation, animals were esteriotaxically implanted with guide cannulas in the lateral ventricle. After 3 days of post-surgery recovery, experimental subjects had access to the HF diet during 10 additional days. At the end of the HF diet exposure (10th day, 1h before the onset of the dark cycle) rats received intra-ventricular injections of vehicle (saline+saline, control group), MC3r agonist (saline+[D-trp8]-γ-MSH, agonist group), or MC3r antagonist (SHU9119+saline, antagonist group). After i.c.v injections, rats were video-recorded during 1 h and the analysis of BSS was conducted. Finally, rats were sacrificed and their brains extracted and processed for immunohistochemistry. RESULTS: Intra-ventricular administration of [D-trp8]-γ-MSH decreased food intake (g) in comparison to control group. In contrast, administration of SHU9119 stimulated HF diet consumption (g) compared to the

agonist group. Moreover, injection of [D-trp8]-γ-MSH reduced the number of α-MSH-positive neurons in the ARC, while intra-ventricular injection of SHU9119 increased the number of c-Fos-positive neurons and decreased α-MSH- immunoreactivity in the ARC. According to the BSS analysis, i.c.v administration of [D-trp8]-γ-MSH induced disruption of the satiety process (BSS). On the contrary, injection of SHU9119 did not altered typical behavioral pattern of BSS. CONCLUSION. Activation of MC3r reduced intake of a HF diet by interrupting the satiety sequence, and this effect may be related to the reduction of α-MSH immunoreactivity in the ARC. On the other hand, antagonism of MC3r stimulated HF diet consumption and preserved the behavioral pattern of the BSS, probably as a result of the reduction of the α-MSH and/or by activation of orexigenic neurons in the ARC (as revealed increase of c-Fos immunoreactivity).

Title: Ghrelin receptors in the VTA mediate stress induced changes in caloric intake during chronic social defeat

Authors: *S.-B. PARK[1], T. RODRIGUES[1], C. WALLACE[2], K. MEZHER[1], L. HYLAND[1], M. KLEIN[3], A. EDWARDS[1], Z. R. PATTERSON[1], H. MACKAY[1], A. ABIZAID[1];
[1]Neurosci., [2]Psychology, Carleton Univ., Ottawa, ON, Canada; [3]Pharmacol., Biomed. Sci. Institute, Univ. of São Paulo, São Paulo, Brazil

Abstract: Ghrelin, a gut-derived peptide hormone, is associated with feeding, energy balance, and the stress response. Exposure to stressors lead to elevated plasma levels of ghrelin, and these are associated with metabolic changes generated to meet the demands of the stressor. In mice, exposure to chronic social defeat leads to increases in caloric intake, and in particular, the intake of carbohydrate rich diets, and these effects are mediated in part by increased ghrelin secretion. It is not, however, the site at which ghrelin acts to mediate this effect. To determine this, we examined differences in the expression of the ghrelin receptor (GHSR) in regions of the brain that are associated with food intake, and the stress response including the ventral portion of the hypothalamus (vHYP), ventral tegmental area (VTA), prefrontal cortex (PFC), and the hippocampus (HIPP). As expected, exposure to chronic social defeat resulted in elevated plasma

ghrelin level ($p. < 0.05$), and significant changes in GHSR mRNA expression that were site dependent. Of these, the VTA was the only region where GHSR mRNA expression was significantly elevated ($p. < 0.05$). To examine the relevance of elevated GHSR expression in the VTA, we conducted an experiment where animals received a GHSR antagonist (JMV2959) or vehicle chronically infused into the VTA via cannula attached to the osmotic minipump while being stressed. Stressed mice treated with JMV2959 showed attenuated intake of the carbohydrate rich diet compared to stressed animals receiving vehicle, suggesting that GHSR in the VTA is important for the increase in carbohydrate intake during chronic social defeat.

Title: Emesis elicited by thapsigargin administration in the least shrew is due to activation of ERK1/2 signaling and Substance P release in the brainstem

Authors: W. ZHONG, S. CHEBOLU, *N. A. DARMANI;
Coll Osteo. Med. Pacific, Western Univ. Hlth. Sci., Pomona, CA

Abstract: Thapsigargin inhibits the Ca2+-transporter ATPase mediated uptake of Ca2+ into sarcoplasmic/endo-plasmic reticulum, thereby enhancing the cytoplasmic free concentration of Ca2+. Previously we had proposed that Ca2+ mobilization functions as a critical factor in the induction of emesis. In the present study, we established that i.p. injection of thapsigargin induces vomiting in a bell-shaped manner in the least shrew, with maximal efficacy (100%) at its 0.5 mg/kg dose. We then explored the potential mechanisms associated with this observation. As shown by immunohistochemistry, thapsigargin (0.5 mg/kg) triggered the activation of c-Fos and pERK expression in the brainstem dorsal vagal complex (DVC) emetic nuclei including the area postrema (AP), nucleus tractus solitarius (NTS) and dorsal motor nucleus of the vagus (DMNX). In addition, thapsigargin (0.5 mg/kg, i.p.) led to enhancements of 5-HT and Substance P (SP) immunoreactivity in brainstem sections. We then assessed the antiemetic potential of a selective 5-HT3- and NK1 -receptor antagonist, palonosetron and netupitant respectively. Nutepitant but not palonosetron attenuated evoked emetic parameters, suggesting that thapsigargin-elicited vomiting is mediated by NK1Rs and is independent of 5-HT3R activation. In addition,

pretreatment with the ERK inhibitor PD98059 (5 mg/kg., i.p.) 30 min prior to thapsigargin administration abolished thapsigargin-evoked responses including increases in SP content and vomiting behavior. In sum, this is the first study to demonstrate that the Ca2+ mobilizing agent thapsigargin, induces emesis, via the ERK-SP-NK1R pathway in the brainstem. This work was supported by WesternU funds.

Title: Impact of cafeteria diet and voluntary exercise on behavioural effects of dynorphin and orexin peptides in the PVN

Authors: *C. E. PEREZ-LEIGHTON, L. GAC;
Univ. Andres Bello, Santiago, Chile

Abstract: The orexin/dynorphin (ox/dyn) neurons release both orexin and dynorphin, neuropeptides that affect food intake and energy expenditure. While the orexins peptides have been extensively studied, less is known about the role of dynorphin peptides released from these neurons. How orexin and dynorphin peptides act together to modulate energy balance is unclear. The hypothalamic paraventricular nucleus (PVN) is important to feeding behavior and physical activity, and recent work from our laboratory has focused on the interaction between orexin and opioid/non-opioid dynorphin peptides in the PVN. To understand how obesity modulates the effects of orexin and dynorphin peptides on food intake, we cannulated Balb/c mice (n = 16) aiming at the PVN. Next, using a repeated measured design, orexin-A (0, 200, 400 pmol) and the opioid DYN-A_{1-13} (0, 0.625, 1.25, 2.5, 5 nmol) were injected into PVN before and after feeding with either a control diet (standard rodent chow, n = 8) or cafeteria diet (CAF diet, n = 8) for 10 weeks. Prior to the dietary interventions, DYN-A_{1-13} and orexin-A both significantly increased short-term chow intake (2h post-injection, one-way repeated measured ANOVA, $P < 0.05$). Mice fed CAF diet were classified as either obesity prone (OP, n = 4) or obesity resistant (OR, n = 3) based on whether their increase in fat mass percent was higher (OP) or lower (OR) compared to

maximum value of control fed mice. In OP and control diet-fed mice, we observed no change in the ability of orexin-A or DYN-A_{1-13} to increase short-term chow intake relative to the pre-dietary treatment (paired t-test per dose, $P > 0.05$). However, in OR mice we observed a trend toward increased ability of orexin-A to promote short-term chow intake (paired t-test, orexin-A at 400 pmol dose, $P = 0.13$) and no trends for changes in the effectiveness of DYN-A_{1-13}. Currently we are repeating this experiment and extending these results by testing if voluntary physical activity (wheel running) alters gene expression of the orexin and dynorphin genes in the ox/dyn neurons in the lateral hypothalamus, and whether these changes influence the behavioral effects of orexin and dynorphin peptides injected into PVN. These experiments will improve our understanding of the mechanisms by which the orexin/dynorphin neurons control energy balance.

Title: A new obesity model reveals the hypophagic properties of PACAP involve the regulation of homeostatic feeding in the ventromedial hypothalamic nucleus and hedonic feeding in the nucleus accumbens

Authors: *M. M. HURLEY, B. MAUNZE, J. M. RESCH, M. M. FRENKEL, M. J. REILLY, M. BLOCK, D. A. BAKER, S. CHOI;
Biomed. Sci., Marquette Univ., Milwaukee, WI

Abstract: Binge eating in humans is a complex disorder that often involves discrete, compulsive feeding sessions of highly palatable foods even in the absence of a deprivation state or hunger. Binging can be effectively modeled in rodents by providing subjects with limited access to a palatable food source (Western Diet; WD) as an adjunct to ad lib access to normal chow (Standard Chow; SC). Although this design recapitulates several fundamental characteristics observed in binge eating disorder, the binge eating observed in this paradigm is likely a product of both hedonic and homeostatic drives with the need to balance energy stores still present. To isolate these feeding drives, we have developed a novel feeding regimen that modifies the classic limited access binge model to effectively delineate and separate homeostatic feeding from motivational feeding. This is achieved by entraining male Sprague-Dawley rats to a restricted feeding schedule (two hours per day) of SC followed by a short 15 minute limited access meal of

either SC or WD (Restrict Fed-Limited Access; RFLA). The RFLA paradigm allows for the examination of pituitary adenylate-cyclase activating polypeptide (PACAP) on palatable food consumption in a fully satiated subject. PACAP has previously been shown to suppress feeding behavior when injected into the hypothalamus. In the current study, PACAP injected into the ventromedial hypothalamic nuclei (VMN) suppressed the two hour homeostatic SC meal, but not the subsequent 15 minute limited access meal of WD. By contrast, PACAP bilaterally administered into the nucleus accumbens (NAc) produced the opposite effect with PACAP suppressing the consumption of WD but not SC. Thus, PACAP mediated signaling in the VMN appears to be involved in homeostatic regulation of energy stores, whereas PACAP signaling in the NAc regulates feeding driven by palatability or hedonic qualities.

Title: Synergistic interaction between cholecystokinin agonist, (pGlu-Gln)-CCK-8 and urocotin-1 injected intraperitoneally on feeding in rats

Authors: *L. WANG, Y. TACHÉ, J. R. REEVE, Jr.;
UCLA, Los Angeles, CA

Abstract: Cholecystokinin (CCK) is one of the gut hormones signaling the brain to induce short term satiety (Dockray GJ, J. Physiol. 2014), and urocortin (Ucn)-1, a neuropeptide of corticotropin-releasing factor family reported to inhibit food intake when administered systemically in rodents (Wang L et al., AJP 2001, Peptides 2011; Hope PJ et al., 2000). Previously we showed that Ucn-1 or Ucn 2 has synergistic effect with CCK to inhibit food intake in overnight-fasted mice (Gourcerol G et al., 2007). (pGlu-Gln)-CCK-8 sulfated is a long acting CCK agonist shown in mice to reduce food intake and body weight (Irwin N et al., Diabetology 2012, Biochim Biophys Acta 2013). In this study, we assessed the synergistic effect of (pGlu-Gln)-CCK-8 and Ucn-1 on food intake and meal pattern of nocturnal feeding in non-fasted rats using an automated episode feeding monitoring system. SD rats were acclimated for 1 week to the feeding monitoring system (BioDAQ, Research Diets, Inc.). Peptides and vehicle (saline) were injected intraperitoneally (ip) before the onset of the dark phase. (pGlu-Gln)-CCK-8 was

tested first for effective doses at 0.3, 1 and 2.5 μg/kg (0.2, 0.6 and 1.8 nmol/kg). (pGlu-Gln)-CCK-8 at 0.6 and 2.5 μg/kg reduced the 2 h dark phase food intake by 48% and 78%, respectively compared to ip saline. Meal structure analysis showed significantly reduced meal size (-36% and -77%) and frequency (-41% and -53%), bouts (-46% and -68%) and time spent on meals (-53% and -69%) and prolonged latency to the 1st meal (69.9 ± 18.4 and 96.0 ± 13.3 vs 5.4 ± 2.8 min in ip saline). The changes in meal structures were no longer observed in 4-h cumulative feeding. Neither (pGlu-Gln)-CCK-8 at 0.3 μg/kg nor Ucn-1 at 10 μg/kg showed significant effect on the 2 h food intake and meal pattern. The peptides co-injection reduced the 2-h food intake by 60%, meal size by 66% and rate by 45%, and prolonged the onset of the first meal (60.5 ± 18.3 vs. 0.5 ± 0.1 min). Ucn-1 alone had a delayed inhibitory effect on the 4-h cumulative food intake (-32%) and meal size (-29%) and rate (-20%), and (pGlu-Gln)-CCK-8 plus Ucn-1 resulted in a higher inhibitory response (-48%, -46% and -37% respectively) which did not reach significance compared to Ucn-1. During the 12 h of dark phase, there was a significant synergistic reduction of the cumulative food intake (-20%) and average meal size (-36%). However, the satiety ratio was not significantly changed. These data indicate that Ucn-1 and (pGlu-Gln)-CCK-8 potentiate each other to induce a long-lasting reduction of dark phase food intake with alterations of meal structures (delayed onset of feeding and reduced meal size and eating rate) in rats, indicative of inhibition of orexigenic signals.

Title: The opioid beta-endorphin in the arcuate nucleus is involved in food intake

Authors: *Q. WEI, S. MOORE, S. WATSON, G. MURPHY, H. AKIL;
Mol. Behav. Neurosci. Inst., Ann Arbor, MI

Abstract: The arcuate nucleus (Arc) of the hypothalamus is an important site for the central regulation of food intake, energy expenditure, and body weight. There are two classes of peptide-producing neuronal populations in the arcuate nucleus that are thought to exert opposing actions

on feeding -- the orexigenic neurons that express NPY and AGRP, and the anorexigenic neurons that express POMC and CART. However, it should be noted that the gene encoding the precursor proopiomelanocortin (POMC) gives rise to two different groups of peptides, the melanocortins and beta-endorphin that are putatively co-released at axon terminals, and yet are thought to have opposing effects on feeding behavior. The role of melanocortins in the regulation of feeding and metabolism has been well defined by pharmacological and genetic methods, indicating an anorectic effect. On the other hand, pharmacological studies have generally indicated that opioids stimulate food intake, the opposite effect of melanocortins. While these components have been studied in isolation, we are unaware of studies that have selectively activated POMC neurons directly, thereby causing the release of both melanocortins and beta-endorphin while studying the impact on food intake. Thus, the current study used optogenetic stimulation to examine the effects of activating POMC neurons in the Arc on food intake in mice. In addition, we studied the impact on pain regulation, since this is one of the classical and well established effects of beta-endorphin on behavior. Surprisingly, activation of both dorsal and lateral Arc or of the lateral Arc alone led to a rapid and dramatic increase in food intake. This increased feeding could be largely blocked by pretreatment with the opioid receptor antagonist, naloxone, in a dose-dependent manner. Activation of both the dorsal and lateral Arc also induced an acute analgesic effect, which could be completely blocked by naloxone. In contrast, there was no analgesic effect of optogenetic stimulation in the lateral Arc. We also evaluated the cFos response following optogenetic stimulation in the Arc. Activation of the Arc resulted in an intensive cFos response in several brain regions. Importantly, the cFos response in these brain areas was abolished by pretreatment with naloxone. Together our findings demonstrate that the acute increase in food intake following activation of the arcuate is mediated by activation of the opioid system, and likely engages an extensive neural system in the brain. The exact physiological conditions that engage the appetite enhancing and appetite suppressive effects of POMC neurons remain to be fully understood.

Title: Neurotensin receptor 1-expressing neurons in the ventral tegmental area modify energy balance

Authors: *H. M. BATCHELOR[1], H. WOODWORTH[1], J. BROWN[1], R. BUGESCU[1], P. FULLER[2], G. LEINNINGER[1];
[1]Michigan State Univ., East Lansing, MI; [2]Neurol., Harvard Med. Sch., Boston, MA

Abstract: Dopamine (DA) neurons in the Ventral Tegmental Area (VTA) and Substantia Nigra (SN) modulate feeding, drinking, and locomotor behaviors, but the signals that regulate DA neurons to dictate behavioral output remain unclear. We examined how the neuropeptide neurotensin (Nts) could modulate DA-mediated behaviors. Nts signals via the G-protein coupled receptors neurotensin receptor-1 (NtsR1) and neurotensin receptor-2 (NtsR2). To determine whether NtsR1 or NtsR2-expressing neurons are present in the midbrain we crossed NtsR1-Cre and NtsR2-Cre mice onto a cre-mediated GFP reporter background, such that only NtsR1 or NtsR2 neurons express GFP and can be visualized. Examination of these mice revealed NtsR1 and NtsR2 neurons in the VTA, most of which also contain tyrosine hydroxylase, and are therefore DAergic. We also identified NtsR1 neurons in the SN, but found essentially no NtsR2 neurons in this brain region. Together, these data suggest that NtsR1 is the predominant receptor isoform in midbrain neurons and is expressed on DA neurons. Since NtsR1 is implicated in the regulation of ingestive behavior and locomotor activity we further hypothesized that disruption of midbrain NtsR1 signaling would impair energy balance. We therefore injected adult NtsR1-Cre mice in the VTA with either a cre-dependent viral vector expressing GFP (generating NtsR1-GFP mice with intact NtsR1 neurons) or the diphtheria toxin subunit A (DTA) to selectively ablate NtsR1 neurons (NtsR1-DTA mice). NtsR1-DTA mice exhibited increased locomotor activity, oxygen consumption and food intake compared to NtsR1-GFP controls. Despite their increased feeding, however, the NtsR1-DTA mice remain leaner than their NtsR1-GFP counterparts, suggesting improved metabolic efficiency. Thus, NtsR1 neurons in the VTA are important for dictating locomotor activity and ingestive behavior, and suggest a role for Nts signaling in modulating DA-mediated behaviors and energy balance.

Title: PTP1B deficiency attenuates hypothalamic inflammation through the activation of Jak2-Stat3 signaling pathway downstream of TNFα receptor under high fat diet conditions

Authors: *T. TSUNEKAWA, R. BANNO, M. SUGIYAMA, T. TOMINAGA, T. ONOUE, M. GOTO, H. ARIMA;
Dept. of Endocrinol. and Diabetes, Nagoya Univ. Grad. Sch. of Med., Nagoya, Aichi, Japan

Abstract: Protein tyrosine phosphatase 1B (PTP1B) negatively regulates leptin signaling in the hypothalamus. While a high fat diet (HFD) causes leptin resistance and obesity, whole body or brain specific PTP1B deficiency protects against obesity due to HFD by enhancing leptin sensitivity. PTP1B has also been implicated in the regulation of inflammatory responses in the periphery, while the role of PTP1B in the hypothalamic inflammation under HFD conditions has not been fully elucidated. In the present study, we investigated the effects of PTP1B deficiency on the expression of tumor necrosis factor-alpha (TNFα) and interleukin-10 (IL-10) expression in the hypothalamus. TNFα mRNA expression in the hypothalamus was significantly decreased while IL-10 mRNA expression was significantly increased in the PTP1B whole body knock-out mice (KO) compared to wild-type mice (WT) on HFD at the age of 7 weeks when body weight and visceral fat pad weight were similar between genotypes. While incubation with TNFα significantly increased TNFα mRNA expression in the hypothalamic explants, the expression levels were significantly decreased in KO compared to WT. In contrast, IL-10 mRNA expression was significantly increased with TNFα treatment in the KO hypothalamic explants compared to WT. Incubation with TNFα also increased the phosphorylation of both Jak2 and Stat3 in hypothalamic explants, and the effects were more prominent in KO than in WT, while other signal-transducing protein phosphorylation such as p65, p38, JNK and ERK were similar between genotypes. Incubation with JSI-124 or S31-201, inhibitors of stat3 phosphorylation, suppressed TNFα-induced Stat3 phosphorylation and cancelled the down-regulation of TNFα and up-regulation of IL-10 mRNA expression in KO hypothalamic explants treated with TNFα without affecting other signal-transducing protein phosphorylation such as p65, p38, JNK and ERK. These results suggest that PTP1B deficiency activates Jak2-Stat3 signaling pathways downstream of TNFα receptor, leading to the attenuation of hypothalamic inflammation under HFD conditions.

Title: Comparison between water and stevia intake. Expression of IGF-II and its receptor IGF-IIR in Central Nervous System from BALB/c mice

Authors: *E. MORALES, I. CONTRERAS, J. A. ESTRADA;
Univ. Autonoma Del Estado De México, Toluca, Mexico

Abstract: Abstract. Currently, chronic non-communicable pathologies like diabetes mellitus type 2, obesity, hypertension and metabolic syndrome are related to dietary modifications, especially excess intake of carbohydrates, for which alternatives to conserve the sweetness without adding calories have been found in the form of sweeteners, such as esteviol derivatives. Although sweeteners made from esteviol are considered safe, the effects of chronic high-dose intake of these compounds have not been fully determined. The objective of this study was to determine the expression of IGF-II and IGF-IIR in the brain and spinal cord of 8 week old mice supplemented with commercial esteviols for 6 weeks. After supplementation, the brain and spinal cord were used for protein extraction and analyzed by western blot. Our results showed no differences in IGF-II expression in the central nervous system of supplemented mice. An additional band ≥ 250 KDa was found to be expressed differentially in the brain and spinal cord of the animals. It may correspond to the molecule bound to its receptor. We were unable to detect IGF-IIR; however, we found additional bands at ~ 130 KDa, increased in the control group, and another band at ~ 50 KDa, increased in the esteviol group, both from brain tissue. Our data suggest there are no differences in IGF-II or IGF-IIR expression in mice supplemented with esteviols.

Title: Brain-derived insulin is induced by Wnt signaling and secreted in the hypothalamic cells

Authors: *J. LEE[1], K. KIM[1], S.-W. YU[1], E.-K. KIM[1,2];
[1]Dept. of Brain and Cognitive Sci., Daegu Gyeongbuk Instititue of Sci. and Technolo, Daegu, Korea, Republic of; [2]Neurometabolomics Res. Ctr., Daegu Gyeongbuk Inst. of Sci. and Technol., Daegu, Korea, Republic of

Abstract: Insulin plays diverse roles in the brain. Insulin is produced by pancreatic β-cells, and it is a major source of brain insulin, which passes cross the blood-brain barrier. Recent studies support that insulin is produced locally within the brain. However, the mechanisms underlying the production and the distinct function of this brain-derived insulin (BDI) are unknown yet. Here, we examined the effect of Wnt3a, which is involved in the synthesis of insulin in the pancreas, in BDI expression in the hypothalamic cell line. Wnt3a treatment significantly increased the expression of *Ins2* gene, which is the predominant form in the mouse brain, through the activation of Wnt/β-catenin signaling via GSK3β. Moreover, the concentration of insulin in cultured media was higher in Wnt3a-treated group than non-treated group. Interestingly, neurogenic differentiation 1 (NeuroD1), which is a target of Wnt/β-catenin signaling and one of transcription factors for insulin, was also induced by Wnt3a treatment in a time- and dose-dependent manners. Knockdown of NeuroD1 through lentiviral shRNA reduced the basal expression of *Ins2*, and suppressed the Wnt3a-induced *Ins2* gene expression. Taken together, these results suggest that BDI expression is regulated by Wnt/β-catenin/NeuroD1 pathway in the hypothalamus.

Title: Lateral hypothalamic neurotensin neurons engage the mesolimbic dopamine system to regulate water intake and locomotor activity

Authors: *H. WOODWORTH, H. BATCHELOR, J. BROWN, R. BUGESCU, G. LEINNINGER;
Michigan State Univ., East Lansing, MI

Abstract: The lateral hypothalamic area (LHA) acts in concert with dopamine (DA) neurons in the ventral tegmental area (VTA) to regulate the motivation to feed, drink and move. It remains unclear, however, how specific LHA neuronal populations modify ingestive and locomotor behaviors. We examined how LHA neurons expressing the neuropeptide neurotensin (Nts) engage the DA system to regulate behavior. LHA Nts neurons project to the VTA, where many DA neurons co-express neurotensin receptor 1 (NtsR1). Furthermore, these VTA NtsR1-DA neurons project to ventral striatal brain regions that regulate ingestive behavior and locomotor

activity, such as the nucleus accumbens (NA). Selective activation of LHA Nts neurons using DREADD technology increases pCREB expression in the VTA and NA, confirming that LHA Nts neurons functionally modulate the mesolimbic DA system. Next we examined the physiological role of this circuit by activating LHA Nts neurons in normal mice (WT) and in mice that lack NtsR1 (NtsR1KO mice). Activation of LHA Nts neurons increased locomotor activity and oxygen consumption in WT and NtsR1KO mice, but these effects were blunted by the DA receptor 1 (DR1) antagonist, SCH23390. Acute activation of LHA Nts neurons did not alter chow intake in sated WT mice, but it significantly increased their water consumption. Intriguingly, drinking behavior was not blunted by inhibition of DR1, but was suppressed in NtsR1KO mice, suggesting a specific role for NtsR1 in ingestive behavior. Together, these data reveal that LHA Nts neurons engage the mesolimbic DA system to modify drinking and locomotor behaviors via distinct signaling mechanisms. Intact action via the LHA Nts neuronal circuit is thus crucial for coordinating physical activity and intake of natural rewards, such as water.

Title: Galanin neurons in the lateral hypothalamus modulate locomotor activity

Authors: *E. QUALLS-CREEKMORE, S. YU, C. MORRISON, H. MUNZBERG; Central Leptin Signaling, Pennington Biomed. Res. Ctr., Baton Rouge, LA

Abstract: The lateral hypothalamus (LHA) is an important integrator of reward and appetitive behavior. Previous work in our lab has shown that LHA galanin (Gal) neurons which co-express leptin receptors (LepRb) are implicated in food reward. Using the incentive runway test, we found that mice lacking the leptin receptor on galanin neurons (Gal-LepRbKO) retrieved a palatable treat faster, were less distracted, and showed increased running speed. LHA galanin neurons strongly project to LHA orexin neurons and also to the locus coeruleus, both regions

which are important regulators of reward as well as arousal and locomotor activity. Because locomotor activity is an important component of both feeding behavior and reward, we hypothesized that altered locomotor activity in Gal-LepRbKO mice may contribute to increased performance in the incentive runway test. In this study, we investigated the role of LHA galanin and leptin signaling in locomotor activity. We tested if the increased completion speed of Gal-LepRbKO mice could be attributed to an increase in gross locomotor activity. Gal-LepRbKO show increased gross locomotor activity, which is only significant during the light cycle. Next, we examined the effect of chemogenetic activation of LHA galanin neurons on gross locomotor activity as well as general locomotor activity in the open field test. Here we found that activation of LHA galanin neurons resulted in a robust increase in gross locomotor activity as well as increased distance traveled and average speed in the open field test. Thus, LHA galanin neurons clearly modulate locomotor activity, but the importance of Gal-LepRb neurons vs. the entire population of LHA galanin in select aspects of locomotor activity (e.g. motivational aspect of food reward behavior, general locomotor activity, or stress related activity) remains unclear and is currently under investigation.

Title: Prepro-orexin gene promoter is regulated *in vitro* by the transcription factor ebf2 in glial and neural cells

Authors: *R. VIDALTAMAYO[1], A. SÁNCHEZ-GARCÍA[2], R. ORTIZ-LÓPEZ[2], V. ZOMOSA-SIGNORET[2];
[1]Univ. of Monterrey, San Pedro, Mexico; [2]Univ. Autónoma de Nuevo León, Monterrey, Mexico

Abstract: Orexins or hypocretins are neurotransmitters produced by a small population of neurons in the lateral hypothalamus. This family of peptides modulates sleep-wake cycle, arousal and feeding behaviors, and the mechanisms regulating their expression are not completely understood. There is an interest in defining the key molecular elements in orexin regulation, as

these may serve to identify targets to generate novel therapies for sleep disorders, obesity and addiction. We have previously shown that orexin levels decrease in ebf2 KO mice and that the promoter region of the prepro-orexin gene contains two *olf-1* binding sites. Moreover, overexpression of the transcription factor ebf2 induces activity from this promoter *in vitro*, in a non-neural cell line. Here, we analyze the regulation of expression of luciferase driven by the putative promoter region of the murine prepro-orexin gene in lentivirus-transduced C6 glial cells overexpressing ebf2 and in the mHypoA-41 line, that is a cell line derived from male adult C57Bl6 mouse hypothalamic neurons, where we were able to show expression of the ebf2 transcription factor. Both hypothalamic and ebf2-expressing glial cells showed increased luciferase signals, with respect to the original parental C6 line (ANOVA, Bonferroni´s post-hoc test: $P<0.05$). Deletion of the olf1-like proximal to the transcription start site increases the luciferase signal, while the deletion of the distal olf1-like site results in a signal decrease. Mutations of either, or both, *olf1*-like sites do not alter luciferase expression. Our results show that the transcription factor ebf2 can induce gene expression driven by the promoter region of the prepro-orexin gene in different cell lineages.

Title: Effects of oral and intragastric glucose delivery on insulin receptor phosphorylation in nucleus accumbens

Authors: *C. WOODS[1], Z. GUTTMAN[2], A. RABINOWITSCH[3], R. KOLARIC[3], K. JONES[3], S. CABEZA DE VACA[3], A. SCLAFANI[4], K. CARR[3];

Abstract: Insulin is a metabolic hormone synthesized in beta cells of the pancreas and released upon detection of blood glucose. Insulin actively crosses the blood-brain-barrier and insulin receptors are distributed widely throughout the brain. Insulin activity is dependent upon brain region, and insulin dysregulation in the brain is associated with a variety of disorders. Stouffer et al (presentation, SfN 2012, New Orleans, LA) used fast scan cyclic voltammetry in brain slices

to demonstrate that insulin increases evoked extracellular dopamine concentrations in the Nucleus Accumbens (NAc). The enhancing effect of insulin was greatest in chronically food-restricted (FR), and least in diet-induced obese (OB) rats. In order to translate these findings into an *in vivo* model, we investigated whether consumption of glucose triggers a short latency activation of insulin receptors (IR) in the NAc. Rats that drank 8 ml of 16% glucose during a 7 minute access period displayed increased IR phosphorylation relative to rats with 7 minute access to water. To eliminate the cephalic phase insulin response and achieve precise control over rate and amount of glucose delivery, rats received a 7 minute intragastric (IG) infusion of 8 ml of either 16% glucose or water. IG glucose increased NAc IR phosphorylation at 7 but not 17 or 27 minutes following initiation of infusion. To examine the effect of diet, the experiment was repeated in FR, OB and ad libitum (AL) rats. While both FR and AL rats displayed glucose-induced IR phosphorylation, OB rats did not. These findings parallel the results previously obtained in striatal slices. Finally, in a follow-up behavioral study it was demonstrated that inactivation of insulin, via NAc microinjection of insulin antibodies, interfered with formation of a flavor-glucose preference, while microinjection of IgG did not. Overall, these data suggest that glucose intake triggers a short latency activation of insulin receptors in the NAc which is dependent upon diet and contributes to reinforcement of preference for a flavor that signals a glycemic load. This work was supported by NIH grant DA033811 and the NSF GRFP.

Abstract: Orexin neurons originate in the hypothalamic region and project to different brain areas. They produce two different neuropeptides: orexin A (Orx A) and orexin B (Orx B) and two receptors for the orexin system has been characterized: OxR1 and OxR2. OxR1 binds orexin A with 30 nM affinity but has much lower affinity for orexin B, whereas OxR2 binds both orexin

peptides with similar high affinity. Several studies reported that orexinergic neurons in the lateral hypothalamus (LH) are involved in motivated behavior for drugs of abuse as well as natural rewards. In particular administration of orexin A has been shown to stimulate food consumption, and orexin signaling in VTA is implicated in intake of high-fat food. It has been shown that LH orexin neurons project to the ventral tegmental area (VTA) indicating that the VTA is an important site of action for orexin's role in reward processing. Mesolimbic dopamine (DA) in the nucleus accumbens (NAc) shell is also involved in the rewarding mechanisms of food consumption. Is there a cooperation between DA and Orx A? In our study we investigated by brain microdialysis the responsiveness of NAc shell DA transmission in food consumption after intravenous administration of Orx A encapsulated in different targeted and not-targeted stealth liposomes prepared using film hydration method. Orx A per se produced a later increase of DA in the NAc shell (peaking at 80 min sample) and strengthened the DA responsiveness in this area after sucrose pellets feeding. We registered also an increase of the number of eaten pellets. These effects on DA and on feeding were blocked by intraperitoneally injection of the antagonist of the OxR1 (SB 334867, 30mg/Kg). We can speculate that the strengthening of DA response during food consumption exerted by Orx A administration could increase the rewarding properties of food and could be one of the mechanisms that underlie food addiction. These findings could suggest new targets for a new treatment of eating disorders.

Title: Hippocampus and cortical plasticity following a virtual spatial memory intervention program promote spontaneous hippocampus-dependent navigation strategies in healthy older adults

Authors: *D. DUCHARME[1], D. SODUMS[1], K. KONISHI[1], L. DAHMANI[1], L. BHERER[2], V. D. BOHBOT[1];

Abstract: Aim: Studies conducted in our laboratory indicate that healthy individuals initially navigate virtual environments by using one of two spontaneous strategies: the hippocampus (HPC)-driven spatial memory strategy or the caudate nucleus-mediated stimulus-response strategy. The use of these strategies has been linked to increased functional activity and grey matter in their respective brain loci. Because the HPC is affected in both function and volume during normal aging, we created a computer-based spatial memory intervention program (SMIP) specially designed to stimulate this area by promoting the use of spatial memory strategies. Methods: Twenty one healthy older adult participants attended 16 1-hour sessions twice a week over the course of 8 weeks where they learn the relative positions of objects, landmarks, or rooms in virtual environments. Participants underwent a Magnetic Resonance Imaging scan before and after the SMIP as well as multiple virtual navigation tasks such as the 4-on-8 virtual maze to assess potential changes in spatial memory. The 4-on-8 virtual maze is a task that requires remembering the locations of 4 objects in an 8-arm radial maze. A probe trial whereby all landmarks are removed allows the discrimination of spatial versus response spontaneous navigational strategies because errors are made only in people who used landmarks. Results: After intervention, 11 of the 21 participants showed a significant increase in grey matter in the right posterior HPC. When comparing the responders (those who showed grey matter increase) and non-responder groups, it was found that responders had more probe errors on the 4on8 virtual maze ($p<0.05$). Furthermore, increases in grey matter positively correlated with number of errors during the probe trial ($r=0.78$, $p<0.001$), which is indicative of using a spatial strategy to learn the task. Conclusion: These results indicate the potential efficacy of a spatial memory intervention program at facilitating the spontaneous use of hippocampus-dependent spatial navigational strategies over stimulus-response strategies. Our results also show that the degree of increase in hippocampal grey matter following training is directly related to the extent of spatial memory strategy use.

Title: Landmark use during navigation is associated with increased visual attention to peripheral targets

Authors: B. DRISDELLE[1], K. KONISHI[3], P. JOLICOEUR[1], V. BOHBOT[3], *G. WEST[2,1]; [1]Univ. of Montreal, Montreal, QC, Canada; [2]Psychology, Univ. of Montreal, Outremont, QC, Canada; [3]McGill Univ., Montreal, QC, Canada

Abstract: Aim: When navigating, people adopt different strategies. The spatial strategy involves building relationships between landmarks in an environment to create a cognitive map. The response strategy, in contrast, entails learning a series of movements (e.g., left and right turns) from given positions that act as stimuli. The current study investigated whether different navigation strategies are associated with differences in visual attention performance during a target detection task. Methods: We measured participants' navigation strategies (response vs. spatial), using the 4-on-8 virtual maze (4/8VM). The 4/8VM consists of an 8-arm radial maze, in which 4 arms are accessible and 4 are blocked. Participants have to retrieve objects located at the end of the 4 accessible arms. Then, all 8 arms become accessible and participants have to retrieve objects now located in the 4 arms that were previously blocked. After participants have learned the task, a probe trial is given in which all landmarks are removed. The probe trial allows to dissociate spatial and response learners, as spatial learners make more mistakes compared to response learners Participants were divided into two groups based on their probe score which indicated those who used landmarks (n = 37) and those that did not (n = 16) during navigation. To measure differences in visual attention performance between both groups, we employed an ERP target detection task that was designed to elicit a robust ERP component, the N2pc (N-2-posterior-controlateral), a lateralized component thought to be modulated by target selection and distractor inhibition in the visual domain. The task had both central and peripheral target conditions. Results: Our results revealed a robust correlation between N2pc amplitude produced by peripheral targets and 4/8VM probe errors. Further, when comparing the N2pc amplitude of both groups, a main effect was found where the landmark group produced a larger N2pc than the no-landmark group. Corrected post-hoc comparisons confirmed that this difference was driven by the peripheral target trials. Conclusion: Our results indicate that individuals who rely on landmarks during navigation show increased deployment of visual attention to peripheral targets.

Title: Selective increase in hippocampus grey matter following a virtual spatial memory intervention program is associated with corresponding memory gains in healthy older adults

Authors: *D. SODUMS[1], K. KONISHI[1], L. DAHMANI[1], L. BHERER[2], V. BOHBOT[1]; [1]Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada; [2]CRIUGM, Dept. of Psychology, Univ. of Montreal, Montreal, QC, Canada

Abstract: Aim: Different navigation strategies dependent on separate memory systems are available to people when they navigate in a virtual environment. Specifically, the use of spatial memory strategies is associated with increased activity and grey matter in the hippocampus (HPC) while the use of stimulus-response strategies is associated with increased activity and grey matter in the caudate nucleus. Since healthy aging affects the function and volume of the HPC, we developed a computerized spatial memory intervention program (SMIP) to specifically stimulate this region. This program is designed to promote the use of spatial memory strategies, taking particular attention to avoid use of stimulus-response strategies Methods: Healthy older adult participants (n=21) underwent the SMIP or control condition (n=33). Each participant underwent a Magnetic Resonance Imaging scan before and after the SMIP and performed independent virtual navigation tasks, such as the Concurrent Spatial Discrimination Task (CSDLT), 4on8 virtual maze, and Go/No-Go task to assess changes in spatial memory. The CSDLT and Go/Go-No tasks are virtual 12-arm radial mazes in which participants have to learn the location of objects within 6 pairs of arms. The 4 on 8 virtual-maze is a task that requires remembering the locations of 4 objects in an 8-arm radial maze. VBM was used to regress grey matter increases with performance improvements on the pre/post intervention tasks. Results: After the SMIP, there was an increase in grey matter throughout cortex, including the bilateral HPC. Participants were categorized as responders (n=11) or non-responders (n=10) depending on whether they showed a significant increase in grey matter. In the responder group, the area with greatest increase in grey matter was the right posterior HPC. When correlating the amount of change in this region with the amount of change in navigation performance from pre- to post-training in all 21 participants, we found that increases in grey matter correlated with fewer trials needed to reach criterion on the 4-on-8 virtual-maze following the training program. There was a significant negative correlation between increase in grey matter and time spent time spent finding all the target objects in both the CSDLT and Go/No-Go tasks, following the SMIP. Conversely, those who did not show increases in grey matter showed no memory gains on the pre/post intervention tasks. Conclusion: These results show that increased grey matter of the HPC is associated with improved memory gains, on tasks independent of the SMIP. These findings suggest that the SMIP is effective at reducing memory deficits associated with loss of HPC grey matter during aging.

Title: Multivariate pattern analysis of human intracranial electrocorticography predicts location in a virtual spatial navigation task

Authors: *A. A. ROBBINS[1], P. HORAK[2], A. CONNOLLY[2], B. JOBST[2];
[1]Dartmouth Neurol., Lebanon, NH; [2]Neurol., Geisel Sch. of Med., Lebanon, NH

Abstract: Spatial navigation tasks are often used in experimental neuroscience to investigate the mechanisms of learning and memory. These tasks provide insight into the dynamics of the brain processes involved in memory tasks. In this study we recorded intracranial EEG (iEEG) from depth and strip electrodes that were implanted in patients with intractible epilepsy while they performed a spatial working memory task. We designed a virtual T-maze memory task (vTMT) for this purpose using the Valve™'s Source Engine. When performing the task, the subjects learn to travel to alternating sides of the maze in order to collect rewards. The vTMT has three levels, which differ in the number visual cues available to distinguish the two sides of the maze. iEEG data were collected at 1600Hz and down-sampled to 200Hz. We calculated a Morlet wavelet transform on 60 log-spaced frequency bands from 2-100Hz to determine the power and phase of each frequency band. The power data were used to train a linear discriminant analysis (lda) classifier to predict whether subject were in the central corridor or an arm of the maze. We were able to predict virtual locations with above chance accuracy ($p<0.05$, student's t-test) in a cohort of 5 subjects. We previously reported that beta power in the hippocampus is higher in the central corridor than in the choice arms of the vTMT. This analysis provides additional evidence that it is possible to distinguish the location of subjects in a virtual environment from iEEG recordings.

Title: The neural correlates of arithmetic learning in children: A fNIRS study

Authors: *M. SOLTANLOU[1,2,3], C. ARTEMENKO[4], T. DRESLER[4,5], F. HAEUSSINGER[5], S. HUBER[3], A. J. FALLGATTER[5,4], A.-C. EHLIS[5,4], H.-C. NUERK[1,3,4];

Psychiatry, Eberhard Karls Univ., Tuebingen, Germany

Abstract: Arithmetic training can improve the mathematics competence. For multiplication, this competence increase is reflected in a shift from effortful processing to fast retrieval, which is accompanied by specific changes in brain activation patterns. Studies in adults show less activation in frontal areas such as the inferior frontal gyrus and parietal areas including the intraparietal sulcus and the inferior parietal lobe. Stronger activation is found in the left angular gyrus. However, children's brain functioning in numerical tasks differs from that of adults. In the current study, we investigated interactive multiplication learning in children to examine if they rather reflect similar changes as in development or learning effects as observed in adults. 24 children from grade 5 (age between 10 and 12 years) were measured using functional near-infrared spectroscopy (fNIRS) before and after multiplication training. In a within-subject design four different conditions were investigated: trained simple, trained difficult, untrained simple, untrained difficult. Children were trained on a simple and difficult set (8 trials each), while they did not receive any training for two other matched sets of multiplication. Children underwent seven training sessions over the course of two weeks. Behavioral results consist of number of correct responses and reaction time. Dependent t-test analyses of correct responses and RTs, separately, revealed that children improved significantly in trained simple, trained difficult, and untrained difficult; but not in untrained simple condition after the training. FNIRS results showed that after these sessions the trained difficult condition now indicated notably less frontal and parietal engagement, especially right. However, the engagement of involved brain areas in trained simple and in both untrained conditions did not differ considerably. Moreover, post-training contrast (trained versus untrained) revealed significantly less frontal and parietal engagement in the difficult, but not in the simple condition. Unexpectedly, stronger left angular activation was not found in the present study. The findings point to the idea that multiplication learning in children may not involve only a strategy shift such as in adults, but also reflect a facilitation of a developmental maturation process.

Title: Brief episodes of memory reactivation enable perceptual learning

Authors: *R. AMAR[1], S. NEMNI[2], N. CENSOR[1,2];
[1]Sch. of Psychological Sci., [2]Sagol Sch. of Neurosci., Tel Aviv Univ., Tel-Aviv, Israel

Abstract: Perceptual learning refers to improvements in perception thresholds with practice. Previous studies have shown that following initial encoding and consolidation of the perceptual memory, perception thresholds can continue to gradually improve over multiple training sessions, similar to other forms of procedural learning. Thus in the context of procedural learning, consolidation refers not only to stabilization of the memory but also to improvements in performance that occur after the end of practice, referred to as offline gains (Censor, Sagi and Cohen, 2012). Here we show that following initial training, brief sessions in which the encoded visual memory is reactivated, are sufficient to enable perceptual learning comparable to learning achieved with repeated standard practice sessions. Participants trained with the texture discrimination task (Karni and Sagi, 1991). The texture stimulus was presented for 10ms, followed by a patterned mask which was presented for 100ms. Observers decided whether an array of 3 diagonal bars embedded in an array of horizontal bars (19×19) was horizontal or vertical. The target-to-mask asynchrony (SOA) was randomly changed within the session (14 SOAs ranging between 40ms and 340ms, 18 trials per SOA, 252 trials total) to obtain a psychometric curve, from which the SOA discrimination threshold was derived. The memory was first encoded and consolidated following a full session on Day 1. Then, participants returned for three daily reactivation sessions (Days 2-4) of only 5 trials each, at a near-threshold SOA (derived from Day 1). On Day 5, participants returned for a full test session (identical to Day 1 session). Learning, measured as improvement in discrimination thresholds from Day 1 to Day 5, was significant and comparable to total Day 1 to Day 5 learning in a control group of subjects performing 5 regular full daily sessions. The control group showed standard gradual threshold improvements over the course of 5 days. These results suggest that brief reactivations of consolidated perceptual memories may enable efficient perceptual learning, possibly via reactivation-reconsolidation cycles of memory strengthening (Lee, 2008; Dudai, 2012; Nader and Hardt, 2009). This interpretation may have an important role in understanding the mechanisms underlying perceptual learning, and enable the development of novel strategies geared to substantially reduce the amount of practice needed to enable learning in normal conditions and following neurological diseases or brain injuries.

Title: Women and men use different default spatial strategies to solve a real world navigation task

Authors: ***M. FIDA**, E. L. ZELINSKI, R. J. SUTHERLAND;
CCBN, Lethbridge, AB, Canada

Abstract: Sex differences in spatial behavior have been reported in many mammalian species, including humans. The Morris Water Task (MWT) is an often-used behavioral assay of spatial ability in rodents that has been adapted to use in humans, typically as virtual reality or tabletop versions. Such variations have lead some to hypothesize that males and females implement different strategies to solve spatial problems. Typically, men use cardinal directions, whereas women use landmarks. However, it could be the case that peri-personal tasks recruit different neural systems than would be engaged during large-scale, real-world traversals. Thus, we developed a dry-land version of the MWT wherein subjects were required to traverse a circular, outdoor area (diameter: 20-meters). We hypothesized that men and women (aged 19-25) would implement different strategies to solve the task. Forty-four subjects (27 women) were asked to locate a single, hidden target location over several trials with varying start locations. Both sexes reached the same level of performance by the end of training, but the results demonstrated that men and women use, as a default, allocentric and egocentric strategies, respectively. A second cohort containing seventeen subjects (13 women) performed the task, but the starting location remained constant for the first and second trials. In the second condition, women proceeded directly to the platform location on the second trial. Together, these results indicate that although men and women can both solve spatial tasks, the default strategy is allocentric for men and egocentric for women.

Title: Behavioural and electrophysiological characteristics of virtual navigation task performance in men and women

Authors: *E. L. ZELINSKI, M. FIDA, R. J. SUTHERLAND;
Neurosci., Canadian Ctr. For Behavioural Neurosci., Lethbridge, AB, Canada

Abstract: Examination of the neurological underpinnings of spatial abilities often requires human subjects to be stationary. Thus, virtual reality is a commonly used tool for elucidating how we process information about the world around us. We hypothesized that differences in navigational skill would impact the strategy implemented by subjects, whether they would notice changes to the environment, and the electrophysiological responses to the presentation of manipulated vs. non-manipulated and remembered, non remembered, and novel scenes during performance of a virtual navigation task. Object-location memory was assessed within a large-scale, virtual environment whilst recording dense array EEG. Subjects were restricted to a central circular area by a fence, but the world beyond (e.g., mountains, seascape, forest) remained visible. In addition to these distal cues, various naturalistic objects (e.g., boulders, trees) were present within the navigable portion of the environment to provide proximal cues. During the exploration phase of the task, subjects moved through the environment until all object-location pairs were encountered. During the second phase of the task, subjects were shown pictures of the objects with background images that were either congruent with the original object-location pair or incongruent. Subjects began each trial at a central start location and rotated until their perceived optimal approach angle followed by direct traversal to the current trial target location. The final phase of the task required subjects to place objects in their original locations over a topographical representation of the environment. Several factors influence performance including sex and experience playing video games.

Title: Transcranial alternating current stimulation strengthens learning of color-orientation associations

Authors: *Y. LIU[1,2], K. KAR[1,2], B. KREKELBERG[1];
[1]Ctr. for Mol. and Behavioral Neurosci., [2]Behavioral and Neural Sci., Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstract: Transcranial current stimulation (tCS) has been found to improve cognitive function in various domains (e.g. memory, language, vision, cognitive aging, etc.). Despite its growing use, the underlying neural mechanism remain unclear. To investigate how tCS influences learning, we examined the effects of transcranial alternating current stimulation (tACS) on the McCollough Effect (ME). In contrast to many visual aftereffects that typically extinguish within a few seconds, the ME is an orientation-contingent color aftereffect that can persist for days. This long time scale as well as the orientation contingency of the ME indicate that the acquisition of the ME can serve as a low level model of a learning process that associates orientation and color in the visual pathway. Moreover, there is strong evidence to suggest that the ME originates in primary visual cortex (V1). These properties make the ME a suitable phenomenon to study the neural basis of tACS' influence on learning. We induced the ME in participants with two alternating sets of gratings paired with two complementary colors (vertical-red and horizontal-green, alternated every 1 s for 4 s: induction stimuli). After induction, a test pattern (300 ms) of neutral white gratings was perceived to be tinted with colors complementary to the original pairing (i.e., vertical-green and horizontal-red). We quantified this ME by adjusting the colors of the test patterns to null participants' perceived ME. This procedure was repeated to build up the strength of the ME. In the tACS condition, electrical stimulation (0.5 mA, 50 Hz) was applied with one electrode over area V1 (Oz) and one on the vertex (Cz). Stimulation was only applied during the presentation of the induction stimuli. In the absence of tACS, the build-up of the ME typically saturated within a few minutes. In the presence of tACS, however, no such saturation was observed. As a consequence, the ME was significantly larger in the tACS compared to the no-tACS condition. In other words, tACS strengthened the learning of color-orientation association that is necessary for perceiving the ME. Based on our previous work (Kar and Krekelberg, J. Neurosci. 34.21 (2014): 7334-7340), we speculate that tACS attenuated the adaptation of early visual neurons sensitive to orientation or color. This reduced adaption would result in stronger input to neural populations that detect the conjunction of orientation and color, and this could enhance the learning of the orientation-color association. These results lay the groundwork for future experiments that will test this hypothesis using behavioral experiments and electrophysiological recordings in macaque V1.

Title: Learning on a musical-interval discrimination task through a combination of task practice and stimulus exposure alone

Authors: *D. F. LITTLE, H. CHENG, B. A. WRIGHT;
Communication Sci. and Disorders, Northwestern Univ., Evanston, IL

Abstract: Introduction A fundamental component of musical skill is the ability to discriminate between and identify musical intervals, fixed ratios between pitches. Learning this skill is challenging because the same musical interval can be instantiated by multiple pairs of pitches, and even identification of a single instance of an interval is difficult. Here we asked whether a training regimen that combined periods of task practice with periods of stimulus-exposure alone facilitates musical-interval learning. Similar regimens have been particularly effective at inducing learning on basic discrimination tasks in audition and vision. These outcomes are of particular interest because the practice-plus-exposure combination can yield learning even when neither element does so in isolation. If this regimen yields musical-interval learning, it would indicate that it aids discrimination as well as category formation. **Methods** In four different 4-day training regimens, each day was divided into four ~8 minute blocks of either practice, stimulus exposure, or silence. During practice blocks, listeners discriminated multiple instances of perfect 4ths from major 3rds, perfect 5ths, and major 6ths, for 60 trials. During exposure blocks, listeners performed a written matching task while 60 examples of perfect 4ths were presented in the background. During silence blocks, listeners performed a mock musical-interval discrimination task in silence. On each day, listeners (n=7 per group) received either (1) 180 stimulus exposures (Exposure+Silence), (2) 180 practice trials (Practice+Silence), (3) 360 practice trials (All Practice) or (4) 180 trials + 180 exposures (Practice+Exposure). **Results** Discrimination accuracy improved by ~24 percentage points with the Practice+Exposure regimen, compared to ~11 to ~14 percentage points for the Exposure+Silence, Practice+Silence and All-Practice regimens. The improvement was greatest for the Practice+Exposure regimen (all $p < 0.001$), and did not differ significantly among the remaining three regimens ($p \geq 0.934$). The benefits conferred by the Exposure+Practice regimen generalized to untrained stimuli (triangle tones) for the trained task and to an untrained task (interval identification) for the trained musical interval (the 4th). **Conclusions** Pairing practice with stimulus-exposure alone yielded learning on a musical-interval discrimination task, extending the demonstrated benefits of this regimen beyond basic discrimination tasks to a challenging case requiring category formation that is of practical use. This result suggests that a similar mechanism drives the observed enhancements to learning in both cases.

Title: The impact of olfactory stressors on perceptual recall and timing behavior

Authors: *J. E. WILLIAMS, M. A. WILLIAMS;
Dept. of Psychology, Eastern Illinois Univ., Charleston, IL

Abstract: This experiment extends our previous work testing people's ability to correctly perceive the amount of time that occurs as well as amount of information recalled during the presentation of differing suspenseful endings to a video which may or may not lead to a stress response. It was previously shown that auditory and visual stimuli significantly reduced recall and increased judgements of passage of time. It was therefore hypothesized that olfactory factors related to the body's response in stressful situations would also cause impairment of the ability to determine correctly how long the presentation was, and reduce total recall of events, especially for the group viewing the video with higher stress inducing content, i.e., the more stressful film ending, in conjunction with a noxious odor. 137 undergraduate subjects provided informed consent, were presented with a 3-5 minute video clip from a recent movie title "Hide and Seek", and then completed survey questionnaires about the video along with two survey components which measured the subjects vulnerability to stress and the extent to which they experience stress related symptoms in their life. Each of the subject groups viewed one of two alternate endings to the movie not presented in the original release of the movie. One group was shown a happy or "non-menacing" clip and another group was shown a clip containing "menacing" content believed to induce a stress response. The groups were tested with the addition of either a eucalyptus odor, or a deer repellant (rotten egg/urine) odor. Results suggest that while physical stressors (sights, sounds), and psychologically charged material cause impairment of recall and perception, the presentation of olfactory stimuli also leads to significant increases in perception of time passage and a decrease in total recall. Data are discussed relevant to the ability of emergency responders to perform during high stress context situations. The possibility exists that professional responding during emergency situations is differentially affected by context.

Title: Perceptual learning for detection of multiple features produces non-independent processing: Behavioral and neurophysiological evidence

Authors: *M. J. WENGER[1,2], S. E. RHOTEN[1];
[1]Ctr. for Applied Social Res., The Univ. of Oklahoma, Norman, OK; [2]Div. of Nutritional Sci., Cornell Univ., Ithaca, NY

Abstract: We previously (SfN 2014) reported EEG and behavioral data (response frequencies) supporting the hypothesis that that perceptual learning can be obtained with multiple features and that learning involves the development of non-independence at perceptual and decisional levels. This is consistent with evidence suggesting that multiple levels of processing and representation may be involved in perceptual learning. The present study explores these notions using EEG and response times (RTs), testing the hypothesis that learning of multi-feature patterns results in processing that is non-independent and parallel, as would be expected if the stimuli were learned as integral objects. Stimuli contained contrast-defined features, extracted from the 1865 drawing of the Cheshire Cat in Alice's Adventures in Wonderland. Participants began by performing a detection task implemented as a double-factorial paradigm (DFP), in which stimuli contained 0, 1, or 2 targets, at two levels of contrast, and were instructed to give a positive response if they judged the stimulus to have either 1 or 2 targets. They then practiced with all possible stimuli for 10-15 days, using an adaptive staircase procedure to track thresholds. Finally, they again performed the DFP detection task with stimuli presented at threshold and the two initial levels of contrast. EEG data were collected during both pre- and post-practice performance of the DFP. Analysis of the RT data, at both the level of the mean and the distribution, suggested that the stimuli were initially processed serially, with practice resulting in a transition to dependent parallel processing and modulations of amplitudes of early ERP features, pre- and post-stimulus spectral power, and reductions in post-stimulus γ−band power, selective to frontal electrodes. These results are consistent with the idea that perceptual learning of multi-feature patterns produces shifts in fundamental characteristics of processing consistent with the learning of an integral object.

Title: Long-term high-variability training for new adult cochlear implant users

Authors: *J. L. LOEBACH;
Psychology, St. Olaf Col., Northfield, MN

Abstract: When an individual receives a cochlear implant (CI) as a treatment for deafness, they undergo an intense period of perceptual learning to be able to hear with their prosthesis. However, the process of perceptual learning is not fully understood, and there is much debate regarding the types of materials that training should include, and how well they will generalize to novel tasks. An analytic approach to training focuses on phoneme discrimination with the hopes that it will generalize to sentences and real world listening contexts. A synthetic approach focuses on understanding the meaning or gist of the sentence, in hopes that it will generalize to phoneme identification and real world listening situations. While both approaches can yield successes, they tend to be limited to similar conditions that were experienced during training, and may not generalize broadly to new materials and environments. In addition, postlingually deafened adult cochlear implant users generally do not receive any formal training after their implants are activated. As a result, there is a great deal of variability among individual CI users in terms of their satisfaction, performance and comfort in using their implant. It is possible that the lack of training yields to the development of vastly different neurocognitive mechanisms across users, contributing to the variability in satisfaction and use and possibly limiting their performance in real world listening situations. A main objective of our research is to develop a long-term high-variability training program to help new adult cochlear implant users learn to hear with their devices. Utilizing tasks that engage higher-level language (meaningful and anomalous sentences), lower level linguistic (phoneme discrimination) in addition to nonlinguistic speech (talker identification) and general auditory tasks (environmental sound identification), this program trains neurocognitive systems that overlap between linguistic and nonlinguistic systems. This poster will present an overview of the program, including data from normal hearing listeners who helped develop and pilot the project, experienced adult CI users who provided the baseline measurements so that we can build a set of expectations for performance after training, and new CI users who have tested the program over of a 1 month period. Since most adult CI users to not undergo any formal training or rehabilitation, our findings have both theoretical and clinical significance. The results will be discussed in terms of perceptual learning, and interactions between general auditory and speech specific cognitive abilities.

Title: Grounding symbolic fractions in the ratio processing system: A developmental fMRI-A study

Authors: *E. Y. TOOMARIAN, M. R. LEWIS, J. V. BINZAK, E. M. HUBBARD;
Univ. of Wisconsin-Madison, Madison, WI

Abstract: Children and adults experience difficulties when attempting to understand fractions, leading some theorists to propose that fractions might lack a cortical specialization analogous to the Approximate Number System. However, emerging data have suggested that newly identified circuits may be ideally suited for learning about fractions (Lewis, Matthews and Hubbard, in press). This system, known as the Ratio Processing System (RPS), represents the magnitudes of nonsymbolic ratios such as the relative lengths of two lines. Previous single-unit physiology studies in non-human primates and fMRI studies in humans have demonstrated that nonsymbolic line ratios and symbolic fractions elicit responses in regions of the intraparietal sulcus (IPS) and prefrontal cortex (PFC) (Jacob, Vallentin & Nieder, 2012). However, none of these previous studies have tested a critical prediction of the RPS theory: the same neural systems that support nonsymbolic ratio processing should also support symbolic fraction processing, and should do so in a semantically meaningful way. To test whether symbolic fractions are grounded in the RPS, we used an fMRI adaptation (fMRI-A) paradigm in a developmental sample to demonstrate cross-notation recovery from adaptation to nonsymbolic ratio magnitudes. During fMRI scanning, participants were adapted to a specific non-symbolic ratio magnitude- a series of line ratios in which the component line lengths varied but the shorter line length was always the same fraction of the longer line, i.e., 3/10 or 7/10 across runs. This was followed by presentation of either symbolic or non-symbolic deviant magnitudes, either close to or far from the adapting value. Deviants that were close to 3/10, like 2/9, were numerically distant from 7/10, and deviants that were numerically close to 7/10, like 7/9 were far from 3/10. Activation in right mid-IPS recovered in a distance-dependent fashion (greater response for far deviants than close deviants) when either a nonsymbolic ratio or corresponding symbolic fraction was presented. The fact that adaptation transferred from nonsymbolic line ratios to symbolic fractions in a distance-dependent manner suggests that symbolic fractions are semantically mapped to more basic RPS represention of nonsymbolic ratio magnitude. We are currently exploring how these mechanisms change with development during the acquistion of symbolic fraction knowledge during the early school years. A better understanding of these brain systems that support ratio processing may lead to improved educational methods for fractions.

Title: Orientation discrimination performance improves after "LTP-like" visual stimulation applied via Oculus Rift video device

Authors: ***A. MARZOLL**[1], E. KEßEL[1], H. R. DINSE[1,2];
[1]Inst. für Neuroinformatik - Neural Plasticity Lab., Ruhr-Universität Bochum, Bochum, Germany; [2]Neurologische Klinik am Berufsgenossenschaftlichen Universitätsklinikum Bergmannsheil, Ruhr-Universität Bochum, Bochum, Germany

Abstract: Recently, it was shown that sensory performance in the tactile and visual domain could be selectively enhanced or impaired by employing peripheral stimulation protocols (Ragert et al., 2008; Beste et al., 2011). The temporal properties of these protocols mimicked those used to induce Hebbian forms of plasticity in cellular studies and were thus dubbed "LTP-like" and "LTD-like". Here, we investigated whether it is possible to improve perceptual performance in a visual orientation discrimination (OD) task by administering visual LTP-like stimulation. To find an innovative and simple way to apply visual stimulation concurrent to normal viewing, subjects wore a head-mounted display device (Oculus Rift DK2, Oculus VR®) for three hours while either LTP-like or sham stimulation were presented superimposed on a movie. LTP-like stimulation consisted of a rectangular field of sinusoidal gratings flickering intermittently between two orientations (30° and 120° at 1 cpd) for 5 s duration and a subsequent period of 5 s where no gratings were displayed, for 1080 stimulation cycles per subject. Sham stimulation for the control group consisted of static display (30 s periods) of the same gratings, matching the total display duration of LTP-like stimulation. For assessment of OD performance, before and after stimulation subjects performed a visual OD task for the two stimulated orientations (30°/120° at 1 cpd). As control conditions, one of the stimulated orientations was tested at another spatial frequency (30° at 2 cpd), and a non-stimulated orientation was tested (75° at 1 cpd). Subjects had to indicate whether a Gabor-patch deviated from the target orientation in a clockwise or counter-clockwise manner. Participants who were subjected to LTP-like stimulation improved their OD thresholds specific to the orientations presented during stimulation by, on

average, more than 10%. No such improvement happened for the control orientation (75°) or in subjects receiving sham stimulation. Our data demonstrate that passive visual stimulation can be used to induce plastic changes in an OD task specific to the parameters of repetitive stimulation. Unlike previous studies in the visual domain, which investigated the influence of stimulation on attentional processes (Beste et al., 2011), here we could show improved discrimination ability for a low-level visual feature, suggesting an enhanced representation. Stimulation via head-mounted devices promises to be viable and practical means of inducing changes of visual perception, which might be of considerable benefit in conditions where perceptual training can be difficult, e.g. in stroke rehabilitation.

Title: Contingency awareness as a prerequisite for contextual fear conditioning

Authors: ***P. MEYER**, C. BAEUCHL, M. HOPPSTAEDTER, H. FLOR;
CIMH, Heidelberg Univ., Mannheim, Germany

Abstract: We employed functional magnetic resonance imaging to investigate the acquisition of contextual fear in humans in in a sample of 96 young healthy subjects using two context-pictures, of which one (CS+) was paired with an aversive electrical shock (US) in 50 percent of the trials, whereas the other picture (CS-) was not shock associated. The context-pictures were comprised of identical sets of features in different spatial arrangements and demand a configural context processing strategy in order for successful conditioning to occur. In addition, we simultaneously recorded skin conductance responses (SCR) and asked subjects to rate the stimuli on arousal, valence and contingency awareness. On the single subject level, contrast estimates that reflect the effect of fear conditioning (CS+unpaired > CS-) were calculated. Then we created two groups of subjects named “contingency aware” (n = 41) and “contingency unaware” (n = 55) based on their differential rating of the perceived contingency between CS+ and US. The comparison of blood oxygen level dependent (BOLD) activation between both groups (contingency aware > contingency unaware) revealed responses in bilateral insula, inferior frontal gyrus, superior medial gyrus and bilateral inferior parietal lobule. In addition, there was significant transient activation of the hippocampus in contingency aware subjects but not in contingency unaware ones. SCRs of the whole experiment were divided into three time bins and

CS+unpaired trials were compared to CS- trials using separate t-tests. In all three time bins, SCRs were larger for CS+unpaired than for CS- in contingency aware subjects compared to contingency unaware subjects. Finally, the stimulus ratings revealed significant differences between the groups with higher ratings on arousal and emotional valence for CS+ than for CS- in contingency aware relative to contingency unaware subjects. Taken together, our results support the notion that consciousness awareness of the CS+/US contingency is necessary for the acquisition of contextual fear when the discrimination of contexts is particularly demanding.

Title: Survival of the fittest gamer or: How video games improve probabilistic learning

Authors: ***S. SCHENK**, R. K. LECH, B. SUCHAN;
Neuropsychology, Ruhr Univ. Bochum, Bochum, Germany

Abstract: The present fMRI study examines the effects of video game playing on the strategy usage and the related neural correlates of probabilistic learning. Previous studies have shown that successful probabilistic learning correlates positively with activity in the tail of the caudate nucleus, the putamen and the extrastriate cortex (middle temporal gyrus). While the putamen is associated with the analysis of stimulus-outcome probabilities, the caudate nucleus integrates performance and represents cognitive control demands. Besides, both implicit and explicit strategies could be used in probabilistic classification learning. Sixteen healthy right-handed video-gamers and fifteen healthy right-handed non-gamers were scanned in a 3T scanner while performing a modified version of the weather prediction task, a well-known probabilistic classification learning task. The behavioral data yield evidence for a better categorization performance of gamers, particularly at more uncertain card combinations. Furthermore, a post-experimental questionnaire showed that video-gamers used mostly a multi cue strategy while non gamers used more often an explicit single cue or singleton strategy. Analysis of the functional imaging data revealed a between group effect. Non-gamers showed higher activations of the left middle temporal gyrus as well as in the superior parietal lobe. It seems that probabilistic categorizations required more effort for non-gamers under the usage of an explicit top down driven visual processing. Separate group analyses yielded in both groups activations in the left tail of the caudate and the right putamen. However, while gamers showed higher activations in

the left tail of caudate for high probable weather choices, non-gamers showed higher activations in the right putamen. Gamers exhibit strong performance integration and high cognitive control demands, whereas non-gamers place emphasis on stimulus-outcome probabilities. Overall, video-gamers presented a more implicit processing. These results are in line with previous studies which suggested that video game playing enhances probabilistic inference, which promote cognitive flexibility and improves performance in a wide variety of tasks.

Title: Successive training of two tasks in three-week periods still leads to behavioral interference

Authors: ***M. SENDEN**, G. LANGE, A. RADERMACHER, R. GOEBEL, P. DE WEERD; Cognitive Neurosci., Maastricht Univ., Maastricht, Netherlands

Abstract: Previous studies [1,2] have shown that skill learning, although quite stable in general, can be interfered with by additional training at a later time on similar tasks/stimuli. Commonly, these behavioral interference effects are attributed to the disruption of a time-limited offline memory consolidation process. Interestingly, behavioral interference has been shown to occur for time intervals of up to 24 hours [1] or longer [2], which raises the question whether it is best accounted for by disrupted consolidation. Alternatively, memory traces after their formation may remain malleable, and behavioral interference might occur when memory formation in two tasks recruits a largely shared (i.e. insufficiently segregated) neuronal population subjected to incompatible requirements on network connectivity. To evaluate this possibility, we first implemented a learning mechanism in a recurrent model of orientation selectivity characterized by representational overlap. We used this neural network model to simulate the effects of orientation discrimination learning as well as of varying contributions of consolidation on the interference between two tasks. In these tasks, efficient orientation discrimination learning required opposite network connectivity changes. Secondly, we designed an empirical experiment, in which training between the two tasks was done serially in time blocks of three weeks, thereby maximizing the possibility that one task would induce a fully consolidated memory trace before onset of the next one. Nevertheless, we found strong interference between the two tasks, similar to what has been observed for intervals in the range of 0-24h [1]. Our model simulations show that our results can be more straightforwardly explained in terms of reactivation and representational competition than in terms of disruption of consolidation. Title: Examining changes in functional connectivity during human perceptual learning with population receptive fields

Authors: *V. R. BEJJANKI, N. B. TURK-BROWNE;
Dept. of Psychology and Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: When we repeatedly look at the same stimulus, we get better at seeing it. How does such perceptual learning occur in the brain? A recent computational theory (Bejjanki et al., 2011, *Nat Neurosci*) proposed that changes in connectivity between visual areas may be responsible, by increasing the fidelity with which task-relevant information is transmitted. In the current study, we sought to test this proposal in humans using fMRI. We tested the hypothesis that perceptual learning at one location in space should lead to increased connectivity between voxels in areas V1 and V4 that have population receptive fields (pRFs) with coverage of the trained location. Moreover, the extent to which a particular pair of V1 and V4 voxels increase in connectivity should be related to how much their pRFs overlap with each other. We used a task in which observers detected one of two novel shape stimuli, each a mirror reflection of the other, with one shape presented in the upper-right quadrant and the other in the upper-left quadrant. Observers were trained to detect one of the shapes (the “trained” shape), with sensitivity for this shape and the other “control” shape being assessed before and after training. fMRI data were collected during training over six runs. In a second session, we retinotopically mapped the most effective visual field location for voxels in areas V1-V4 and combined this information with published estimates of pRF extents in these areas (Harvey & Dumoulin, 2011, *J Neuro*) to derive a pRF for

each voxel. Observers showed improved behavioral sensitivity after training, with greater improvement for the exposed vs. control shape. With the fMRI data, we inferred “background” connectivity between voxels in areas V1 and V4 by regressing out stimulus-evoked responses and global noise sources, and computing correlations in the residual BOLD timeseries. We then computed a weighted average of the background connectivity between each V4 voxel and the V1 voxels in its pRF, where the weights were determined by the distance between pRF center locations according to a Gaussian function. Consistent with our hypothesis, there was greater background connectivity between voxels in areas V1 and V4 whose pRFs overlapped the trained vs. control locations across the six training runs. Additional analyses examine pRFs at a finer spatial scale for the envelope and contour of the trained shape. These findings support the proposal that perceptual learning alters functional networks in the visual cortex to improve the transmission of learned information.

Title: Subjective symptoms in MRI operators

Authors: *S. ZAFFINA, JR, V. CAMISA, A. SANTORO, M. VINCI, A. ANTICO, V. CANNATÀ, P. DERRICO;
Children's Hosp. bambino Gesù, Rome, Italy

Abstract: Introduction Operators working in proximity to a MRI scanner are exposed to high levels of electromagnetic fields (EMF) generated by these devices. In these MRI operators an increase of some symptoms, as vertigo, headache, nausea, metallic taste has been reported. This problem is relevant, especially considering that the number of operators, and the strength of MRI scanners is increasing. We have studied the prevalence of symptoms in a group of MRI operators and in controls. Methods In a group of 82 MRI operators (52 M, 30 F, mean age 40 ± 9.5), working in 2 different hospitals, and in 31 Controls (18M, 13F mean age 40 ± 9.9) the occurrence of subjective symptoms has been collected by a physician using a questionnaire based on data reported in previous studies. Main factors inducing symptoms, as ear diseases or drugs, were excluded; MRI operators and controls were similar for all the relevant characteristics except for exposure in MRI. Results We compared the mean number of total symptoms and frequent symptoms in exposed and not exposed and both the mean and the distribution

(respectively 3.8 ± 2.4 SD vs 3.7 ± 2.7 SD and 1.09 ± 1.4 SD vs 1.07 ± 1.5 SD) were similar. Considering total symptoms vertigo was statistically significant comparing cases and controls (Chi square 5,84 p <0,01) while as regards the frequent symptoms in male the difference is significant for headache (Chi square 7,1 p <0,007). Discussion These data confirm a higher prevalence of symptoms in people exposed to MRI possibly due to the EMF; the prevalence of individual symptoms are largely comparable with those finded in the recent studies (tiredness 20%, sleep disorders 13%, nausea and metallic taste 2,2%). An unexpected observation never described before is the different prevalence of symptoms between the two sexes. The collection of data is ongoing, further questionnaire from other subjects will be gathered. This work was supported by grant from the Italian Ministry of Health (RF-2009-1543811)

Title: Aberrant precision in autism: behaviour, computational modelling and noradrenergic function

Authors: ***R. P. LAWSON**[1], C. MATHYS[1], G. REES[2,1];
[1]Wellcome Trust Ctr. for Neuroimaging, [2]Inst. of Cognitive Neurosci., Univ. Col. London, London, United Kingdom

Abstract: New theories of brain function in Autism Spectrum Disorder (ASD) propose that an imbalance of the precision (or gain) ascribed to sensory inputs, relative to top-down predictions of those inputs, might underlie the perceptual atypicalities in the disorder (Lawson et al, 2014, Front. Hum. Neuro., 8, 302). Precision itself rests on the optimal representation of environmental uncertainty and the action of neuromodulators, such as noradrenaline. Here we employ computational models of behaviour and indices of central noradrenergic function to explore aberrant precision setting in ASD. Adults with ASD (n=21) and age and ability-matched neurotypical controls (NT; n=18) took part in a probabilistic associative learning task. Participants heard either a high or low tone, followed by a briefly presented image, and were required to make a button press response indicating whether the image was a face or a house. The probabilistic associations between the tone and the images changed over time. Concurrent pupillometry provided trial-by-trial biomarker of central noradrenergic function (Samuels et al.,

2008, Curr Neuropharmacology, 6, 1-19). Data were modelled using the Hierarchical Gaussian Filter (Mathys et al., 2014, Front. Hum. Neuro., 8, 825), allowing the quantification of individual learning under different levels of uncertainty. NT adults showed a slowing of reaction and an increase in error rates in response to images of increasing outcome unexpectedness (OU), whereas ASD adults showed no modulation of error rates and a significantly reduced RT modulation as a function of OU. Strikingly, the amount of RT slowing in response to images of high OU correlated with autistic traits across all individuals. NT adults also showed a trend towards the predicted pupil dilation to increasing OU whereas ASD adults did not. Modelling of the RT data to characterise individual learning suggests that group status can be predicted from model parameters that characterise the influence of 'high-level' environmental uncertainty on RT. These data provide evidence that adults with ASD are less able than NT adults to use the probabilistic structure in the environment to guide behaviour. Such a pattern of responses is consistent with reduced sensitivity to environmental uncertainty, which itself determines the precision (gain) that one should ascribe to sensory inputs, relative to top-down predictions of those inputs. An absence of pupillometric response to OU further suggests aberrant neural precision (central noradrenergic function) in ASD.

Title: The amount of practice and the acquisition of the internal model in visuomotor learning

Authors: *C. YAMADA[1], Y. ITAGUCHI[3,2], K. FUKUZAWA[1];
[1]Waseda Univ., Tokyo-To, Japan; [2]Waseda Univ., Tokyo, Japan; [3]Sapporo Med. Univ., Sapporo, Japan

Abstract: Our goal is to reveal the relationship between the amount of practice and a visuomotor learning. To investigate the time course of practice-dependent error reduction, we used a tracking task, which less likely to allow a strategic control than a reaching task. In the tracking task, participants were required to follow a randomly moving target as accurate as possible during a trial. Participants were assigned to one of four experimental groups, and completed the tracking task in two successive days. On Day 1, they performed 20 Normal only sessions, 20 Rotation included sessions, 10 Normal only sessions, or 10 Rotation included sessions (N20, R20, N10, and R10). On Day 2, all of the participants completed 10 Rotation included sessions. Additional participants were recruited to define the baseline performance, and they performed 20 Normal only sessions on Day 1 and 10 Normal only sessions on Day 2. We calculated the distance

between the target and the mouse cursor to define the tracking error. We compared two error measures to characterize the performance among the four conditions: the error on the last rotation trial (Last Error), and the increase of the tracking error between the end of Rotation trial and the subsequent Normal trial (After-Effect). The results showed that there was no difference in the Last Error between Day 1 (R10 vs R20) and Day 2 (among the four conditions). The participants in the four groups decreased tracking error to the same level on Day 2 regardless of the different amount of rotation practice on Day 1. In addition, participants only who completed R20 sessions showed a positive After-Effect in the end of Day 1 and 2. These results suggested that the amount of practice which can lead to the learning plateau is not enough to form an internal model for the novel visuomotor environment. Further, the occurrence of positive after-effects might reflect that the visuomotor adaptation is completed, which lasts at least to the next day. The current results support the idea that an extra practice after the learning plateau is needed for better learning.

Title: Dissociable roles for the inferior longitudinal fasciculus and the fornix in perception for faces and scenes

Authors: ***M. A. POSTANS**[1], B. COAD[1], M. ALY[2], C. J. HODGETTS[1], D. E. J. LINDEN[1], A. D. LAWRENCE[1], K. S. GRAHAM[1];
[1]Psychology, Cardiff Univ., Cardiff, United Kingdom; [2]Princeton Neurosci. Inst., Princeton, NJ

Abstract: Inter-individual variation in structural properties of the inferior longitudinal fasciculus (ILF) and the fornix has been shown to be predictive of discrimination accuracy for pairs of visually similar faces and scenes, respectively (Postans et al., 2014). A limitation of this previous work, however, was the use of small sets of repeated stimuli, because over time, stimulus learning and memory may have contributed to performance measures. It is therefore unclear whether category-sensitive contributions of the ILF and fornix to discrimination

accuracy, extend to perception for trial-unique stimuli. In addition, the previous work treated perception as a unitary construct, but recent investigations indicate that two functionally independent types of perception contribute to visual discrimination performance. The relative contributions of these two components - termed *state*- and *strength-based* perception - can be separated using receiver operating characteristics (ROCs; Aly et al., 2012; 2013). Here, we asked whether diffusion-MRI indices of ILF and fornix microstructure (fractional anisotropy, FA, and mean diffusivity, MD), would correlate with markers of state- and/or strength-based perceptual discrimination of trial-unique faces and scenes, respectively. Diffusion-weighted MR images were obtained from healthy participants who had completed a task in which they made confidence-based same/different discriminations to trial-unique, visually similar face and scene pairs. Participants' confidence-based responses were used to plot ROCs, from which state- and strength-based perception were estimated for each stimulus category. Mean FA and MD values were computed for the fornix and ILF of each participant, which were reconstructed using deterministic white-matter tractography. ILF MD was found to correlate with markers of perception for faces but not scenes, whereas fornix MD was found to correlate with markers of perception for scenes but not faces. These findings are consistent with the category-sensitive white matter-behaviour relationships reported in Postans et al., (2014) and show that the dissociable roles for the ILF and fornix in perception for faces and scenes extends to perceptual discriminations that minimize the contribution of learning and memory to performance. Title: Repetition priming in object naming is associated with repetition suppression, earlier termination of activity, and changes in task-engaged neural synchrony

Authors: *S. J. GOTTS, A. OSSOWSKI, S. C. MILLEVILLE, A. MARTIN;
Lab. of Brain and Cognition, NIMH/NIH, Bethesda, MD

Abstract: Object repetition commonly leads to long-lasting improvements in the speed and accuracy of identification ("repetition priming"), along with decreased neural activity ("repetition suppression"). In the current study, we use fMRI and overt picture naming (N=32 subjects) to evaluate several prominent models of the relationship between repetition priming and suppression. Subjects named a set of 100 pictured objects 3 times prior to fMRI. During fMRI, they overtly named "old" pictures randomly intermixed with "new" pictures that were matched in category and name frequency. The use of a slow-event-related fMRI design aided in movement artifact separation, as well as improved isolation of BOLD responses to individual trials for the purposes of task-based functional connectivity analyses. In addition to the standard effects of repetition suppression in occipitotemporal and lateral frontal regions, we also observed a significant alteration in the time course of the BOLD response following repetition, with earlier termination for old pictures, consistent with predictions of Facilitation and Predictive Coding models. Functional connectivity analyses performed on the individual item responses further revealed that: 1) increased connectivity with left inferior frontal cortex during old relative to new pictures predicted greater priming magnitudes across subjects (consistent with the Synchrony model), and 2) increased connectivity with dorsal parietal regions during new pictures also predicted greater priming through slower new RTs, consistent with slowed responding due to a heightened novelty/orienting response. Thus, priming appears to reflect a combination of more rapid, synchronized activity to old pictures and novelty-related slowing and heightened attention to new pictures.

Title: Virtual environmental enrichment through video games

Authors: *G. D. CLEMENSON, C. E. STARK;
UC Irvine, Irvine, CA

Abstract: In animals, it is well understood that exposing animals to a more stimulating environment, known as environmental enrichment, can stimulate neuroplasticity and improve hippocampal function and performance on hippocampally-mediated memory tasks. We are interested in whether these manipulations that successfully enhance cognition (or mitigate

cognitive decline) also influence humans in a similar manner. Although humans, in many ways, already live in an enriched environment, we are constantly adapting to new experiences and situations within our own environment on a daily basis. Here, we hypothesize that the exploration of the vast and visually stimulating virtual environments within video games, is a human correlate of environmental enrichment. We show that video gamers who specifically favor 3D video games performed better on a demanding recognition memory task that assesses participants' ability to discriminate highly similar lure items from repeated items to behaviorally tax hippocampal pattern separation. In addition, after two weeks of training on the 3D video game Super Mario 3D World, naïve video gamers showed improved mnemonic discrimination ability and improvements on another hippocampal-dependent task - a virtual water maze. Two control conditions (passive and training in a 2D game, Angry Birds), showed no such improvements. In addition, we provide preliminary data exploring the functional involvement of the human hippocampus during video game play. Thus, our results suggest that modern day video games may provide meaningful stimulation to the human hippocampus.

Title: Fast knowledge-mediated visual disambiguation process in humans: a magnetoencephalographic study

Authors: *T. URAKAWA[1,2], K. OGATA[2], T. KIMURA[2], Y. KUME[2], S. TOBIMATSU[2]; [1]Tokyo Univ. of Sci., Dept. of Applied Physics, Katsushika-ku, Japan; [2]Dept. of Clin. Neurophysiol., Kyushu Univ., Fukuoka, Japan

Abstract: Ever-changing visual environment is full of noisy visual scenes. To adequately adapt to such environment, the disambiguation of the noisy scenes with prior knowledge is essential and needs to be implemented in the brain as fast as possible under the limited capacity of visual image processing. However, the temporal profile of the disambiguation process has not yet been fully elucidated. The present study attempted to determine how quickly knowledge-mediated disambiguation began to proceed along visual areas after the onset of a two-tone ambiguous image using magnetoencephalography. From the predictive coding framework, we focused on activity reduction for the two-tone ambiguous image as an index of the implementation of disambiguation. Twelve healthy volunteers participated in this study. An unambiguous

photograph was first repetitively presented, and three different two-tone images were then successively presented in random order. Participants were first required to look at a photograph and then to report whether or not the following two-tone images were disambiguated with the prior photograph on a trial-by-trial basis. Under this scheme of image presentation, two sessions were established. The two-tone images used in one session were identical with those in the other session. The disambiguation was set to be difficult in the first session and to be easy in the second session for one of the two-tone images with a replacement of a preceding photograph, keeping the other ambiguous images difficult in disambiguating for both sessions. Source analysis revealed activity reduction at around 120 ms in the lateral occipital area but not for the preceding activity (about 115 ms) in the cuneus when participants disambiguated the two-tone image. Further analyses showed that the activity reduction was not observed for the other two-tone images which were not perceptually disambiguated. These results suggested that knowledge-mediated disambiguation may be implemented as early as approximately 120 ms following an ambiguous visual scene, at least in the lateral occipital area, and provided an insight into the temporal profile of the disambiguation process of a noisy visual scene with prior knowledge.

Title: The human retrosplenial cortex and thalamus code head direction in a global reference frame

Authors: ***J. SHINE**[1], J. P. VALDÉS-HERRERA[1], M. HEGARTY[2], T. WOLBERS[1,3]; [1]DZNE, Magdeburg, Germany; [2]Dept. of Psychological and Brain Sci., Univ. of California, Santa Barbara, CA; [3]Ctr. for Behavioral Brain Sci., Magdeburg, Germany

Abstract: Spatial navigation is a multisensory process involving integration of visual and body-based cues. In rodents, head direction (HD) cells, which are most abundant in the thalamus, integrate these cues to code facing direction. Human fMRI studies examining HD coding in virtual environments have reported effects in retrosplenial complex and (pre-)subiculum, but not the thalamus. Furthermore, HD coding appeared insensitive to global landmarks. These tasks, however, provided only visual cues for orientation, and attending to global landmarks did not

benefit task performance. In the present study, participants explored a VE comprising four separate locales, surrounded by four global landmarks. To provide body-based cues, participants wore a head-mounted display so that physical rotations changed facing direction in the VE. During subsequent MRI scanning, subjects saw stationary views of the environment and judged whether their orientation was the same as in the preceding trial. Parameter estimates extracted from anatomical masks of the retrosplenial cortex and the thalamus revealed significantly reduced BOLD response in both regions associated with repeating HD. Moreover, consistent with rodent findings, the signal did not continue to adapt over repetitions of the same HD. These results were supported by a whole-brain analysis showing additional repetition suppression in the precuneus. Together, our findings demonstrate that (i) consistent with the rodent literature, the thalamus integrates body-based, and visual, orientation cues, (ii) global reference frame cues can be used to integrate HD across separate individual locales, and (iii) immersive training procedures providing full body based cues may help to elucidate the neural mechanisms supporting spatial navigation.

Title: Distraction suppression and video game training: far transfer effects to fluid intelligence

Authors: ***A. E. HARWOOD**[1,2], D. CISLER[2], R. PARASURAMAN[2], P. GREENWOOD[2]; [2]Psychology, [1]George Mason Univ., Fairfax, VA

Abstract: There is ongoing interest in developing interventions to heighten fluid intelligence (Gf). Based on evidence that (a) action "first person shooter" video games (AVGs) improve distraction suppression (Bavelier et al., 2012) and (b) high Gf depends on ability to ignore distracting events (Wiley et al., 2011), we hypothesized that a training regimen which increased distraction suppression should also induce far transfer to Gf. We tested this by comparing two different training task regimens aimed at distraction suppression (AVG and visual perception) with training task aimed at reasoning (active control). Specifically, 10 hours of the following training was randomly assigned: (a) first person shooter AVG, (b) commercial visual perception training (previously found to transfer to Gf, Berry et al., 2010), (c) real time strategy game Rise of Nations. We assessed changed performance on a battery of transfer tasks administered before

and after training. Visual perception training transferred positively to distractor suppression and episodic memory while the AVG had a negative impact on both. Reasoning training had little effect. In contrast to previous claims about AVG, we did not find transfer to Gf. These results confirm our previous finding that perception training is particularly effective in transferring to Gf (Strenziok et al., 2014).

Title: Differential contributions of positive and negative reinforcement in temporal order visual processing

Authors: *K. HU[1], A. K. ANDERSON[2], W.-M. LUH[4], E. D. ROSA[3];
[1]Cornell University, Ithaca, NY, Ithaca, NY; [2]Dept. of Human Develop., Cornell Univ., Human Neuroscience Institute, NY; [3]Dept. of Human Develop., Cornell Univ., Cornell University, NY; [4]Cornell MRI Facility, Cornell University, NY

Abstract: Previous research has made significant progress in identifying the neural basis of the reward effect in cognitive and perception. However, the neural mechanism that positive and negative reinforcement shapes low level visual information remains poorly understood. Here we investigated the interaction between value reinforcement across spatial frequency channels. Positive and negative reinforcement was used in two experiments, respectively. In the conditioning phase, value was manipulated by linking fast and accurate responses to horizontal or vertical gratings of varying spatial frequency. In study 1, participants received positive reinforcement (gains) for correct responses. In study 2, participants received negative reinforcement (avoiding losses) for correct responses. Following conditioning phases, participants were required to observe those conditioned stimuli while conducting side-based temporal order judgment (TOJ) task where stimuli were presented at varying stimulus onset asychronies (SOA). We found that bilateral activation along the calcarine fissure in primary visual cortex was sensitive to SOA temporal order. Positive reinforcement resulted in similar pattern of visual cortical recruitment relative to neutral trials, further recruiting the cuneus and right posterior cingulate cortex (CGp). By contrast, Negative reinforcement (avoiding losses) did not have such an effect on primary visual cortical regions responsive to SOA. These results suggest positive but not reinforcement influences the neural bases of onset detection in primary

visual cortex and that CGp and cuneus may play special roles for early visual perception in positive reinforcement.

Title: Resting-state fMRI correlates of rapid brain plasticity following brief auditory exposure

Authors: ***M. S. KOYAMA**[1], S. ORTIZ-MANTILLA[2], L. HELFERSTAY[2], J. PARASCANDO[2], C. ROESLER[2], J. MORGANBYRNE[2], M. P. MILHAM[1], A. A. BENASICH[2];
[1]Child Mind Inst., New York, NY; [2]Rutgers Univ., Newark, NJ

Abstract: INTRODUCTION: Neuroimaging studies have investigated long-term experience-induced brain plasticity, particularly in the auditory domain (e.g., musicians). However, only a few fMRI studies have examined rapid changes following sensory experience, which most focused on the motor domain. Here, we used resting-state fMRI (R-fMRI) to address this gap, mapping neural correlates of rapid plasticity following auditory experience in adults. METHODS: 24 healthy monolingual adults (mean age/SD=25/15yrs), with no reported history of learning or psychiatric disorders, participated in behavioral (WASI full IQ; WRAT word reading) and R-fMRI experiments. 14 participants were passively exposed in the scanner to complex tones, whereas 10 controls experienced only a silent gap. Each 5 min period was inserted between two R-fMRI scans. The auditory stimuli used were novel to all participants, and the groups did not differ in age, gender, IQ, reading, or head motion. R-fMRI was acquired for whole-brain 180 volumes (TR=2ms; voxel-size=3x3x3; duration=6m). MRI data were preprocessed by CPAC. We focused on two R-fMRI derivatives, Regional Homogeneity (ReHo) and Voxel-Mirrored Homotopic Connectivity (VMHC), which are considered to assess regional specialization and inter-hemispheric functional connectivity, respectively. At the group level, a paired t-test was performed to map effects of the auditory exposure. RESULTS: For ReHo (Fig 1.A), the auditory group showed a significant increase in the left precuneus (Pre)/superior parietal lobule (SPL), which was associated with shorter response time for word reading. That is, the greater the increase, the faster the reading. The same brain-behavior relationship was observed for VMHC in Pre/SPL (Fig 1.B). These results suggest that brain's ability to alter intrinsic functional properties in the parietal cortex, immediately after new sensory experience,

may index higher cognitive efficiency in adults. We will further discuss the findings in light of functions of the default mode and attention networks.

Title: The utility of reinforcement learning for EEG based passive auditory-neurofeedback

Authors: ***M. DINOV**, A. GUNASEKARA, R. LEECH;
Computational, Cognitive and Clin. Neuroimaging Lab., Imperial Col. London, London, United Kingdom

Abstract: Electroencephalography (EEG) based neurofeedback (NFB) is a biofeedback approach that uses a person's brain signals for performance optimization in healthy and in clinical groups. There are techniques that automate the process of influencing cognitive states, which are more convenient as they require no effort on the part of the subject - these are termed passive NFB. One passive NFB method of temporarily improving reaction time (RT) during sustained attention tasks in both clinical and healthy groups is phasic alerting. Though phasic alerting is not new, we extend previous work by a) optimizing various alerting-related parameters previously unexplored to this extent and b) creating an extensible and general framework for EEG based attentional monitoring and improvement system that is primarily based on reinforcement learning (RL), but also uses EEG signal prediction using artificial neural networks (ANNs) for predicting attentional lapses before they happen and phase-dependent

alerting. We used Q-Learning for RL and show here that RL is a flexible and powerful approach for exploring a EEG-defined brain state space for various parameters. The RL-based approach successfully learns to prefer alerting in higher alpha states (lower attention states) and not disturb the user during lower alpha power states (higher attention states), with no explicit programming to do so. This is achieved through two simple reinforcement rules. We have implemented these methods in the context of the Psychomotor Vigilance Task (PVT), which is a commonly used vigilance task. We compared and found differences between four variants of the task: simple adaptive PVT with alerting (saPVTa), RL PVT with alerting (rlPVTa), PVT where alerting occurs without reference to the real time alpha power (PVTa), alerting only within the inter-stimulus interval (ISI) for 20 percent of ISIs, and PVT with no alerting as a reference. RL allows an ongoing realtime optimization of various NFB-related parameters without the need to specify a threshold a priori as in the saPVTa. The RL also allows for easy integration of non-alpha EEG signals, and we have explored some of these uses and show that non-alpha attention-related signals can successfully be found and used, by themselves or in conjunction with the alpha signals. However, additional brain signals quickly enlarge the state space. Sufficient exploration of the RL state space can take a long time for larger state spaces, so simpler or shorter tasks may benefit from using a more constrained (but still functional) alpha-only state space (to the exclusion of other brain signals) or even a simple moving threshold approach.

Title: Nobody expects the Spanish Inquisition: Expectations about the source of surprise dictate the relationship between feedback-related EEG signals and learning

Authors: ***M. R. NASSAR**[1], R. BRUCKNER[2], M. J. FRANK[1];
[1]Metcalf Hall, Brown Univ., Providence, RI; [2]cDepartment of Educ. and Psychology, Freie Univ. Berlin, Berlin, Germany

Abstract: Successful decision-making requires learning expectations based on experienced outcomes. This learning should be calibrated according to the surprise associated with an outcome, as well as the most likely source of surprise. For example, when occasional change points are expected, surprising outcomes can render past information irrelevant and demand increased learning. In contrast, when signal corruption is expected to occur occasionally,

surprising outcomes can suggest a corrupt signal that should be ignored by learning systems. Previous work has identified feedback-related EEG deflections sensitive to surprise and may play a role in behavioral updating, but it is unknown whether these signals, or behavior, are sensitive to the source of surprise. Here we explore whether, and how, humans combine surprise with source expectations to rationally govern learning. To do so we collected EEG and behavioral data using a computerized task that required subjects to estimate the target of a virtual cannon based on noisy observations. On each trial the subject observed the circular position of a single cannonball and adjusted the position of a "shield" in order to block the next one. The exact dynamics of the cannon were the key task manipulation: in "change point" blocks the cannon remained stable but underwent occasional discontinuous changes, whereas in "signal corruption" blocks cannon aim drifted from trial-to-trial but cannonball positions were occasionally drawn uniformly from an independent process. Subjects adjusted learning in accordance with surprise and their expectations about the source thereof. In change point blocks participants increased learning when confronted with surprising cannonball positions, whereas in the signal corruption blocks participants decreased learning in response to surprising outcomes. Thus the effects of surprise on learning depended critically on subjective expectations about the source of surprising observations. Despite this behavioral interaction, feedback-related EEG signals were agnostic to the source of surprise. A large positive medial prefrontal deflection peaking 350 ms after outcome presentation was enhanced for surprising outcomes in both conditions equally. Computational fits to behavior showed that the impact of this signal on learning differed across conditions: larger EEG deflections predicted more learning in change point blocks but less learning in signal corruption blocks. Taken together these findings suggest that medial prefrontal surprise signals do not naively reflect increased behavioral updating, but may be used adaptively to modulate learning in either direction.

Title: A human single-neuron correlate of error monitoring in anterior cingulate cortex and pre-supplementary motor area neurons

Authors: *Z. FU[1,4], A. N. MAMELAK[4], I. B. ROSS[6], J. M. CHUNG[4], R. ADOLPHS[2], U. RUTISHAUSER[3,5];
[1]Div. of Engin. and Applied Sci., [2]Div. of the Humanities and Social Sci., [3]Div. of Biol., Caltech, Pasadena, CA; [4]Neurosurg., Cedars-Sinai Med. Ctr., Los Angeles, CA; [5]Neurosurg., Cedars-Sinai Med. Ctr., Pasadena, CA; [6]Huntington Mem. Hosp., Pasadena, CA

Abstract: To monitor our own actions, detect and compensate for errors is a key feature of human executive function and learning. Given the conceptual importance of error feedback in human and machine learning, significant effort has been devoted to search for such a mechanism, and substantial progress has been made over the last 20 years with the discovery of an electroencephalographic correlate recorded from the scalp: the error-related negativity (ERN). However, how this ERN might be reflected in the activity of single neurons remains unknown. We used human intracranial electroencephalography (iEEG) and single unit recordings to investigated error detection in anterior cingulate cortex (ACC) and pre-supplementary motor area (pre-SMA). 24 epilepsy surgery candidates with implanted intracranial depth electrodes participated in the study and performed 71 sessions of a speeded version of a color-word Stroop task. Behaviorally, subjects showed a robust Stroop interference effect (155 ms) and post-error slowing effect (76ms). We isolated 232 neurons in ACC and 187 in SMA/pre-SMA. A substantial subset of these well-isolated neurons in ACC and pre-SMA changed firing rate immediately after subjects made an error, well before feedback was presented. 24% (55/232) of ACC and 22% (41/187) of pre-SMA neurons increased firing rate significantly while 15% (34/232) of ACC and 23.5% (44/187) of pre-SMA neurons decreased their firing rate significantly after errors relative to correct trials. A significant percentage of ACC, but not SMA, neurons was modulated in the correct trials that followed an error, a phenomena termed post-error modulation (13.4% increase while 12% decrease firing rate). This suggests that the ACC is involved in cognitive control mechanisms that detect and compensate for errors. We simultaneously recorded iEEG from macro electrodes and local field potential from microwires. In both we identified error-related potentials in ACC and pre-SMA. These error-related potentials had a negative and positive going component with waveform and latency similar to classical studies of the ERN (Falkenstein et al 1990, Gehring et al,1993). Theta power increased significantly more in error trials than correct trials (ACC: 44% of all sessions, SMA: 60% of all sessions). The temporal patterns of the ERN and error-related neuronal activity suggest that we have identified a single-neuron correlate of the classic scalp-recorded ERN. In surprising contrast, we did not find any single-neuron correlates of conflict monitoring. Together, our findings provide the first potential circuit-level mechanism for well-known theories of error monitoring by ACC and pre-SMA.

Title: Agency, learning and reward: a study using temporal binding

Authors: S. DI COSTA[1], H. THÉRO[2], *P. HAGGARD[1];
[1]Univ. Col. London, London, United Kingdom; [2]École normale supérieure, Paris, French Guiana

Abstract: The sense of agency refers to the feeling that we control our actions and, through them, effects in the outside world. Laboratory research on sense of agency often lacks ecological validity. Studies typically investigate associations between one simple action, and an arbitrary, direct effect of the action. Outside the laboratory, actions are embedded in a rich perceptuomotor, affective and social landscape. People frequently select one action from several possible in a given situation, based on a goal they wish to achieve. Thus, the sense of agency seems intimately related to value-based decision making. However, few studies have attempted to link sense of agency with outcome valence. Accordingly, we combined measures of agency (described below) with reward-based decision-making, seemingly for the first time. We used a reversal learning approach, which requires participants to track occasional changes in the mappings between two keypresses and two outcomes, and adjust actions accordingly, to maximise reward. In three experiments, participants chose between two action alternatives, which differed in reward probability. We also measured shifts in perceived time of actions and subsequent outcomes, or "temporal binding" as an implicit proxy for sense of agency. In the first experiment, switching between actions produced greater binding of the action towards the outcome than repeating actions. Further, negative outcomes showed stronger binding of outcome towards action than positive outcomes. Both effects were absent when participants made timing judgements before the reward value was known, suggesting a reconstructive effect of rewards on action experience (Experiment 2). Experiment 3 disentangled the effects of reward and contingency, with an additional condition having the same occurrence patterns as unrewarded trials, but irrelevant to reward and to overall performance. Switching between actions again produced stronger action binding, but no effect of valence on outcome binding was found. This suggests that valence effects on sense of agency may be consequences of the frequent and contingent relation between action and positive outcomes in instrumental learning. Finally, we used mixed-model regressions to explore the sources of variability in individual timing judgements across all 3 experiments. This showed a single reliable relation at the trial-to-trial level, between strong action binding and failure to earn reward on the previous trial. Our work suggests a novel relation between sense of agency and reward-based decision-making.

Title: Positive reinforcement enhances encoding of upcoming information

Authors: *D. G. DILLON[1], M. FRANK[2], D. BADRE[2], D. A. PIZZAGALLI[1];
[1]Ctr. for Depression, Anxiety and Stress Res., McLean Hospital/Harvard Med. Sch., Belmont, MA; [2]Cognitive, Linguistic & Psychological Sci., Brown Univ., Providence, RI

Abstract: Each day we form many short-term memories, most of which rapidly decay. However, some episodes stay with us for years, even decades. What triggers memory retention? We hypothesized that positive reinforcement is critical: by activating brain reward networks that communicate with medial temporal lobe memory regions, positive reinforcement may promote consolidation. To test this hypothesis in Experiment 1, 36 adults viewed 240 natural and man-made images and decided to keep or reject each one. Decisions were reinforced by delivery of "rewards" (monetary feedback) or "zeros" (no monetary feedback), and the reinforcement rate for stimulus/response pairings varied over the two blocks of the task. Participants returned a day later for a surprise recognition memory test. We predicted that recognition accuracy (hit rate) would be higher for images followed by rewards versus zeros, but this was not the case for images from either encoding block (effect of current feedback on hit rate, by block: $Zs < 1.40$, $ps > 0.16$). However, there was a reliable effect of prior feedback: recognition accuracy was higher for images preceded by delivery of rewards versus zeros (effect of prior feedback on hit rate, block 1: $Z = 4.42$, $p < 0.001$; block 2: $Z = 3.03$, $p = 0.002$). In Experiment 2, 22 adults completed the same task during functional magnetic resonance imaging. Replicating Experiment 1, recognition accuracy was higher for images preceded by rewards versus zeros (block 1: $Z = 4.28$, $p < 0.001$; block 2: $Z = 1.95$, $p = 0.051$), but was unaffected by feedback delivered following image presentation ($Zs < 1$). A whole-brain "reward versus zero" contrast revealed activation of bilateral hippocampus (left, $Z = 4.59$; right, $Z = 5.09$) and ventromedial prefrontal cortex ($Z = 4.91$), regions consistently implicated in episodic encoding and reward valuation (cluster $ps < 0.05$, FWE-corrected). Because the memory tests were unexpected, these results cannot be attributed to strategic effects at encoding. Thus, positive reinforcement elicits robust hippocampal activation and appears to facilitate incidental encoding of upcoming information in this task, leading to better retention. To strengthen this interpretation, ongoing analyses are focused on determining whether there is a significant interaction between the hippocampal response to (1) reward versus zero delivery and (2) subsequently remembered versus forgotten

images. These findings may be relevant to understanding the co-occurrence of anhedonia and memory deficits in certain psychiatric conditions, such as unipolar depression.

Title: Dissociable effects of reinforcement valence and learning rate on incidental encoding and consolidation of episodic memory

Authors: ***A. I. JANG**[1], M. NASSAR[1], D. DILLON[2], M. FRANK[1];
[1]Brown Univ., Providence, RI; [2]McLean Hospital/Harvard Med. Sch., Belmont, MA

Abstract: Maintaining accurate beliefs in a changing environment requires learning from rewards and penalties, but also adjusting the rate of learning according to environmental statistics. For example, learning should be enhanced when outcomes are surprising or beliefs are uncertain but reduced when beliefs are reliable and outcomes are noisy. In such scenarios, adaptive learning is thought to involve two major neuromodulators: dopamine, which is thought to signal outcome valence relative to expectations, and norepinephrine, which is thought to signal how much should be learned from a new outcome. These two neuromodulators are also thought to affect memory encoding and consolidation through actions on the temporal lobe. However, recent studies designed to elicit dopamine release during decision-making have reported very different effects on subsequent memory recall for trial-specific stimuli. Here we try to clarify the effects of dopamine in a behavioral task by de-correlating outcome valence (thought to be signaled by dopamine) from overall learning rate (thought to be signaled by norepinephrine) and measuring the effects of both factors on incidental memory encoding and consolidation. To do so, we designed a novel 2-part task that required reinforcement learning amid change points followed by a surprise recognition memory test that was administered online via Amazon Mechanical Turk. In part 1, inferring the best choice ('play' for potential reward, or 'pass') on each trial required subjects to integrate information about trial value (sampled independently on each trial and displayed numerically), reward probability (evolving according to a change-point structure and learned by integrating feedback across trials), and stimulus

category (depicted by a unique exemplar image). Subjects rationally adjusted learning from trial-to-trial and these learning rates were largely uncorrelated with expected and actual trial values. The recognition memory test was administered either 5 minutes or 24 hours after the decision task and required subjects to report whether each of a series of images had been used as a category exemplar during the decision task. We found that feedback valence and learning rate made dissociable contributions to subsequent recall. Positive feedback on play trials elicited improvements in consolidation for the subsequent trial exemplar, whereas surprise-driven learning enhancements led to diminished encoding of the previously displayed exemplar. This work should help clarify seemingly contradictory accounts of the role of feedback signals in episodic memory consolidation and informs future studies directed at inferring mechanisms.

Title: Reinforcement mechanisms underlie use-dependent plasticity in human motor behaviors

Authors: ***F. MAWASE**[1], S. UEHARA[1], A. BASTIAN[2,4], P. CELNIK[1,2,3];
[1]Physical Med. and Rehabil., [2]Neurosci., [3]Neurol., Johns Hopkins Univ., Baltimore, MD;
[4]Kennedy Krieger Inst., Baltimore, MD

Abstract: Use dependent plasticity (UDP) has been defined by the presence of movement direction biases resulting from movement repetition. Although these biases have been observed in many transcranial magnetic stimulation (TMS) and behavioral human studies, little is known about the mechanisms that underlie UDP. In particular, the effects of reinforcement mechanisms in previous studies are hidden behind the goal of the task and likely go unnoticed. Therefore, one suggested hypothesis is that UDP is insensitive to reward and reflects the history of the repeated actions. Alternatively, it is conceivable that reinforcement mechanisms may also play a role in UDP. Here we assessed UDP in a series of brain stimulation and behavioral experiments in which reinforced repeated actions and non-reinforced repeated actions could be distinguished. We performed two complementary experiments with independent samples. The first experiment explored the effect of implicit reinforcement during skill learning on UDP, while the second experiment explored the effect of explicit reinforcement during simple repetition on UDP. In the first experiment, two groups of subjects learned a pinch force task where forces mapped to lateral

cursor displacement. Subjects were asked to move the cursor sequentially to set of five targets by applying isometric forces in one predefined direction. Group 1 trained on consistent trials of a logarithmic map, which allows performance improvement, whereas group 2 were exposed to random maps that markedly decreased the number of successful trials and thus prevented accumulation of learning. A second experiment included two additional groups of subjects that were instructed to move the cursor to a single target by applying isometric force. We dissociate reinforced repeated actions from non-reinforced repeated actions by giving explicit binary reward associated with task success (group 3) and random rewards independent to task success (group 4), respectively. We found that TMS-evoked movement directions were biased toward directions that were either implicitly or explicitly reinforced (group 1 and 3), suggesting that rewarded actions might be a mechanism that is critical to develop movement direction biases. Critically, these biases were not present when repetitions were not associated with learning (group 2) or when they were accompanied by random reinforcement (group 4). Altogether, our findings support a crucial role of reinforcement mechanisms on use-dependent plasticity and suggest that use-dependent processes might underlie formation of motor habits, in our case expressed as biases towards previous rewarded actions.

Title: Behavioral studies with the cue-approach task show it can enhance preferences towards faces and fractals

Authors: *T. SALOMON[1], R. BOTVINIK[2], S. ISRAEL[2], T. SCHONBERG[3];
[2]Sagol Sch. of Neurosci., [3]Dept. of Neurobiology, The George S. Wise Fac. of Life Sci. and Sagol Sch. of Neurosci, [1]Tel Aviv Univ., Tel Aviv-Yafo, Israel

Abstract: How the brain constructs value is a basic question in decision neuroscience. We recently presented replicable results with of cue-approach task, where the mere-association of a tone and a button press led to preference changes of snack food items without external reinforcement or context changes. Here we present novel findings showing that the task can be used to enhance preferences of a wide range of stimuli such as faces and fractals. Two independent samples were collected: 28 participants (16 F, ages 18-32, (mean 24.8 ± 3.8)) completed the task with neutral and happy face images. Another sample with 24 participants (14 F, ages 18-27, (23.2 ± 2.2)) completed the task with color fractal images. To obtain individual rankings of faces and fractals, we used a binary ranking method. We then split the items and

defined half of the items as higher valued (HV) and the other items as lower valued (LV) items. Images of 60 faces or fractals were presented on the screen for 1 sec. Participants were instructed to press a button as fast as they could only when they heard a tone. Out of the 60 items, 20 or 24 (10 or 12 HV and 10 or 12 LV) were consistently associated with the tone in the face and the fractal task, respectively. The items were presented 12 times each during training. In the probe phase, participants were presented with pairs of items from the same value category that had similar rankings, but only one of the items in each pair was associated with the signal in the training phase (e.g. GoHV vs. NoGoHV). Participants were asked to choose one item per trial based on their preferences. To measure the success of training we compared the ratio of choices of the Go vs. NoGo items (within HV or LV pairs). We found that faces associated with the go-signal during training were chosen significantly more often during probe: for HV items 58% of trials p=0.003; LV items in 58% of trials, p=0.03. We found that fractals associated with the go-signal during training were chosen significantly more often during probe: for HV items 64% of trials p=0.002; LV items in 61% of trials, p=0.03. Thus, we show that cue-approach training can be extended to items that have no pre-existing preference and experience such as unfamiliar faces and fractals. The ability to change preference towards faces suggests a novel therapeutic approach for depression to enhance liking of happy stimuli. The known neural mechanism of face processing will allow us to track the underlying neural mechanisms of the preference change in the task. The ability to enhance choices of fractals suggests that preference towards neutral and positive stimuli can be enhanced with the cue-approach paradigm, which speaks to the generality of the underlying mechanism.

Title: Modulating EEG source activities in the frontal cortex by using tEIC increases learning rate during decision making

Authors: ***M. WATANABE**[1,2,3], A. HOTTA[1], A. MATANI[1];
[1]Grad. Sch. of Information Sci. and Technol., [2]Grad. Sch. of Arts and Sci., The Univ. of Tokyo, Tokyo, Japan; [3]RIKEN Brain Sci. Inst., Wako, Japan

Abstract: During value-based decision making, action values which are learned by trial and error can be altered by unexpected environment changes. Facilitating learning rates in response to environmental changes should be effective to adapt such changes. Studies have shown that neural activities in the frontal cortex reflect environmental changes and suggested that this region

may have a role of modulating learning rate (Behrens et al., Nature Neuroscience, 2007; McGuire et al., Neuron, 2014). However, it has not yet been investigated whether activation in the frontal cortex is sufficient to increase learning rate. We examined a role of the frontal cortex in value learning by facilitating or inhibiting neural activities with transcranial extracellular impedance control (tEIC), which is a noninvasive technique to increase (with Type I tEIC) or decrease (with Type II tEIC) EEG source activities by controlling extracellular impedance (Matani et al., PLoS ONE, 2014). A pilot study revealed that environmental changes were clearly observed in EEG between Fz and the right electrodes. We hence attached tEIC between these two locations. Six volunteer subjects participated in the following decision making task. Subjects selected left or right target on a PC monitor to earn a reward in each trial as high as possible. The two alternatives were set to provide rewards following normal distributions with each different mean and the common variance, which enables subjects to learn which selection leads better outcome. When learning seemed to be over, or selection showed on-side dominance, the environment, or the reward setting, was changed unexpectedly to them. Half of environmental changes were randomly selected and tEIC was applied for first 10 trials after the selected changes; the rest half was set to Sham accordingly. This study received approval from the Ethics Committee of the University of Tokyo. We demonstrated that Type I tEIC significantly increased learning rates compared to Sham (Wilcoxon signed-rank test, $p=0.03$), while it did not affect other parameters such as exploiting rate ($p>0.05$). Inhibiting the neural activities with Type II tEIC resulted in no significant changes in learning rate or other parameters. These results show that neural responses observed in the frontal EEG are quit relevant to learning rate. Moreover, since Type I tEIC, at least in theoretical, increases neural inputs in the cortex, the frontal cortex may integrate information on environmental changes with other neural inputs and provide output to facilitate learning.

Title: Neural networks underlying aversive context conditioning in humans

Authors: ***L. MARSTALLER**, H. BURIANOVÁ, D. REUTENS;
Univ. of Queensland, Brisbane, Australia

Abstract: Previous studies have shown that the hippocampus plays an important role in the contextual modulation of conditioned fear responses. However, the functional connectivity between limbic and cortical regions underlying aversive context conditioning in humans is still unclear. The purpose of this fMRI study was to investigate brain connectivity during aversive context conditioning in healthy male adults. The participants were presented with two simple visual stimuli in two alternating, visually distinct contexts. In the danger context but not the safe context, one of the stimuli was paired with cutaneous electro-tactile stimulation (CS+, 60% reinforcement), whereas the other, control stimulus (CS-) was never paired with stimulation. Electrophysiological data showed a significant difference in skin conductance responses between CS+ and CS- in the danger context as well as between CS+ in the danger and the safe context. Analysis of functional connectivity with bilateral amygdala revealed an extensive fear acquisition network that was engaged during CS+ in both contexts as well as during CS- in the danger context. The fear acquisition network included bilateral amygdala, hippocampus, caudate, and cingulate, somatosensory, middle frontal, and anterior temporal cortices. The results further showed a right lateralized temporal-limbic-occipital network that was activated whenever a stimulus was presented in the safe context. Importantly, this network was anti-correlated with activity in the striatum, the salience, and fronto-parietal networks. Our results suggest that the acquisition and contextual regulation of fear in humans can be differentiated by the functional connectivity of the right amygdala with its left hemispheric counterpart and the hippocampus.

Title: Up and down: Punishment, relief and emotional instability

Authors: *E. ELDAR[1,2], P. DAYAN[3], R. J. DOLAN[1,2];
[1]Wellcome Trust Ctr. for Neuroimaging, UCL, London, United Kingdom; [2]Max Planck Univ. Col. London Ctr. for Computat. Psychiatry and Ageing Res., London, United Kingdom; [3]Gatsby Computat. Neurosci. Unit, Univ. Col. London, London, United Kingdom

Abstract: Challenges to maintaining emotional equanimity come from both dashed and delivered hopes of the arrival of rewards and avoidance of punishments. We tested 48 participants whose emotional instability had been assessed through a questionnaire on two gamble-based card games involving probabilistic increases and decreases in both aversive and appetitive outcomes. In one game, a gamble could result in either avoiding or receiving a painful electrical shock; in the other, winning or losing a monetary reward. Participants could always

decline a gamble and opt for an intermediate outcome (i.e., 50% probability of shock or no change in monetary bonus). In both games, participants played with three different decks of cards, and had to learn by trial and error how likely a gamble was to be successful with each. We assessed responsivity to the different types of outcomes by examining how participants adjusted their gambles given the outcomes they had observed for each deck, and also monitored their galvanic skin responses. Selectivity to emotional instability was only apparent in the game involving shocks. Whereas most participants mainly learned through repeating successful gambles that had helped them avoid shocks, the more unstable participants primarily learned by declining previously unsuccessful gambles for which they had received shocks ($r = 0.66$, $p = 0.002$ corrected). In addition, high emotional instability scores were associated with weaker skin conductance responses to avoided-shock outcomes. Our findings suggest that a weaker response to a decrease in aversive outcomes might play a role in emotional instability.

Title: Adaptive prediction error coding in the human midbrain and striatum correlates with behavioral adaptation and learning efficiency

Authors: *K. M. DIEDEREN, T. SPENCER, P. FLETCHER, W. SCHULTZ;
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Learning to accurately predict upcoming rewards presents a challenge of everyday life. Most rewards are not singular events with constant magnitude, but fluctuate from one moment to the next, thus complicating learning. Learning may, however, be improved by scaling updates to match environmental variability. I.e., prediction errors (PEs) are more meaningful when rewards vary less. Importantly, the mechanism by which the PE signal is normalized to fluctuations in reward value may be facilitated by neurons encoding these errors in units of standard deviation (SD). Such adaptive coding puts PEs of different ranges on the same scale and enables the brain, despite its limited processing capacity, to discriminate between PEs equally well regardless of their absolute magnitudes. Although previous fMRI studies reported adaptive PE coding in contexts where task contingencies are explicit, it is, unclear whether the human brain encodes PEs normalized to reward variability during learning. Here, we investigated

adaptive coding during learning and established whether the degree of adaptive coding correlates with behavioral adaptation and task performance. Participants predicted the magnitude of upcoming rewards drawn from distributions with different SD's (5, 10 and 15). After each prediction, participants received a reward, yielding trial by trial PEs that spanned the full range of distributions. Fitting with computational models showed that participants decreased learning rates in conditions with a higher SD, suggesting behavioral adaptation. In line with the notion of adaptive coding, regression slopes in the midbrain and ventral striatum were steeper for PEs occurring in distributions with smaller SDs. Indeed, BOLD responses varied with normalized (PE/SD) instead of non-normalized PEs. Adaptation was not instantaneous but only occurred as trials progressed. In addition, BOLD encoding slopes for conditions with medium variability (SD 10) decreased when paired with a lower SD (SD 5) and increased when paired with a higher SD (SD 15), revealing additional contextual effects on adaptation. Adaptive PE coding was paralleled by behavioral adaptation to reward variability, revealing a tight relation between behavioral and neural measures of adaptation. Indeed, the individual degree of behavioral adaptation correlated strongly with the individual extent of adaptive PE coding in the striatum and midbrain. Crucially, a higher degree of BOLD adaptation in the midbrain and ventral striatum was related to improved task performance. These results suggest that adaptive PE coding during learning facilitates behavioral adaptation and supports efficient learning.

Title: Spontaneous eyeblink rate predicts increased recruitment of a model-based learning strategy

Authors: *T. C. SHI, L. E. HUNTER, Y. L. SOUFIAN, J. H. DECKER, C. A. HARTLEY; Sackler Inst. for Developmental Psychobiology, Weill Cornell Med. Col., New York, NY

Abstract: Individuals can recruit different strategies to make everyday decisions. Reinforcement learning theories distinguish two such strategies: a "model-based" strategy builds and recruits a cognitive model of the decision state space to flexibly evaluate and select actions, while a "model-free" strategy simply increments the probability of repeating previously successful actions. Deficits in model-based learning, proposed to support prospective goal-directed decisions, are thought to heighten vulnerability to multiple disorders of compulsivity (Voon et al., 2015). However, determinants of individual variability in the recruitment of these two strategies are only beginning to be understood. Previous studies using pharmacological

manipulations (Wunderlich et al., 2012) and PET imaging (Deserno et al., 2015) have demonstrated a link between increased central dopamine levels and increased model-based choice. Based on an extensive literature associating increased central dopamine levels with higher spontaneous eyeblink rate (SEBR), we hypothesized that individuals exhibiting higher resting SEBR would show more model-based decision-making. To test this hypothesis, we recorded resting SEBR in healthy adults who subsequently completed a two-stage sequential reinforcement learning task designed to dissociate model-free and model-based choice behavior (Daw et al., 2011). We fit a hybrid reinforcement learning model to quantify the degree to which participants' choice behavior reflected model-based computations. Preliminary results revealed a significant positive correlation between resting SEBR and model-based choice (indexed by a continuous weighting parameter). Corroborating previous evidence that dopamine modulates the recruitment of model-based versus model-free learning, these findings further suggest that resting SEBR represents a valid measure for examining the relationship between dopaminergic function and choice behavior.

Abstract: Objective: Positive and negative feedback provides substantial information about our environment and drives learning and behavioral adaptation. Phasic variations in cardiac responses have been found to be sensitive to motivationally significant stimuli and are typically associated with a strong and partly prolonged deceleration for task-relevant feedback [1,2]. Previously, it has been reported that individuals with obesity show altered choice behavior and neural responses in feedback-based food and non-food related tasks [3,4,5]. Here, we

investigated the cardiac concomitants of positive and negative feedback in monetary gain and loss processing and their association to reinforcement-based learning in individuals with obesity. Methods: Obese (BMI >=30 kg/m2) and lean (BMI 18.5-24.9 kg/m2) adults comparable in age and education performed a probabilistic learning task. In separate gain, loss, and neutral monetary conditions participants learned to choose between a high and low reinforcement probability option in order to maximize their financial outcome. An electrocardiogram was acquired during this task. Participants' feedback-evoked heart period (HP) was analyzed using three inter-beat-intervals (IBI) around the time of feedback onset. Additionally, we modelled participants' learning performance using a Q-learning algorithm. Results: Behavioral analysis and computational modelling revealed decreased learning performance for participants with obesity in both monetary gain and loss trials. The presentation of negative feedback was associated with a typical prolonged HP deceleration that was particularly pronounced in the early stage of the experiment. Individuals with obesity showed a blunted cardiac deceleration compared to lean controls, which was related to learning performance. Conclusion: Our results suggest that obesity is associated with decreased feedback-based learning performance. Altered physiological responses to non-food reinforcement stimuli could be an indicator of an altered feedback-based monitoring system impairing the reinforcement-based learning process in individuals with obesity. Title: Neural oscillatory patterns during associative learning

Authors: *B. M. ROBERTS, A. CLARKE, C. RANGANATH;
Ctr. for Neurosci., Univ. of California, Davis, Davis, CA

Abstract: Much of our learning in everyday situations depends on our ability to learn new and sometimes arbitrary associations. This kind of learning has been studied in rodents and

nonhuman primates, and is known to depend on interactions between distributed brain regions including the prefrontal cortex, hippocampus, and striatum. In rodents, theta oscillations have been correlated with associative learning, but it is unclear whether these findings generalize to human associative learning. The purpose of this study was to characterize changes in oscillatory activity during learning of arbitrary visuomotor associations. We recorded EEG from 18 subjects recruited from the UC Davis student community during performance of an associative learning task. Each trial began with presentation of an abstract shape at the center of the screen. After a short delay period, subjects were prompted to press a button on the keyboard (numbered 1, 2, 3, or 4). Following each response, feedback was provided to indicate whether the response was correct or incorrect. Subjects were instructed to use the feedback to help learn which button presses corresponded to each of the shapes. For each block (4 blocks total), subjects learned button presses for 12 distinct abstract shapes. Each shape was presented 12 times in randomized order. Behavioral results indicated that subjects learned the majority of these associations, and at the final repetition, subjects performed at an average of 87.04± 2.63% accuracy, which was significantly above chance ($p=5.8x10^{-123}$). Preliminary analyses of EEG data revealed differences in cue and delay period oscillatory activity across repetitions. Specifically, frontal theta power increased across learning, but become maximal once performance reached around 80% correct, and subsequently decreased during the final repetitions. These results indicate the importance of frontal theta oscillations during learning and strengthening of associations, but suggest that theta activity declines once the associations are well-learned. Learning-related changes in oscillatory activity also occurred during the delay period, particularly within alpha and gamma bands. Unlike theta oscillations, alpha and gamma power increased throughout learning. These oscillations may be more related to the maintenance of the visual stimulus during preparation for the motor response. Further analyses will investigate feedback-related activity and relate oscillatory power changes to behavioral performance. The present results, nonetheless, suggest that associative learning is associated with robust changes in brain activity that might be used as biomarkers in clinical studies.

Title: The effect of economic competition on the neural mechanisms of decision-making

Authors: *M. MARTINEZ-SAITO[1], B. GUTKIN[1,2], A. SHESTAKOVA[1], V. KLUCHAREV[1]; [1]Ctr. for Cognition and Decision Making, Higher Sch. of Econ., Moscow, Russian Federation; [2]Ecole Normale Superieure, Paris, France

Abstract: Behavioral economics has extensively studied how people make economic decisions in environments with different levels of supply and demand (i.e. with different levels of economic completion). However, the neural mechanisms underpinning such decisions remain unidentified. Here we study the neural mechanisms underlying decisions in different conditions of economic competition. Additionally, we aim to investigate the learning processes that lead to adaptive bargaining strategies, and how these are modulated by the degree of economic competition. Fifteen subjects played the role of buyers in simultaneous games against different numbers of prerecorded buyers and sellers. We used a modified Ultimatum Game (double auctions) in 50-minute 3T fMRI scanning sessions. Overall, the game allowed us to identify the effects of competition (number of sellers and buyers) on subjects' willingness to pay (the size of bids). Behavioral results demonstrated that subjects adjusted their trading price during the game based on the perceived competitiveness of the environment. We observed a progressive, yet incomplete convergence towards the optimal strategy predicted by a game-theoretic analysis. Intriguingly, the data hint at two separable learning processes involved: the subjects' overall scales of bid values are mainly influenced by the market environment, whereas subjects' trial-by-trial adjustment of bid values instead display a skewed distribution modulated by the outcome of the previous trial. Preliminary fMRI data analysis showed significant differential activations and differential dynamics of the activity in the basal ganglia in the different competitive conditions. The results of the pilot study indicate that people learn to alter trading price based on the perceived competitiveness of the environment and suggest a profound role of the dopaminergic system in behavioral adaptations during economic competition.

Title: Effects of dopamine on the consolidation of incremental learning: implications for Parkinson's disease

Authors: *M. SHARP[1], K. FOERDE[2], K. DUNCAN[1], D. SHOHAMY[1];
[1]Psychology, Columbia Univ., New York, NY; [2]Psychology, New York Univ., New York, NY

Abstract: There is accumulating evidence that dopamine plays an important role in various types of learning and memory. Much of this work has focused on the acquisition stage of learning, in particular the role of striatal dopamine in stamping in stimulus-response associations. Much less is known about the factors that influence the consolidation of these associations. Some clues come from the study of explicit memory where there is evidence that through its facilitation of long-term potentiation, the presence of dopamine at the time of encoding is critical for the consolidation of long-lasting episodic memories. Additionally, dopamine is thought to contribute to the specificity of long-term memory by selectively enhancing rewarding or otherwise motivationally salient memories. Here we aim to address two questions: First, does dopamine at the time of acquisition similarly lead to enhanced consolidation of incrementally learned stimulus-response associations? Second, does dopamine differentially enhance the consolidation of incremental learning from positive versus negative outcomes? We adapted an incremental learning paradigm that allows us to test the persistence of learning over time. Participants gradually learn probabilistic associations and on each trial, the outcome is indicated by a trial-unique image that, by its category assignment, signals whether they were correct or incorrect. The key feature of our design is that we test participants on two sessions separated by a one-week delay. This allows us to assess off-line consolidation of learning by comparing performance immediately after acquisition to performance after a long delay. Our design also allows us to test the effect of reward on off-line consolidation and, in parallel, to test the effect of reward on the consolidation of episodic memory for the trial-unique images. Preliminary data in healthy control participants shows that participants learn successfully, that both learning from positive feedback and learning from negative feedback persist similarly over the one-week delay, and that episodic memory is better for reward-associated images. To directly test the role of dopamine in off-line consolidation we will also present data from patients with early stage Parkinson's disease. One group of patients is tested ON medications at both sessions and one group is OFF medications at both sessions, thus allowing us to isolate the effects of dopamine on off-line consolidation from its effects on acquisition and performance.

Title: Decision-making in Parkinson's patients during a strategic game

Authors: *A. C. PARR, B. C. COE, G. PARI, D. P. MUNOZ;
Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada

Abstract: During social games, each player's actions and their associated outcomes change dynamically based on their opponent's actions, and experience is used to predict future outcomes by estimating the value of actions. In reinforcement learning models, a reward prediction error signal drives learning the value of actions, widely thought to be encoded by midbrain dopaminergic neurons. Deficits in reward-based learning, and corresponding decreases in striatal prediction error signalling, have been observed in Parkinson's disease (PD), which is associated with the loss of dopaminergic input to the striatum. Dopaminergic medication results in increased learning rates in dynamic decision-making tasks requiring reinforcement learning in PD. We investigated stochastic decision-making in patients with mild PD (stage 1-2) and age-matched controls while they competed in a color-based version of the strategic game, Matching Pennies, against a dynamic computer opponent that exploited biases in player's response patterns. Players selected one of two different colored visual targets, and were rewarded if their selection matched that of the opponent. Results were contrasted with a control decision-making task wherein reward was linked to a specific visual stimulus, but was otherwise similar to Matching Pennies in terms of sensory input, motor output, and reward rate. Participants indicated their choices with either a saccade or a button press. Both groups completed 2 sessions; PD patients both off- and on-medication. The PD group displayed a leftward direction bias during both tasks, which correlated with the severity of motor deficits on the contralateral side. During Matching Pennies, the PD group displayed a color bias, but no significant differences in overall reward rate compared to controls. PD patients had higher error rates during the control task, resulting in significantly lower reward rates compared to controls. In the PD group, we observed a significant main effect of medication on reward, and an interaction of medication by task, with a trend toward higher reward rates in the off-medication condition than the on-medication condition during Matching Pennies, however, this effect was not observed during the control task. We demonstrate that differences in dynamic choice behavior in PD can be investigated using strategic games.

Title: Is dopamine necessary for reward-related incidental learning improvements? Evidence from patients with Parkinson's disease

Authors: *M. V. FREEDBERG[1], J. SCHACHERER[2], K.-H. CHEN[3], K. NARYANAN[3], E. UC[3], E. HAZELTINE[2];
[2]Psychology, [3]Neurol., [1]The Univ. of Iowa, Iowa City, IA

Abstract: Midbrain dopamine neurons respond to both the presence of an unexpected reward and the absence of an expected reward (Schultz, 1998). This dopamine reward-prediction signal has been inferred to be involved in various forms of learning including incentive learning and instrumental learning (Wachter et al., 2009; Frank et al., 2004). However, recently it has been demonstrated that rewards can be used to bolster incidental learning, even when participants demonstrate little to no awareness of which associations were rewarded (Freedberg et al., in review). The primary pathology in Parkinson's disease (PD) is the degeneration of dopaminergic neurons in the midbrain with projections to brain regions important for motor function, cognition, and behavior. Here, we examine the role of dopamine neurotransmission in supporting reward-related improvements by comparing the performance and learning of patients with Parkinson's disease (PD), who are not demented and live independently, to age-matched comparisons. Participants performed a single-session experiment in which they were asked to respond to pairs of faces in which half the pairs were linked to a monetary reward. Immediately following training of the rewarded and unrewarded combinations participants performed a transfer block where they were asked to perform the same pairs without rewards. The data indicate that patients with PD showed significantly less reward-related incidental learning improvements compared to age-matched comparisons ($F(1, 10) = 9.794$, $p < 0.05$). These results may emphasize a critical role of dopamine neurotransmission in acquiring rewarded information as well as highlight the potential learning deficits of patients with PD in acquiring rewarded information.

Title: Perceptual learning affects post-sensory processing on a visual decision making task

Authors: *J. DIAZ, M. PHILIASTIDES;
The Inst. of Neurosci. and Psychology (INP), Univ. of Glasgow, Glasgow, United Kingdom

Abstract: Training and experience lead to long-lasting improvements in our ability to make decisions based on ambiguous sensory information - a phenomenon commonly referred to as perceptual learning. Despite the obvious prevalence of perceptual learning in everyday life, its underlying neural substrates are still not well understood. Recent primate electrophysiology experiments have provided compelling evidence that perceptual learning during decision making does not change how sensory information is represented in the brain, but rather how sensory representations are interpreted, particularly by higher-level areas involved in the decision process itself (Law & Gold, 2008). To test this interpretation formally in humans we recorded electroencephalography (EEG) during a visual two-alternative forced choice discrimination task (face vs. car discrimination). Using this task we previously identified two temporally distinct EEG components discriminating between the two image categories, which were associated with early encoding of the sensory evidence and post-sensory encoding of the decision evidence, respectively (Philiastides and Sajda, 2006). Here we measured how the strength of these components (i.e. our ability to discriminate between face and car trials) changed over the course of three days. We used single-trial multivariate discriminant analysis of (EEG) data collected from fourteen participants to identify the latency and strength of the early and late components highlighted above (i.e. sensory and decicion evidence, respectively). We found that discrimination performance for the early component remained unchanged during training, whereas that of the late component systematically improved over the three days. Importantly, we also observed that the onset time of the late component, but not the early one, moved earlier in time with learning, consistent with a more efficient representation of decision evidence later in the course of training. Taken together these findings suggest that perceptual learning has a strong influence on the readout of the relevant decision evidence later in the process consistent with previous accounts from the primate literature. Finally, we showed that a simple reinforcement learning (RL) mechanism can account well for the training effects we observed in our data by correlating the trial-by-trial amplitude fluctuations in our EEG components with single-trial decision variables obtained from a RL model.

Title: Spatiotemporal characteristic of reward-based learning in humans

Authors: *E. FOURAGNAN[1], C. RETZLER[2], K. MULLINGER[3], M. PHILIASTIDES[1]; [1]Inst. of Psychology and Neurosciences, Univ. of Glasgow, Glasgow, United Kingdom; [2]Dept. of Behavioural & Social Sci., University of Huddersfield, United Kingdom; [3]Sch. of Physics and Astronomy, Sir Peter Mansfield Magnetic Resonance Ctr., University of Nottingham, United Kingdom

Abstract: Adaptive decisions depend on accurate outcome representations associated with potential choices. These representations can be acquired with reinforcement learning mechanisms that use the prediction error (PE) - the difference between expected and actual outcomes - as a learning signal to update expectations. PE signals are characterized by their valence and magnitude components; however, the relative contributions and neural systems associated with each component remain debated. Here, we collected simultaneous EEG and fMRI data while participants performed a probabilistic reversal task. Exploiting the trial-by-trial variability in the two modalities we provided a characterization of the global network dynamics associated with PE processing and reward learning in humans. Specifically, we identified two spatiotemporally distinct processing stages of PE valence: an early process driven by an automatic alertness response to negative outcomes and a later, more deliberate, valence assessment, along both outcome types, required for updating value expectations. Importantly, these two valence systems interact to promote switching behavior following negative outcomes. Parallel to the late PE valence evaluation, we found that the brain also represents quantitative information about PE magnitude, in a largely separate network. Intriguingly, we also found an overlap between the late PE valence and magnitude networks in a few nodes. These areas exhibited a response profile consistent with a linear superposition of the two PE components rather than a fully monotonic response as would be expected for a signed PE signal. This finding emphasizes the importance of separate but potentially simultaneous contributions of PE valence and magnitude signals during learning. Crucially, we demonstrate that these findings were missed using conventional model-based fMRI.

Title: Spatiotemporal characterization of value-based decision making in humans using simultaneous EEG/fMRI

Authors: *M. PISAURO[1], E. FOURAGNAN[1], C. RETZLER[1,2], K. MULLINGER[3,4], M. PHILIASTIDES[1];

Abstract: Current computational work suggests that value and preference-based decisions involve an integrative mechanism in which subjective value information supporting different decision alternatives accumulates over time to an internal decision boundary. However, the neurobiological validity of this proposition remains unclear. A recent study in humans using electroencephalography (EEG) data suggests this temporal accrual of decision evidence is captured on parietal and frontal electrode sites (Polanía et al., Neuron 2014). However, due to the low-spatial resolution of the EEG the full spatiotemporal characteristics of the decision process could not be inferred. The goal of this study was to couple high temporal resolution, single-trial EEG with simultaneously acquired fMRI to characterize the global network dynamics associated with value-based decisions in humans. Twenty-four subjects participated in the study. EEG and fMRI data were acquired simultaneously on a 64-channel MR-compatible Brain Products EEG system and a 3T Philips Achieva MR scanner, respectively. Subjects performed a two-alternative forced choice task between pairs of snack items, which they have previously rated individually using a 5-point likert scale. Difficulty in the task was controlled by adjusting the overall difference in value between the pairs of items. On average, participants' behavioral performance declined as task difficulty increased (i.e. reaction times increased and accuracy dropped). We fit a sequential sampling model (Ornstein-Uhlenbeck process) to the behavioral data of individual subjects in order to generate predictions on the temporal profile of the underlying accumulating activity. We then correlated these model predictions with the EEG to identify sensor activity mirroring a process of evidence accumulation. Consistent with previous reports, we found two clusters on parietal and frontal electrode sites, which were highly correlated with the temporal dynamics of the decision process as predicted by the model. Finally, we exploited single-trial variability in the slope of the relevant EEG activity in the two clusters of interest to build EEG-informed fMRI regressors to further infer the spatial extent of the brain networks involved in value-based decisions.

Title: Working memory contributions to reinforcement learning: an fMRI study

Authors: *A. G. COLLINS[1], B. A. CIULLO[1], M. J. FRANK[1,2], D. BADRE[1,2];
[1]Brown University, CLPS, Providence, RI; [2]Brown Inst. for Brain Sci., Providence, RI

Abstract: Many cognitive processes contribute to our ability to learn from reinforcement. One such process, referred to as reinforcement learning (RL), relies on the accumulation of reward prediction errors to estimate choice values, and has been related to dopaminergic and striatal function. However, other processes, such as working memory (WM), are also involved in learning. Disentangling their contributions is essential to understanding the role of different neural systems, such as prefrontal cortex, hippocampus and striatum, to human learning. To that effect, we previously developed a task that provided preliminary evidence that WM and RL contributions to learning are supported by prefrontal and dopaminergic striatal function (Collins & Frank 2012). Here we investigate the interactions between the neural processes involved using functional neuroimaging. Using truthful reinforcement, participants learned to pick 1 of 3 actions for each stimulus of a set presented in a given block. To manipulate WM demands and separate the capacity-limited WM system from the RL system, we varied the set size: in each block, participants learned responses for 1 to 6 new visual stimuli. Behavioral results (N = 22) replicated previous findings: subjects learned slower with increasing set-sizes, and their accuracy decreased with the delay between two successive presentations of the same stimulus, two indicators of capacity-limited, short-term working memory. We fit subjects' behavior with our computational model accounting for learning as a mixture of WM and RL, and extracted individual subjects' RL reward prediction errors (RPE) for model-based fMRI analysis. A central question relates to the nature of the interaction between the two systems. If they collaborate, WM should provide expectations that yield lower RPEs in the RL system, and this should be observable in low set sizes or in low delay trials within high set sizes. If they compete, when the WM system dominates in lower set sizes, RPE representations in the RL system should be attenuated for all outcomes. Finally, if RL systems learn independently of explicit memory maintenance, RPE representation should not be sensitive to those factors. fMRI analyses reveal that hippocampus and left intraparietal sulcus were modulated by set size, confirming their role in the WM system. In contrast, inferior frontal sulcus and bilateral ventral striatum were increasingly sensitive to RPE with higher set size. Our results offer preliminary evidence for an

interactive account of RL and WM contributions to learning; subsequent analysis will reveal the nature of the interactions between these dynamic learning systems.

Title: Frontal beta oscillations reflect encoding of information related to desired task performance irrespective of feedback valence

Authors: *A. HAJIHOSSEINI, C. B. HOLROYD;
Dept. of Psychology, Univ. of Victoria, Victoria, BC, Canada

Abstract: Several studies have shown that reward feedback stimuli elicit increased beta power (20-30 Hz) over frontal areas of the human scalp. In a previous study, we proposed that frontal beta power reflects the transfer of information about recently rewarded actions from dorsolateral prefrontal cortex (PFC) to brain areas responsible for task execution (SFN, 2014). Here we used a novel guessing task that included on each block of trials separate choice and recall phases to test whether frontal beta power is specifically sensitive to remembering rewarded actions. During the initial choice phase on each block, subjects were required to select 10 stimuli sequentially from a group of 12 stimuli on the screen representing 12 decks of cards. Following each selection, they were presented with either reward (5 cent), error (0 cent), or neutral (1 cent) feedback. Depending on condition, they were given instructions to remember either the rewarded decks (remember reward: RR) or the decks followed by error feedback (remember error: RE), or were not provided with instructions (no-recall: NR). In a subsequent recall phase in the RR and RE conditions, they were asked to select either the previously rewarded (RR) or the error (RE) decks from the previous choice phase. Principle component analysis applied to post-feedback beta power revealed 3 components distributed over the frontal-central, frontopolar, and frontal-lateral areas of the scalp. A 3x3x2 ANOVA with frontal 'virtual channel' (central, polar, lateral), memory condition (RR, RE, NR), and valence (reward, error) on beta power revealed a significant main effect of valence ($F(1,29) = 4.25$, $p = 0.048$) and an interaction between memory condition and valence ($F(2,58) = 3.48$, $p = 0.049$). Post-hoc tests indicated that beta power to reward feedback was larger in the NR and RR conditions compared to the RE condition ($t(29) = 2.8$, $p = 0.01$; $t(29) = 1.9$, $p = 0.06$). Further, beta power to reward and error feedback in the choice phase was negatively correlated with reaction times for correct recalls in the RR ($r = -$

0.37, p = 0.042) and RE (r = -0.57, p = 0.001) conditions, indicating that high beta power in the choice phase predicted faster correct responses in the recall phase, irrespective of the feedback valence. These results point to an important role for frontal beta oscillations in mediating a working memory process elicited by performance feedback irrespective of its valence. In the context of our previous studies, we suggest that this process is elicited by feedback stimuli for the purpose of transferring information about recent sequences of actions maintained in the PFC to downstream areas for task execution according to desired performance.

Title: Different momentums: lifespan age differences in the adaptive regulation of learning rates

Authors: *B. EPPINGER[1], R. BRUCKNER[2], M. R. NASSAR[3], S.-C. LI[1];
[1]TU Dresden, Dresden, Germany; [2]Max Planck Inst. for Human Develop., Berlin, Germany; [3]Brown Univ., Providence, RI

Abstract: Adaptive behavior in uncertain environments depends on the ability to dynamically adjust the rate of learning according to environmental statistics. Results of several previous studies suggest that children and older adults have problems in this type of flexibility. These age-related deficits in adaptive control have been attributed to age differences in the structure and function of the medial prefrontal cortex. However, the computational mechanisms that lead to these deficits are still not well understood. In this study we used a predictive inference task to investigate factors that could contribute to lifespan developmental differences in the adaptive adjustment of learning in a dynamic task environment. Using Bayesian modeling and regression analyses, we dissociated three factors, surprise, uncertainty and reward, which differentially affect learning-rates in children (8-10 years; n=33), adolescents (13-17 years, n=29), younger adults (20-28 years, n=32) and older adults (65-80 years, n=30). We found that children and older adults showed overall reduced learning rates compared to adolescents and younger adults, indicating that they tend to adjust their behavior less to changes in the environment. Furthermore, our results showed that children were particularly sensitive to surprising outcomes (substantial changes in the environment) when compared to the three other age groups. In contrast, in older adults we found a specific deficit in the ability to learn from unsurprising outcomes. Based on

simulations using the computational model we could further show that these deficits are consistent with a diminished capacity to represent uncertainty in older adults. Finally, we found that adolescents were overly sensitive to rewarding outcomes and disproportionately updated their predictions after receiving reward. This reward bias is consistent with the previous literature and was less pronounced in children, younger and older adults. To summarize, our findings point to substantial lifespan developmental differences in the factors that govern adaptive learning in dynamic task environments. It seems conceivable that these developmental changes reflect transformations in the interplay of neuromodulatory systems (such as the locus coeruleus norepinephrine (NE) and the frontal-striatal dopamine (DA) systems) and the medial prefrontal cortex across the human lifespan.

Title: Effects of affective arousal on choice behavior, reward prediction errors, and feedback-related negativities in human reward-based decision making

Authors: *H.-H. LIU[1,4], M.-H. HSIEH[4], Y.-F. HSU[1,2,3], W.-S. LAI[1,2,3];
[1]Psychology, [2]Grad. Inst. of Brain and Mind Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan; [4]Psychiatry, Natl. Taiwan Univ. Hosp., Taipei, Taiwan

Abstract: Emotional experience has a pervasive impact on choice behavior, yet the underlying mechanism remains unclear. Introducing facial-expression primes into a probabilistic learning task, we investigated how affective arousal regulates reward-related choice based on behavioral, model fitting, and feedback-related negativity (FRN) data. Sixty-six paid subjects were randomly assigned to the Neutral-Neutral (NN), Angry-Neutral (AN), and Happy-Neutral (HN) groups. A total of 960 trials were conducted. Subjects in each group were randomly exposed to half trials of the pre-determined emotional faces and another half of the neutral faces before choosing between two cards drawn from two decks with different assigned reward probabilities. Trial-by-

trial data were fit with a standard reinforcement learning model using the Bayesian estimation approach. The temporal dynamics of brain activity were simultaneously recorded and analyzed using event-related potentials. Our analyses revealed that subjects in the NN group gained more reward values than those in the other two groups; they also exhibited comparatively differential estimated model-parameter values for reward prediction errors. Computing the difference wave of FRNs in reward vs. non-reward trials, we found that, compared to the NN group, subjects in the AN and HN groups had larger "General" FRNs (i.e., FRNs in no-reward trials minus FRNs in reward trials) and "Expected" FRNs (i.e., FRNs in expected reward-omission trials minus FRNs in expected reward-delivery trials), indicating an interruption in predicting reward. Further, both AN and HN groups appeared to be more sensitive to negative outcomes than the NN group. Collectively, our study suggests that affective arousal negatively regulates reward-related choice, probably through overweighting with negative feedback.

Title: The relationships between age, associative memory performance and the neural correlates of successful associative memory encoding

Authors: *M. A. DE CHASTELAINE[1,2], J. T. MATTSON[3], T. H. WANG[4], B. E. DONLEY[2], M. D. RUGG[2];
[1]Neurobio. & Bahavior, [2]Ctr. for Vital Longevity, Univ. of Texas At Dallas, Dallas, TX; [3]Southwestern Med. Ctr., The Univ. of Texas, Dallas, TX; [4]Dept. of Psychology, Univ. of Texas at Austin, Austin, TX

Abstract: Previous fMRI studies have indicated that encoding-related activity in the inferior frontal gyrus (IFG) is sometimes more lateralized (left > right) in younger relative to older adults, and that greater right frontal activity in older adults is associated with poorer episodic memory performance. In contrast, prior findings also suggest that greater encoding-related hippocampal activity in older adults is predictive of better memory performance. The current fMRI study used an associative recognition procedure to investigate the relationship between episodic memory performance and encoding-related neural activity in young, middle-aged and older adults (total n = 136). Participants were scanned while they made relational semantic judgments on visually presented word pairs and then subsequently made associative recognition

judgments on studied, rearranged (items studied on different trials) and new pairs. Subsequent memory effects were employed to identify successful encoding activity - we focus here on the effects taking the form of greater activity for studied pairs later correctly identified as intact relative to the activity elicited by pairs later endorsed as rearranged. Across groups, subsequent memory effects were identified in a left-lateralized cortical network, including IFG and the hippocampus. There was little evidence that these subsequent memory effects differed with age. Left IFG effects were reliable in all groups while right IFG effects could not be independently identified in any age group. However, IFG effects in the younger group were found to be more lateralized (L > R) than in the older group. In the middle-aged group only, right IFG effects were negatively correlated with later associative memory performance. In both the young and middle-aged groups, right IFG effects were also negatively correlated with an offline measure of verbal memory ability. In contrast, hippocampal subsequent memory effects were positively correlated with later memory performance in all age-groups. The results replicate previous findings in showing greater asymmetry in frontal (IFG) subsequent memory effects in young relative to older adults, and extend prior findings of a negative relationship between right frontal subsequent memory effects and associative recognition in older participants to a middle-aged sample. The findings also replicate a previous report of a positive relationship between encoding-related hippocampal activity and memory performance. In all, the findings suggest that similarities across age groups in the neural correlates of successful associative encoding overshadow any between-group differences.

Title: Scanpath entropy during study predicts subsequent spatial reconstruction accuracy

Authors: *H. D. LUCAS, P. D. WATSON, J. M. MONTI, E. MCAULEY, A. F. KRAMER, N. J. COHEN;
Beckman Inst. for Advanced Sci. and Technol., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: The ability to encode complex information given limited time and resources is an important cognitive skill. Previous work has implicated hippocampal-prefrontal and

hippocampal-striatal brain networks in guiding advantageous study decisions via environmental exploration. However, little is known about how eye movement patterns relate to the ability to optimize intake of currently visible information. We recorded eye movements while a group of 78 healthy elderly participants studied a series of displays, each consisting of several objects in varying arbitrary spatial configurations. Participants were given 20 seconds to study each display, which they then attempted to reconstruct from memory. We found that participants' scanpath entropy during study- a measure of the randomness or unpredictability in their item-to-item fixation patterns- showed a significant negative relationship to subsequent reconstruction accuracy. In particular, participants who engaged in higher-entropy (e.g more random) scanning patterns showed a greater tendency to later "swap" or reverse the relative positions of objects within the array. Importantly, scanpath entropy while studying the displays also showed a significant negative relationship to performance on a separate auditory test of delayed story recall, suggesting that this measure may reflect an ability to self-organize information that extends to multiple stimulus domains and modalities. Finally, participants who reported more depressive symptoms also showed higher scanpath entropy, perhaps as a result of changes to the dopaminergic hippocampal-VTA circuit. While depressive symptoms did not directly correlate with memory performance, including entropy as a mediator revealed indirect effects of depressive symptoms (mediated by entropy) on both later spatial reconstruction accuracy and delayed story recall. These data suggest that scanpath entropy constitutes a useful tool with which to quantify the organization of strategic viewing behaviors, and may also provide a window into alterations to such behaviors in neurological and psychiatric disorders.

Title: Familiarity-novelty detection is an intrinsic property of cortical microcircuits with NMDA receptor-dependent synaptic plasticity

Authors: *X. ZHANG[1], H. JU[3], T. B. PENNEY[2], A. M. VANDONGEN[3];
[1]NUS Grad. Sch. for Integrative Sci. and Engin., [2]Psychology, Natl. Univ. of Singapore,

Singapore, Singapore; [3]Neurosci. & Behavioral Disorders Program, Duke-NUS Grad. Med. Sch., Singapore, Singapore

Abstract: Humans instantly recognize a previously seen face as "familiar" and are capable of recognizing thousands of faces. The ability to rapidly assess whether a sensory input is familar or novel is not restricted to faces and does not appear to require a conscious effort. To investigate the mechanisms underlying this familiarity-novelty detection ability we used a neural network model of cortical microcircuits consisting of spiking neurons with random recurrent connections, following the "liquid state machine" paradigm. To allow for unsupervised learning, we introduced NMDA receptor-dependent synaptic plasticity processes. Synaptic weights are initially set to random values and are subsequently altered by sensory experience through LTP, LTD and STDP processes. In the experiments we presented images of human faces, dog faces and car fronts to networks of 2,000-15,000 spiking neurons organized in a 3D topology. To facilitate analyzing the effects of plastic changes, overall pixel intensity levels of the images were adjusted so that the cumulative firing rate was the same before learning. Network activity evoked by the image stimuli altered synaptic efficacy, which in turn resulted in the network responding more strongly to a previously seen image. As a result, the networks distinguished familiar from novel images in their overall firing rate. Small networks of 2,000 spike neurons were able to encode the features of a single human face image through unsupervised learning and identifiy it accurately out of a set of 30 test images. Large networks of 15,000 spiking neurons were able to learn and memorize multiple faces simultaneously with high accuracy. Some of the best-performing networks could memorize 60 human faces. These results indicate that small cortical microcircuits containing NMDA receptor-dependent synaptic plasticity have an intrinsic ability for detecting whether a sensory input is familiar or novel. This abilty does not require a specialized wiring diagram or supervision, and therefore can be expected to emerge naturally in developing cortical circuits.

Title: Episodic memory is affected by emotional valence, not just arousal: Evidence from behaviour and Event-Related Potentials

Authors: *G. MACKENZIE, D. I. DONALDSON;
Psychology, Univ. of Stirling, Stirling, United Kingdom

Abstract: Research shows that emotion can enhance episodic memory, and amygdala activity projecting to the hippocampus is likely to be responsible. Emotionally arousing stimuli generate more amygdala activity than neutral stimuli and are therefore encoded and then retrieved preferentially in the hippocampus. There are, however, two principal dimensions of emotion - arousal and valence - and the amygdala-hippocampus model only provides an adequate account of how arousal affects memory. In practice, most research conflates the effects of arousal and valence on memory, but independent effects of valence on source memory have been reported, with behavioural impairment for negative but not positive pictures (MacKenzie, Powell & Donaldson, 2015). Here, we ask whether the neural basis of episodic memory is sensitive to emotional valence. Participants performed a source memory task in which the emotional valence (negative/positive) of stimuli was manipulated while arousal was equated across conditions. Pictures were studied with either a square or circle pattern superimposed on the image. Later, participants discriminated between studied and new pictures, making circle/square source judgments for pictures that were recognised. Source memory performance was better for positive than negative pictures. Furthermore, Event-Related Potential (ERP) old/new effects from 500-800msec post-stimulus onset had different scalp distributions for negative and positive pictures. Negative pictures were associated with a left parietal old/new effect, which is typically interpreted as a neural correlate of recollection. By contrast, positive pictures were associated with a more broadly distributed effect, extending to sites over frontal cortex. This pattern of ERP results indicates that negative and positive pictures are recollected differently, and that the superior source memory performance for positive pictures is linked to recruitment of additional retrieval processes. Most importantly, the enhanced source memory observed for positive pictures occurred despite any differences in arousal between the sets of pictures. These findings show that effects of emotion on episodic memory cannot be reduced to effects of arousal as the amygdala-hippocampus model suggests. Rather, the emotional valence of stimuli can affect episodic memory directly, at least during performance of source memory tasks.

Title: Prestimulus parahippocampal/hippocampal activity predicts associative retrieval success

Authors: *K. L. VILBERG, M. D. RUGG;
Ctr. for Vital Longevity, Sch. of Brain & Behavioral Sci., Univ. of Texas, Dallas, Dallas, TX

Abstract: While there exists a growing literature on how prestimulus fMRI activity at encoding relates to subsequent memory performance, to our knowledge, no prior study has evaluated whether prestimulus fMRI activity at test differs according to retrieval success. We conducted two experiments in which recollected information had to be maintained in working memory prior to a behavioral response. In both experiments, word-image pairs were studied in an intentional encoding task. In one experiment, words served as test items, and in the other experiment, images served as test items. Participants were instructed to try to recall the paired associate of the test item and hold it in mind until a question appeared at which time they were to answer the question with respect to the retrieved information, or if not recollected, to respond 'old, associate not recollected' or 'new'. In each case, a variable fixation preceded test item onset, allowing pre-stimulus, stimulus, and delay-related activity to be deconvolved. In the current analysis, we modeled the onset of the prestimulus fixation character, the onset of the test item onset, and a variable duration maintenance interval in order to distinguish between brain regions exhibiting recollection effects according to their time courses. In line with our prior findings in which the prestimulus fixation was not explicitly modeled, a large network of lateral cortical regions exhibited sustained recollection effects, whereas regions such as medial prefrontal cortex, retrosplenial cortex/posterior cingulate, and parahippocampal cortex displayed transient positive recollection effects. Prestimulus recollection effects were identified in bilateral parahippocampal cortex, extending into the posterior hippocampus. In each cluster, activity associated with test item recognition in the absence of associative retrieval exceeded that for trials associated with successful associative retrieval prior to stimulus onset and until roughly 3.5s thereafter at which point these differences reversed direction. The results raise the possibility that a reduction of ongoing activity in the parahippocampal cortex/posterior hippocampus prior to the onset of a retrieval cue facilitates associative retrieval.

Title: Associative activation and its relation to exploration in the brain

Authors: *S. BAROR, M. BAR;
Bar- Ilan Univ., Ramat Gan, Israel

Abstract: We tend to think about associative activation as an automatic process, whereby if A is associated with B, B is activated every time A is activated. Sometimes the activation of associated concepts depends on context (e.g., a towel in the shower and the same towel on the beach is associated with different items), but even then it is possible that irrelevant associations are still being activated, at least briefly. Here we challenged this implicit assumption of automaticity in associations by manipulating load. In a series of 4 experiments, participants responded in a free association task while load could be either high or low. Three types of load were employed: working memory load, cognitive load unrelated to working memory, and perceptual load. In all experiments we found that the associations provided by participants under the low-load conditions were significantly more diverse than the high consensus obtained under high load. In other words, with less load participants seem to activate more remote associations. These findings imply that high load has an inhibitory effect on active resources invested in the retrieval of associations. It is suggested that, by default, activation of associations is an active process of exploration, which under high load is narrowed to the immediate associations. Implications to exploration vs. exploitation in the brain, as well as to mood disorders and creativity will be discussed.

Title: An optimal slow-wave phase for learning-related auditory cues during sleep to improve subsequent memory performance

Authors: *L. BATTERINK, J. CREERY, K. A. PALLER;
Northwestern Univ., Evanston, IL

Abstract: Slow-wave sleep is characterized by synchronized EEG activity appearing as high-amplitude slow waves (0.5-4 Hz). These slow waves correspond to the alternation of active (Up) and quiescent (Down) states in cortico-thalamic networks. The Up state is a period of excitation, in which cortical neurons are depolarized and likely to fire action potentials; the Down state is a period of inhibition, in which neurons are hyperpolarized and unlikely to fire. Slow oscillations are known to play an important role in memory consolidation, presumably coordinating network

interactions (e.g., hippocampal-cortical and cortico-cortical). Research using a technique known as targeted memory reactivation (TMR) during slow-wave sleep shows that sensory stimulation with cues associated with previous learning can enhance memory consolidation through reactivation of individual item memories. In the present study, we hypothesized that the phase of the slow oscillation at which a learning-related cue is presented (i.e., corresponding to Up versus Down states) would influence whether the associated memory would be strengthened. In two separate studies, participants were taught arbitrary associations (picture-location or picture-word). During learning, each picture was also paired with a related environmental sound (e.g., cat with meow). Memory was assessed with an associative recall test. During an afternoon nap, half of the sounds were presented at a low intensity. After awakening, each association was tested again. Consistent with our hypothesis, slow-wave phase prior to sound onset predicted the extent to which memory strength changed. Memories that were subsequently strengthened versus subsequently weakened showed opposite phases for slow waves during the pre-stimulus period. These results suggest that TMR stimuli are more likely to be processed and trigger memory reactivation when they occur at the optimal phases of a slow oscillation. This optimal phase may correspond to the cortical Up state, enabling communication and synchronization across brain regions. These findings provide insights into the mechanisms underlying spontaneous memory reactivation during sleep, suggesting that reactivation is most likely to occur during cortical Up states.

Title: Meta-analysis specifying the core-network supporting episodic memory and episodic simulation

Authors: *R. G. BENOIT, D. L. SCHACTER;
Psychology, Harvard Univ., Cambridge, MA

Abstract: It has been hypothesized that our capacity to simulate hypothetical episodes is based on an episodic memory system that provides access to stored episodic details and the constructive processes to recombine these details into novel episodes. Key evidence for this constructive episodic simulation hypothesis has been provided by a number of neuroimaging experiments, which indicate that both episodic simulation and episodic memory are supported by

the same core network of brain regions. Here, we employed Activation Likelihood Estimation (ALE) to quantitatively summarize the results of those experiments. Specifically, we only included experiments that formally tested for spatial overlap of episodic memory and episodic simulation (e.g., by employing a conjunction approach), thus providing strict evidence for the core-network. At the same time, we included studies that examined the simulation of a variety of different hypothetical episodes (i.e., possible personal future, fictitious, and counterfactual past episodes), thus increasing the generalizability of our results. Our meta-analysis revealed the expected convergence of activation within the medial temporal lobes, large parts of the medial surface as well as parts of the lateral temporal and inferior posterior parietal cortices. In addition, episodic simulation and memory both consistently recruited a few other regions including parts of the bilateral dorsolateral prefrontal cortex. All of the identified regions overlapped with the default network. Episodic simulation - compared with episodic memory - presumably further requires stronger engagement of some parts of the core network (e.g., for the retrieval of disparate episodic details) and also recruitment of additional brain regions (e.g., for the novel recombination). A second ALE analysis indeed identified regions that were consistently more strongly engaged during episodic simulation than episodic memory. These included parts of the core network in the left dorsolateral prefrontal cortex and inferior posterior parietal lobe in addition to auxiliary regions that were broadly distributed across the default and fronto-parietal control networks. Together, the analyses quantitatively specify the set of regions engaged during episodic simulation, thus providing a foundation for further inquiries into their interactions and specialized contributions.

Title: The influence of mental countermeasures on memory detection using an fMRI-based Concealed Information Test

Authors: *J. PETH[1], T. I. BROWN[2], A. D. WAGNER[2], M. GAMER[1];
[1]Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [2]Dept. of Psychology and Neurosciences Program, Stanford University, CA

Abstract: The Concealed Information Test (CIT) is an implicit psychophysiological technique that aims to detect memory for crime details based on multiple-choice questions including crime related and equally plausible neutral answer options. Previous CIT studies revealed increased neural activity in a ventral frontal-parietal brain network (i.e. bilateral inferior frontal gyrus, right

middle frontal gyrus, right temporoparietal junction) for the comparison between crime details and neutral details. Countermeasures (CM) are techniques to voluntarily manipulate physiological responses during the CIT which might challenge the test's validity and its application in real life (e.g. courtroom) settings. Physical CM have been shown to strongly decrease validity of an fMRI-based CIT for autobiographic information. The impact of mental CM on neural activation during the CIT is unclear. To close this gap, the current mock crime study compared three groups of subjects. After completing a mock crime, the "guilty" subjects either attended the CIT without previous training (standard guilty group, n = 20) or following a detailed mental CM training (CM group, n = 20). The mental CM strategy involved imagining an emotional scene for half of the neutral answer options during the CIT in order to increase physiological similarity to remembering crime details. The CM details were memorized by the CM group prior to the test. Finally, uninformed innocents (innocent group, n = 20) completed the same CIT without any knowledge about the mock crime. All three participant groups performed the CIT while undergoing fMRI scanning, and univariate and multivoxel pattern classification analyses (MVPA) were used to detect brain activity distinguishing crime and neutral details. For the standard guilty group, univariate analyses demonstrate increased activity for crime details in the expected frontal-parietal brain regions and enabled a valid differentiation from innocent subjects. However, these regions were also activated for neutral details when employing mental CM in the CM group and decreased the CIT's validity to chance level. MVPA results demonstrate that the pattern classifier is still able to differentiate between crime details and CM details, and distinguish each of them from neutral details. Thus, recognition of crime details and practiced CM details seems to activate partly different brain regions. The current findings replicate the successful detection of memory for crime details in guilty subjects. In addition, our data reveal potential limitations of CIT applications in real life but we also found some evidence for successful detection of mental CM usage.

Title: Spatial cueing biases recognition memory judgments

Authors: ***K. MIYOSHI**, H. ASHIDA;
Kyoto Univ., Kyoto, Japan

Abstract: Different researchers have reported that the processing fluency of the stimulus significantly affects recognition memory judgments. In the present study, the effect of processing fluency induced by spatial cueing on recognition memory judgments was assessed. Participants memorized pictures of everyday objects, and their spatial attention was manipulated in a Remember/Know recognition memory test. Stimulus location was either predicted (congruent condition) or unpredicted (incongruent condition) using an arrow cue. The results revealed that participants exhibited familiarity-based false recognition more frequently in the incongruent condition. This increased false recognition was associated with participants' liberal response bias, not with decreased response accuracy. In the incongruent condition, participants may have attributed part of the perceived disfluency to the spatial cue and overestimated the fluency for the stimulus, leading to increased false recognition. In contrast, in the congruent condition, participants may have attributed some parts of the perceived fluency to the spatial cue and underestimated the fluency for the stimulus, leading to decreased false recognition. In short, stimulus-irrelevant spatial cueing induces unintentional reasoning about the source of fluency and biases familiarity-based recognition memory. The present results have significant implications for everyday situations, in that the incidental manipulation of attention could occur outside the laboratory. Possibly, déjà vu might be one manifestation of the effect reported here.

Title: Practice makes perfect in memory recall

Authors: *M. KATKOV[1], S. ROMANI[2], M. TSODYKS[1];
[1]Weizmann Inst. of Sci., Rehovot, Israel; [2]Janelia Res. Campus, Howard Hughes Med. Inst., Ashburn, VA

Abstract: Human memory is able to store vast amounts of information, however retrieval of this information when no cue is provided is challenging. For instance, in the classical free recall paradigm, participants are requested to recall words from randomly assembled lists in an arbitrary order. Typically, they cannot recall complete lists of more than 5 words. Nevertheless, there is a large variability in the number of recalled words both within and across participants. Here we asked whether individual differences in performance result from different patterns of recall, and whether there is an effect of practice. Analysis of the large dataset of free recall data collected in the lab of M. Kahana (UPenn) revealed a small fraction of participants that were able to recall complete lists of 16 words ("perfect trials") in many trials. Inspection of the recall patterns of these participants revealed that they widely apply one of 4 positional grouping strategies: "forward chaining" - recall of words in the order they were presented; a number of positional chunking where words from one chunk (a set of consequitively presented words) are recalled before any words from another chunk. In particular, we identified "4444", "33334" and "43333" chunking, where each digit represents the number of consequitive words in a chunk. We quantified the extent of positional grouping applied by participants in each trial. In trials with strong positional grouping, we observed that the average time to recall a new word is substantially smaller (and was approximately constant across output positions) when next recalled word is within the same chunk than when it is from a different chunk. The average performance of all participants was modestly increasing for the first 4 days, saturating afterwards. All participants showed increase in the number of perfect trials, but for the high performance participants this increase was especially pronounced - from few percent initially towards 30% during last day, whereas the rest of participants showed increase from 1% to 6%. Also the increase in the extent of positional grouping was significantly higher for high performance participants compared to the rest. Our results indicate that practicing free recall of randomly assembled lists cannot substantially improve the performance for most people, possibly due to hard limitations arising from random encoding of words in long-term memory; utilizing positional strategies could be the only efficient way to improve the recall but only a small fraction (around 10 percent) of participants could acquire them on their own with single exposure to each list.

Title: Competitive effects of pre-existing and new memory traces during reconsolidation of stimulus-response associations

Authors: *A. RICHTER[1], M. GUITART-MASIP[2], A. BARMAN[1], C. SEIDENBECHER[1], B. SCHOTT[1];
[1]Leibniz Inst. For Neurobio., Magdeburg, Germany; [2]Aging Res. Center, Karolinska Inst., Stockholm, Sweden

Abstract: The term reconsolidation refers to a process in which consolidated memories are reactivated and thereby become labile and can be modified before getting consolidated again. Depending on the treatment (e.g. injection of a drug, behavioral manipulations) and different parameters (e.g. memory types prone for reconsolidation, characteristics of successful reactivation), that are currently being investigated, the memory trace can be strengthened, updated or weakened. The aim of our study was to elucidate neuropsychological and brain mechanisms of reconsolidation processes in human probabilistic stimulus-response (S-R) association learning. To this end we designed a task including a probabilistic learning, a relearning and a retrieval session over three consecutive days. On the first day, participants learned S-R assciations that were reconfigured on the second day. Participants who reactivated the initial S-R pairings before relearning showed improved memory for the original associations from day 1, but impaired memory for the reconfigured associations from day 2. On the other hand, participants who did not reactivate the original associations did not exhibit such a pattern. Furthermore the effect of reactivation vanishes, when the relearning (day 2) is prolonged. These results suggest that reactivating memory for previously learned probabilistic S-R associations can induce a competition of pre-existing and newly acquired memory traces. Currently we are planning to investigate the neural correlates of the competitive effects of pre-existing and new memory traces during reconsolidation.

Title: An individualized approach to treatment of prospective memory in people with brain injury

Authors: *E. AIKEN, Z. BITAN, S. RASKIN;
Trinity Col., Hartford, CT

Abstract: Three case studies of Kosakoff's syndrome, meningioma, and traumatic brain injury (TBI), will be presented to illustrate the variety of cognitive deficits across different individuals

with ABI. This study uses cognitive rehabilitation therapies to target individual cognitive symptoms. Results and discussion place emphasis on the use of prospective memory (PM) training for treating Kosakoff's syndrome. The Memory for Intentions Screening Test (MIST) served as the assessment for PM analysis pre and post rehabilitation. The data from this study will be used as a model for a larger study analyzing the effectiveness of different cognitive rehabilitative therapies: PM training, attention process training (APT) and executive function training, in treating ABI that are individualized based on cognitive symptoms.

Title: Stable representations of lifelike events over the course of one week

Authors: ***C. OEDEKOVEN**, J. KEIDEL, S. BERENS, C. M. BIRD;
Sch. of Psychology, Univ. of Sussex, Brighton, United Kingdom

Abstract: Episodic memory for events is a crucial part of our everyday lives. While we experience events we combine incoming information with our prior knowledge to create coherent memories. The active rehearsal of these memories further stabilizes them and thus improves later recall (Roediger and Karpicke, 2006). The aim of our fMRI study was to investigate the stability of memories for lifelike events over the course of a week. We report results in a group of 21 young adults (aged 25.6 years, range 18-35, 11 female) who were scanned twice. During their first scan participants encoded and silently recalled 24 short video clips. Vividness was rated after each recall. Following a 7 day delay, they silently recalled all 24 videos again in the scanner and then described the videos afterwards. Univariate analyses were conducted using SPM8 and whole- brain searchlight representational similarity analyses (RSA) using the CosmoMVPA toolbox. Participants recalled 11.5 details from each video after one week, whilst vividness ratings for the recall phases dropped by 20%. RSA identified a network of regions including posteriomedial cortex, bilateral parahippocampal gyri, bilateral temporoparietal junction and right anterior temporal lobe where patterns of activity during encoding correlated with immediate recall of the same video. A strikingly similar network of regions was found when comparing patterns of activity during immediate recall and recall of the same videos a week later. Interestingly, within the left dorsal medial frontal lobe, the strength of representational similarity between immediate and delayed recall correlated with the amount of

detail recalled for each video. In the univariate analyses, this region showed higher activity during both recall phases but not encoding. Overall, we identified a stable network of regions that showed very similar patterns of activity during encoding, immediate recall and delayed recall, despite the fact that ratings of vividness decreased over the course of a week. This shows that during encoding, participants created a coherent representation of the content of each video which was reinstated within the network at both immediate and delayed recall. Since the events within each video took place in multiple locations, this representation cannot simply reflect spatial context but instead must include a more abstract representation of its narrative. This interpretation is further supported by the correlation of dorsal medial frontal lobe activity with the amount of detail recalled and is consistent with the proposal that these regions integrate episodic information with prior semantic knowledge (Binder et al., 2009).

Title: Post-encoding theta-burst TMS to lateral occipital cortex impairs associative memory retention

Authors: ***A. TAMBINI**, M. D'ESPOSITO;
Helen Wills Neurosci. Inst., UC Berkeley, Berkeley, CA

Abstract: The formation of stable long-term memories is thought to be dependent on both brain activity during the initial encoding of an event, but also on processes that unfold during post-encoding time periods. In addition to the importance of sleep, recent work has suggested that awake rest periods immediately after encoding may play a role in memory consolidation. Here, we sought to casually test the role of post-encoding rest periods in memory by asking whether post-encoding transcranial magnetic stimulation (TMS) applied to a cortical site involved in stimulus processing is sufficient to 1) impair memory retention and 2) disrupt putative consolidation-related activity during post-encoding rest. To address these questions, participants performed an incidental object-face associative encoding task during fMRI scanning, which has previously been shown to influence patterns of post-encoding resting connectivity. The encoding task was preceded by BOLD and perfusion ASL rest scans. Immediately after encoding, participants performed a brief (~10 minute) memory test followed by continuous theta-burst TMS (TBS) to either the posterior portion of the lateral occipital complex (LO, involved in

object processing) or a control site (primary somatosensory cortex, S1) and a series of BOLD and perfusion rest scans lasting for approximately 40 minutes. Participants returned to perform delayed memory tests approximately 2 and 24 hours after TMS. The retention of both associative and item memory was measured between the initial memory test and delayed memory tests. Associative memory retention across a two-hour delay was significantly reduced when TBS was applied to LO versus the control site and a behavioral control group that did not undergo TMS. In contrast to associative memory, measures of item memory retention did not differ as a function of TMS site. Experience-related increases in regional cerebral blood flow (rCBF) from pre- to post-encoding rest were found in the control group in LO and the hippocampus, but these increases were not present when TBS was applied to LO. These findings suggest that interfering with brain activity within a window of approximately 10 minutes to 1 hour after encoding with TBS is sufficient to impair later associative memory performance. More broadly, these data highlight the potential role of post-encoding rest periods in associative memory retention.

Title: How is conceptual knowledge represented in the temporal pole? A cross-modal perspective and familiarity effects

Authors: *L. T. LIKOVA[1], C. W. TYLER[2], K. MINEFF[2], S. NICHOLAS[2];
[1]Smith-Kettlewell Eye Res., San Francisco, CA; [2]Smith-Kettlewell Eye Res. Inst., san Francisco, CA

Abstract: How is conceptual knowledge represented? Do the temporal poles (TP) form a unified bilateral representational system for conceptual knowledge, or is there instead left/right specialization? To address this controversial issue and its generalization to non-visual modalities, we took a novel cross-modal approach in a brain imaging study of writing and drawing from conceptual memory in blind participants. Methods: FMRI was conducted in a Siemens 3T scanner with a custom tablet system for the recording of haptic output. The conceptual information was presented tactilely through reading of a Braille text, and its retrieval from memory was expressed through two non-visual modes - Braille writing and blind drawing. Blind participants read Braille paragraphs describing objects, faces, scenes and navigation sequences, then expressed their comprehension of each by i) non-visual (Braille) writing-from-memory, and

ii) non-visual drawing-from-memory (20s/task). To assess familiarity effects, each form of output was repeated a second time after a 20 sec delay. Results/Conclusions: Two adjacent subdivisions of the temporal pole - the apex (TPa) and a dorso-medial region (TPdm) showed contrasting behavior as a function of task-domain and familiarity. TPdm responses appeared only in the familiarity (second) phase for both Braille writing and drawing. Comprehension of the Braille text expressed through the Braille writing-from-memory task produced inter-hemispheric push-pull behavior with a strongly left-lateralized response in both TPa and TPdm, combined with extensive contralateral suppression. In contrast, however, the blind drawing-from-memory task showed a remarkably different behavior of fully bilateral responses in both areas with no inter-hemispheric push-pull, thus conforming to the bilateral TP model for conceptual knowledge representation. The familiarity assessment, on the other hand, revealed a profound inter-region push-pull of the bilateral drawing signals, being dominant in TPa in the unfamiliar phase, switching to dominating in TPdm in the familiar phase, thus revealing a previously unexplored form of familiarity dissociation. Conclusions. This first Braille writing and Braille-derived drawing study thus reports a distinctive form of hemispheric specialization and differential familiarity effects in the TP. These results indicate a strong task-domain dependency of the localized functional architecture in the TP, which may explain some of the controversies in the literature. Overall, the current findings extend the study of conceptual knowledge representation beyond the visual modality for both encoding and retrieval.

Title: Simulations on the effect of external semantic interference in lexical retrieval and priming in memory

Authors: *R. CHANDRAMOULI[1], K. HATALIS[2];
[1]Temple/ St. Luke's Med. Sch., Bethlehem, PA; [2]Lehigh Univ., Bethlehem, PA

Abstract: Abstract: *Background:* Memory retrieval is partly based on semantic organization and response times based on priming. Once an object has been presented in memory multiple times, it is considered to be primed for rapid retrieval. During this priming process, semantic memory plays an important role. By observing objects with similar semantic features we can create an organized “thesaurus” of an object so it can be easily retrieved from memory. This would include trucks, trains, and boats, in the example of a car, which are all modes of transportation. When this primed object of a car is retrieved from memory, it will initially collect

all objects within the same semantic framework. During this incremental learning process there are interfering effects for retrieval known as cumulative semantic interference. Interference occurs when there is an impaired ability to remember an item when it is similar to other items stored in memory. When a person names a picture under the blocked-cyclic naming paradigm, they would take longer to recall an object when they observe repeated pictures from the same semantic category. We highlight the hypothesis that words with similar phonemes, such as a penguin and puffin, have amplified interference that occurs during lexical retrieval. *Methods:* We present a two-layer neural network with a distributed semantic input layer and a lexical output layer with added neurons for external activations to analyze the phonological influence on lexical retrieval and priming. Homogeneous and heterogeneous word test sets were created with semantic only, phonological only, and both semantic phonological similarities. *Results:* Our computer model provides a mapping for retrieval pathways and interference patterns during memory retrieval. Results show that retrieval based on mean selection time per naming cycle is delayed for homogeneous sets when sequential items presented to the network contain both semantic and phonological similarities vs only semantic. *Conclusion:* We examine through simulations that semantic interference is further exacerbated by the same phonemes among two words. For neurological conditions involving memory, the idea of external semantic activation and interference using computer models can assist in research by modulating further understanding about learning processes and ways of improving memory retrieval outcomes.

Title: Configural learning engages the semantic memory system but generalisation involves the hippocampus

Authors: *S. C. BERENS, C. M. BIRD;
Univ. of Sussex, Brighton, United Kingdom

Abstract: Configural learning entails forming a conjunctive representation of individual stimuli. Structural learning, a configural learning subtype, additionally specifies the temporal or spatial arrangement of stimuli. While non-structural configural learning may be subserved by the perirhinal cortex, lesion studies in rodents suggest that structural learning is dependent on the

hippocampus. The hippocampus has also been implicated in generalising previously acquired knowledge including learned configural information (e.g. Eichenbaum & Cohen, 2001). In the present fMRI study we investigate the brain regions involved in configural learning and generalisation. Fifteen right-handed participants (aged 18-35; 8 females) engaged in a virtual reality trial-and-error learning task with spatial-structural and non-structural trials. To investigate the generalisation of configural information post-acquisition, stimuli from structural trials were rearranged to produce a test of discrimination transitivity. We observed monotonic increases in BOLD activity coincident with both structural and non-structural memory acquisition in the inferior temporal lobes (bilaterally), left angular gyrus and basal forebrain (bilaterally). Contrary to predictions, no areas within the medial temporal lobes (including the hippocampus and perirhinal cortex) showed overall levels of activity that correlated with learning or differentiated between structural and non-structural trial types. Nonetheless, a multivoxel pattern analysis demonstrated that the hippocampal, parahippocampal, perirhinal, and entorhinal cortices did contain trial relevant information throughout the task. Moreover, the strength of this information in early trials predicted subsequent behavioural performance in the final trials. Lastly, during the generalisation test, behavioural performance of individual participants positively correlated with their BOLD activity in the right posterior hippocampus. We suggest that participants perform this task using their semantic memory system; new configural representations are created in the inferior temporal cortex and selection between competing similar representations is supported by the angular gyrus. This is consistent with these regions known roles in semantic memory storage and semantic control respectively. By contrast, the hippocampus is likely to be required when initially forming these representations and then generalising the information to novel situations. This supports the proposed role of the hippocampus in flexibly expressing newly formed memories on novel situations.

Title: Relationship between clinical and electrophysiological measures of prospective memory in individuals with brain injury

Authors: *S. A. RASKIN, C. PEDRO, E. AISENBERG, T. BLOOMQUIST, M. RACE, N. KAUR;
Trinity Col., Hartford, CT

Abstract: Prospective memory (PM) involves the ability to form and realize intentions after a time delay (Einstein & McDaniel, 1990). This experiment aims to examine the relationship between clinical measures of PM and an event-related potential paradigm (West & Ross-Munroe, 2002). Electrophysiological data was collected while performing a computerized laboratory PM measure and was compared to a clinical measure, the Memory for Intentions Screening Test (MIST) (Raskin, Buckheit, & Sherrod, 2011) in healthy adults (HA), individuals with severe acquired brain injury (sABI) and mild acquired brain injury (mABI). Results revealed that individuals with sABI performed significantly worse than individuals with mABI and HA on all variables of the MIST. Results also showed reduced amplitudes in individuals with sABI, on ERPs that have been associated with intention formation and intention retrieval when compared to individuals with mABI and HA. In addition, total score on the MIST was related to variables associated with attention retrieval. Overall, these findings suggest that individuals with sABI have deficits in PM compared to individuals with mABI and HA and that the MIST may be a valid measure of underlying brain processes in PM.

Title: Neuroanatomical evidence for a multidimensional representation of impulsivity: a voxel-based lesion symptom mapping approach

Authors: *V. MANDOSKE[1], A. CHAU[1], K. K. HAUNER[1,2,3], F. KRUEGER[4,5], J. GRAFMAN[1,2,3];

Abstract: Impulsivity is considered a multifaceted construct that encompasses a range of behaviors including poor impulse control, premature decision-making, and the inability to delay gratification. To better understand the neural correlates of impulsivity and its facets, we performed a voxel-based lesion mapping (VLSM) analysis in a large sample of patients (N=131) with focal, penetrating traumatic brain injuries (TBI). Impulsivity was assessed using the Barratt Impulsiveness Scale (BIS-11), a 30-item self-report questionnaire, which allows for separate

measurement of global impulsivity as well as its individual facets (e.g., "motor" impulsivity). We found that heightened global impulsivity was associated with damage to multiple areas in bilateral prefrontal cortex (PFC), left insula and anterior cingulate gyrus, left temporal gyrus, and left hippocampus. Moreover, we identified a distinct cluster within left PFC (including dorsolateral PFC) associated specifically with motor impulsivity. Our results are consistent with existing literature on bilateral prefrontal cortical involvement in behavioral impulsivity, but also provide new evidence for a multidimensional representation of impulsiveness, including a left-lateralized network supporting motor impulsivity.

Title: Event-related potential assessment of cognitive tasks in post traumatic stress disorder

Authors: *V. TAN, K. CORREA, A. ANKROM, C. BERKA, R. JOHNSON;
Advanced Brain Monitoring, Inc., Carlsbad, CA

Abstract: Exposure to traumatic or stressful events can lead to pathological changes within the neurobiological and psychophysiological domains that manifest, in part, as impaired cognition and abnormal reactions to everyday stimuli. Cognitive deficits such as information processing abnormalities and attention and memory dysfunction have been reported as primary symptoms in patients diagnosed with post-traumatic stress disorder (PTSD). Studies have shown that impairment can be objectively measured by using electroencephalography (EEG) to capture the event related potentials (ERPs) that are generated in response to stimuli. Previous reports revealed distinctive N2 and P3 ERP components in PTSD patients; both are commonly elicited in visual-attentional paradigms. The P3 is related to categorical and speed of information processing, and the N2 corresponds to the degree of visual attention that is being allocated to the stimulus. The present study sought to examine cognitive differences between veterans with combat-related PTSD and healthy controls using EEG and the resulting ERP measures. Thirty PTSD and thirty-six healthy comparisons were recruited for the study and were administered visually-based vigilance and memory tasks. Initial results show that the PTSD group compared to that of the healthy controls have shorter latency and attenuated amplitude of the P3 component along the central and parietal sites during the active vigilance task. In contrast, they exhibit an

overall longer latency but similar attenuation of the N2 and P3 amplitude during a recognition memory task. In addition, results show a greater amplitude for the P2 component--related to the comparing of visual input with internal representation--for the PTSD group. Overall, the results reflect evidence of lasting neuropsychological changes that occur after serious traumatic events. These changes manifest clearly in behavior and could be a valuable focal point when investigating solutions for symptomatic mitigations.

Title: Power spectrum scale invariance as a neural marker of age, cocaine misuse and cognitive control

Authors: ***J. S. IDE**[1,2], S. HU[3], S. ZHANG[3], L. MUJICA-PARODI[2], C.-S. LI[3];
[1]UNIFESP, Sao Jose Dos Campos, Brazil; [2]Stony Brook Univ., Stony Brook, NY; [3]Yale Univ., New Haven, CT

Abstract: Background: Recent research suggests power spectrum scale invariance (PSSI) of cerebral blood oxygenation level dependent (BOLD) signals as an important neural marker of cerebral activity. In particular, because flexibility and constraint of brain circuit affect the dynamics of the hemodynamic response in a single node, PSSI can also be used to quantify circuit-wide regulation of the network. Studies by ourselves and others demonstrate that as circuits become increasingly dysregulated, signal complexity of affected nodes deviates from that critical point (Radulescu and Mujica-Parodi, 2014), as observed in trait anxiety, schizophrenia, autism, epilepsy, etc. Here we examined PSSI as a neural marker of age, cocaine misuse and cognitive control. Methods: Eighty-eight healthy (HC) and seventy-five cocaine dependent (CD) adults participated in fMRI of a stop signal task. BOLD data are preprocessed using standard methods available in SPM8, followed by additional preprocessing (de-trending,

and regressing out head movements, and white-matter and cerebrospinal fluid signals) in order to compute PSSI. The PSSI β is estimated from each FFT-transformed time series S(f) as per S(f) ∝ f^(-β) within a frequency window of 0.01-0.25 Hz. The PSSI β images are carried to second level analyses. In linear multiple-regression, we examined age related changes in PSSI each in HC and CD, and PSSI in association with years of cocaine use in CD. A critical component of cognitive control is post-signal behavioral adjustment, which is compromised in cocaine dependence. Therefore, we examined PSSI in association with post-signal slowing and compared the changes between CD and HC. Results: PSSI values are negatively correlated with age in several brain regions (fronto-parietal circuit, caudate, thalamus, as well as default-mode circuit) in the HC group, and fewer regions in the CD group. Interestingly while overall PSSI decreased with age, in several brain regions these values significantly increased with years of cocaine use (inferior frontal gyrus, putamen, parietal cortex, dorsolateral cortex). PSSI values are increased with post-signal slowing in multiple regions (ventromedial cortex, inferior frontal gyrus, dorsolateral and parietal cortex) in the HC but not in the CD groups. Conclusions: We found that PSSI is overall decreased with age, and increased with behavioral adjustment in the HC individuals. However, the same patterns are absent in the CD group, in which increased PSSI values are associated with years of cocaine use. These results highlight PSSI as a neural biomarker of cocaine misuse and its associated deficits in cognitive control.

Title: Safety and feasibility of using low frequency deep brain stimulation of the subthalamic nucleus to improve cognitive performance in patients with Parkinson's disease

Authors: *K. W. SCANGOS, K. SHAHLAIE;
Dept. of Psychiatry and Behavioral Sci., Univ. of California, Davis, Sacramento, CA

Abstract: Cognitive impairment is a common feature of Parkinson's disease (PD) that results in significant disability. Executive function deficits are most frequently observed and are thought to arise from disruption in the prefrontal loop through the basal ganglia. The subthalamic nucleus (STN) is part of the indirect pathway that modulates activity through the fronto-striatal circuitry. Deep brain stimulation (DBS) of the STN is typically used to deliver continuous high frequency

stimulation to improve the motor symptoms in patients with advanced PD. It is not known if this stimulation paradigm affects cognition. In fact, there is data suggesting that high frequency stimulation of the STN impairs cognition. In contrast, some data suggests that low frequency stimulation in the theta range enhances cognitive performance. We hypothesized that theta frequency stimulation in the STN may improve executive performance in patients with Parkinson's disease. Therefore, we designed a feasibility study that would provide safety and initial-efficacy data of low frequency STN DBS on cognition. Specifically, we are testing executive task performance in 20 patients with PD at baseline and following bilateral STN DBS placement under no frequency, low frequency, and high frequency conditions. We are also examining cognitive function under a variable duration of low frequency stimulation. Executive performance is being measured through reaction time and error rates on the Stroop, N-back, and verbal fluency tasks. Safety is being monitored through the examination of psychological, cognitive, and motor consequences of low frequency stimulation. Understanding the effects of different stimulation frequencies on non-motor tasks will help elucidate the mechanism behind cognitive impairment in PD, and inform new treatment plans that optimize both motor and cognitive domains.

Title: The test-retest reliability of a computerized neuropsychological cognitive test battery in chronic stroke survivors: Application for dual-task paradigms

Authors: *J. P. VORA[1], R. VARGHESE[2], T. BHATT[3];
[1]Physical Therapy, Univ. of Illinois At Chicago, chicago, ; [2]Physical Therapy, Univ. of Illinois At Chicago, chicago, IL; [3]Physical Therapy, Univ. of Illinois at Chicago, chicago, IL

Abstract: Introduction: Dual task methodologies using a secondary cognitive task are widely utilized to measure attention of the primary motor or cognitive function. While traditional paper-pencil tasks provide with valuable information regarding psychological function in an individual, they require specialized training, are prone to manual error and are not feasible to use in a dual task paradigm, limiting its overall usability particularly in clinical settings. This warrants the need for sensitive, accurate, reliable, yet affordable options of computerized testing. The purpose of this study was to establish the test- retest reliability of a computerized, custom-designed cognitive test battery in chronic stroke survivors. **Methods:** Twelve adults with chronic stroke performed the cognitive test battery that was custom-designed in and administered using

DirectRT™, Empirisoft. This battery included tasks that measured 1) visuo-motor function, via a simple and choice reaction time task (*Spot & Click, SC*); 2) associated memory, via a paired associated learning task (*Number & Position, NP*); 3) phonemic memory, via a category fluency task (*Animal Naming, AN*); 4) executive function, via the congruent and incongruent visual stroop tasks (*Color Naming, CN*); 5) discriminant decision-making, via the spatial working memory task (*Unveil the Star, US*) and 6) visual working memory, via the 1-back and 2-back tasks (*Triangle Tracking, TR*). The outcome variables consisted of reaction time in the *SC* task; accuracy for the *NP*, *CN*, *US* and *TR* tasks; total time of completion for the *US* and *CN* tasks and total number of responses in the *AN* task. The average total time to implement this battery was 25 minutes. The intraclass correlation coefficient (ICC) was used to determine test-retest reliability for all outcome variables. **Results:** There was a good to excellent test-retest reliability for all the six tasks ($p<0.05$). The ICC for *SC* task was 0.72 for simple and 0.81 for choice reaction time. Further, the ICC for accuracy on *NP* task 0.86; 0.92 for the congruent and 0.99 for the incongruent subset of the *CN* task; 0.78 for the *US* task; 0.71 for 1-back and 0.76 for 2-back for the *TR* task. The ICC for total time of completion was 0.99 for the congruent and 0.99 for the incongruent subset of the *CN* task and 0.77 for the *US* task. The ICC for the total number of responses was 0.96 for the *AN* task. **Conclusion:** Findings from this study revealed that our method of computerized cognitive testing was highly reproducible for several domains of cognitive function. Given the reliability and portability of this test, clinicians could easily implement and incorporate it in their dual-tasking assessment and intervention programs.

Title: The effects of acute psychosocial stress on higher cognitive functions: false memory formation and anchoring and adjustment

Authors: *E. PARDILLA-DELGADO[1], E. W. ASP[3], T. J. CUNNINGHAM[2], K. A. WARNER[4], J. D. PAYNE[2];
[2]Psychology, [1]Univ. of Notre Dame, South Bend, IN; [3]Psychiatry, [4]Psychology, Univ. of Iowa, Iowa City, IA

Abstract: It has been proposed that one of the functions of the prefrontal cortex (PFC), crucial for higher-order cognitive functions, is to affix ‘false tags’ to cognitive representations. Stress can negatively affect PFC activity, due to the high density of glucocorticoid receptors in this region. In this study we tested the effects of stress-related cortisol in two higher cognitive

functions: anchoring and adjustment (A&A) and false memory formation. A&A are human heuristics that are recruited when an individual needs to make a judgment or estimate a specific quantity. Individuals will use an anchor as an initial starting point, which is then adjusted until a reasonable response is reached. For example, if asked "What year was Washington elected president?" people commonly use the signing of the Declaration of Independence as an anchor. The PFC's ability to false tag helps individuals adjust away from anchors in a way that is similar to the way we correctly reject a false memory (i.e., by appropriate source monitoring). In the current study, we used a psychosocial stress task to increase stress and decrease normal PFC function. We then measured the impact of stress exposure on the executive functions of adjusting away from an anchor and source monitoring. Participants arrived in the laboratory and completed the Deese-Roediger-McDermott (DRM) false memory task and the Knowledge Estimation Task (KET) in counterbalanced order. The DRM task entailed encoding 8 lists of related words (nurse, hospital, etc.) each with an unpresented 'gist/false word', ('doctor'). After a distractor task, they completed a free recall test to assess false memory for the un-presented gist words. The KET, used to assess A&A, presented participants with questions to which they had to provide an estimation of the correct answer. For half of the questions, a true statement regarding the estimation (the anchor) was presented before the actual question. After they finished the 2 tasks, subjects were randomly assigned to a stress or control condition (n=14 per group). Following, subjects had to complete different versions of the same 2 tasks. Although data collection is still in progress, we already see that stress marginally increased recall of un-presented words compared to the control group ($t=1.91, p=.07$ for intrusions, $t=1.7$, $p=.1$ for false words). No effects were observed for recall of studied words. Thus far there are no significant differences in the KET. These preliminary results show that stress increases false memory in the DRM task, arguably by disrupting monitoring abilities, which are dependent on PFC functioning. However, we found no evidence that stress affects anchoring and adjustment.

Title: The role of executive function on the reading ability of Chinese adolescents: an fMRI study

Authors: *S. W. WONG[1,2], J. C. M. LO[1], H. K. F. MAK[4], K. K. H. CHUNG[3,2,1];
[1]Special Educ. and Counselling, [2]Educational and Developmental Neurosci. Unit, [3]Early Childhood Educ., The Hong Kong Inst. of Educ., Hong Kong, China; [4]Dept. of Diagnos. Radiology, The Univ. of Hong Kong, Hong Kong, China

Abstract: This study examined the role of the executive function network on the adolescent reading ability. Previous studies showed that dyslexia is associated with the deficits of cognitive abilities associated with the reading ability of adolescent students (Chung et al., 2009). However, the role of executive function on reading ability is still unclear. In this study, a counting Stroop task is used to activate the executive function network involved in resolving cognitive interference and to examine how the response of this network correlates with the reading ability of typically developing and dyslexic adolescents. The counting Stroop task is a button-press variant of the original Stroop task and is validated for examining the neural substrate of cognitive interference effect in the fMRI environment (Bush et al., 2006). **Methods:** Three typically developing male adolescents (mean age: 14) and three age-matched diagnosed Hong Kong Chinese adolescents with dyslexia completed two runs of the counting Stroop task while their brain activities were monitored with BOLD fMRI. We hypothesized that, relative to the congruent and neutral trial, the incongruent trial would elicit a stronger BOLD response within the executive function network. The reading ability of the participant is quantified with a digit rapid automatized naming (RAN) task outside the scanner. The RAN task required participants to name a series of Arabic numerals presented on a computer screen as fast as possible. The fMRI experiment was performed with the Philips 3T scanner at the MRI Unit at the University of Hong Kong. The acquired data were analyzed with SPM12. BOLD images were realigned, normalized and smoothed. A two-level statistical paradigm was used to analyze the preprocessed images. A voxel-wise generalized linear model was used to estimate the BOLD response associated with the three conditions. The RAN data were included as a covariate at the second-level model. **Results and Discussion:** The behavioral data of the counting Stroop confirmed the cognitive interference effect that the response time of the incongruent trials is significantly longer than the ones of the congruent and neutral trials. The fMRI data showed that participants' RAN performance correlated with the BOLD signal at dorsal anterior cingulate cortex (dACC) and dorsolateral prefrontal cortex (DLPFC). More specifically, participants with a higher RAN score exhibited a stronger activation at dACC and DLPFC in the incongruent trial than in the congruent or neutral trial. Our preliminary data indicated that the efficacy of dACC and DLPFC in resolving cognitive interference correlates with the reading ability of Chinese adolescents.

Abstract: Background: The hemodynamic response function (HRF), the change in brain blood flow in response to neural activity, arises from communication between neurons and the vasculature that supplies them by means of glial intermediaries known as astrocytes. In demyelinating diseases, such as Multiple Sclerosis (MS), the integrity of the white matter structure known to facilitate neural-vascular communication, of which astrocytes are an integral part, is damaged. This damage compromises the ability of neurons to adequately convey their metabolic needs, resulting in insufficient oxygen and nutrient perfusion. In this study, we isolated particular components of the HRF that could index the extent to which damaged white-matter affects neural-vascular coupling, and cognitive symptoms. Method: Fifty-one participants, 28 MS patients and 23 healthy controls, were fMRI-scanned during performance of a simple reaction time task and an fMRI-adapted version of the Digit Symbol Substitution task (DSST). A model-free approach was used to analyze the fMRI data, eliminating dependence on assumptions regarding HRF shape that may not hold for diseased populations. Several HRF metrics were calculated, including crest and trough amplitude, time-to-peak, time-to-fall, and FWHM, following the fitting of piecewise linear-B spline functions to fMRI time-series data. Results: Several metrics were significantly different, most notably crest amplitude, an index of neural activity in healthy young adults, which was attenuated in MS patients relative to controls. The extent of white matter damage, as indexed by radial diffusivity (measured by DTI), predicted the decreases seen in MS patients' HRF crest amplitudes. Further, while HRFs of healthy controls demonstrated greater variance, the incidence of non-canonical HRFs was more frequent in MS patients. Conclusions: These results support the hypothesis that dysfunction of the neural-vascular coupling system (as a result of disrupted astrocytes) leads to compromised blood flow response and cognitive impairment experienced by white-matter disease patients.

Title: Acute mild exercise boosts executive performance in older adults by eliciting positive-arousal-related prefrontal activations: an fNIRS study

Authors: *K. BYUN, K. HYODO, K. SUWABE, G. OCHI, H. SOYA;
Fac. of Hlth. and Sport Sci., Univ. of Tsukuba, Tsukuba, Japan

Abstract: Executive function, which refers to higher cognitive function localized in the prefrontal cortex, decreases with aging. Although long-term mild exercise has been proven to reduce cognitive impairment in older adults, it is not known whether acute mild exercise has an enhancing effect on executive function and its neural substrates. To address this question, we examined the effect of acute mild exercise on executive function and its neural substrate using the color-word matching Stroop task (CWST), which produces a cognitive conflict in the decision-making process. Twenty-two sedentary elderly subjects (mean age: 68.8 ± 1 years; 11 females) participated in two count-balanced sessions: Exercise (Ex) and Control (Con). Subjects performed a CWST and completed a two-dimensional mood scale (TDMS) measuring psychological mood changes before and after 10 minutes of low-intensity (30% V̇O2peak) exercise on a cycle-ergometer for the Ex session, or without exercise for the Con session. During the CWST in both sessions, cortical hemodynamic changes of the prefrontal cortex were monitored using functional near-infrared spectroscopy (fNIRS). The acute mild exercise led to improved Stroop performance. It also evoked cortical activations related to Stroop interference on the left dorsal lateral prefrontal cortex and frontopolar area. Moreover, these exercise-induced cortical activations significantly corresponded with both enhanced Stroop performance and increased positive-arousal levels after exercise. These findings are consistent with our recent fNIRS study of younger adults (Byun et al., 2014), and further suggest that regardless of age, mild exercise has beneficial effects on executive function mediated by increasing task-related cortical activations.

Title: Ventral striatum dysfunction in cocaine dependence - a framework for resting state functional connectivity mapping analysis

Authors: *S. ZHANG, S. HU, C.-S. LI;
Yale Univ. Sch. of Med., New Haven, CT

Abstract: Background: Recent studies started to elucidate altered resting state functional connectivity (rsFC) in individuals with cocaine dependence (CD), highlighting the effects of cocaine use on both the activities and connectivities of the ventral striatum (VS). In the current study, we developed a framework to employ rsFC and identify altered functional subclusters of the VS in cocaine dependence. **Methods**: Resting state fMRI data (3T, 10 minutes, eye closed) of 66 CD and 66 age/gender matched HC were analyzed. We performed for individual subjects linear regressions between the averaged time course of each of the 116 AAL masks and the time courses of each individual voxel of the VS. The correlation coefficients were converted to z scores by Fisher's z transform, and a two-sample t-test was applied to the "z maps" to identify altered rsFC between each VS voxel and each of the 116 masks in CD as compared to HC. We then used the 116 connectivity effect sizes (t values) of each VS voxel to functionally segment the VS with K-means clustering. **Results**: The results showed the VS being divided into 3 functional subclusters, in the area of the dorsal anterior nucleus (daVS), dorsal posterior nucleus (dpVS), and ventral nucleus (vVS), each in association with different pattern of rsFC. Besides the shared reduced rsFC with bilateral parahippocampal gyri (PHG), the three subclusters each showed increased rsFC with pre-supplementary motor area (preSMA), reduced rsFC with ventromedial prefrontal cortex (vmPFC), and increased rsFC with visual cortex in CD compared to HC, specifying the VS subregions with altered pattern of connectivity. Furthermore, the connection strengths of daVS – PHG positively correlated, while the connection strengths of vVS – PHG and dpVS – preSMA negatively correlated with the number of days of cocaine use in the past month each for females, males, and females only. **Conclusions**: These findings suggest a distinct pattern of altered rsFC of VS subnuclei in cocaine dependence. The proposed analytic framework may provide new insight to using resting state fMRI data to delineate circuit level deficits in cocaine dependence and other neuropsychiatric conditions. Title: Synchronizing brain rhythms with electrical stimulation improves adaptive control in healthy people and those with schizophrenia

Authors: *R. M. REINHART, J. ZHU, S. PARK, G. F. WOODMAN;
Vanderbilt Univ., Nashville, TN

Abstract: The ability to exert control over our behavior is fundamental to human cognition. For people with psychiatric and neurological disorders impairments in adaptive control are pervasive. Schizophrenia patients in particular show deficits in reacting to errors. These enduring difficulties with executive control mechanisms that allow us to adapt have direct implications for the lives of these patients in the real world. In the present study, we report novel evidence for the neural mechanisms of adaptive control that distinguish healthy people from those with schizophrenia. We used transcranial electrical stimulation to safely, noninvasively, and casually manipulate neural activity in a targeted brain region. We combined this causal stimulation method with measurements of electrical brain activity that are hypothesized to index the large-scale neural networks underlying adaptive control. Whereas our healthy control subjects had strongly coherent low-frequency oscillations across frontal and prefrontal cortex following errors in our baseline measurements, the patients did not. However, when we passed electrical current through the medial-frontal cortex for 20 minutes, we improved adaptive control and the phase structure of patients' neural oscillations. This noninvasive stimulation phase aligned the low-frequency oscillations that were elicited after patients committed errors, requiring adaptive control to change how information is being processed. Moreover, this stimulation also causally enhanced the patterns of long-range functional connectivity carried by the theta band (4-8 Hz) across medial and lateral prefrontal cortex. This resetting of the theta-band oscillator with brain stimulation caused dramatic improvement in behavioral signatures of adaptive control, most notably the reaction time (RT) slowing observed after an error is made. Strong single-trial

correlations between theta rhythms and post-error slowing provided further behaviorally relevant insights into the neural mechanisms of adaptive control. Following stimulation the neural and behavioral indices of adaptive control were improved such that patients were indistinguishable from healthy control subjects. Theories of cortical dysconnectivity in schizophrenia are supported by our causal manipulation. But most important for translational neuroscience is the contribution our results make to the development of new, drug-free, intervention therapies for psychiatric and neurological patients with cognitive deficits.

Title: Prevalence of cognitive dysfunction apart from memory loss following traumatic brain injury from blast versus non-blast exposure in a veteran population

Authors: ***A. PAPAZYAN**[1], K. L. PANIZZON[2], J. RAMOS[3], W. STEFANOS[2], J. WATSON[2], E. A. LICHT[2], R. A. WALLIS[2,4];

Abstract: OBJECTIVE: To evaluate the prevalence of cognitive dysfunction apart from memory loss after blast versus non-blast traumatic brain injury (TBI) in Operation Enduring Freedom (OEF) and Operation Iraqi Freedom (OIF) veterans. BACKGROUND: TBI has been a signature injury in OEF/OIF veterans. After TBI, residual deficits are often seen, including cognitive dysfunction. METHODS: We conducted a retrospective chart review of patients with TBI in the Poly-Trauma Clinic of the VA Greater Los Angeles Healthcare System, regarding cognitive dysfunction in OEF/OIF veterans. RESULTS: A total of 563 charts were reviewed with 312 OEF/OIF veterans with a confirmed TBI diagnosis. The racial/ethnic distribution of subjects was 44 % Caucasian, 12% African-American, 25% Hispanic, 12% Asian and 7% other. The mean age of subjects with blast TBI was 33 ± 1 years and for non-blast TBI, 32 ± 1 years. Of 312 subjects with TBI, a mean 81 ± 6% (n = 254) were noted to have cognitive dysfunction. In subjects with post-TBI cognitive dysfunction, 57 ± 9% (n = 129) had blast-TBI, while 53 ± 9% (n = 116) had non-blast TBI. CONCLUSION: This data suggests that post-TBI cognitive dysfunction occurs often in OEF/OIF veterans.

Title: Increased dual-task cost during 70-day 6° head-down bed rest (HDBR): a functional magnetic resonance imaging (fMRI) study

Authors: ***P. YUAN**[1], V. KOPPELMANS[1], P. REUTER-LORENZ[2], Y. DE DIOS[4], D. SZECSY[5], N. GADD[4], S. WOOD[6], R. RIASCOS[7], I. KOFMAN[4], J. BLOOMBERG[8], A. MULAVARA[8,9], R. SEIDLER[1,2,3];

Ctr., Houston, TX; [8]NASA Johnson Space Ctr., Houston, TX; [9]Universities Space Res. Assn., Houston, TX

Abstract: Head-down tilt bed rest has been used as a microgravity analog to study the effects of microgravity exposure on human physiology and cognition on earth. It is reported that concurrent performance of motor and cognitive tasks can be impaired during space missions, and such dual-task costs increase during spaceflight. Effects of HDBR on brain structure have also been documented. Thus, understanding the consequences of HDBR for neural control of dual-tasking may provide insight into the cognitive effects of spaceflight. In the current study, we evaluated how dual-task costs changed as a function of HDBR. Seventeen healthy men (aged 25 to 39 years) participated in this HDBR study. They remained continuously in the 6° head-down tilt position for 70 days. Functional MRI for finger tapping was acquired during both single-task (finger tapping only) and dual-task conditions (simultaneously performing a secondary cognitive

task), and repeated at 7 time points: 12 days pre-, 8 days pre-, 7 days in-, 50 days in-, 70 days in-, 8 days post-, and 12 days post-HDBR. At all 7 time points, increased activation for finger tapping in dual-task compared to single-task condition was observed in bilateral occipital lobe and posterior parietal cortices. Additionally, increased activation in the dual-task relative to the single-task condition was significant in bilateral inferior frontal cortices and supplementary motor area during HDBR, but not before or after HDBR. Significant post-pre HDBR differences in dual-task cost were found in the left inferior parietal region. The dual-task cost of neural activity observed in the inferior frontal cortex is consistent with previous reports that the inferior frontal area is involved in the coordination of dual-task interference. Its presence during HDBR but not pre-HDBR implies that in head-down position, more neural control is needed for dual-task execution. The relationship between brain activation and behavioral performance differences in single-task and dual-task conditions will also be considered. This work was funded by the National Space Biomedical Research Institute through NASA NNX11AR02G, PF0401, NASA NCC 9-58, NASA Flight Analogs Project, National Institutes of Health, and National Center for Advancing Translational Sciences, 1UL1RR029876-01.

Title: Functional activities and resting state connectivity of the thalamus in non-dependent alcohol drinkers

Authors: ***S. HU**[1], S. ZHANG[1], J. IDE[2], J. KRYSTAL[1], C.-S. R. LI[1];
[1]Yale Univ., New Haven, CT; [2]Stony Brook Univ., New York, NY

Abstract: The thalamus is critical to many cognitive functions and has long been implicated in alcohol misuse. In this study, we examined the role of the thalamus in response inhibition and its resting state connectivity in association with problem drinking and duration of alcohol use. Fifty-seven non-dependent drinkers and 57 non-drinkers participated in one 40-minute fMRI scan of the stop signal task, and 44 of the drinkers also participated in a 10-minute resting state scan. Data were pre-processed and modeled using SPM8. In a GLM, we contrasted stop and go trials

with fMRI signals modeled at signal onset to identify neural correlates of response inhibition. In a group-level linear regression, we examined correlation of response inhibition with the Alcohol Use Disorders Identification Test (AUDIT) score and years of alcohol consumption. In drinkers, AUDIT score but not years of drinking was positively correlated to the stop signal reaction time. Bilateral thalamus, bilateral cerebellum, left insula, left anterior cingulate cortex (ACC), and right lateral prefrontal cortex (PFC) showed decreased activation with increasing AUDIT score. The supplementary motor area (SMA) extending to ACC and mid-cingulate cortex showed decreased activation with longer duration of alcohol use, an effect that was independent of age. In resting state functional connectivity, the thalamus as a seed region showed positive connectivity to a large array of regions including the cerebellum, ACC/SMA, dorsal medial PFC, bilateral insula, and precunues, and negative connectivity to the ventromedial PFC, precuneus, bilateral inferior parietal lobules, and bilateral middle occipital gyri. Notably, positive connectivity to the cerebellum increased with higher AUDIT score and the ACC/SMA connectivity decreased with duration of alcohol use. These results suggested altered activation of the thalamus, cerebellum, and ACC/SMA as a mechanism for deficits in response inhibition as associated with problem drinking.

Title: A multimodal meta-analysis of VBM and fMRI studies in obsessive-compulsive disorder and autism spectrum disorders

Authors: ***C. O. CARLISI**[1], L. NORMAN[2], S. LUKITO[2], J. RADUA[3], D. MATAIX-COLS[4], K. RUBIA[2];
[1]Inst. of Psychiatry, King's Col. London, London, United Kingdom; [2]Child and Adolescent Psychiatry, [3]Inst. of Psychiatry, King's Col. London, London, UK, United Kingdom; [4]Dept of Clin. Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: Obsessive-compulsive disorder (OCD) is characterised by intrusive thoughts (obsessions) and repetitive actions (compulsions), while autism spectrum disorders (ASD) are characterised by restricted, repetitive behaviours and interests. OCD and ASD, however, share deficits in cognitive control. However, it is unclear whether these shared behavioural deficits that contribute to their respective symptom profiles are mediated by common or distinct neural

mechanisms. The aim of the meta-analysis was to assess shared or disorder-specific neural underpinnings of inhibitory control and brain structure in these two disorders. For this purpose, we conducted a voxel-wise meta-analysis of 1) whole brain voxel-based morphometry (VBM) studies of brain structure and 2) functional magnetic resonance imaging (fMRI) studies of inhibitory control to compare regional grey matter (GM) volume and activation in OCD and ASD relative to their respective controls using Signed Differential Mapping (SDM). Multimodal analyses within each group also allowed the examination of regional differences common to both VBM and fMRI studies. Eighty-three studies across diagnostic groups and methodologies met inclusion criteria. Across fMRI studies, OCD patients (N=267) showed disorder-specific enhanced cerebellar activation while ASD (N=193) showed disorder-specific enhanced activation in lateral and ventromedial orbitofrontal cortex compared to controls. Both groups relative to controls shared underactivation in anterior cingulate cortex (ACC). In VBM, OCD patients (N=737) relative to ASD patients (N=791) had disorder-specific enhanced striato-insular and cerebellar but reduced left superior temporal and inferior frontal GM volumes. Both groups shared decreased ACC volumes relative to controls. Multimodal analyses in ASD and in OCD show that the ACC is reduced in both disorders in activation as well as GM volume. Results suggest both distinct and shared neural pathways underlying cognitive control in OCD and in ASD. Striato-insular and cerebellar regions were specifically associated with OCD and left prefrontal and superior temporal regions were specifically associated with ASD in one or both modalities, supporting evidence for disorder-specific mechanisms driving similar cognitive phenotypes of inhibitory abnormalities in each disorder. Shared mechanisms involved volumetric reduction and underactivation in ACC, presumably related to shared top-down control deficits.

Title: Changes in executive function associated with tobacco cessation therapy

Authors: A. G. STIVER[1], *W. M. MEIL[1], A. SESTI[2], L. M. HAMMER[1], J. A. MILLS[1], D. J. LAPORTE[1];
[1]Psychology, [2]Alcohol, Tobacco, and Other Drugs Program, Indiana Univ. Pennsylvania, Indiana, PA

Abstract: This study examined changes in functions associated with the prefrontal cortex as a result of tobacco cessation treatment in college students. Fourteen participants seeking tobacco cessation treatment from a university based tobacco cessation program and seventeen control participants were tested with the battery of neuropsychological measures prior to treatment and again 1 ½ months later. Participants were administered the Delis-Kaplan Executive Function System (D-KEFS) test battery and completed questionnaires including the Sensation Seeking Scale V (SSS-V), the Frontal Systems Behavioral Scale (FrSBe), the Perceived Stress Scale (PSS), the Fagerstrom Test of Nicotine Dependence (FTND), and answered questions regarding their frequency of tobacco use. Tobacco cessation treatment included the option of receiving the Nicotine Replacement Patch and Motivational Interviewing Therapy. Tobacco cessation treatment participants attended an average of 4.5 (SD = 2.34) meetings with treatment personnel. They were provided an average of 3 (SD =1.35) boxes of nicotine patches. The mean number of days between the first and last treatment meeting was 35.85 (SD = 17.74).There was a significant decrease in FTND scores between the first (M = 3.38, SD = 2.57) and second testing session (M = .923, SD =.93; $t(12) = 3.39$, $p = .004$). A Mixed Model Analysis of Variance was used to compare treatment condition and test time on SSSV, PSS, FrSBe subscores, and D-KEFS composite scores. Significant Interactions were observed between treatment condition and test time on SSSV ($F(1,27) = 5.14$, $p = .032$, partial $\eta 2 = .160$), FrSBe Apathy subscores ($F(1,28) = 6.40$, $p = .017$, partial $\eta 2 = .186$), FrSBe Disinhibition subscores ($F(1,28) = 4.48$, $p = .043$, partial $\eta 2 = .138$), and FrSBe Executive Function subscores ($F(1,28) = 7.07$, $p = .013$, partial $\eta 2 = .202$). Tobacco cessation participants showed decreases across test times while control subjects scores tended to increase. Difference scores on the FrSBe Executive Function subscale were significantly correlated with the number of nicotine patches participants were provided ($r = .81$, $p = .001$), the number of days between the first and last treatment session ($r = .58$, $p = .029$), and approached significance for the number of meetings with treatment personnel ($r = .53$, $p = .053$). These results suggest tobacco cessation therapy is associated with short-term improvements in executive function particularly when using ecologically based self-report measures of frontal lobe function.

Title: Resting state functional connectivity of the ventral striatum: hemispheric laterality, gender difference and cocaine addiction

Authors: *C.-S. R. LI, S. ZHANG, S. HU;
Dept Psychiatry, Yale Univ., New Haven, CT

Abstract: BackgroundResting state functional connectivity (rsFC) is widely used to examine cerebral functions. The rsFC of the ventral striatum (VS) has been implicated in motivated behaviors and clinical conditions that compromise motivated behaviors. There is a literature that suggests functional differences between left- and right- hemispheric VS. The current study investigated this issue and explored the effects of gender and cocaine addiction. MethodsWe used flexible factorial analyses to examine whole-brain rsFC and left and right VS and the effects of gender in a sample of 250 young healthy adults and examine the effects of cocaine addiction on left and right VS connectivity in a cohort of 66 cocaine-dependent (CD) and 66 age- and gender- matched healthy individuals (HC). Data preprocessing and computation of individuals' correlation maps followed our previous work (Zhang et al., 2012 Cereb Cortex). We also employed the AAL masks in ROI analysis to further confirm the findings. ResultsFirst, left- and right- VS each showed greater rsFC with regions within the same hemisphere with women showing qualitatively greater laterality. With both VS combined, men showed greater rsFC to the SMA, dACC, thalamus, insula, midbrain, while women showed greater rsFC to the visual cortex, OFC, caudate head, temporal pole, and cerebellum, at $p<0.05$ FWE. Compared to HC, CD showed greater VS rsFC to bilateral OFC, lateral PFC, visual cortex, and caudate head and less rsFC to parahippocampal gyri (PHG), inferior temporal cortex, temporal pole, vmPFC, posterior cingulate cortex/precuneus. There were no notable differences between CD and HC in the laterality effects. Furthermore, the connection strengths of VS - PHG and VS - lateral PFC negatively correlated with the average amount of cocaine per use in the past month each for males and for females only. And the connection strengths of VS - vmPFC positively correlated with the cocaine abstinence days for males but not for females. ConclusionsThese findings highlight significant effects of gender and cocaine addiction in VS rsFC and along with a broader literature suggest the importance of considering gender in studies of VS functioning in cocaine addiction and many other clinical conditions.

Title: The influence of a single session of aerobic exercise on error processing and subsequent executive control during a flanker task

Authors: *K. B. BEYER[1], M. D. SAGE[2], W. E. MCILROY[2];
[2]Kinesiology, [1]Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Aerobic exercise may positively influence response conflict and error monitoring processes that engage executive control to improve future behaviour. After a behavioural task trial containing a response error (inherently high in response conflict), the performer will slow down on the next trial to ensure a correct response. Furthermore, cortical activity related to processing a response error is predictive of changes in behaviour (e.g., speed and accuracy) and cortical activity related to executive control on subsequent trials. Aerobic fitness and long-term aerobic training are associated with changes in behaviour following an error as well as cortical activity related to both error processing and executive control. Even a single session of aerobic exercise can influence cortical activity related to executive control, but it is unclear how cortical activity related to error processing following a response error and subsequent behaviour are influenced. We used behavioural and electrophysiological measures to probe the relationship between response errors, subsequent behaviour, and associated cortical activity and examined how this relationship was influenced by a single session of aerobic exercise. Participants performed a modified flanker task before and after a 40-minute session of moderate-intensity cycle ergometry. For each flanker trial, reaction time was the time elapsed from stimulus presentation to EMG onset. Response accuracy was the percentage of trials with the correct response. Electroencephalography was used to index cortical activity related to error processing and executive control (e.g., ERN and P3 ERP components). On incongruent flanker trials immediately following an error, participants reacted slower and were more accurate than after a correct response indicating an error-related increase in executive control on subsequent trials. After aerobic exercise, participants reacted even slower following error trials indicating a further enhancement to executive control in response to errors. These findings indicate that, like aerobic fitness and long-term aerobic training, a single session of aerobic exercise can influence executive control of behaviour following a response error. Ongoing analysis is examining the relationships between cortical activity associated with error processing, cortical activity associated with executive control, and the observed changes in behavioural performance on trials following a response error.

Title: Effect of an acute bout of soccer heading on executive function in soccer players

Authors: *C. WALLACE[1], K. BRYK[2], A. D. WRIGHT[1], M. KENNEFICK[1], P. VAN DONKELAAR[1];
[1]Human Kinetics, [2]UBC Okanagan, Kelowna, BC, Canada

Abstract: Concussion often causes executive function deficits, which can be measured using a simple task-switching paradigm. However, little is known about subconcussive impacts and their influence on executive function. This particular study examined executive function in college-aged soccer players immediately prior to and following an acute bout of soccer heading, with the participant heading a soccer ball fired from a Sports Tutor soccer machine 20 times in 5 minutes, along with a sham condition where participants used their chest to direct the ball. Switch costs for both conditions showed no statistical difference. We conclude that an acute bout of soccer heading has no immediate effect on executive function when compared to a sham condition.

Abstract: ***Background***: It is postulated that balance centers within the central nervous system share attentional resources with the centers for cognitive processing. This results in deterioration of either one or both tasks under dual-task (DT) conditions, known as cognitive-motor interference (CMI). Apart from the beneficial effects on balance control, yoga positively influences several aspects of cognition, especially executive function. In spite of its motor and cognitive benefits, the effect of yoga practice on DT performance during varied balance tasks has not been examined. ***Purpose***: The purpose of our study was to investigate the effects of yoga on reducing CMI for maintaining dynamic balance during varied balance tasks. ***Method***: Yoga

practitioners (N=10) and age-similar non-practitioners performed three balance tasks including the Limits of Stability test (LOS) (intentional balance), Motor Control test (MCT) (reactive balance), and Sensory Organization Test (SOT) (condition 6 - inducing somatosensory and visual conflicts) under single-task (ST) and dual-task (DT) conditions (in conjunction with a serial subtraction task). The motor performance was assessed by recording the response time (RT) and movement velocity (MV) of the center of pressure (CoP) on LOS task, weight symmetry (WS) of CoP on the MCT task and equilibrium (EQ) of CoP on the SOT task. Cognitive performance was assessed by recording the number of correct responses in sitting (ST) and the DT conditions. The motor cost (MC) and cognitive cost (CC) was computed using the formula ([ST-DT]/ST)*100 for the motor and cognitive variables. Greater cost values indicate lower performance under DT versus ST conditions. ***Results***: The yoga group showed a significantly lesser motor cost for the spatial variables on the LOS, MCT and SOT tests (MV, WS, EQ respectively, $p<0.05$) in comparison with the control group. For the RT, the yoga group compared with the control group had a significantly lesser cost for the LOS task (intentional balance) but not for the MCT task (reactive balance). Similarly, the cognitive costs were significantly lower for all the three balance tasks for the yoga group than the control group ($p<0.05$). ***Conclusion***: Our results suggest that yoga practice can significantly reduce CMI by improving allocation and utilization of attentional resources for both dynamic balance control and cognitive functioning; hence resulting in better performance under DT conditions. Yoga practice could thus reduce fall risk by improving balance control under challenging environmental conditions that may require simultaneous processing of information from multiple sources.

Title: Influence of selective attention on brain network reconfiguration during working memory

Authors: *C. L. GALLEN[1], K. HWANG[1], T. G. LEE[2], M. D'ESPOSITO[1];
[1]Helen Wills Neurosci. Inst., UC Berkeley, Berkeley, CA; [2]Dept. of Psychological and Brain Sci., UC Santa Barbara, Santa Barbara, CA

Abstract: Selective attention underlies our ability to attend relevant stimuli while ignoring irrelevant stimuli, a critical process for prioritizing information in working memory. Recent evidence suggests that brain networks reconfigure during working memory performance, such that there is more integration across network modules (i.e., less modular) with increased working memory load. However, it is not yet understood how brain networks reconfigure between the processing of relevant and irrelevant stimuli in the service of working memory. Here, we investigated the effects of selective attention on network structure during working memory performance. We created networks from fMRI data collected during a modified one-back working memory task for 38 subjects. In each trial, subjects viewed a series of faces and scenes. Attention to the stimuli was manipulated in three conditions. Subjects were instructed to (1) attend faces and ignore scenes, (2) attend scenes and ignore faces, or (3) categorize the image as a face or scene. We used the first two conditions to examine processing of relevant (i.e., attended) and irrelevant (i.e., unattended) stimuli during working memory performance. The third condition served as a comparison in which no working memory was required. We created networks for each condition and three metrics were used to assess changes in modular network organization due to attention demands. We first examined modularity, a comparison of within- to between-module connections. We also directly quantified the number of between-module network connections. Finally, we identified nodes that had many within-module connections in the categorize condition and assessed how these changed due to selective attention. Participants had reduced modularity and increased between-module connections for relevant stimuli compared to irrelevant and categorize conditions. Further, nodes with many within-module connections in the categorize condition decreased their within-module connectivity during the relevant condition. We next investigated how network reconfiguration due to attention demands is related to task performance, by grouping subjects into fast and slow performers for relevant stimuli. Fast subjects showed greater decreases in modularity and increases in between-module connections to relevant compared to irrelevant stimuli. These results suggest that networks rapidly reconfigure while attending relevant stimuli to adopt a more globally distributed organization in which there is greater communication between modules. Further, more integration across network modules to attended stimuli supports better working memory performance.

Title: Dopamine-dependent functional network reorganization in Parkinson's disease and its relationship to working memory

Authors: *R. L. WHITE[1,2], M. D'ESPOSITO[2];
[1]Univ. of California San Francisco, San Francisco, CA; [2]Helen Wills Neurosci. Inst., Univ. of California Berkeley, Berkeley, CA

Abstract: Parkinson's disease (PD) is often accompanied by impairment in executive function and working memory (WM), which may be related to the dopamine depletion that occurs in PD. Exogenous dopamine can either enhance or disrupt WM in PD patients, depending on baseline characteristics. While recent evidence suggests that global integration of brain networks supports WM in healthy individuals, it is not clear how network properties are modulated in PD or how this affects WM function. We hypothesized that brain network organization would be altered in PD patients, and would be ameliorated after administration of dopaminergic medication. Furthermore, we hypothesized that the magnitude of network reorganization would capture changes in WM performance. We created network graphs from fMRI data collected during a resting-state scan in 24 PD patients and 20 matched control subjects. Each patient was scanned both ON and OFF their usual dopaminergic medication on separate days, with order counterbalanced across subjects. Performance of a WM task with distraction was measured immediately following the scan. Metrics derived from network graphs allowed us to assess functional network properties that were altered in PD and modified by exogenous dopamine. Graphs were generated from functional connectivity matrices between 333 cortical atlas nodes and were then partitioned into communities. Modularity was used to quantify the clustering of nodes into communities. The participation coefficient (PC) of nodes was used to quantify the proportion of connections between communities. We found that modularity was reduced in patients OFF medication and was normalized ON medication. WM performance (accuracy and reaction time) was impaired OFF medication and also improved ON medication. However, drug-induced changes in modularity were not directly correlated with changes in WM performance. Instead, dopamine-induced changes in WM performance correlated with more dopamine-induced PC of nodes in the default and somatomotor networks, indicating that these sub-networks increased their coupling with other sub-networks in support of WM. These results provide evidence that dopamine loss in PD is associated with a more modular, less distributed brain network organization at rest, and dopamine-dependent changes in the connectivity between sub-networks appear to play an important role in PD-related WM dysfunction. These results suggest that dopamine-induced changes in functional brain organization may be an important factor in determining the effects of dopamine on behavior.

Title: Brain network predictors of cognitive training-related gains in young adults

Authors: *P. L. BANIQUED[1], C. L. GALLEN[1], M. B. KRANZ[2], A. F. KRAMER[2], M. D'ESPOSITO[1];
[1]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [2]Beckman Inst. for Advanced Sci. and Technology, Dept. of Psychology, Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: The brain operates via networked activity in separable groups of regions called modules. Modularity is quantified as the relative number of connections between modules to connections to within modules, and thus characterizes the balance of integration and segregation in a network. We have previously demonstrated that higher baseline brain modularity can predict response to cognitive training in patients with traumatic brain injury (TBI). In healthy adults, however, the functional significance of modularity in predicting training outcomes is not known. Here we examined brain modularity in young adults aged 18-30 who underwent cognitive training with working memory and reasoning (WM-REAS) casual video games. At post-training, WM-REAS participants improved in divided attention measures relative to an active control game group and a no-contact control group. In the WM-REAS groups (N=81), we derived brain networks using data obtained from a six-minute resting state fMRI scan administered prior to training. Modularity was computed from functional connectivity matrices generated using 264 predefined nodes. Similar to TBI patients, modularity measured at baseline was positively correlated with improvement in divided attention following training. Baseline cognitive ability as assessed by six tests of fluid intelligence (Gf) was negatively related to divided attention gain, and highlights the role of individual differences in predicting training improvement. We performed a median split based on individuals' pre-training Gf scores and found that baseline modularity predicted training-related divided attention gain in low Gf, but not high Gf participants. In the low Gf group, individuals with higher baseline modularity showed greater improvements in divided attention, even after controlling for baseline Gf. These results are

consistent with the idea that a more modular brain may allow for greater adaptive re-organization during cognitive training. On a broader scale, these findings suggest that, in low-performing individuals, global network properties can capture unique aspects of brain function that are important in understanding individual differences in learning.

Title: Decreasing the amplitude of contingent negative variation through long-term consecutive visual search

Authors: *K. OKI[1], R. KOSHIZAWA[2], M. TAKAYOSE[3];
[1]Nihon Univ., Funabashi, Chiba, Japan; [2]Col. of Commerce, Nihon Univ., Setagaya, Tokyo, Japan; [3]Nihon Univ., Narashino, Chiba, Japan

Abstract: We investigated the influence of a long-term consecutive visual search on the contingent negative variation (CNV). Ten subjects, who were all male, performed a choice reaction task (CRT) before and after a long-term consecutive visual search task. In CRT, the up- or down-pointing arrow was shown at the center of the display as the warning stimulus (S1), and a square target as the imperative stimulus (S2) subsequently appeared upside or downside of the central cue. When the direction of S1 and S2 corresponded (this is called the target stimulus), each subject, conducting 80 trials, was supposed to respond with his right thumb pressing the joystick button. As for the long-term consecutive visual search task, the Advanced Trail Making Test Random Task (ATMT Task R) was introduced, in which a subject, using a computer mouse, clicked a black circle with the numbers from 11 to 40 in serial order. Once a numbered target was clicked, it was to disappear and another circle with the clicked number plus 30 showed up at the same time, all the circles rearranged at random; 30 circles were on the screen at any time. Each subject performed the task 40 times. During these trials, the subjects' EEG was recorded from Cz electrode along with the international 10-20 system. The averaged EEG patterns of each subject, were utilized in our analysis. The mean amplitudes of the early CNV components (550-750 ms after S1) and the late CNV components (1800-2000 ms after S1) were calculated, and the values before and after the long-term consecutive visual search were compared. It was clarified that the amplitudes of both the early and the late CNV components significantly decreased after the search, compared with those before the search. As the early CNV components reflected the orienting attention to S1 and, on the other hand, the late ones were closely related to the

attention, anticipation and response preparation to S2, the long-term visual search impaired the orientation to S1 and the three factors to S2.

Title: The relationship between prefrontal cortex activity during preparatory period and inhibition task performance

Authors: ***M. TAKAYOSE**[1], R. KOSHIZAWA[2], K. OKI[3];
[1]Nihon Univ. Col. of Industrial Technol., Chiba, Japan; [2]Nihon Univ. Col. of Commerce, Tokyo, Japan; [3]Nihon Univ. Col. of Sci. and Technol., Chiba, Japan

Abstract: The prefrontal cortex (PFC) plays a critical role in response inhibition. PFC activity during the preparatory period affects task performance, but the mechanism by which PFC activity contributes to accurate response inhibition remains unclear. To elucidate this mechanism, contingent negative variation (CNV) was compared in different task performances. In the present study, CNV during a modified stop-signal task was examined in 10 healthy right-handed participants. Participants were required to press a button when a go signal was presented but to withhold the response when the go signal was followed by a stop signal. EEG data were recorded from the scalp using 128 channels. Six channels (Fz, F3, F4, Cz, C3, and C4), in accordance with the international 10—20 system, were adopted as regions of interest. Surface electromyograms (EMGs) were recorded from the abductor pollicis brevis. Task performances were separated into unsuccessful inhibitions (UI), successful inhibitions with EMGs (SI-EMG), and successful inhibitions without EMGs (SI-noEMG). The preparatory period of each performance was compared and analyzed. Early CNV amplitudes of F4 and C4 were larger with UI than that with the other performances. Late CNV amplitudes of all channels, with the exception of C4, were smaller with SI-EMG than that with the other performances. These findings suggest that the contribution of PFC activity to response inhibition differs according to the components of CNV. Late CNV likely facilitates the inhibition process after the presented go signal, whereas early CNV facilitates the execution process.

Abstract: The hippocampus (HPC) and retrosplenial cortex (RSC) are inter-connected structures that play prominent roles in learning and memory processes, and show functional and structural alterations in psychiatric illness. For example, damage to either region can result in amnesia, and deficits in RSC and HPC connectivity are associated with serious mental illnesses, such as depression and schizophrenia. Both the RSC and HPC are heavily innervated by cholinergic projections from the medial septum and diagonal band of Broca. In addition, the cholinergic system has been strongly implicated in memory, as well as anxiety- and depression-like behavior. We therefore investigated the role of cholinergic neurotransmission in both of these regions in mouse models of fear-related learning and memory, and affective behaviors, including contextual fear conditioning, novel object recognition, novelty-suppressed feeding, and the forced swim test. Utilizing both pharmacological and genetic techniques, we demonstrated the specific roles of the M1 and M3 muscarinic receptor subtypes in each region for these behaviors, and examined their potential downstream signaling pathways. Identifying these mediators of cognitive and affective behavior is crucially important for developing a complete model of and potential therapies for memory and mood disorders.

Title: Altered states: amnestic treatments alter coherent activity between retrosplenial cortex and associated structures during memory retrieval

Authors: *K. A. CORCORAN[1], B. J. FRICK[1], L. M. KAY[2], J. RADULOVIC[1];
[1]Psychiatry & Behavioral Sci., Northwestern Univ., Chicago, IL; [2]Dept. of Psychology, Inst. for Mind and Biol., Univ. of Chicago, Chicago, IL

Abstract: Activity in retrosplenial cortex (RSC) is often reflected in human disorders characterized by aberrant memory processing: it is one of the earliest brain regions to show metabolic decline in Alzheimer's disease, and increased activation of RSC is consistently seen during retrieval of traumatic memories in PTSD patients. Memory retrieval requires both activity in RSC and is associated with changes in coherent activity between RSC and connected structures. Many disorder-related memory deficits can be modeled using amnestic drugs that target specific neurotransmitter systems, but how these drugs affect inter-regional activity within memory networks is unknown. We therefore explored the patterns of RSC oscillatory activity underlying retrieval of fear-evoking memories, and during retrieval failure after amnestic treatment. Mice were trained to fear a context paired with footshock, and then tested for memory retrieval beginning the following day. Retrieval tests were performed after systemic injection of the muscarinic cholinergic receptor antagonist scopolamine, the NMDA glutamate receptor antagonist MK-801, or the extrasynaptic GABAa receptor agonist gaboxadol. Using a wireless NeuroLogger system (TSE Systems), we obtained simultaneous recordings of continuous local field potential (LFP) activity during memory retrieval from RSC as well as hippocampus, lateral septum, and anterior cingulate cortex (ACC), regions connected to RSC that have also been implicated in fear memory. We measured coherence of activity between these regions through a range of frequencies along with changes in coherence during memory retrieval both on and off drugs. Identifying specific LFP patterns has the potential to unravel subtle mechanisms of circuit interactions associated with memory retrieval and how amnestic agents function to disrupt memory retrieval at a network level.

Title: Nitric oxide in the extinction memory formation of lithium-induced conditioned taste aversion learning

Authors: *J. JAHNG[1], V. RYU[2], J. Y. KIM[1], J. .-H. LEE[1];
[1]Seoul Natl. Univ. Sch. Dent., Seoul, Korea, Republic of; [2]Dept. of Biol., Georgia State Univ., Atlanta, GA

Abstract: Lithium chloride is conventionally used as an unconditioned stimulus (US) in the formation of conditioned taste aversion (CTA), a form of classical conditionings. Lithium chloride increases both the synthesis and activity of nitric oxide synthase in the brain regions implicated in CTA learning, and nitric oxide donors have been reported to produce a CTA in rats. This study was conducted to examine tentative implications of nitric oxide and nicotinic receptor activation in the acquisition and extinction of lithium-induced CTA learning. Rats were pretreated with nitric oxide synthase inhibitor N^{ω}-nitro-L-arginine methyl ester (L-NAME) or nicotinic acetylcholine receptor antagonist mecamylamine either at the conditioning (sucrose-lithium pairing) or at each drinking test. L-NAME prior to lithium chloride (US) did not affect the lithium-induced CTA formation; however, L-NAME at a dose of 30 mg/kg prior to each sucrose (conditioned stimulus; CS) drinking test significantly suppressed CS intake. Mecamylamine prior to US did not affect the acquisition of lithium-induced CTA, but at high dose (2 mg/kg) it facilitated the extinction. Mecamylamine (2 mg/kg) prior to each CS test delayed the extinction of lithium-induced CTA memory. Results suggest that nitric oxide may be implicated in the extinction memory formation of lithium-induced CTA, possibly in relation with the activation of nicotinic acetylcholine receptor.

Title: PHLPP1 knockout promotes spine actin polymerization, long-term potentiation, and learning in male but not female calpain-1 knockout mice

Authors: *Y. LIU, Y. WANG, J. SUN, D. LOPEZ, X. BI, M. BAUDRY;
Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Our previous studies have shown that long-term potentiation (LTP) elicited by theta burst stimulation (TBS) as well as learning of hippocampus-dependent tasks are impaired in calpain-1 knock-out (KO) mice. Calpain-mediated truncation of the Leucine rich repeat Protein Phosphatase 1 (PHLPP1) and the resulting stimulation of local protein synthesis play an important role in LTP induction and consolidation. To further evaluate the role of PHLPP1 in calpain-related signal pathways, we generated calpain-1-/- and PHLPP1-/- (DKO) and their respective controls, calpain-1-/- and PHLPP1+/+ (C1KO) mice. As previously reported, TBS produced a normal enhancement of field EPSPs in hippocampal slices prepared from C1KO mice but EPSPs returned to baseline by 30 min after TBS. In contrast, LTP in slices from male but not female DKO mice stabilized at levels found in wild-type controls. TBS-induced actin polymerization within dendritic spines, an essential event for stabilizing LTP, was absent in slices from C1KO mice but was clearly present in those from male but not female DKO mice. Long-term memory scores in a fear-conditioning paradigm were reduced by 30% in C1KO mice but were comparable to values found in wild-type control and in male but not female DKO mice. Consistent with these findings, C1KO mice displayed significant deficits in novel object recognition but wild-type control mice and male but not female DKO mice. Together, these data support the critical role of calpain-1-mediated cleavage of PHLPP1 in LTP induction. Deletion of both calpain-1 and PHLPP1 possibly trigger LTP and the resulting actin polymerization and learning of hippocampal tasks by activating a different signaling pathway. Further studies are needed to account for the dramatic sex differences in the DKO mice.

Title: Modelling a relationship between hippocampal theta frequency and long-term potentiation in anxiety tests

Authors: *G. CASTEGNETTI[1], D. BUSH[2], D. R. BACH[1,3];
[1]Dept. of Psychiatry, Psychotherapy and Psychosomatics, Univ. of Zurich, Zurich, Switzerland; [2]Inst. of Cognitive Neurosci., [3]Wellcome Trust Ctr. for Neuroimaging, Univ. Col. London, London, United Kingdom

Abstract: Rodent approach/avoidance conflict tests such as the elevated plus maze or the open field test elicit anxiety-like behaviours which are reduced by anxiolytic drugs. Compared to familiar environments, these tests also increase the power of theta oscillations (4-8Hz) of the hippocampal local field potential (LFP). The frequency of these oscillations is slightly but consistently reduced by anxiolytic drugs. Beyond anxiety models, theta oscillations are known to appear during translational movement and arousal, to modulate the firing rate and spike timing of principal cells in the hippocampal formation and amygdala, and to be important for spatial memory function. However, their functional relation to anxiety-like behaviours is currently unclear. Synaptic plasticity is crucial for encoding threat memories through potentiation of amygdala inputs. Here, we simulate the impact of perturbations of theta frequency on long-term potentiation. We model two integrate-and-fire neurons connected by a single synapse, the weight of which is governed by a calcium dependent synaptic plasticity rule. These neurons receive constant feed-forward excitation and theta rhythmic inhibition which causes them to present a periodic behaviour of the membrane potential. Our simulations demonstrate that the frequency of the theta oscillation affects synaptic plasticity in a scenario where the presynaptic neuron fires once in each theta cycle. Under such conditions, theta frequency has a positive, monotonic relationship with increases in synaptic strength during learning. This modulatory effect is more pronounced when the postsynaptic neuron is weakly excited. In this case, the slope of the predicted relationship between theta frequency and synaptic strength supports the possibility that frequency variations as small as those typically elicited by anxiolytics might suffice to significantly reduce long-term potentiation. Our results suggest that theta frequency changes evoked by anxiolytic drugs might be related to an altered encoding of threat predictions, possibly explaining changes in observed anxiety-like behaviours.

Title: Habenular spike-tiggered analysis of spike firing in hippocampal neurons

Authors: *N. SHAFEGHAT[1], H. AIZAWA[2], H. OKAMOTO[1], T. FUKAI[1];
[1]Riken, Saitama Prefecture, Japan; [2]Tokyo Med. and Dent. Univ., Med. Res. Institute, Tokyo Med. and Dent. Univ., Tokyo, Japan

Abstract: The lateral habenula (LHb) has drawn growing attention as this region could contribute to the regulation of dopaminergic and serotonergic activities in the central nervous system. We previously showed that LHb activity is crucial for the maintenance of hippocampal theta oscillation and that the majority of hippocampal neurons exhibit phase-locked activity to the oscillation. These results and the well-known theta phase precision of hippocampal neuronal firing during spatial navigation motivated us to investigate whether the hippocampus displays spike sequences time-locked to firing of LHb neurons. To this end, we analyzed the data of simultaneous multiunit recordings of LHb and hippocampal neuron ensembles in sleeping and behaving rats. Our inhouse spike sorting algorithm (EToS4) yielded sufficiently many units for this analysis. Cross-correlation analysis revealed sharp peaks at various timings within theta cycle time window in the cross-crrelograms between a LHb neuron and multiple hippocampal neurons. The results indicate that triggered by LHb activity, some hippocampal neurons fire in a specific temporal order of millisecond timescale. Such sequences may have implications in positive and/or negative reward-driven processing of memory.

Title: Dendritic reorganization in medial prefrontal cortex of male and female rats following recovery from chronic stress

Authors: *K. M. MOENCH, C. L. WELLMAN;
Dept. of Psychological and Brain Science, Program in Neurosci., Indiana Univ., Bloomington, IN

Abstract: Chronic stress produces differential dendritic remodeling of pyramidal neurons in medial prefrontal cortex of male and female rats (Garrett & Wellman, 2009). In males, the dendritic remodeling is reversible, with dendritic lengths returning to unstressed levels by 21 days after the cessation of stress (Radley et al, 2005). However, the timeline of this recovery, as well as the potential for reversibility in females, has yet to be established. Here, we examined dendritic recovery of pyramidal neurons in prelimbic cortex of male and female rats following

chronic restraint stress (3 h/day for 10 days). Following chronic stress, half of the rats were perfused immediately, and half of the rats were perfused following a 10 day recovery period. This time point was chosen due to previous work demonstrating this to be a sufficient amount of time for recovery of hippocampal pyramidal neurons following chronic stress (Conrad et al., 1999). Rats were overdosed and brains were stained using a Golgi-Cox procedure. Pyramidal neurons in layer II-III of prelimbic cortex were drawn in three dimensions, and the morphology of apical and basilar arbors was quantified. As expected, chronic stress produced apical dendritic retraction prelimbic cortex in males. Further, after recovery, morphology of neurons from stressed rats resembled that of unstressed animals. Dendritic retraction was also seen in female rats. However, the magnitude of this retraction was reduced compared to that seen in male rats. Additionally, hemispheric differences were found in the pattern of apical retraction in females but not males, with greater retraction in the left hemisphere. Similar to males, dendritic retraction in females was ameliorated by 10 days post-stress. However, given the sex difference in the magnitude of retraction, males showed a more pronounced recovery. This pattern of results suggests that following chronic stress, neurons in prelimbic cortex of both males and females demonstrate remarkable plasticity, with full recovery by 10 days post-stress.

Title: Arginine vasopressin at nanomolar concentrations blocks bumetanide-sensitive GDPs in the perinatal rodent hippocampus

Authors: *P. SEJA, J. LINDFORS, A. SPOLJARIC, E. RUUSUVUORI, J. VOIPIO, K. KAILA;
Univ. of Helsinki, Helsinki, Finland

Abstract: During the perinatal period, a number of allostatic physiological mechanisms are activated in mammals to facilitate the transition to extrauterine life (Tyzio et al., Science 2006). Recent studies on humans (Wellmann et al., J Clin Endocrinol Metab 2010) have demonstrated a massive release of arginine vasopressin (AVP) in the neonate during birth, but the neurobiological consequences of this mechanism have not been studied. Here, we made electrophysiological experiments on rat hippocampal slices and on whole hippocampi *in vitro* at the end of the fetal period (E20-21); within 2h after birth; and during the first two postnatal days

(P0 and P1). At all these time points, CA3-driven network events known as Giant Depolarizing Potentials (GDPs) were observed, and they were blocked by bumetanide, a selective inhibitor of Cl^- uptake by NKCC1, indicating a key role for depolarizing GABA in their generation . The perinatal depolarizing action of GABA was further confirmed by fluorescent imaging (Fluo-4AM) of intraneuronal cell-autonomous Ca^{2+} transients evoked by $GABA_A$ agonists. GDPs were strongly suppressed by exposure to 5-10 nM AVP. The AVP effect was prevented by the V1a receptor antagonist SR49059 (20 nM). The suppression of GDPs by AVP was transient with a maximum at 200-300s, and the GDPs retained their sensitivity to bumetanide after recovery in the presence of AVP. AVP induced a massive increase in the frequency of TTX-sensitive spontaneous IPSCs (sIPSCs) in CA3 pyramidal neurons both in the presence and absence of ionotropic glutamate receptor blockers. Under the latter conditions, a pronounced desynchronization of synaptic events took place, which readily explains the suppression of GDPs (Sipilä et al., J. Neurosci. 2005). Thus, we conclude that during birth, AVP exerts neuroprotective actions and prevents pathophysiological plasticity by desynchronizing neuronal network activity. This is an intriguing finding, especially in the light of studies, which show that AVP release during human birth is further enhanced under pathophysiological conditions such as birth asphyxia (Schlapbach et al., BMC Pediatrics 2011).

Title: Deconstructing ventral hippocampal control of innate and learned fear behavior

Authors: *J. C. JIMENEZ[1], A. GOLDBERG[1], G. ORDEK[1], L. DREW[2], V. LUNA[1], M. WRIGHT[3], R. HEN[1], M. A. KHEIRBEK[1];

Abstract: Recent studies implicate functional heterogeneity in projection specific populations within affective circuits, including the ventral hippocampus and amygdala. How these specialized circuits contribute differentially to anxiety and fear related behaviors, however, is not understood. In this study, we have focused on the ventral hippocampus (vHPC), and leveraged

optical technologies to determine how the extended vHPC circuit can modulate innate and learned fear behavior. In order to understand the mechanisms by which the vHPC may control anxiety-related and learned fear behavior, we have used *in vivo* functional calcium imaging and optogenetic terminal modulation in mice exploring safe and anxiogenic environments. Our imaging studies revealed that vHPC neurons exhibit a higher rate of calcium transients during exploration of innately anxiogenic environments, including the center in the Open field Test and open arms of the Elevated Plus Maze, but not during exploration of a novel object. Next, we dissected the relative contribution of vHPC outputs to innate and learned fear. We focused on outputs to two limbic regions implicated in emotional behavior, the amygdala and hypothalamus. Channelrhodopsin-assisted circuit mapping confirmed that vHPC sends a direct monosynaptic projection to the lateral hypothalamic (LH) area and the basomedial nucleus of the amygdala (BMA). Acute optogenetic modulation of vHPC-BMA terminals impaired contextual fear conditioning without impacting behavior in tests of innate anxiety. In contrast, optical activation of vHPC-LH terminals was anxiogenic and aversive, without affecting learned fear measures. These studies implicate a projection-specific functional dissociation of vHPC outputs during innate and learned fear behavior. Further, our *in vivo* imaging data indicates a specialized representation of anxiogenic environments within the local vHPC circuit. Our ongoing studies are aimed at comparing vHPC population activity during innately anxiogenic tasks to activity in contextual fear conditioning paradigms. Further, we are examining the interplay between vHPC activity and anxiety state through pharmacological and behavioral manipulations.

Title: alphabetadelta-GABA-A receptors at excitatory axo-spinous synapses of the dorsal hippocampal CA1 of adolescent female rats contributes towards suppression of food restriction-evoked excessive wheel running, an animal model of anorexia nervosa, but is not affected by food restriction alone or rearing in isolation and is up-regulated by exercise

Authors: *C. J. AOKI[1], T. G. CHOWDHURY[2], W. PIPER[2], Y.-W. CHEN[2];
[1]Ctr. Neural Sci., [2]Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: We have previously shown that GABA-A receptors containing alpha4 and delta subunits (α4βδ-GABAARs) occur on spine membranes of the hippocampal CA1 of adolescent female rats forming excitatory synapses. The levels of these receptors are up-regulated in stratum radiatum of the dorsal hippocampal CA1 field within 4 days of exposure to food restriction (P41-P44), when this is combined with access to a running wheel (P36-P44). Because food restriction-induced hyperactivity captures two hallmarks of anorexia nervosa (AN) - excessive exercise and voluntary food restriction (animals choose to run, instead of eating, even during the limited periods of food access), leading to exaggerated weight loss, it has been used as an animal model for AN, called activity-based anorexia (ABA). α4 level was shown previously to be correlated negatively with the extent of hyperactivity. We have also shown that the extent of running following ABA is correlated with anxiety. We hypothesize that up-regulation of these GABAARs contribute towards anxiolysis, suppression of wheel running and protection from excessive weight loss. In order to evaluate the specificity of the ABA induction, we determined whether wheel running alone (EX) or food restriction alone (FR) also up-regulates α4βδ-GABAARs. Moreover, since animals had to be housed in isolation in order to measure wheel activity, we also tested whether isolated housing contributes towards the up-regulation. These questions were analyzed by repeating the electron microscopic immunocytochemical analysis to quantify α4 subunit immunoreactivity (ir) at 200 randomly sampled spines from the same brain region of 7 FR, 7 EX, 8 CON (neither food restricted nor given access to a running wheel), 8 isolated-CON and 8 pair-housed-CON age-matched animals. We observed no effect of isolated housing. The averaged values of α4-ir across the animals were significantly elevated for the EX group (67%), even more than for the ABA group (37%), relative to CONs, while FR did not evoke an elevation (-9%, relative to CONs). Running on the first day of food restriction correlated strongly and negatively with α4 level among the ABA animals (R=-0.84, p=0.009), recapturing what we observed in a previous cohort, but this correlation was absent for the equivalent day's running of the EX group (R=0.25, p=.59). Instead, EX group's α4 level correlated strongly and positively with their running on days 2 plus 3 of wheel access (R=0.84, p=0.02). These findings confirm that α4βδ-GABAARs in the dorsal hippocampus contribute towards suppression of food restriction-evoked excessive exercise but also supports motor learning on the wheel, when food restriction stress is absent.

Title: Immunoreactivity for the NR2A and NR2B subunits of NMDA receptors is increased at axo-spinous synapses of hippocampal CA1 of adolescent female rats exhibiting food restriction-evoked hyperactivity, an animal model of anorexia nervosa

Authors: *L. KLINGENSMITH, H. ACTOR-ENGEL, Y.-W. CHEN, T. G. CHOWDHURY, C. AOKI;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Adolescence is a developmental period of increased vulnerability to psychological disorders and specifically eating disorders. Anorexia Nervosa (AN) is a neuropsychiatric disorder of unknown etiology, more common among females than males, with the first onset usually around puberty. AN is characterized by self-induced restricted caloric intake and an extreme pursuit of thinness that ultimately leads to emaciation, and in some cases death. Due to recorded changes in cognitive function and synaptic plasticity during puberty, we sought to investigate whether the expression of NR2B and NR2A subunits of the N-methyl-D-aspartate receptor (NMDAR) changed in the CA1 region of the adolescent females' dorsal hippocampus in response to the induction of an animal model of AN, Activity-Based Anorexia (ABA). ABA induction involves exposing animals to running wheel access for 8 days (P36-P44) and food restriction (FR) during the last 4 of those days (P41-P44). ABA captures two hallmarks of AN - over-exercise and voluntary FR. We used electron microscopic (EM) immunocytochemistry to quantify changes in the level of NR2B and NR2A immunoreactivity (ir) at synaptic and non-synaptic sites of axo-spinous junctions. We analyzed at least 100 synapses from each of 8 ABA and 4 Control animals. NR2A- and NR2B-subunit ir was significantly greater post-synaptically for synapses of ABA animals compared to Controls', using post-embed gold immunolabel (PEG) as the unit for counting to quantify levels of ir or synapse as a unit, to quantify the proportion of ir synapses. Both the NR2A- and NR2B-ir were driven by those animals that responded to FR with higher activity (ABA-High). In addition, NR2B-NMDARs were also increased pre-

synaptically for the ABA tissue, driven by the ABA-Low animals that responded minimally to FR. When non-synaptic zones were included, both subunits were higher within axon terminals of ABA-Low animals. These findings suggest that the experience of FR-evoked hyperactivity of ABA increases NMDAR-mediated synaptic plasticity. However, the increased excitation at spines would increase excitability of the hippocampus, and this may be contributing to stress-induced anxiety as well as increased vulnerability to ABA. Finally, presynaptic NR2B expression correlated negatively with running activity two days prior to food restriction and on the first day of FR, suggesting that these receptors participate in animals' resilience to the maladaptive behavior of FR-evoked hyperactivity.

Title: Habituation and fear conditioning in neonatal ventral hippocampal lesioned rats

Authors: *W. P. JORDAN[1], C. DI LEO[2];
[1]St Mary's Col. of MD, St Marys City, MD; [2]Psychology, St Mary's Col. of MD, St. Mary's City, MD

Abstract: The neurodevelopmental aspects of schizophrenia are modeled in rats with lesions to the hippocampus early in life (Lipska & Weinberger, 2000). A variety of behavioral abnormalities emerge post-adolescence (see Tseng, Chambers, & Lipska, 2009 for a review). Animals with NVHL lesions have been found to show deficits in Pavlovian fear conditioning (e.g., Gilmartin, Balderston, & Helmstetter, 2014) and its extinction (Quirk, Garcia, & Gonzalez-Lima, 2006)--deficits also found in human schizophrenic patients (Braff, Saccuzzo, & Geyer, 1991). The present study looked at lick suppression habituation to a noise CS in NVHL-lesioned animals, followed by fear conditioning and then extinction. 7 Sprague-Dawley rats received bilateral ibotinic acid lesions to the hippocampus on post-natal day 7, while 8 rats received sham lesions or were unoperated controls. In adulthood rats were water deprived and trained to lick. Habituation training consisted of 3 daily presentations of a noise stimulus (88dB, 30s) while the animal was licking. Rats then were conditioned to fear the noise CS by paired it with foot shock (0.5mA, 0.5s). One CS/US pair was given each day until each rat's licking during the CS met a suppression criterion. Conditioning was followed by 8 extinction sessions. Both groups showed

equal suppression to the first CS presentation, but Control animals showed more long-term habituation across days. Across the five conditioning sessions, Control animals showed robust fear conditioning. NVHL animals also showed significant conditioning and reached a common asymptote to the Controls, but the unequal starting points produced a significant group by day interaction. During extinction, the two groups initially were equally suppressed, but Control animals were faster to extinguish producing significant group differences before reaching a common extinction asymptote. The habituation deficit in NVHL animals makes difficult the interpretation of the differences during conditioning. The habituation deficits in NVHL-lesioned animals are of interest theoretically and empirically, as the animal hippocampal literature often makes a distinction between habituation within different response systems such as exploration, startle, and lick suppression (e.g., Leaton, 1981). These potential deficits in habituation, fear conditioning, and extinction are compatible with reports from human schizophrenics, although it is difficult to attribute the deficits to any one of these three learning processes or to a more general problem with behavioral perseveration.

Title: Astroglial changes in the hippocampus of aged rats exposed to chronic variable stress

Authors: ***D. L. MORAN TORRES**[1], D. RUESGA-BARCENAS[1], S. LUQUIN[1], J. GARCÍA-ESTRADA[2], R. RAMOS-ZUÑIGA[1], F. JAUREGUI-HUERTA[1];
[1]Neurociencias, Univ. De Guadalajara, Guadalajara, Mexico; [2]Neurociencias, Ctr. de Investigación Biomédica de Occidente. IMSS, Guadalajara, Mexico

Abstract: In this study, we exposed adult aged rats to a chronic variable stress model and compare astroglial changes as a function of wether or not the rats were exposed to stress early in their lives. Experiments were carried out on 18-month-old male rats divided in 4 groups as follows: Control (old rats under standard laboratory conditions), Early-life stress (old rats who were exposed to environmental noise from postnatal days 21 to 35), Chronic variable stress + Early-life stress (old rats exposed to a chronic stress protocol which previously were exposed to the early-life noise stress) and Chronic variable stress (old rats who were exposed only to the chronic stress protocol). Immunohystochemistry against BrdU+GFAP was conducted in the hippocampal regions DG, CA3, CA2 and CA1. We confocally analyzed astrogenic

(BrdU+GFAP labeled cells) and morphological (GFAP labeled cells) changes produced by these conditions. We found with this procedure that senile rats exposed to chronic stress, improved their astroglial proliferative rate when this experience was preceded by early life stress. Region specific changes were also observed on astroglial morphology. Then, our results support the idea that previous exposure to stressing agents may exert important modulating effects on astroglial activity of aged subjects.

Title: The effect of the swearing on hippocampal subregions in adolescence

Authors: *D. KIM, J. YOO, S. LEE, B. JEONG;
KAIST, Daejon-City, Korea, Republic of

Abstract: Introduction The peer verbal abuse (PeVA) is serious and widespread problem in adolescence. It can damage not only emotion but also brain, especially hippocampal regions. However most adolescent frequently use swear words without recognition of the detrimental effects of swearing. In our study, various analytic methods were applied to find the negative impacts of PeVA on the structural changes in the hippocampus and its subregions, and we also tried to determine relationships between the structural changes of hippocampus and behavioral measurements including depression and anxiety to verify the meaning of structural changes **Method** We enrolled 43 high school students. They were classified into 2 groups according to score of Verbal abuse Questionnaire (VAQ), the cut-off value of which was 40. We obtained clinical and MRI data. Some subjects, who has depression or organic brain problem were excluded from study. Finally 31 subjects was enrolled study (PeVA group 15, control group 16). The Hippocampal subfield tool from Freesurfer software was used for segregating each hippocampal subregion including fimbria, CA2_3, CA1, CA_DG, Presubiculum, subiculum, hippocampus. Data from each participant were entered into general linear model, using R software 3.0.1 to obtain volume of each subregion. Effects of IQ score of subject and internal cranial volume were corrected, as they can affect volume of hippocampus. Correlation analysis was conducted to identify correlation of hippocampal volume with severity of parental verbal abuse (PVA) and PeVA, using R software 3.0.1 **Results** We found that the volume of left hippocampus and subiculum was negatively related to severity of PeVA(Fig.1). Volume of left hippocampus and subiculum in PeVA group was smaller than that in normal control. The

hippocampus volume changes were associated with individual's anxiety trait in adolescence who reported substantial PeVA experiences. PVA did not have significant correlation with volume of hippocampal region **Discussion** Correlation between hippocampal volume and severity of PeVA show that quantity of PeVA play a role in hippocampal damage. Volume reduction only in the left sided hippocampus might suggest that verbal memory was processed at left hippocampus. Volume reduction in subiculum may relate to change of level of stress hormone, because subiculum mediate hypothalamic-pituitary-adrenal axis. We identified structural effect of swearing on hippocampus in this study. We also need to identify functional effect of swearing in the future.

Title: A role for endogenous CRH in the hippocampus?

Authors: *B. G. GUNN, Y. CHEN, G. LYNCH, T. Z. BARAM;
Univ. of California Irvine, Irvine, CA

Abstract: Rationale: The release of corticotropin-releasing hormone (CRH) from neuroendocrine cells of the hypothalamic paraventricular nucleus is integral to the initiation of the stress response. However, CRH is additionally expressed in a number of brain regions including the hippocampus, amygdala and bed nucleus of the stria terminalis. Hippocampal functions are impacted by stress, suggesting a potential role of hippocampal CRH (Joels & Baram, 2009). CRH is expressed in hippocampal interneurons in CA1 and CA3, whilst the receptors for this peptide (CRHR1 and CRHR2) appear to be located almost exclusively in discreet subcelluar domains on pyramidal cells. In addition, exposure to stress results in the release of hippocampal CRH (Chen et al, 2012) and contribution by the peptide to the stress-related effects on memory (Chen et al, 2010). In slice preparations, exogenous CRH results in an increase in excitability of hippocampal pyramidal cells (Aldenhoff et al, 1983; Hollrigel et al, 1998). Here we explore the notion that endogenous CRH may play a role in modulating neurotransmission within the hippocampus. Methods: C57BL/6 mice (P21-P40) were

decapitated, the brains dissected and horizontal brain slices (300-350 μm) prepared using standard procedures. The whole-cell voltage-clamp configuration was applied to record spontaneous excitatory postsynaptic currents (sEPSCs) from CA3 pyramidal cells. The presence of an endogenous CRH tone was determined by the bath application of the competitive, non peptide antagonist, NBI 30775 (1 μM). Results: In our first set of experiments, blocking the actions of endogenous CRH reduced the frequency of sEPSCs recorded from CA3 pyramidal cells, whilst having only modest effects upon the peak amplitude and decay kinetics of these currents. Additional experiments are ongoing. Conclusions: This observation would suggest that endogenous CRH, released from a population of hippocampal interneurons, modulates excitatory synaptic transmission in an acute brain slice preparation. Title: Interleukin-1 α in the ventral hippocampus mediates aspects of stress vulnerability

Authors: *J. PEARSON-LEARY[1], D. EACRET[1], R. CHEN[1], L. WILSON[1], S. BHATNAGAR[1,2];
[1]Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Chronic psychological stress is associated with cognitive, emotional, and physical disturbances. Several immune changes have been observed in the brains of animals subjected to chronic stress. Importantly, some animals are resilient to the effects of chronic stress, while other animals are vulnerable. Using an adult male rat model of social defeat stress we have identified subpopulations of rats that are either vulnerable (short-latency; SL) or resilient (long-latency; LL) to the effects of social defeat stress. Behaviorally, vulnerable SL rats have increased depressive- and anxiety-like behaviors, while resilient LL rats are no different from controls. PCR array analyses identified changes in patterns of immune signaling molecules in the ventral

hippocampus (vHPC) of SL and LL rats. Of specific interest, interleukin-1 alpha (IL-1α) and its receptor interleukin-1 receptor type 1 (IL1R1) were increased in the vHPC of SL rats relative to LL rats. To determine whether vHPC IL-1α was important for stress vulnerability, we delivered recombinant IL-1α or recombinant interleukin-1 receptor antagonist (IL1-RA; an endogenous antagonist to interleukin-1) to the vHPC of rats 1 h prior to social defeat stress for 5 d. As expected, IL-1α lowered defeat latencies consistent with the vulnerable phenotype while IL1-RA increased defeat latencies consistent with the resilient phenotype. Rats treated with intra-vHPC IL-1α were not different from controls during a social interaction task of anxiety-like behaviors, while IL-1RA-treated rats showed decreased anxiety-like behaviors relative to control and IL-1α-treated rats. Analyses of brains from treated rats showed increased blood vessel density and microglial activation in vHPC of IL-1α-treated rats relative to control and IL1-RA-treated rats. These data suggest that while IL-1α treatment was sufficient to activate inflammation in the vHPC and increase some behaviors associated with stress vulnerability, IL-1α was insufficient in producing the anxiety-like phenotype that is known to occur with stress vulnerability. Taken together, our data suggest that interleukin-1 signaling in the vHPC is involved in some components of stress vulnerability.

Title: The hippocampus is not required for context discrimination in a pavlovian fear conditioning task

Authors: *J. Q. LEE, R. J. SUTHERLAND, R. J. MCDONALD;
Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: The hippocampus is thought to be important for discriminating between contexts, but not for basic context conditioning. Results are mixed on whether increased amounts of training can overcome context discrimination deficits in rats with hippocampal damage. Notably, studies that support the idea that increased training can overcome deficits did not examine lesion extent. Thus, spared hippocampal tissue might have supported context discrimination. In order to resolve these inconsistencies, rats with complete hippocampal lesions (> 75%) were trained for one or three conditioning sessions in a discriminative fear conditioning task. Rats with

hippocampal damage demonstrated clear discriminative freezing between shock-paired and unpaired contexts and a weaker preference for the unpaired context. In subsequent experiments, the parametric limitations of hippocampal and extra-hippocampal contributions to context discrimination in both anterograde and retrograde directions, and the discriminanda that influence these abilities were also assessed. Our findings contribute to recent advancements in understanding the role of the hippocampus in long-term memory for emotional events and the specific places in which they occur.

Abstract: The hippocampus is a complex brain structure involved in learning, memory and emotional responses and its functioning is affected in various brain disorders. Despite conserved intrinsic circuitry, behavioral and anatomical studies suggest the existence of discrete regions along its longitudinal axis, each orchestrating distinct cognitive operations and accounting for its functional diversity. More recently, high-resolution gene expression analysis identified multiple, spatially segregated molecular domains and subdomains. Lipids are major constituents of the brain and growing evidence implicates their role in physio- and pathological processes. Little is known about the brain's lipidome, particularly of the hippocampus along its longitudinal axis. Here, we used an unbiased mass spectrometry approach to characterize the lipid composition of the dorsal (DH) and ventral (VH) areas of the rat hippocampus. Additionally, we evaluated each region's functional flexibility to modulate its composition under treatment with corticosterone, a

model for chronic exposure to stress. We confirmed a conserved intrinsic composition of both DH and VH relative to other brain areas. However, both domains differed significantly in sphingolipid and phospholipid metabolism, suggesting differential regulation of lipid signaling pathways. Additionally, we found that while overall biochemical coherence between both areas of the hippocampus is conserved under stressful conditions, they present identical responses to some extent. Most strikingly, cholesterol esters and ceramide accumulate upon exposure to high corticosterone levels. Diacylglycerol and phosphatidic acid present region-specific fatty-acyl profiles suggesting a differential impact on their metabolizing enzymes along the hippocampal axis. Moreover, lipid changes linearly correlate with blood corticosterone levels ($R2>0.4$). Our results confirm a multipartite view of the hippocampus based on its lipid signature. These findings highlight the importance of understanding lipid metabolism in the context of brain function with potential implications to disorders such as chronic exposure to stress and Alzheimer's disease. A thorough knowledge of the boundaries within the hippocampal axis will provide new tools to understand and manipulate each region's function, both in health and disease.

Title: Unpaired fear conditioning yields hippocampus-dependent responding

Authors: M. R. HERBST[1], A. F. POSTLE[1], M. S. FANSELOW[2], *J. J. QUINN[1]; [1]Psychology, Miami Univ., Oxford, OH; [2]Psychology, UCLA, Los Angeles, CA

Abstract: The hippocampus (HPC) plays a critical role in the formation of conjunctive representations among stimuli. This may explain why manipulations of HPC function alter learning in a variety of procedures including the formation of spatial maps, unified representations of context, and episodic memories. Using a backward trace fear conditioning procedure, we previously showed that responding to a tone that was not explicitly paired with footshock produced a moderate level of freezing when tested later. In addition, this freezing was eliminated by post-training neurotoxic lesion of the dorsal HPC (DH). The present experiments were designed to assess whether other explicitly unpaired conditioning procedures similarly yield HPC-dependent responding. Five conditioning procedures were used: footshock US-only,

intermixed, backward trace, tones→footshocks, footshocks→tones. Thus, all rats received ten tones (except US-only) and ten footshocks, but the order of stimulus presentation within the session differed between groups. One day following training, half of the rats in each training condition were given a neurotoxic, NMDA-induced lesion of the DH while the others received a sham surgery. Seven to ten days following surgery, rats were tested for freezing to both the original training context and to the tone in a novel context. Results from Experiment 1 indicate a high level of HPC-dependent context freezing in all groups. Further, there was significant freezing to the tone in all groups that had received the tone during conditioning, but not in the US-only group. Tone freezing was also HPC-dependent. One concern was the high level of baseline freezing that was observed in the novel, tone test context. Therefore, Experiment 2 was identical to Experiment 1 except that three exposures to the tone test context were introduced prior to the tone test. These context exposures significantly reduced baseline freezing (to near-zero levels) in all groups. Despite this very low baseline freezing, tone and post-tone freezing was observed in all groups and this responding was HPC-dependent. The data will be discussed in terms of the formation of a HPC-dependent conjunctive representation of the conditioning episode.

Title: Digital fear conditioning in rats: utilizing LCD-based visual context manipulations during conditioning

Authors: ***N. J. MURAWSKI**[1], A. ASOK[2];
[1]Ctr. For Behavioral Teratology, San Diego, CA; [2]Dept. of Psychological and Brain Sci., Univ. of Delaware, Newark, CA

Abstract: Contextual fear conditioning (CFC) is a powerful behavioral assay for examining the neurobiology of learning and memory. The simple behavioral setup and robust long-lasting memories formed during conditioning have made CFC an ideal paradigm for incorporating methodological innovations in behavioral neuroscience. CFC is highly context-specific in that higher levels of conditioned freezing are observed when training and testing occur in the same, versus a different, context. Discriminating between similar, but not identical contexts requires

neural processes that are distinct from those required for discriminating between two non-similar contexts (Nakashiba et al., 2012, Cell 149: 188-201). However, experimental differences between "similar" and "non-similar" contexts can be ambiguous: Typically, one context is made distinct from another by manipulating one or more features of a context (e.g., spatial, visual, tactile, or olfactory) - similar contexts share more features than non-similar contexts. Developing new methodologies to systematically alter contexts can improve experimental control over context features and help better identify the neural substrates that support contextual fear conditioning. Previous research demonstrates that rats can utilize changes in visual contexts projected onto LCD screens to perform a hippocampus-dependent response selection task (Kim, et al. 2012, Frontiers in Behavioral Neuroscience 6: 1-10). Here we ask if adult male rats can show the context pre-exposure facilitation effect by utilizing visual contextual information provided by four LCD screens surrounding a conditioning chamber. Rats received a 5-min pre-exposure session on Day 1, an immediate 1.5 mA foot shock on Day 2, and a 5-min context test on Day 3. Rats were either pre-exposed to Context A or B on Day 1. Context A and Context B only differed in the visual image projected onto the LCD monitors. Immediate shock and context test occurred in Context A. Rats pre-exposed to Context A froze significantly more than rats pre-exposed to Context B during testing. These results indicate that rats 1) can learn fear to a visual context, 2) that changes to a visual context mediate differential conditioning, and 3) that visual features of the context can be parametrically controlled via LCD screens. Quantitative control and temporal precision of contextual features afforded by digital context presentations can greatly aid researchers in their understanding of discriminating and generalizing fear to aversive contexts.

Title: Differential myelination in individual responses to stress and stress-induced anxiety

Authors: *K. LONG[1], D. KAUFER[2];
[1]UC Berkeley, Berkeley, CA; [2]Integrative Biol., Univ. of California, Berkeley, Berkeley, CA

Abstract: Individuals show a spectrum of responses to traumatic stress, ranging from normal behavior to extreme anxiety and post-traumatic stress disorder. Animal models have begun to elucidate the neural underpinnings of such disparate responses; for example, extremely affected

individuals show dendritic atrophy of hippocampal pyramidal cells, while minimally affected individuals show arborization that is indistinguishable from unexposed controls[1]. Literature from human patients suggests that, in addition to changes to gray matter, trauma and subsequent PTSD may also be associated with increases in hippocampal white matter. In addition, our lab has shown that stress causes an increase in oligodendrogenesis and myelination in the rat hippocampus[2]; however, whether effects on myelination and white matter are correlated with the spectrum of responses to stress is not understood. In this study, we used a rodent model of PTSD to evaluate myelination in extremely affected and minimally affected individuals, with the hypothesis that extremely affected individuals will show increased hippocampal myelination. Adult, male Sprague-Dawley rats were exposed to three hours of immobilization and fox urine. Seven days post-stress, animals were evaluated for anxiety behavior on the open field, elevated plus maze, and acoustic startle response and subsequently classified into the behavioral profiles of minimal behavior response (MBR) and extreme behavioral response (EBR) based on cutoff behavioral criteria[1]. Fourteen days after stress, animals were sacrificed and brains perfused for immunohistochemical analysis of oligodendrocytes and myelination. The results presented will demonstrate the role of myelination in individual stress reactivity and open the door to studies of the causal role of myelination in stress-induced anxiety. 1. Title: Contextual representations along the proximodistal axis of CA1

Authors: Y. NAKAZAWA, K. TANAKA, A. PEVZNER, *B. J. WILTGEN;
Ctr. for Neurosci., UC Davis, Davis, CA

Abstract: Neurons in the rodent hippocampus form place fields that are stable in a given environment. Activation of these cells is assumed to mediate the encoding and retrieval of spatial/contextual memories. However, space is not uniformly represented across the proximodistal axis of the hippocampus, giving rise to potential functional differences. For example, place cells in proximal CA1 (pCA1) are more spatially selective than those in distal CA1 (dCA1). This difference could be explained by the unique connectivity that each of these

regions has with the entorhinal cortex (EC). pCA1 is reciprocally connected with the medial portion of the EC (MEC), which exhibits spatially selective firing (e.g. grid cells). In contrast, dCA1 is connected with the lateral EC (LEC), which is only weakly modulated by spatial inputs. Based on these differences, it is likely that proximal and distal CA1 make unique contributions to learning and memory retrieval. To examine this idea, we used TetTag mice to determine the stability of context representations in each of these regions. In our first experiment, active neurons were tagged during context fear conditioning with the long-lasting protein H2B-GFP. During subsequent testing, we found that tagged neurons in pCA1 were significantly more likely to be reactivated (measured via c-Fos expression) than cells in dCA1. This same effect was observed 1) when mice were exposed to the same context twice in the absence of shock and 2) when mice received multiple fear conditioning tests in the same environment. Subsequent analyses also revealed greater than chance reactivation in regions connected to pCA1 (MEC and distal CA3) but not those connected to dCA1 (LEC and proximal CA3). We are in the process of conducting fiber sparing NMDA lesions of proximal and distal CA1 to determine their functional contributions to the retrieval of context fear memories.

Title: The influence of environmental parameters on hippocampal reactivation

Authors: *A. HAMIDI[1], B. J. WILTGEN[2], A. PEVZNER[3];
[2]Psychology, [3]Neurosci., [1]Univ. of California At Davis, Davis, CA

Abstract: The hippocampus plays a key role in the generation and retrieval of contextual representations. Previous research has shown that hippocampal place cells are sensitive to changes in physical parameters of the environmental context (Burgess et al, 2006). To visualize the recruitment of hippocampal cells during context exposure, our lab uses the H2B-GFP-TetTag mouse, which relies on the temporally specific activation of IEGs. Successful memory retrieval is cellularly indexed by tagging active cells, during two different context exposure sessions, with H2B-GFP and c-fos, respectively. Cells that co-localize H2B-GFP and c-

fos are operationally defined as “reactivated”. Given that neural reactivation is a commonly used cellular metric of memory retrieval, understanding how this measure varies based on the features of the testing environment is key for the consideration of future project designs. Previous data from our lab has shown that reactivation of cells in CA1 is correlated with expression of a hippocampal dependent context memory (Tanaka et al, 2014). The parameters of the environmental context, which drive the observed reactivation, however, have not yet been fully explored. Recently, we demonstrated that two exposures to large environment did not reliably result in above chance reactivation in proximal CA1 (pCA1). Neither an increase in time spent on the arena, nor spatial training on the large environment, was sufficient to drive increased reactivation. Surprisingly, the addition of boundaries in the large environment was able to rescue the low reactivation levels in pCA1. (Pevzner et al, 2014). Notably, these reactivation levels were still lower than those generated from our group’s previous data exposures to a fear-conditioning chamber (a substantially smaller environment), suggesting that area is also an important factor (Nakazawa et al, 2013). In this experiment, we have extended previous findings by investigating the effects of adding borders to a small environment (the same surface area as the fear conditioning chamber) and compared this to a small environment without borders. Future experiments will be aimed at investigating whether the addition or removal of environmental boundaries within the large and small environmental arenas can further drive levels of cellular reactivation in the hippocampus.

Title: Direct hippocampal-prefrontal input is required for anxiety-related neural synchrony and behavior

Authors: ***N. PADILLA**[1], S. S. BOLKAN[1], G. M. PIERCE[1], D. R. BLACKMAN[3], T. SPELLMAN[1], J. A. GORDON[1,2];

[1]Neurobio. and Behavior, [2]Dept. of Psychiatry, Columbia Univ., New York, NY; [3]Barnard Col., New York, NY

Abstract: The ventral hippocampus (vHPC) and medial prefrontal cortex (mPFC) are both required for the expression of anxiety-like behavior in rodents. Theta-frequency (4-12 Hz) synchrony within this circuit correlates with anxiety-like behavior. Moreover, cells in the mPFC that encode the aversive structure of the environment are phase locked to theta oscillations in the vHPC. We hypothesized that the direct vHPC input to the mPFC is necessary for avoidance behavior, anxiety-induced theta synchrony and mPFC encoding of aversion. To address this hypothesis, multi-site neural recordings were obtained while optogenetically inhibiting the direct vHPC-to-mPFC projection. Previously we have demonstrated that inhibition of vHPC input to the mPFC during the elevated plus maze (EPM) decreased avoidance of the open arms, as well as theta synchrony between mPFC and vHPC (Padilla et al. 2014, SfN). Here we demonstrate that this effect is frequency specific, as there were no changes in synchrony in delta (1-4 Hz), beta (12-30 Hz), or gamma (30-70 Hz) frequency ranges. Moreover, inhibition of vHPC-mPFC pathway did not affect theta synchrony between BLA-mPFC and BLA-vHPC. Inhibition of the vHPC input to the mPFC also disrupted arm-type encoding by mPFC single units. Interestingly, inhibition of this pathway in a non-aversive maze also disrupted arm-type encoding, suggesting that the vHPC input to the mPFC is necessary for representation of both aversive and non-aversive contexts within the mPFC. Finally, silencing another major excitatory input to the mPFC, the medial dorsal thalamic input, did not disrupt avoidance behavior nor disrupted mPFC encoding of the EPM. These results reveal a frequency- and pathway-specific role for the vHPC-mPFC projection in anxiety-related vHPC-mPFC synchrony and the spatial encoding of aversive information within the mPFC.

Title: Immunohistological quantification of parvalbumin- and somatostatin-expressing interneuron activity during fear expression and extinction

Authors: S. GOLDBERG[1], J. M. STUJENSKE[2], *J. A. GORDON[3];
[1]Biol., Barnard Col., New York, NY; [2]Columbia Univ., New York, NY; [3]Columbia Univ/NYSPI, New York, NY

Abstract: Inhibitory circuits have been implicated in controlling the expression and extinction of fear memories. In particular, interfering with GABAergic signaling in the basolateral amygdala (BLA) has been shown to alter the expression and extinction of fear. However, the role of specific BLA interneuron subtypes in regulating the expression and extinction of fear memories is not well understood. In order to investigate the relevance of two major BLA interneuron subtypes, parvalbumin-positive (PV+) and somatostatin-positive (SOM+) neurons, to extinction learning, we quantified cellular activity during fear expression and extinction using c-Fos expression. C57Bl/6 mice were trained to associate a tone (CS+) with a mild foot-shock. They were divided into three groups for testing: a “fear group” that was exposed to a CS- followed by the CS+, an “extinguished group” multiply re-exposed to the CS+, and a “control” group that heard only the CS-. Tissue was harvested 2 hours after exposure and processed for immunstaining for c-Fos, PV, and SOM. Preliminary data show increased c-Fos/SOM co-labeling in the BLA from mice in the extinguished group and the control group compared to that of the fear group ($p<.05$). These findings suggest that SOM+ interneurons decrease activity during fearful states. Unexpectedly, there was no significant difference in c-Fos co-labeling with PV between the three groups. These data suggest that SOM+ interneuron activity may be downregulated during the expression of learned fear, and that this downregulation is reversed during extinction.

Title: Attenuating the mania-like hyperactive, risk-preferring, and high motivation behavioral profile of mice with low dopamine transporter levels using a dopamine D1 receptor antagonist

Authors: *M. B. MILIENNE-PETIOT[1,2], M. A. GEYER[1,3], J. W. YOUNG[1,3];
[1]Psychiatry, UCSD, La Jolla, CA; [2]Div. of Pharmacol., Utrecht Univ., Utrecht, Netherlands;
[3]Res. Service, VA San Diego Healthcare Syst., San Diego, CA

Abstract: Introduction - Bipolar disorder (BD) is a serious mental illness characterized by switches between episodes of the low-energy/amotivation state of depression and the abnormally high-energy/risk-taking state of mania. These behavioral domains can be quantified using cross-species tests such as the Iowa Gambling Task (IGT), behavioral pattern monitor (BPM), and progressive ratio breakpoint (PRB). Mice with reduced dopamine transporter (DAT) levels (knockdown; KD) exhibit abnormal behavior consistent with mania patients. Some forms of reward-seeking behavior can be attenuated via dopamine D1 receptor (DRD1) antagonist treatment. Hence, we hypothesized that treatment with the (DRD1) antagonist SCH23390 (SCH) would attenuate mania-relevant behaviors of DAT KD mice while not affecting wild-type (WT) mice. Methods - Sixty male DAT KD and WT littermates were trained to nose-poke in 5-choice operant chambers and then treated with 0.03 or 0.01 mg/kg SCH or vehicle 10 min prior to testing in a within-subjects design for the IGT, and between-subjects design for the PRB and BPM. Results - DAT KD and WT good performers increased their selection of advantageous choices from the first to the last 20-min time bin [$F(2;5) = 67.9$, $p<0.05$] and [$F(2;4) = 16.4$, $p<0.01$] respectively. However, good-performing DAT KD tended to make fewer advantageous choices compared to WT [$F(1,46) = 3.8$, $p=0.08$]. SCH treatment pushed good and bad performing mice to chance levels. The highest SCH dose reduced impulsivity in good-performing DAT KD mice as measured by the % premature responses [$F(2;5) = 6.6$, $p<0.05$]. The %omission and mean choice latency were higher at this dose in the DAT KD compared to vehicle [$F(2;5) = 16.2$, $p<0.05$] and [$F(2;5) = 8.7$, $p<0.01$] respectively. Additionally, SCH reduced activity [$F(2;48) = 35.6$, $p<0.01$] exploration [$F(2;48) = 13.0$, $p<0.01$], and the higher motivation of DAT KD mice [$F(2;53) = 5.0$, $p<0.01$]. Conclusion - DAT KD mice exhibited a mania-relevant profile across domains. SCH lowered preferences in the IGT to chance while reducing impulsivity in good-performing DAT KD mice. SCH reduced activity, exploration, and motivation of DAT KD and WT mice. Thus, DRD1 antagonism exerted main effects on behavior while attenuating only some mania-like aspects of DAT KD mice.

Title: Non-hippocampal memory systems contributing to overtrained context fear memory

Authors: *E. H. SHEPHERD, C. CARTER, H. LEHMANN;
Psychology, Trent Univ., Peterborough, ON, Canada

Abstract: Damage to the hippocampus (HPC) typically causes retrograde amnesia for contextual fear conditioning in rodents. Distributed contextual fear conditioning or overtraining, however, can mitigate the retrograde amnesic effects of extensive HPC damage, suggesting that overtraining can make a context memory become HPC independent. The aim of this study was to determine the structures within the non-HPC memory system supporting this newly HPC-independent memory. Specifically, we examined whether the perirhinal cortex (PRH) and anterior cingulate cortex (ACC), two regions previously associated with context fear memory, are critical components of the non-HPC system supporting overtrained context fear memory. Two experimental approaches were taken: 1) immediate early gene expression assessment in rats tested following contextual fear overtraining and 2) examination of the retrograde amnesic effects of combined HPC+PRH or HPC+ACC damage on overtrained context fear memory. The rats either received 10 context-shock pairings in a single 30-min session (Standard condition) or 10 3-min sessions distributed across five days, each involving one context-shock pairing (Overtraining condition). Thus, the amount of context exposure and the number context-shock pairing were identical in both conditions. Replicating previous findings, lesions of the HPC caused retrograde amnesia in the Standard but not the Overtrained condition, suggesting that overtraining indeed made context fear memory become HPC independent. Expression of the immediate early gene zif268 was found to be significantly greater in the posterior region of the PRH of Overtrained rats compared to Standard condition rats. In addition, the combined HPC+PRH, but not the HPC+ACC lesions impaired the overtrained memory. Therefore, these findings suggest that the PRH, and not the ACC, critically supports a contextual fear memory that has become HPC independent because of overtraining.

Title: Hippocampal-prefrontal theta-gamma coupling increases with difficulty in a spatial working memory task

Authors: *M. TAMURA[1,3], T. J. SPELLMAN[1], A. M. ROSEN[1], J. A. GOGOS[2], J. A. GORDON[1];
[1]Dept. of Psychiatry, [2]Dept. of Neurosci., Columbia Univ., New York, NY; [3]Mitsubishi Tanabe Pharma Corp., Yokohama, Japan

Abstract: Cross-frequency coupling contributes to the hierarchy of brain rhythms and is apparent during a variety of cognitive functions. In particular, the amplitude of gamma-frequency (30-120 Hz) oscillations can vary with the phase of theta-frequency (4-12 Hz) oscillations. Theta-gamma coupling can even occur across brain regions. However, little is known about whether and how it contributes to spatial working memory. We examined long-range theta-gamma coupling during performance of a delayed-non-match-to-sample T-maze task. Local field potentials were recorded from wild-type mice (n=9) and mice heterozygous for a deletion of Zdhhc8 (Zdhhc8+/- mice; n=8), a gene within the 22q11.2 microdeletion region that contributes to cognitive dysfunction. Zdhhc8+/- mice showed enhanced vHPC theta-mPFC slow gamma (30-70 Hz) coupling only when the mice successfully performed a spatial working memory task ($p=0.04$), whereas vHPC theta-mPFC fast gamma (80-120 Hz) coupling was not affected by Zdhhc8 haploinsufficiency ($p=0.14$). Theta-gamma coupling strength was also increased by introducing a long delay ($p = 0.04$), or by optogenetically interfering with encoding in wild type mice ($p = 0.02$), two manipulations that increase task difficulty. Finally, single unit analysis revealed that hippocampal theta-prefrontal slow gamma coupling was associated with increased neural synchrony within the mPFC ($r2 = 0.46$, $p = 0.0022$). These findings suggest that enhancement of theta-slow gamma coupling between vHPC and mPFC reflects a compensatory mechanism to maintain spatial working memory performance in the setting of increased difficulty.

Title: Reciprocal thalamo-prefrontal and prefronto-thalamic projections support overlapping and dissociable spatial working memory processes

Authors: *S. S. BOLKAN[1], S. PARNAUDEAU[1], T. SPELLMAN[1], A. CLARK[1], J. A. GORDON[2], C. KELLENDONK[3];
[1]Neurobio. and Behavior, [2]Dept. of Psychiatry, [3]Dept. of Psychiatry and Pharmacol., Columbia Univ., New York, NY

Abstract: Working memory impairment is a core cognitive symptom of schizophrenia, yet the neural mechanisms underlying working memory remain unclear. Functional imaging studies in patients and healthy subjects, and neurophysiological and lesion studies in model organisms have implicated activity in the mediodorsal thalamus (MD) and prefrontal cortex (PFC) as supporting working memory. However, given the dense, reciprocal connectivity between the MD and multiple PFC subregions, it is unclear (1) whether direct thalamo-prefrontal input to particular PFC subregions may support working memory, (2) whether reciprocal prefronto-thalamic projections may also support working memory, and (3) whether activity in these projections support the processes of working memory encoding, maintenance, or retrieval. To investigate the role of activity in these connections in a temporally precise and reversible manner, we employed the light-driven proton pump eArch3.0 to achieve projection-specific optogenetic inhibition in mice performing a delayed non-match to sample (DNMS) T-maze test of spatial working memory. We find that post-acquisition inhibition of MD-to-mPFC, but not MD-to-OFC, projections impairs behavioral performance when working memory length is increased from 10s to 60s. Inhibition of reciprocal mPFC-to-MD projections similarly caused a delay-dependent impairment in behavioral performance. Interestingly, while temporally precise Sample (encoding) phase inhibition of either projection did not impair behavioral performance, inhibiting activity during the Delay (maintenance) phase of the task lead to robust behavioral impairments with MD-to-mPFC inhibition (RM ANOVA, VirusXLight $p<0.05$) and trend-level impairments with mPFC-to-MD inhibition (RM ANOVA, VirusXLight $p=0.073$). Strikingly, only mPFC-to-MD inhibition during the Choice (retrieval) phase impaired behavioral performance during of the task (RM ANOVA, VirusXLight $p<0.05$). These findings suggest reciprocal thalamo-prefrontal

activity supports the process of working memory maintenance while direct prefronto-thalamic activity supports the process of working memory retrieval and action selection. In an effort to reveal physiological mechanisms supporting these processes, we have obtained simultaneous *in vivo* recordings of dorsal hippocampal and MD local field potentials and mPFC single-units in mice (9 eArch3.0, 9 EYFP) receiving task phase specific MD-to-mPFC inhibition while performing the DNMS T-maze.

Title: Contribution of nucleus reuniens of the thalamus to associative recognition memory

Authors: ***G. R. BARKER**[1], E. C. WARBURTON[2];
[2]Physiol. & Pharmacol., [1]Univ. of Bristol, Bristol, United Kingdom

Abstract: Associative recognition memory, the ability to associate an object with a location or position in a sequence, requires interactions between the perirhinal cortex, hippocampus and medial prefrontal cortex (Barker et al 07, Barker & Warburton 11). The nucleues reuniens of the thalamus is reciprocally connected with all 3 brain regions in the associative recognition memory network (McKenna & Vertes 04, Vertes et al 06), and is therefore well placed, anatomically, to be engaged in associative recognition memory formation. Therefore this study aimed to assess the nucleus reuniens contribution to associative recognition memory formation. Two cohorts of male Lister hooded rats were used. The first cohort received either lesions of the midline thalamic nuclei or sham lesions. Associative recognition memory was tested using the object-in-place, temporal order and temporal location tasks, with either a short (5min) or a long delay (3h), non-associative recognition memory was assessed at a long delay (3h) using the object recognition and object location tasks. The second cohort of rats were implanted with guide cannula targeted at the nucleus reuniens. Associative recognition memory performance was assessed using the object-in-place task with memory performance assessed with either a short or a long delay. Intra-cerebral infusions of a number of selective receptor agonists and antagonists into the nucleus reuniens occurred either before the sample phase or before the test phase in order to disrupt different stages of memory processing. Lesions of the midline thalamic nuclei resulted in a delay dependent deficit in all three associative recognition memory tasks tested,

thus performance at the short delay was not altered, while at the long delay lesioned animals showed a significant deficit in memory performance compared to sham animals. Performance in the non-associative recognition memory tasks was not altered. Inactivation of the nucleus reuniens via infusion of muscimol before the sample phase resulted in a delay dependent impairment in associative recognition memory performance, in addition inactivation of the nucleus reuniens before the test phase impaired retrieval. Inhibition of either muscarinic or nicotinic cholinergic receptors but not NMDA receptors in the nucleus reuniens before the sample phase impaired associative recognition memory performance. Therefore these results demonstrate that the nucleus reuniens plays a critical role in long term associative recognition memory and in addition identifies the importance of cholinergic neurotransmission in the nucleus reuniens.

Title: The influence of decision-making in conditional responding

Authors: *M. J. FRANCOEUR, B. A. WORMWOOD, R. L. A. MILLER, D. C. CHASE, H. D. ROBERTSON, A. G. DRAKE, K. C. ERICKSON, E. S. JALBERT, C. E. WANTE, B. M. GIBSON, R. G. MAIR;
Psychology, Univ. of New Hampshire, Durham, NH

Abstract: Medial prefrontal cortex (mPFC) supports decision-making functions required for delayed nonmatching-to-position (DNMTP). To understand these functions we compared the responses of mPFC neurons in rats performing two tasks: DNMTP and a serial lever pressing (SLP) task in which rats perform all the actions associated with DNMTP without making a choice between response alternatives. Both tasks are trained in octagonal arenas (61 cm in diameter) with four retractable levers located 90° apart. Drinking spouts (for delivery of water reinforcement) and panel lights (to signal reinforcement) are located above each lever. Isolated activity was recorded from 900 neurons in 6 rats performing the DNMTP task. Significant behavioral correlations defined by peri-event timed histogram (PETH) responses beyond the 99% confidence interval were observed for 288 neurons (32%). PETH analyses revealed 10 distinct response types that accounted for 273 (95%) of behaviorally correlated cells: 267 with a unique type and 6 with a combination. Response types were related to initiation, action, outcome,

and memory delays. We are currently studying mPFC activity in rats performing the SLP task. Here levers are extended one at a time, following the pattern used for DNMTP training. Trials begin with a randomly selected base lever extending. This retracts with pressed and the lever 90° to the left or right is extended (equivalent to the DNMTP sample response). This retracts when pressed and is followed by delivery of water reinforcement in the spout immediately above. The base lever for the trial is again extended after a 3 s delay. This retracts when pressed (equivalent to the DNMTP delay response) after which a lever 90° to the left or right is extended. On 70% of trials this is opposite the "sample lever" and retracts when pressed followed by reinforcement (equivalent to a correct DNMTP choice). On 30% of trials, this is the same as the "sample lever" and retracts without reinforcement when pressed (equivalent to an incorrect DNMTP choice). This distribution of reinforced and unreinforced responses models 70% correct criterion responding in the earlier DNMTP recording study. Our results to date confirm the importance of decision making in driving both the level of activity and event-related coding properties of mPFC neurons.

Title: More than just a relay: The role of medial thalamus in flexible, goal-directed behavior

Authors: R. L. A. MILLER[1], E. B. SMEDLEY[1], M. J. FRANCOEUR[1], B. A. WORMWOOD[1], D. C. CHASE[1], D. MINUKHIN[1], C. J. THERIAULT[1], T. N. KAZAN[1], B. M. GIBSON[1], *R. G. MAIR[2];
[1]Univ. of New Hampshire, Durham, NH; [2]Psychology, Univ. New Hampshire, Durham, NH

Abstract: Convergent evidence suggests that beyond its role as a relay, medial thalamus coordinates the activity of prefrontal cortex (PFC) with distributed neural networks that support intentional responding. The mediodorsal nucleus (MD) is the primary source of specific thalamo-cortical projections to middle layers of PFC while midline and rostral intralaminar nuclei (IL) provide modulatory inputs to deep and superficial layers of PFC and to anatomically-related areas of the basal ganglia and hippocampus. Lesions damaging both MD and IL impair flexible, goal-directed behavior exemplified by delayed non-matching to position tasks (DNMTP). To

elucidate the influence of MD and IL on prefrontal function we recorded the activity of neurons in these nuclei in rats performing a dynamic DNMTP task previously used to characterize medial PFC neuronal activity. Activity was recorded from 8 rats with tetrode arrays that were advanced incrementally through thalamus across 40 to 60 recording sessions. Results were analyzed offline to identify signals from isolated neurons and to correlate activity with specific behavioral events as rasters and peri-event time histograms (PETH) and with spatial location as place fields. Significant behavioral correlations were defined by PETH responses beyond the 99% confidence interval. PETH analyses revealed event-related responses in thalamus consistent with the broad contour of prefrontal response types, with subtle differences in timing. We did not observe evidence of spatially-restricted event-related response observed in PFC. Our results provide evidence that MD and IL have distinct effects on PFC activity.

Title: Medial thalamic modulation of prefrontal cortex: Effects of temporary inactivation

Authors: *B. A. WORMWOOD, M. J. FRANCOEUR, R. L. A. MILLER, D. C. CHASE, E. K. BRASLEY, C. R. LEHET, J. C. MCKEE, A. C. AASEN, B. M. GIBSON, R. G. MAIR; Univ. of New Hampshire, Durham, NH

Abstract: Medial thalamus has reciprocal connections with prefrontal cortex (PFC) that are thought to coordinate its activity with other areas of the telencephalon that support flexible goal-directed behavior. The mediodorsal nucleus is the primary source of specific thalamo-cortical projections to middle layers of PFC while midline and intralaminar nuclei provide modulatory inputs to deep and superficial layers of PFC and to anatomically-related areas of the basal ganglia and hippocampus. Each of these nuclei receive direct cortico-thalamic and indirect cortico- striato-pallidal input from PFC. Medial thalamic lesions impair flexible goal-directed behavior, exemplified by delayed non-matching to position tasks (DNMTP). To elucidate the influence of medial thalamus on PFC function we examined the effects of temporary thalamic inactivation on the response properties of prefrontal neurons in rats performing a dynamic DNMTP task. Cellular activity was recorded throughout medial PFC using a drivable array of

tetrodes. Electrophysiological recordings were analyzed offline to identify signals from isolated neurons and to correlate activity with specific behavioral events as rasters and peri-event time histograms (PETH). We also analyzed cellular activity relative to spatial context using video-tracking data to assess the influence of the animal's location on cell firing rates. Once cells with significant behavioral correlations (PETH responses beyond 99% confidence interval) were identified (day 1), the tetrode array was left in place for two more sessions. On the next day (day 2), central thalamus was unilaterally inactivated using microinjections of the GABAA agonist muscimol. On day 3, activity in the same location was recorded again without thalamic inactivation. We used doses of muscimol previously shown to impair delayed matching to position when injected bilaterally at the same site. Unilateral inactivation had no significant effect on DNMTP performance. Examination of waveforms, inter-spike-interval histograms, cluster analyses, and event related activity (on days 1 and 3) confirmed the identity of single neurons across the three days. Day 2, inactivation was consistently associated with disruption of spatial and event-related activity of prefrontal neurons. Some neurons exhibited increased and others and decreased levels of activity, suggesting both inhibitory and excitatory modulation PFC by thalamus. These data indicate a critical role for medial thalamus in shaping the activity of cortical neurons in relation to actions, outcomes, and context.

Title: Signatures of inference-by-sampling in the prefrontal cortex of rule-learning rats

Authors: A. SINGH[1], A. PEYRACHE[2], *M. D. HUMPHRIES[1];
[1]Univ. of Manchester, Manchester, United Kingdom; [2]The Neurosci. Institute, Sch. of Med. and Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: The inference-by-sampling hypothesis proposes that neural population activity at each point in time represents a sample from an underlying probability distribution. One key prediction is that the distribution during ``spontaneous'' activity (representing the prior) and during evoked activity (representing the posterior) converge over repeated experience. Just such a convergence has been observed in small populations from ferret V1 over development (Berkes et al 2011,

Science, 331: 83-87). Unknown is the extent to which this hypothesis is a general computational principle for cortex: whether it can be observed during learning, or in higher-order cortices, or during ongoing behaviour. To address all these issues, we analysed population activity from the prefrontal cortex of rats learning rules in a Y-maze task. We focussed on sessions where the animal reached the learning criterion mid-session, allowing us to compare activity before and after learning, and compare activity during sleep pre- and post-session. Population activity in each time bin was characterised as a binary vector (or "word") of active and inactive neurons. Our hypothesis was that the "spontaneous" activity in slow-wave sleep (SWS), in the absence of task-related stimuli and behaviour, constitutes the prior distribution. We find that the distributions of words were highly conserved across all vigilance states (SWS pre- and post-session and during task behaviour), consistent with our interpretation of SWS activity as a "prior". Crucially, the task-evoked distribution after learning was more similar to the distribution in post-session than in pre-session SWS. This increase in similarity only occurred for rewarded trials, not for unrewarded trials. Together, these results are consistent with the convergence of the posterior and prior distributions over learning. The samples from the distribution could also be directly linked to behavioural choice on each trial. The population activity vectors that most changed frequency over the task were also strongly predictive of trial outcome. These updated vectors tended to occur only in maze locations relevant to the currently learnt rule. Our results show that signatures of inference-by-sampling can be observed over the course of learning, in higher-order cortices, and directly related to behavioural choice. Consequently, inference-by-sampling is a potential general computational principle of cortex.

Title: Prefrontal cortex afferents to the anterior temporal lobe in the Macaca fascicularis monkey

Authors: *R. INSAUSTI[1], A. MOHEDANO-MORIANO[2], M. MARCOS[2], E. ARTACHO[2], M. ARROYO[2], M. MUNOZ-LOPEZ[2];
[2]Human Neuroanatomy Lab., [1]Univ. of Castilla-La Mancha, Albacete, Spain

Abstract: The anatomical organization of the lateral prefrontal cortex (LPFC) afferents to the anterior part of the temporal lobe (ATL) still needs to be clarified. The LPFC has two subdivisions, dorsal (dLPFC) and ventral (vLPFC) which have been linked to cognitive processes. The ATL includes several different cortical areas, namely temporal polar cortex and rostral parts of perirhinal, inferotemporal and anterior tip of the superior temporal gyrus cortices. Multiple sensory modalities converge in the ATL. All of them (except rostral inferotemporal and superior temporal gyrus cortices) are components of the medial temporal lobe, critical for long-term memory processing. We studied the LPFC connections with the ATL by placing retrograde tracer injections into the ATL: temporal polar (n=3), perirhinal (areas 35 and 36, n=6) and inferotemporal cortices (area TE, n=5), plus one additional deposit in the posterior parahippocampal cortex (area TF, n=1). Anterograde tracer deposits into the dLPFC (A9 and A46, n=2) and vLPFC (A46v, n=2) and orbitofrontal cortex (OFC, n=2) were placed for confirmation of those projections. Results showed that vLPFC displays a moderate projection to rostral area TE and dorsomedial portion of temporal polar cortex; in contrast, the dLPFC connections with the ATL were weak. By comparison, OFC and medial frontal cortices (MFC) showed dense connectivity with the ATL, namely A13 with temporopolar and perirhinal cortices. All areas of MFC projected to temporopolar cortex, albeit with a lower intensity. The functional significance of such paucity of LPFC afferents is unknown.

Title: The effect of rhinal cortex-orbitofrontal disconnection on recognition memory in monkeys: comparison of aspiration lesions and reversible silencing with DREADDs

Authors: *M. A. ELDRIDGE, E. C. MASSEAU, W. LERCHNER, J. M. FREDERICKS, R. C. SAUNDERS, B. J. RICHMOND;
Lab. of Neuropsychology, NIMH, Bethesda, MD

Abstract: Introduction It has been proposed that a circuit that includes rhinal cortex (Rh) and orbitofrontal cortex (OFC) among its components subserves object recognition memory. To test this hypothesis, we produced a functional disconnection between these structures by removing the Rh in one hemisphere, and removing the OFC (n = 4), or reversibly silencing OFC using a DREADD (Designer Receptor Activated by Designer Drug) (n = 2), in the contralateral hemisphere. The performance of both groups was compared to that of controls on a test of familiarity-based recognition. Methods: Task In each trial the monkey had to indicate whether the stimulus displayed was presented for the first or second time within the testing session by releasing a lever in one of two intervals: either immediately, when a stimulus was first presented (first interval) or wait until a small central target changed from red to green (second interval) if it was the second appearance of a stimulus. Stimuli were repeated once within the session, with the interval between stimulus presentations within a session varying between 0 to 128 stimuli. The stimulus set consisted of 6000 images. No stimulus was reused within a 30-day period. Methods: DREADD Two monkeys were injected with a modified lentiviral vector expressing a Gi-coupled receptor, hM4Di, in the OFC opposite a Rh removal. When activated by systemically delivered clozapine-N-oxide (CNO), hM4Di induces neuronal silencing. Results Three control monkeys reliably differentiated between the first and second presentations of a stimulus. In contrast, the performance of the monkeys with crossed Rh-OFC lesions was significantly worse than controls at all retention intervals tested. In the two monkeys injected with a DREADD in the OFC opposite a Rh removal, when activated by systemically delivered clozapine-N-oxide (CNO), performance on the recognition memory task was only mildly impaired compared to sessions without CNO administration. Discussion This pattern of results indicates that: 1) An intact rhinal-orbitofrontal connection may only be necessary during the learning of the serial recognition test used here, 2) the volume of OFC tissue inactivated by the DREADD may have been insufficient to replicate the effect of the permanent removal, and/or 3) the sparing of fibers of passage may have been critical.

Title: Neural correlates of odor span capacity in the medial prefrontal cortex of rats

Authors: *L. AN, J. K. CATTON, Q. GREBA, J. G. HOWLAND;
Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Working memory refers to the transient storage of information that was just experienced or retrieved from long-term memory to guide behavior. The contents of working memory are prone to decay but can be stored for longer periods through active rehearsal strategies. Capacity is a component of working memory that is poorly understood, although studies in humans suggest that capacity may critically depend on activity in prefrontal cortex (PFC). In rodents, working memory capacity can be assessed using the odor span task (OST), a sequential non-matching to sample task. Lesions of medial prefrontal cortex (mPFC), which is considered to be functionally homologous to the primate dorsolateral PFC, disrupt performance of the OST; however, the patterns of neural activity in mPFC during the OST are currently unknown. To measure the firing patterns of mPFC neurons in the OST, five male Long-Evans rats were trained on the task and had multichannel probes implanted in the mPFC to record extracellular neural activity during the task. Behavior of the rats was scored manually by an experimenter and broken down into four possible epochs: baseline, stimulus approach, initiation of digging, and reward consumption (following correct responses). For preliminary analyses, we compared the frequency of neural activity occurring 1000 ms around events. Z-scores were computed using baseline firing rates and compared. Ninety-one putative mPFC pyramidal neurons with a mean baseline firing rate at 0.7±0.1 Hz were analyzed. The portion of neurons that increased activity during the task and were selected for further analysis gradually increased from low (span=1-3; 43%) to medium (span=4-6; 45%) and high (span=7-10; 48%) span stages. Activity of the neurons increased when rats approached a scented bowl and activity increased more after approach to a novel bowl than a familiar bowl. Interestingly, neural activity strongly increased when rats dug in a correct bowl that contained reward than when they dug in an incorrect bowl that did not contain reward for medium and high spans. Compared to the medium span test, a potential increase in burst activity between digging and consuming reward was found for high spans, as evidences of increasing the number of bursts per second, the percentage of spikes in bursts, and burst duration. These findings suggest the neural activity of mPFC differs as the function of encoding- and response-related processes. Moreover, the change of burst activity may indicate a possible mechanism of storage and manipulation of information necessary for situations of high odor span capacity.

Title: Chemogenetic suppression of neural activity in dorsolateral prefrontal cortex impairs spatial working memory in rhesus monkeys

Authors: W. SCHNEBELEN, P. G. F. BROWNING, P. L. CROXSON, P. H. RUDEBECK, S. W. BROOKSHIRE, *M. G. BAXTER;
Dept Neurosci., Mount Sinai Sch. Med., New York, NY

Abstract: The DREADD (Designer Receptors Exclusively Activated by Designer Drugs) methodology allows for expression of an artificial receptor system in an anatomically and/or neurochemically-defined population of neurons. These designer receptors are derived from human muscarinic G-protein coupled receptors, allowing for physiologically relevant manipulations in activity. DREADDs remain quiescent until activated by an otherwise inert pharmacological agent, clozapine-N-oxide (CNO). We placed multiple injections of AAV5 vector containing a construct for the inhibitory hM4Di DREADD receptor, under control of the human synapsin promoter, bilaterally into the dorsolateral prefrontal cortex of male rhesus monkeys. Monkeys performed the delayed response test of spatial working memory in a manual test apparatus. Task performance was unaffected by the surgery or by vehicle injections, but was dramatically impaired by intramuscular injection of CNO. Functional DREADD receptor expression lasted at least a year post-surgery and was verified histologically. The performance of monkeys that had not received DREADD AAV injections was unimpaired by CNO. These initial observations support the effectiveness of this chemogenetic system for neurobiological investigations in macaque monkeys, and open new experimental modalities in this species.

Title: Functional specialization of areas along the anterior-posterior axis of the primate prefrontal cortex prior to training in a task

Authors: *M. RILEY, X. QI, C. CONSTANTINIDIS;
Neurobio. and Anat., Wake Forest Sch. of Med., Winston Salem, NC

Abstract: The prefrontal cortex (PFC) is critical for working memory and executive function. Functional specialization of areas along the anterior-posterior PFC has been speculated but little evidence exists about the functional properties of neurons in these areas. To address this question we segmented the dorsal PFC into 3 regions: posterior-dorsal (area 8A of Petrides and Pandya), mid-dorsal (area 8B and area 9/46), and anterior-dorsal (area 9 and area 46). We contrasted the responsiveness and selectivity of neurons in these regions with the posterior ventral region (area 45). Three stimulus sets were used to evaluate selectivity: a spatial set consisting of 9 white squares arranged in a 3x3 grid of 10° eccentricity between stimuli; a feature set consisting of 8 white geometric shapes matched for total area; and a color set consisting of 8 equiluminant color squares. A total of 1878 neurons were recorded in 6 monkeys passively viewing these stimuli, prior to training in a working memory task. There was no significant difference in the total percentage of neurons that responded to the stimuli between the anterior, mid and posterior dorsal area (chi-square test, $p>0.5$), though the percentage of neurons responding to stimuli in the ventral posterior area was significantly lower than the dorsal areas (posterior-dorsal: 44%; mid-dorsal: 41%; anterior-dorsal 35%; posterior-ventral 20%; chi-square test, $p<0.05$). On the other hand, selectivity for stimuli was highest for the posterior-dorsal area and generally declined along the anterior-posterior axis. When quantified with a selectivity index expressed as (Max-Min)/(Max+Min), significant differences were present for the spatial, feature, and color selectivity values across areas (spatial: posterior 0.693, mid 0.577, anterior 0.566; feature: posterior 0.492, mid 0.385, anterior 0.411; color: posterior 0.420, mid 0.267, anterior 0.256; 1-way ANOVA, $p<0.05$, for each stimulus set). In addition, firing rates during the presentation of the stimuli were significantly higher for the posterior-dorsal area (posterior 14.5 spikes/s, mid 9.9 spikes/s, anterior 10.3 spikes/s; 1-way ANOVA, $p<0.05$). These differences were only seen during the display of the stimuli; activity during the baseline fixation period did not significantly differ between areas (1-way ANOVA, $p>0.07$). Our results provide neurophysiological evidence for a rostral-caudal gradient of stimulus selectivity through the PFC, suggesting that posterior areas are selective for stimuli even when these are not relevant for execution of a task whereas anterior areas may acquire selectivity as a result of task performance.

Title: Physiological differences between the primary visual cortex and dorsolateral prefrontal cortex in primate

Authors: *S. YANG, M. WANG, C. D. PASPALAS, M. ALTMAN, L. E. JIN, V. GALVIN, A. F. T. ARNSTEN, J. A. MAZER;
Dept. of Neurobio., Yale Univ., New Haven, CT

Abstract: Very little is known about the molecular modulation of neuronal firing patterns in the primate primary visual cortex (V1). In classic synapses, cAMP-protein kinase A (PKA) signaling has been shown to increase transmitter release through actions on pre-synaptic vesicles, strengthen post-synaptic mechanisms, and/or increase the uptake of glutamate from the synapse due to increased expression of excitatory amino acid transporters on glia. Immunoelectron microscopy to localize phosphodiesterase PDE4A is consistent with this pattern, where PDE4A is most commonly found in presynaptic glutamate terminals, in peri-synaptic glia, and occasionally in mushroom-shaped spines. In contrast, PDE4A in layer III of the dorsolateral prefrontal cortex (dlPFC) is most evident in long thin spines, anchored near the calcium-containing spine apparatus near HCN channels. In dlPFC, increased cAMP signaling weakens connectivity and reduces the firing of "Delay cells" (neurons that maintain representations of visual space across delay periods) by opening HCN channels on spines. The current research is the first exploration of cAMP-PKA signaling influences on primate V1 neuronal firing for direct comparison to the dlPFC. Single units were recorded from V1 monkeys viewing visual stimuli which are black or white bars presented at and around the receiptive field, while using iontophoresis to deliver minute amounts of charged compounds near the recording site. Results were compared to those from dlPFC recordings from monkeys performing a visual spatial working memory task. In dlPFC, increasing endogenous cAMP levels via iontophoresis of the PDE inhibitor, etazolate, markedly decreased Delay cell firing; this reduction was reversed by simultaneous application of HCN channel blocker, ZD7288. Low doses of ZD7288 alone enhanced the firing of Delay cells, selectively increasing firing for the neurons' preferred direction. In contrast, V1 neurons showed reduced firing with iontophoresis of ZD7288. Etazolate had a mixed influence on V1 neurons, increasing firing in some neurons, having no effect in others, or reducing firing. The reduction in firing of V1 neurons by etazolate was not reversed by ZD7288, indicating a different underlying mechanism (e.g. increasing glutamate transport from the synapse) than the HCN mechanism prevalent in dlPFC. These data show that modulation mechanisms in V1 neurons are fundamentally different from those in dlPFC Delay cells, which may contribute to the resilience of the primary visual cortex in disorders such as Alzheimer's Disease.

Title: Single unit and network dynamics within prefrontal cortex and the basal ganglia during working memory maintenance and updating

Authors: *D. HUIE, K. GHOSE, C. MARTINEZ-RUBIO, A. PAULK, T. M. HERRINGTON, E. N. ESKANDAR;
Massachusetts Gen. Hosp., Boston, MA

Abstract: Working memory is the capacity to briefly hold and recall information, which is both robustly maintained against distractions but may also be flexibly updated when necessary. While working memory maintenance has primarily been ascribed to prefrontal cortex (PFC), the basal ganglia is thought to play a "gatekeeper" role, allowing certain stimuli to access and change working memory while protecting working memory from distracting input. This gating hypothesis has been encapsulated within abstract and computational models, and received empirical support from studies in healthy patients and those with working memory deficits. However, both single-unit and targeted local field potential (LFP) studies to clarify the role of these structures in working memory are lacking. We describe an ongoing study to analyze single-unit activity as well as LFP changes used to characterize network connectivity within the corticostriatal circuit during working memory function. Specifically, we present the results of microelectrode recordings within dorsolateral PFC and the anterior caudate nucleus in two rhesus macaques, trained to perform two working memory tasks designed to examine working memory updating and maintenance. Through simultaneous recordings in both structures, we tested the role of the corticostriatal network in working memory. Loss of working memory is a devastating feature of many neurodegenerative diseases; a detailed understanding of corticostriatal circuit's role may illuminate new therapeutic targets for cognitive deficits in these conditions.

Title: Early phases of learning and novelty encoding by basal forebrain activity correlated with network connectivity to the dorsolateral prefrontal cortex

Authors: *C. MARTINEZ-RUBIO[1], A. PAULK[1], D. SIERRA-MERCADO[2], E. MCDONALD[1], E. ESKANDAR[1];
[1]Neurosurg., Massachusetts Gen. Hosp., Boston, MA; [2]Anat. and neurobiology, Univ. of Puerto Rico, Med. Sci., San Juan, Puerto Rico

Abstract: Stimuli recognition, novelty, and reward are critical factors for learning and consolidating new associations. Brain areas that appear to be major candidates responsible for learning novel associations are the basal forebrain and the prefrontal cortex. This relationship between the basal forebrain and learning is especially evident in patients with dementia and Alzheimer's disease, when degeneration of neurons in the Nucleus Basalis of Meynert (NBM) results in impaired learning and memory. However, the neural signatures via which the NBM is involved in cognitive function, and, in particular, learning, remain unclear. We hypothesized that the firing rate of different populations of neurons in the NBM will differentiate between epochs of an associative learning task. Furthermore, we hypothesize that network connectivity between the NBM and the dorsolateral prefrontal cortex (DLPFC) will change depending on the learning state. To test this idea, we recorded neuronal activity simultaneously from both the NBM and the DLPFC in behaving non-human primates (NHP) performing an associative learning task. During this task, the animal was required to learn, by trial and error, to associate a visual image with a specific direction of eye movement. We recorded from a total of 422 units, with 223 units in the DLPFC and 199 units in the vicinity of the NBM. Our results show that, as the NHPs are exposed to novel stimuli, the firing rate of NBM neurons would often either increase or decrease significantly when the stimulus is novel. Yet, with additional exposures to the stimulus, this modulation reduced significantly to the point that the responses disappeared around trial 50. On the other hand, the DLPFC would modulate neuronal responses depending on what image was presented or would begin to respond later in the trial. We tested whether this was actually due to learning or novelty by presenting the same stimulus later in the experiment but with changed association to eye movement. We found that the NBM neurons would change their firing rates by small amounts early on in the block of training, but this modulation would again disappear as the experiment continued. Contrary to the single unit data, however, we found that high frequency bands (gamma) in the local field potential (LFP) at the NBM and basalis increased as the animal learned. In addition, coherence between the two brain regions increased during the same epochs, speaking to differences in the network dynamics which can be separable from the single-neuron activity. In sum, we found that both the DLPFC and NBM exhibit changes in learning and novelty, which may have major implications for clinical interventions.

Title: Effect of medial prefrontal, anterior cingulate, and retrosplenial cortex lesion on cognitive coordination and flexibility using Carousel maze in rats

Authors: ***J. SVOBODA**[1], I. VOJTECHOVA[1,2], A. STANKOVA[1,2], A. STUCHLIK[1,2]; [1]Inst. of Physiol. CAS, Prague 4, Czech Republic; [2]Natl. Inst. of Mental Hlth., Klecany, Czech Republic

Abstract: Cognitive coordination involves the ability to segregate conflicting stimuli into coherent, but mutually discordant subsets, while cognitive flexibility allows for rapid change of a strategy if the old one is found ineffective. Carousel maze provides a tool to investigate both coordination and flexibility in spatial domain in rodents. On a continuously rotating circular arena, rats have to avoid a place hidden in either the stationary room or the rotating arena frame. They have to selectively attend to cues from the relevant frame and ignore the others. This process is considered to reflect cognitive coordination. Furthermore, in well-trained animals, we can explore two types of flexibility: 1) by interchanging the relevant frame of reference (set-shifting task), or 2) by relocating the prohibited sector within the same reference frame (reversal task). We assessed a role of medial prefrontal (mPFC), anterior cingulate (ACC), and retrosplenial (RSC) cortex in mediating the above mentioned processes by excitotoxic lesions of the corresponding site in male Long-Evans rats. Results showed that particularly RSC, but not mPFC or ACC, contributes to coordination and flexibility and thus complements the role of hippocampus which has been traditionally considered crucial for navigation in Carousel maze. These results may provide a new link between impaired cognitive flexibility in schizophrenia and its substrate in neocortex. The study was supported by GACR 14-03627S.

Title: State-dependent network response to optogenetic stimulation in prefrontal cortex

Authors: *Z. NAVRATILOVA, H. O. CABRAL, F. P. BATTAGLIA;
Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ., Nijmegen, Netherlands

Abstract: We were interested in how local optogenetic stimulation affects larger neural networks, and hypothesized that this effect varies according to the sleep/wake state of the animal. To study these effects, we injected a viral vector containing channelrhodopsin (mChR2) with an alpha-CamKII promoter in medial prefrontal cortex (mPFC), and subsequently implanted an array of 20 independently movable tetrodes along with one or two fibers for optical stimulation. We measured the local field potential and spiking activity during stimulation at these 20 sites distributed up to 1 mm away from the stimulation site. We observed various multi-unit spiking responses (MUA) to the stimulation. Some tetrodes displayed a continuous firing rate increase throughout the stimulation (of up to 200ms), while some showed a transient increase in firing rate at the onset of stimulation, which lasted only about 30ms. Many tetrodes distant from the stimulation site showed a delayed transient increase in firing rate. At the offset of the stimulation, many tetrodes showed a reduction in firing rate to below the non-stimulation average rate. The gamma frequency (50-100 Hz) activity recorded on each tetrode was also enhanced during stimulation, and more so on the tetrodes with high MUA responses. More interestingly, the spiking and gamma responses depended on the sleep state of the rat. During recording, the rats were sitting quietly in a small box, and so sometimes they were alert and showing awake cortical activity, and other times they were sleeping and showing slow wave oscillations. Tetrodes with the highest and fastest firing rate and gamma responses to the stimulation were responsive regardless of state, but tetrodes with low activation responses only showed those responses during the slow oscillatory state. The slow oscillation consists of “up” and “down” states of cortical spiking activity. These states alternate at a rate of 0.5-1 Hz. Down states are associated with delta (1-4 Hz) waves in the LFP, and up states sometimes contain spindle (10-15 Hz) activity. We observed that during the slow oscillation, the offset of optogenetic stimulation was associated with an increased likelihood of down state onset and delta waves. By contrast, during awake states, neither delta waves nor down states were triggered. We compare stimulation-triggered down states and delta waves to those occurring naturally. We conclude that local optogenetic stimulation affects local neural activity similarly during wake and sleep behavioral states, but during more ordered neural network states, such as non-REM sleep, this stimulation can have wider impacts, such as organizing the occurrence of up and down states.

Title: Physiological characteristics of anterior insular and orbitofrontal cortices in representing uncertain reward

Authors: ***S. JO**[1,2], M. W. JUNG[1,2,3];
[1]Inst. For Basic Sci., Daejeon, Korea, Republic of; [2]Ajou Univ. Sch. of Med., Suwon, Korea, Republic of; [3]Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Humans and animals often choose a safe over a risky option even when the risky option has a higher expected value, indicating that decision making is affected by risk. Anterior insular and orbitofrontal cortex (AIC and OFC, respectively) are known to play important roles in decision making under risk. However, risk-related neural activity has not been investigated in the AIC and it is controversial whether the OFC conveys genuine risk signals. To address these issues, we recorded neural activity in the AIC and OFC of rats responding to five distinct auditory cues predicting reward delivery with different probabilities. Both structures conveyed significant neural signals for reward, value and risk, with value and risk signals conjunctively coded. However, value signals were stronger and appeared earlier in the OFC, and many risk-coding OFC neurons responded only to the cue predicting certain (100%) reward. Also, AIC neurons tended to increase their activity following a negative outcome, which persisted until the next trial, and according to previously expected value. These characteristics might underlie distinct roles of the AIC and OFC in decision making under risk. The OFC might play an important role in encoding certain reward-biased, risk-modulated subjective value, whereas the AIC might convey prolonged disgust and disappointment signals.

Abstract: Working memory refers to the system of temporarily maintaining and manipulating information required to perform complex cognitive tasks. Persistent and sequential neuronal discharges have been observed as potential neural substrates for working memory, and properly tuned excitation and inhibition are thought to be critical for such neuronal activity. Although recent studies have begun to reveal distinct roles of different interneuron subtypes in various regions of the brain, specific roles of different inhibitory interneuron subtypes in working memory remain unclear. We investigated discharge characteristics of two major interneuron subtypes, parvalbumin (PV)- and somatostatin (SOM)-positive neurons, in medial prefrontal cortex (mPFC) of mice performing a spatial working memory task. Wide-spike SOM neurons showed target-dependent activity during the delay period, which was comparable to delay-period activity of putative pyramidal neurons, whereas PV and narrow-spike SOM neurons showed little target-dependent delay-period activity. In addition, PV and narrow-spike SOM neurons, but not putative pyramidal and wide-spike SOM neurons, were markedly and homogeneously suppressed after reward delivery. Our results demonstrate distinct activity patterns of PV and SOM neurons related to working memory and reward processing.

Title: Inactivation of CA1, but not CA3, impairs retrieval of spatial memory

Authors: *J. LEE[1], J. LEE[2], Y. JEONG[1], M. JUNG[1,2];
[1]KAIST, Daejeon, Korea, Republic of; [2]IBS, Daejeon, Korea, Republic of

Abstract: Hippocampus is a crucial brain structure for spatial learning and memory. Despite a long history of intensive investigation, roles of each hippocampal subregion (dentate gyrus, CA3 and CA1) in encoding and retrieval of spatial memory are unclear. In this study, we compared effects of suppressing CA3 or CA1 neural activity on the retrieval of spatial memory using a pharmacogenetic approach. We injected virus carrying *Cre*-dependent *hM4Di* bilaterally into dorsal CA3 and CA1 of *Grik4-Cre* and *CamkII-Cre* mice, respectively. Four weeks after the viral injection, the mice were trained to find a hidden platform in a Morris water maze for 7 days, which reduced the escape latency to < 20 s. The animals were then tested with CNO or vehicle (DMSO) injection (i.p.). CNO-injected *CamkII-Cre* mice were significantly impaired, whereas CNO-injected *Grik4-Cre* mice showed intact performance in escaping to the hidden platform. Our results indicate the importance of intact CA1 neural activity for the retrieval of spatial memory. When CA3 neural activity is suppressed, direct entorhinal-CA1 projections and/or dentate gyus-CA2-CA1 projections might be able to support the memory retrieval process. Alternatively, intact CA1 neural activity might be reinstated from partially suppressed CA3 neural activity based on pattern completion.

Title: Task-modulated activity in the infralimbic PFC and accumbens shell during goal-directed vs habitual behavior

Authors: *W. B. GLEN, JR[1], J. M. BARKER[2], L. J. CHANDLER[2];
[1]Neurosciences, [2]Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: Behavioral adaptability allows for flexible responding to rules and contingencies between reward and outcomes. Goal-directed behavior allows for the acquisition of new action-outcome relationships, allowing for the development of new behavioral patterns to capitalize on current contingencies. The transition from goal-directed behaviors to habitual responding allows for more of an increase in efficiency during the prolonged capitalization of such contingencies.

As habitual behaviors are driven by stimuli rather than action-outcome relationships, this increased efficiency comes at a cost to behavioral adaptability. In the face of changing rules and contingencies, previous habits can become suboptimal or even maladaptive. Many psychiatric disorder are characterized in part by the expression of inappropriate habits, including substance abuse, eating disorders, and obsessive-compulsive disorder. A variety of brain regions have been identified as essential for the development and expression of habitual behavior, including the infralimbic cortex (IL). While much attention has been paid to the striatum, relatively less focus has been given to the infralimbic cortex. In this study, multielectrode array recordings were taken in awake and behaving mice in order to to examine the electrophysiological activity in the IL as well as its downstream target in the striatum, the shell of the nucleus accumbens (NAcS). Recordings were taken during the acquisition of two operant responses for sucrose (10%). These responses were reinforced on two different reinforcement schedules: random interval (RI) and random ratio (RR). As expected, we observed that responding on these RR schedules remained goal-directed, while responding on an RI schedule became habitual over time. as assessed through outcome devaluation. Ongoing analysis of electrophysiological data during the acquisition and expression of both RR and RI schedules will examine the spectral and firing properties of activity within the IL and NAcS during behavior. Results suggest a variety of task-modulated changes in activity dependent on the development of habitual behavior, including increased delta power (1-4hz) during RI during late sessions which was not observed in RI early sessions, or RR late sessions.

Title: Identifying functional alterations in neuronal ensembles activated during acquisition of operant learning in rats

Authors: *L. R. WHITAKER, K. B. MCPHERSON, B. L. WARREN, J. M. BOSSERT, Y. SHAHAM, B. T. HOPE;
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: Learned associations between environmental stimuli and rewards drive goal-directed learning and motivated behavior. These associations are thought to be encoded by specific patterns of sparsely distributed neurons called neuronal ensembles that are selectively activated

by reward-predictive stimuli. The question remains as to how neurons in these ensembles are functionally altered during learning, and which of these changes encode learned associations. The objectives of our study were to identify ensembles of neurons strongly activated during acquisition of operant learning, and then to determine functional alterations specific to these neuronal ensembles. During each training session, rats were allowed to lever press for food pellets in the self-administration chambers for one hour. Rats formed an association between lever pressing and food reward over the course of several days of training. Immunohistochemical analysis indicates induction of Fos expression in ventral medial prefrontal cortex and nucleus accumbens on day 1 of training relative to home cage controls. These regions are critical to the acquisition of goal-directed learning and motivated behavior. Interestingly, Fos expression diminished over the course of training in infralimbic cortex, but remained consistent in prelimbic cortex. In future experiments, we will use Fos-GFP transgenic rats in which strong neuronal activation activates the Fos promoter that drives expression of GFP. Whole cell brain slice electrophysiology will then be used to assess functional alterations in behaviorally activated GFP-labeled neuronal ensembles. This work was supported by NIDA Intramural Research Program.

Title: Correlates of inferred associations in orbitofrontal neurons observed during sensory preconditioning

Authors: *B. F. SADACCA[1], H. WIED[2], G. SAINI[3], D. NEMIROVSKY[3], G. SCHOENBAUM[3];
[1]Natl. Inst. On Drug Abuse, Baltimore, MD; [2]Univ. of Maryland Sch. of Med., Baltimore, MD; [3]Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: The orbitofrontal cortex (OFC) has been implicated in a range of functions, but converging evidence points to OFC's role in supporting 'model-based' decision making. Such decisions are characteristically based on the use of inference, where the value of options is calculated on the fly from the animal's broader experience. Our lab has shown that the orbitofrontal cortex was necessary for just such a process through the use of a sensory-

preconditioning task, in which rats learn associations between pairs of cues in the absence of reward, and then learn that one cue of one pair leads to a food reward. Normal rats are able to use information acquired independently in these phases of learning later, to infer the value of the preconditioned cue both to guide behavior and to direct future learning, whereas rats in which the OFC is inactivated cannot. To identify neural correlates of this process, we recorded single-neuron activity in orbitofrontal cortex of 20 rats as they learned a sensory-preconditioning task. During the initial pre-conditioning phase of the task, as rats learned a relationship between pairs of cues in the absence of reward, OFC neurons tracked the association of cue pairs, responding more similarly to cues within an associated pair than to cues which were unpaired. This similarity in responding, while diminished, remained after the subsequent conditioning phase. Specifically, on the final test day, single neuron responses to cues that were paired during pre-conditioning were more similar to each-other than to control cues. . Thus the encoding of the cue pairs established during preconditioning may be the neural basis for OFC's role in inferring the relationship among cues required to perform a sensory preconditioning task and, more broadly, for OFC's role in inferential reasoning.

Title: Lesions of the retrosplenial cortex attenuate context fear conditioning, but not incidental context learning

Authors: *T. P. TODD, N. E. DEANGELI, M. Y. JIANG, D. J. BUCCI;
Psych & Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Contextual fear conditioning can theoretically be supported by two distinct processes: 1) elemental or feature associations, and 2) hierarchical or conjunctive representations (Rudy, 2009; Rudy et al., 2004). In the feature view, individual elements of the context are independently associated with shock. In the conjunctive view, features of the environment are bound together into a configural unit, and the entire representation is then associated with shock.

The conjunctive view gains support from evidence that pre-exposure to the conditioning context alleviates the immediate shock deficit (Fanselow, 2000). With the immediate shock procedure, rats show very little fear to the context, presumably due to an insufficient amount of time to sample the environment. However, pre-exposure alleviates this deficit because it allow for the formation of a cohesive, conjunctive representation of the context, that can then be retrieved by a single feature and subsequently associated with shock. Lesions or temporarily inactivation of the hippocampus disrupt the facilitative effect of context pre-exposure, suggesting the hippocampus has a crucial role in acquiring a conjunctive representation of the context (Rudy, Barrientos, & O'Reilly, 2002). The present experiments examined the role of the retrosplenial cortex (RSC) in contextual fear conditioning. While it has been suggested that neocortical regions support feature and not conjunctive representations, the specific role of the RSC has not been tested. Rats with electrolytic lesions of the RSC were exposed to the conditioning context (Context A) for 2 minutes on 4 consecutive days, while control rats were exposed to Context B. On day 5, all rats were placed in Context A and received a 1 mA, 2 s shock, 7 seconds after placement in the chamber. Rats were tested for contextual fear 24 hours later. Both RSC lesioned and Sham rats showed the context pre-exposure facilitation effect: prior exposure to the context increased fear, relative to rats exposed to a different context. Further, context fear was equivalent between RSC lesioned and Sham rats irrespective of if they were preexposed to Context A or B. In a second experiment, we confirmed that the RSC lesions were efficacious, replicating the finding that pre-training RSC lesions impair context fear learning (e.g., Keene & Bucci, 2008). Our findings suggest that in contrast to the hippocampus, the RSC is not required to form a conjunctive representation of the context. This in turn implies that deficits in contextual fear produce by RSC lesions are likely due to an inability to form associations between context features and shock.

Title: Chemogenetic silencing of the retrosplenial cortex disrupts retrieval of remote trace fear

Authors: *N. DEANGELI, T. P. TODD, D. J. BUCCI;
Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: The retrosplenial cortex (RSC) is positioned at the interface between primary cortical sensory areas and parahippocampal and hippocampal regions, and is strongly interconnected with parahippocampal regions (Sugar et al., 2011). Studies using delay fear conditioning procedures have demonstrated that RSC is involved in contextual fear memory. For example, permanent lesions (Keene and Bucci, 2008) as well as temporary inactivation of RSC impair the retrieval of contextual fear (Corcoran et al., 2011). In contrast, the existing data suggest that RSC is not critically involved in recalling fear to individual cues (Keene and Bucci, 2008). However, these studies have focused on retrieving recent fear memories, whereas the involvement of RSC in retrieving older (i.e. remote) memories remains largely untested. Indeed, preliminary data from our lab demonstrated that lesions of RSC 28 days after conditioning resulted in attenuated retrieval of cue-specific fear. We sought to extend this research by temporarily inactivating RSC at the time of retrieval instead of permanently lesioning RSC. We examined a trace CS-US relationship, considering recent evidence that the RSC is involved in retrieval of *recent* trace fear memories (Kwapis et al., 2014). The RSC was temporarily inactivated using DREADDS (designer-receptors-exclusively-activated-by-designer- drugs, Armbruster et al., 2007; Urban and Roth, 2014). Rats were infused with a viral vector containing the gene for a synthetic inhibitory G-protein-coupled receptor (hM4Di, Gi) into the RSC (n = 8), or a viral vector containing only the gene for green fluorescent protein (GFP; n = 8). Conditioning consisted of a single 10 min conditioning session in Context A, with three cue-shock pairings (there was a 20 s trace between CS and US). The following day, all rats were exposed to Context A following injection of CNO. Silencing RSC neurons had no effect on the retrieval of context fear. After a 28-day retention interval, rats were again injected with CNO 30 minutes prior to being exposed back to Context A for 20 min, for two consecutive days. The next day, rats were placed in Context B for 20 minutes without CNO, in an effort to reduce any baseline fear prior to the tone retrieval session. Finally, all rats were injected with CNO and retrieval of tone fear memory was tested. Silencing neurons in the RSC attenuated retrieval of fear to the tone, indicating that the RSC is involved in the retrieval of a trace conditioned fear memory originally conditioned 28 days prior. Thus, the contribution of RSC to context and cued-fear is more complex than originally thought; it depends upon the age of the memory, and the CS-US relationship.

Title: Lesions of retrosplenial cortex have no impact on renewal of extinguished fear, but attenuate context fear conditioning

Authors: *M. JIANG, N. E. DEANGELI, D. J. BUCCI, T. P. TODD;
Dartmouth Col., Hanover, NH

Abstract: The retrosplenial cortex (RSC) contributes to spatial and contextual learning and memory (e.g., Todd & Bucci, 2015). For example, pre-training lesions of RSC impair contextual fear learning, but have no impact on fear to a Pavlovian conditioned stimulus (CS). However, CSs that undergo extinction (i.e., repeatedly presented alone resulting in a decrease of the conditioned response) are often especially dependent upon the context for retrieval. The purpose of the current experiments is to examine the role of RSC in extinction and renewal of conditioned fear. Rats with either sham lesions or electrolytic lesions of RSC were first trained to lever press for food reinforcement in two distinct contexts (Context A and B). Next, a flashing light stimulus was paired with shock in Context A over the course of two, 2-day cycles. On the first day of the cycle, the light was paired with shock 4 times in Context A. On the second day of the cycle, rats were exposed to Context B and allowed to lever press freely for reinforcement. Following conditioning, the CS was extinguished in Context B. Similar to conditioning, extinction occurred over the course of four, 2-day cycles. On the first day of the cycle, the light CS was presented 8 times in Context B. On the second day of the cycle, rats were exposed to Context A and allowed to freely lever press for reinforcement. In the test for renewal, all rats received 4 nonreinforced presentation of the light CS in both Contexts A and B (test order counterbalanced). Lesions of RSC had no impact on the rate of acquisition, or the rate of extinction to the Pavlovian CS. Further, during renewal testing, there was a robust return of fear for both groups; fear to the CS was high in Context A, but low in Context B. To confirm the efficacy of the RSC lesions, following renewal testing there was a single context fear conditioning session in which the context alone was paired with shock 8 times. During this session, sham rats gradually reduced their rate of lever pressing, whereas RSC lesioned rats did not. Our results suggest that the RSC is necessary for some, but not all, forms of contextual learning. Specifically, when the context is required to disambiguate the meaning of the CSs (e.g., renewal) the RSC does not appear to be necessary. However, RSC is necessary to learn direct associations between context and shock.

Title: Gamma neurofeedback training in monkey's primary visual cortex

Authors: *L. A. CHAUVIERE[1], W. SINGER[2];
[1]Prof. Singer Lab., Max Planck Inst. For Brain Res., Frankfurt, Germany; [2]Singer Lab., Max Planck Inst. for Brain Res., Frankfurt am Main, Germany

Abstract: In humans, neurofeedback training has been successfully used to manipulate brain activity with EEG, fMRI and more recently with MEG recording techniques. In non-human primates, neurofeedback training has been successfully applied at the level of single cell (Schafer & Moore, 2011) and population activity to increase gamma-band activity in the primary motor cortex (Engelhard et al., 2013). In the current study, we chronically implanted two awake behaving macaque monkeys with 32 adjustable microelectrodes (Gray Matter Research) in the primary visual cortex and extracted the power of gamma oscillations within a narrow frequency band (± 15 Hz) from the local field potentials (LFPs) of one electrode. Monkeys that had been trained to fixate were rewarded if they maintained gamma band activity above a given threshold for at least a second while fixating. Correct performance was signaled by a tone and monkeys could increase their reward if able to prolong the tone. Both monkeys were able to increase the power and duration of gamma oscillations above the baseline level once feedback and reward were provided. Control experiments showed that it was also the case without auditory feedback, for trials/sessions when only reward was provided to the monkeys. Increasing the threshold for reward over subsequent trials/sessions led to a gradual increase of the feed back effects, suggesting that the animals learnt to control amplitude and maintenance of gamma oscillations in V1. It is to be expected that further analysis of the responses from the non-conditioned recording sites and the concomitantly registered unit activity will provide further insights into the mechanisms mediating the internally generated enhancement of gamma oscillations.

Title: Visual-cued fear conditioning of mice and the change in the neuronal firing property in the visual cortex

Authors: *M. K. YAMADA[1,2], T. EBINA[2], Y. WADA[3,4];
[1]Isotope Sci. Ctr., The Univ. of Tokyo, Tokyo, Japan; [2]RIKEN, BSI, Saitama, Japan; [3]Isotope Sci. Ctr., Tokyo, Japan; [4]The Res. Ctr. for Advanced Sci. and Technology,The Univ. of Tokyo, Tokyo, Japan

Abstract: Primary visual cortex is one of the most suitable areas of the brain for observation of neuronal firing properties by sensory input in the living animal. The cortical neuronal activity should be changed by visual stimulation, because visually evoked local field potential (VEP) in the visual cortex has been known to be altered in 24 hours by the repetitive stimulation using moving grating toward single-direction. We combined fear-conditioning with this type of visual stimulation, hoping that the footshocks in combination of the moving grating might alter the visual representation faster and more faithfully. Another good point of this method is that the attentiveness and normal sight in each individual mouse in addition to the associative learning at the conditioning period can be certified by change in the freezing behavior. The moving grating is the best known stimulation for the cell-firing in the primary visual cortex, thus we used that toward a single-orientation for the fear-conditioning of freely moving mice. As the result of giving footshocks in combination with moving grating, mice showed freezing behavior selectively to that visual stimulation. The freezing was observed at 3 hr after the conditioning and the level of the selectivity was increased from 3hr to 24hr. That is, after 24 hr, the difference of freezing time between to the moving grating and to the environment, so-called context, become significant. This result means that the mice can be conditioned to a visual stimulation such as the moving grating toward single-orientation in terms of fear response. We named this system as the visual-cued fear conditioning (vFC). Under the multi-photon microscope, mice with GCaMP3-expression in the excitatory neurons were given footshocks in combination with moving grating for a specific direction and the neuronal calcium levels were observed through the cranial window, before, during and after the procedure. (Mouse: NEX-Cre x Gt (ROSA)26Sortm1.1 (CAG-GCaMP3) Imayo; ref, Ebina et al. 2014, Cell Reports 9, 1896-1907). Change in the firing properties that might suggest, at least in part, network mechanism for cortical plasticity will be presented.

Title: Coherence of thalamocortical oscillations during sleep is required for consolidation of cortical plasticity in the visual system

Authors: *J. M. DURKIN[1], A. SURESH[2], J. COLBATH[1], S. J. ATON[1];
[1]Neurosci. Grad. Program, Univ. of Michigan, Ann Arbor, MI; [2]Univ. of Chicago, Chicago, IL

Abstract: Orientation Specific Response Potentiation (OSRP) is a form of cortical plasticity in primary visual cortex (V1), which is initiated by waking visual experience and dependent on subsequent sleep. OSRP is accompanied by an increase in V1 neuron firing following visual stimulus presentation. We have previously found that optogenetic silencing of cortical feedback to the thalamus, which is hypothesized to be crucial for thalamocortical synchrony, during Non Rapid Eye Movement (NREM) sleep disrupts consolidation of experience-dependent cortical plasticity. To understand what mechanisms underlie this disruption, we performed dual site chronic recordings of individual visual thalamus (LGN) and V1 neurons under normal conditions and optogenetic silencing of cortical feedback following initiation of cortical plasticity. Preliminary data suggests that following initiation of cortical plasticity, LGN experiences increases in neuronal firing and optogenetically silencing cortical feedback during NREM sleep eliminates this increase in LGN firing. These preliminary findings suggest that synchrony between cortex and thalamus may be critical for maintaining the increase in LGN firing, which in turn may drive plasticity in visual cortex during NREM sleep.

Title: Hardware and software platform for spatial sequential learning in rodents

Authors: *D. R. EUSTON[1], H. W. STEENLAND[1,2];
[1]Univ. Lethbridge, Lethbridge, AB, Canada; [2]Neurotek innovative technology, Toronto, ON, Canada

Abstract: The testing equipment used in electrophysiology experiments is typically custom-built for a specific task and offers little flexibility. Given the time and effort involved in building such systems, it would be desirable to have control systems that could be quickly re-configured. Such systems need to be flexible enough to be altered for specific experiments and robust enough to control and receive information from the animal, experimenter and the data acquisition system. The field programmable gate array (FPGA) offers a great opportunity to control behavioral experimentation, conferring robust hardware control and sensor integration with the benefits of rapid configuration via software. The FPGA is a high-speed, customizable, parallel processing chip. Here we demonstrate the feasibility of using a National Instruments FPGA technology for a behavioral control system involving a spatial sequence task. A graphical user interface was developed in visual basic, so the experimenter could control the FPGA and receive camera-based tracking information from a data acquisition system. In addition, cable management hardware was developed for plug and play setup. This hardware connects the FPGA systems with lights, sounds, brain stimulation reward, timestamps, clock counts, and multiplexing audio control. Rats with implanted arrays of recording and stimulating electrodes could be taught to navigate a sequence task based on memory of light locations around a circular arena in a number of different spatial sequences or configurations.

Title: Neuronal ensemble dynamics in layer 5b of primary motor cortex during motor learning

Authors: *Q. LI[1], H. KO[2,3], D. CHAN[1], G. ARBUTHNOTT[4], Y. KE[1], W. YUNG[1];
[2]Chow Yuk Ho Technol. Ctr. for Innovative Medicine, Fac. of Medicine, Fac. of Med., [3]Lui Che Woo Inst. of Innovative Med., [1]The Chinese Univ. of Hong Kong, Hong Kong, China; [4]Okinawa Inst. of Sci. and Technol. Grad. Univ., Okinawa, Japan

Abstract: The primary motor cortex (M1) comprises functionally heterogenous neuronal populations, with some encoding motor-related parameters such as direction and velocity. Recent evidence suggests that specific motor memories can be represented by sub-populations of neurons in layer 2/3 and layer 5a of M1. However, it is unknown how this upstream information is eventually conveyed to and reflected in the neuronal ensemble of the output layer 5b. Based on extracellular multi-unit recordings from conscious freely moving rats, we investigated the dynamics of layer 5b pyramidal neurons during learning of a motor skill, namely, the forelimb reaching for food task. We found a subpopulation of task-recruited layer 5b neurons that not only became more movement-encoding during motor learning, but their activities were also more temporally aligned to motor execution with a timescale of refinement in tens of milliseconds. These changes were accompanied by the emergence of a stable and task-specific structure of activity correlation, as well as more reproducible population neuronal activities with higher collective predictive power of motor output. Interestingly, local cortical depletion of dopamine by 6-hydroxydopamine injection degraded motor learning performance and disrupted the emergence of these reproducible spatiotemporal patterns of activities. Our results suggest that the recruitment of L5b neurons in a dopamine-dependent manner is crucial for the generation of more temporally aligned output signal from M1 to downstream circuitry, and may represent a mechanism underlying the enhanced precision of movement during motor learning.

Title: Effects of single prolonged stress: a ptsd validated animal model, on pre- and post-synaptic marker expressions in fear-processing neurocircuitry

Authors: *E. RODRIGUEZ[1], I. LIBERZON[2];
[2]Psychiatry, [1]Univ. of Michigan, Ann Arbor, MI

Abstract: Post-traumatic stress disorder (PTSD) is a severely debilitating anxiety disorder. Core deficits of PTSD include extinction retention and contextual processing. Functionally, prefrontal cortex (PFC)-hippocampus (Hpc)- amygdalae circuitry is critical for these processes. Prolonged exposure to stress or stress hormone has been shown to lead to synaptic atrophy in lab animals. Patients with depression have also been shown to have significant decreases in synaptic

arborization, synapse numbers and expression of markers of synaptic function. To understand synaptogenesis' role in PTSD relevant fear processing of extinction recall we measured synaptogenesis markers following SPS exposure alone as well as in combination with fear learning resulting from fear conditioning, extinction and extinction recall. Synaptogenesis were measured in PTSD relevant neurocircuitry (mPFC, Hpc, and amygdala) using quantitative PCR. Within these regions, both pre- and post-synaptic signaling relevant molecules were measured: Syn1, PSD95, MAP2, GluR1 and BDNF. SPS alone significantly affected expression of BDNF and MAP2 within mPFC and the hippocampus. SPS and fear learning had a significant interaction in the expression of MAP2 and Syn1 in all three areas studied. Dendritic remodeling would represent a modifiable target that could lead to viable treatments as well as furthering our understanding of etiology of this disorder. Treatment targeting dendritic remodeling is currently being investigated for multiple disorders.

Title: Microcircuitry and physiology of the lateral pallium of a weakly electric fish

Authors: *A.-T. TRINH, E. HARVEY-GIRARD, L. MALER;
Univ. of Ottawa, Ottawa, ON, Canada

Abstract: In the weakly electric gymnotiform fish, Apteronotus leptorhynchus, the dorsolateral pallium (DL) is implicated in learning and memory and considered to be homologous to medial and/or dorsal pallium (hippocampus/cortex). Previous studies reveal that there is an expansive representation of sensory input in DL similar to that seen in thalamo-cortical projections. The gymnotiform DL has an apparently uniform architecture composed of randomly distributed multipolar neurons. We used micro neurotracer injections in order to study the microcircuitry of DL. Surprisingly, we have shown that the intrinsic connectivity of DL is highly organized into horizontal bands and vertical columns of excitatory synaptic connections. The horizontal connections subdivide DL into narrow (60 μm) overlapping cryptic layers that are symmetric, sparse and random; the probability of connectivity between neurons drops exponentially with distance. Using a directed random graph model, we have found that the minimal distance for strong connectivity in the horizontal plane is 100 μm. The vertical connectivity on the other

hand, is highly asymmetric with superficial DL cells preferentially projecting towards deeper cells suggesting a cryptic columnar organization. Our experimental data suggest that the overlapping cryptic columns have a width of 100 μm, which is in agreement with the minimal distance required for strong connectivity. The connectivity of DL and the expansive representation of its input, combined with the strong expression of NMDA-Rs by its cells, are in agreement with theoretical ideas regarding the cortical computations of pattern separation and memory storage via recurrent networks. To further investigate if DL can support recurrent networks, we switched to whole-cell recording in acute brain slices in order to characterize the neurons in DL. Preliminary results suggest that DL cells are typically inactive due to having a low resting membrane potential and a high spike threshold. Initial characterization has also revealed that these neurons have a persistent inward Na+ current, strong Ca2+ currents and that spikes are followed by a strong after-hyperpolarizing potential (AHP). Using a pharmacological approach, we have found that the AHP is caused by the SK channels known to be abundantly expressed in DL neurons. The AHP leads to prominent spike-frequency adaptation (SFA) of the response to step depolarization of DL neurons. The combination of a strongly connected network with slow NMDA-R mediated excitation and negative feedback in the form of SFA suggests that DL meets the theoretical requirements for memory storage via bump attractor networks.

Title: Performance of common marmosets in a delayed positional matching-to-sample task

Authors: ***Y. YAMAZAKI**[1,3], M. SAIKI[3], M. INADA[3], S. WATANABE[2], A. IRIKI[3];
[1]Keio Advanced Res. Centers, [2]Dept. of Psychology, Keio Univ., Tokyo, Japan; [3]Lab. for Symbolic Cognitive Develop., RIKEN BSI, Saitama, Japan

Abstract: Working memory is used to solve various daily cognitive problems by maintaining information for some time and then by refreshing this information after certain purposes are achieved. In the present study, we explored common marmosets' ability to perform a delayed positional matching-to-sample (DPMTS) task in a controlled environment using operant

respondings to the touch-sensitive screens. The DPMTS task requires the subjects to respond to the sample stimulus and to select one of two comparison stimuli with a position matching that of the sample stimulus after a programmed delay period. Positional arrangement of the sample and comparison stimuli, which were quasi-randomly determined in each trial, was employed to prevent the subjects from using any strategies based on their own body positions or orientations. The delay intervals between presentations of the sample and comparison stimuli were fixed at 0.5 and 1 sec in the initial phases and were then varied between 5 intervals per delay set (e.g., 0.5, 1, 2, 4, and 8 sec) intermixed in a session. The longest delay interval within a set was gradually increased after the marmosets achieved the criterion of each task. The subjects were successfully trained in the procedure and showed accurate performance, and 4 out of 6 subjects showed above criterion performance even following delays of more than 100 sec. Difference of sex and experimental history had little effect on the delayed performance. The performance was declined as the longest delay intervals prolonged. The response times in the trials suggested that they used different strategies depending on the delay interval length. With the shorter delay intervals, they tended to wait for the comparison stimuli to be presented in front of the response panel. Accuracy was well preserved even when positional memory was disturbed during the long delay intervals. Thus, the present study shows the robust ability of common marmosets in a task requiring positional memory, which is related to their foraging strategy observed in the wild.

Title: Associative memory storage and synaptic connectivity in homeostatically constrained networks of excitatory and inhibitory neurons

Authors: *A. B. STEPANYANTS[1], J. CHAPETON[2], R. GALA[1];
[1]Physics, Northeastern Univ., Boston, MA; [2]NIH, Bethesda, MD

Abstract: Learning and memory formation in the brain are accompanied by changes in synaptic connectivity of the underlying neural network. Yet, the specific effects of learning on connectivity are not understood. There are some connectivity features that are ubiquitously present in local cortical networks. These features include very sparse connectivity of excitatory neuron axons, much denser connectivity established by the axons of many inhibitory neuron

classes, and stereotypically distributed connection weights. To understand if such features can form as a consequence of learning we considered a biologically constrained, exactly solvable model of associative memory storage. The model is based on the hypothesis that cortical areas in the adult function in a steady-state where learning is accompanied by forgetting. The model can include homeostatic constraints on the number or weight of functional synaptic connections and can accommodate multiple excitatory and inhibitory neuron classes. We find that in spite of multiple neuron classes, functional connections between potentially connected cells are realized with less than 50% probability if the presynaptic cell is excitatory and generally a much greater probability if it is inhibitory. We also find that constraining the overall weight of presynaptic connections leads to Gaussian connection weight distributions that are truncated at zero. In contrast, constraining the total number of functional presynaptic connections leads to non-Gaussian distributions, in which weak connections are absent. These theoretical results are compared with experimental measurements of connection probabilities and weights from various cortical areas and species, suggesting that stereotypic features of adult connectivity can form despite functional differences among brain areas and diverse learning experiences of individuals.

Title: Somatostatin interneurons exhibit diverse activities during motor learning

Authors: ***A. ADLER**, W.-B. GAN;
Skirball Inst. of Biomolecular Med., New York Univ., New York, NY

Abstract: Somatostatin (SST) cells account for approximately 30% of cortical GABAergic inhibitory interneurons. Their cell bodies are located in layers 2 to 5 and their axons make extensive contacts with the apical tuft dendrites of pyramidal cells. SST neurons have been shown to directly block the initiation of dendritic calcium spikes in response to sensory stimuli. Furthermore, active or passive whisker stimulation leads to hyperpolarization and reduced activity of all SST cells. These lines of evidence suggest that during sensory processing, the activities of SST cells are inhibited to allow for enhanced excitability and sensory processing. Here we explored the function of SST cells in the motor cortex during motor learning by examining their responses to different motor learning tasks. *In vivo* calcium imaging was used to

monitor the activity of SST cells in mice subjected to running forward or backward on a treadmill. SST-IRES-Cre mice were injected with adenoviruses expressing the genetically encoded calcium indicator, GCaMP6 specifically in layer 2/3 of the forelimb region of the primary motor cortex. We found that SST interneurons displayed diverse response patterns, with both increased and decreased activities in response to forward and backward running. The responses to forward and backward running within individual SST cells were highly selective as different motor learning tasks induced significantly different activity patterns. This response selectivity was manifested in the cells' response polarity, i.e. if a SST cell increased its activity to forward running, it was likely to decrease its activity to backward running and vice versa. Our results suggest that unlike sensory cortex, SST neurons in the motor cortex do not function as a single dimension uniform unit during motor learning.

Title: Membrane potential dynamics of specific cortico-cortical projection neurons correlated with goal-directed behaviour

Authors: *T. YAMASHITA[1,2], C. C. H. PETERSEN[2];
[1]Res. Inst. of Envrn. Med., Nagoya Univ., Nagoya, Japan; [2]Brain Mind Inst., EPFL, Lausanne, Switzerland

Abstract: How sensory information is segregated in primary sensory cortex to generate multiple processing streams towards other cortical areas is a fundamental issue in studying sensory processing. However, the cellular and synaptic mechanisms underlying such distinct signalling pathways are poorly understood. By making *in vivo* whole-cell recordings in primary somatosensory barrel cortex (S1) of awake behaving mice, we have previously shown that S1 neurons projecting to primary motor cortex (M1) and those projecting to secondary somatosensory cortex (S2) have different intrinsic membrane properties and exhibit markedly different membrane potential dynamics during behaviour (Yamashita et al., Neuron, 2013). Here we questioned how output signals from S1 to M1 or S2 would be changed by learning a simple detection task where evoked S1 activation is needed for execution of goal-directed, licking behaviour (Sachidhanandam et al., Nature Neuroscience, 2013). Early sensory-evoked responses

in the M1- or S2-projecting neurons were not significantly changed by learning the task. In hit trials, late depolarization at 100-300 ms after whisker deflection, however, became larger in S2-projecting neurons after learning, but not in M1-projecting neurons. In well-trained mice, S2-projecting neurons, but not M1-projecting neurons, showed depolarization during spontaneous non-rewarded licking which was marginal during licking in naive water-deprived animals. Interestingly, these learning-induced changes in membrane potential dynamics in S2-projecting neurons were observed within a few hours at the first training day, in a subset of mice which quickly learned the task. These results suggest that learning the S1-related detection task reorganizes S1 microcircuits to specifically enhance "ventral stream" S1-S2 signals correlated to goal-directed motor outputs.

Title: Sensitive method to follow dynamics of remote memory in mice using social transfer of food preference

Authors: *A. SINGH, S. KUMAR, V. SINGH, S. SHRIDHAR, J. BALAJI;
Ctr. for Neurosci., Indian Inst. of Sci., Bangalore, India

Abstract: Long term memories have been hypothesized to undergo various transitions in its content as well as the loci of storage as memory gets consolidated. Recent studies have shown that synaptic activation and gene expression in neocortex is required even during recent memory formation for the stable formation of remote memory. This is in contrast with the conventional notion that all the plasticity mediated events happen in hippocampus during formation of recent declarative memories. In this context, we hypothesize that neocortical synaptic activation at recent time point precedes transcriptional activation of neurons and stabilization of remote memory trace. Using behavior paradigm of social transfer of food preference (STFP) we have

observed that memory of demonstrated flavor can be retrieved in mice as long as forty five days after behavior. This provides us with a window of sufficient time to observe the dynamics of consolidation events happening during and post STFP training. We incorporate novel photonic tools and fluorescent probes to follow and test our hypothesis.

Title: Excitability-dependent memory allocation and manipulation in feedforward neural network model

Authors: ***P. KANCHANAKANOK**, W. CHOI, S.-B. PAIK;
Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Memory plays an important role in human life and relates to learning ability. It has been reported that memory allocation is influenced by intrinsic neural properties, such as neural excitability, and can be manipulated by varying those parameters (1, 2). Particularly, neural excitability is known to be a critical factor in the allocation of fear memory in the amygdala (3). To understand the relationship between neural excitability level and selective memory allocation, we developed a simple neural network model and observed changes in memory traces during excitability manipulation. Our hypothesis is that higher neural excitability would result in higher chance to be involved in memory allocation with strengthened feedforward synaptic connections between input and target neurons. Moreover, we assume that recurrent connections would play a critical role in the transition of memory allocation in the circuit so that a feedforward-only network model cannot reproduce the transition observed in animal studies. To confirm the idea, we developed a feedforward-only network model of leaky integrate-and-fire neurons which receives spike inputs from sparse-and-random synaptic connections. We first confirmed that our network model could learn and memorize a specific input pattern with a simple spike timing dependent plasticity rule. Next, to test the effect of high neural excitability, we intentionally increased the resting membrane potential of a group of neurons (group A) and observed that group A neurons have noticeably higher probability to be involved in the memory trace. After this, to simulate the memory transition between neuron groups, we increased the resting potential of another neuron group (group B) while group A's resting potential was turned back to a normal

state. After memory training simulation, we found that group B's response could not surpass group A's response for memorized pattern and that both group A and B cells were involved in the memory trace. Our result suggests that the memory allocation can be achieved by simple Hebbian learning rule, and the achieved memory trace highly depends on neural excitability level. It also shows that memory allocation in a neural network is variable so that the involved neural population for particular memory may not be unique. Moreover, in the absence of recurrent connections, memory transition could not be readily achieved. Further studies with a recurrent network model would show a mechanism of competitive activities among in-layer cells in memory allocation and transition. Title: Neural computation with assemblies and assembly sequences

Authors: *C. POKORNY, R. LEGENSTEIN, W. MAASS;
Inst. for Theoretical Computer Sci., Graz Univ. of Technol., Graz, Austria

Abstract: Simultaneous recordings from large numbers of neurons have found in many cortical areas of mice stereotypical spatio-temporal patterns in their firing activity, commonly referred to as assemblies, assembly sequences, or trajectories of network states. These characteristic spatio-temporal patterns (abbreviated STPs) of neural activity occur both spontaneously and stimulus evoked in primary sensory areas A1, V1, S1 (Luczak et al, 2007; Sadovsky et al., 2014; Miller et al., 2014). They have also been found in areas PFC (Fujisawa et al., 2008) and PPC (Harvey et al., 2012) as neural traces of specific behaviours and movement plans. We address in this poster the question what these experimental data tell us about the organization of brain computations, and how models for brain computations should be modified in order to take them into account. This question is of particular interest, since the recorded activity is quite different from an asynchronous irregular firing regime (that was previously proposed in theoretical studies as best supporting neural computation). The experimental data also suggests that computations on the network level cannot be described adequately by attractor networks, since one finds stereotypical TRANSIENT activity patterns, rather than convergence to specific network states or limit cycles. We report in this paper first results of a new computational theory that is based on the

assumption that the experimentally found stereotypical STPs play an important role in network computations. We show that STPs enable computation and learning in a context-dependent manner. We also show that STPs may enable selection and switching between different functional networks for specific computational tasks. Our computational theory builds on concepts and mathematical tools provided by recent work on computations in cortical microcircuit models with biologically realistic amounts of noise (S. Habenschuss et al., 2013, Klampfl , 2103). REFERENCES S. Fujisawa, A. Amarasingham, M.T. Harrison, G. Buzsáki; Nat. Neuroscience, 2008 S. Habenschuss, Z. Jonke, W. Maass; PLOS Comp. Biol., 2013 C.D. Title: Differential influence of neocortical networks (mental schema) in relational and abrupt learning

Authors: *V. SINGH[1], S. SHRIDHAR[1], S. KUNDU[1], R. BHATT[1], S. SAM[2], A. SINGH[1], S. KUMAR[1], J. BALAJI[1];

Abstract: Memories of related events and facts are stored in the form of neocortical associative networks (mental Schema) and they help in rapid consolidation of new memories that are similar in character. Although neocortex is shown to be involved in rapid learning of small modifications to existing schema, it is not clear if this is true for learning larger information sets with content richness similar to the initial schema. We show that a pre-existing schema may or may not influence such new learning depending on the mode of training. Further, we show that if the novelty is introduced in relation to pre-formed schema (relational learning) the learning is

rapid even when acquiring/forming a new memory of similar complexity. We established event arena based behavioural paradigm in mice to test the schema formation and used it to teach mice two maps of equal complexity. Initially, one map was taught while the other was taught later in relation to the first. The animals demonstrated rapid encoding of the second map (presented later).We also found that relational learning is faster than incremental learning. We will also present our results for the role of such neocortical networks in advanced cognitive scenarios such as problem solving.

Title: Tracking changes in spikes rates as a function of t ask covariates within a single session

Authors: *F. A. MUNOZ[1], G. JENSEN[2,1], B. KENNEDY[3], V. P. FERRERA[1,4], H. TERRACE[2];
[1]Neurosci., [2]Psychology, [3]Neurosurg., [4]Psychiatry, Columbia Univ., New York, NY

Abstract: The development of analytical tools for correlating neu rophysiological recordings with behavior during learning has been hampered by pr actical and conceptual roadblocks. Although current analytic methods permit the e xperimental demonstration of tuning functions that have previously be en learned over the course of a lengthy training regimen, the processes under lying learning itself remain mysterious. Of particular note is the problem of parameter estimation in non-stationary data: Although kernel smoothing procedure s have enjoyed great success in characterizing firing over the course of trials du ring stable performance, they are not appropriate for evaluating f iring rates during the initial acquisition of a behavior, during which neuronal acti vity is continuously changing. We propose a novel method for mapping firings rates ove r the course of a single experimental session, using multivariate adaptive regre ssion splines. This nonparametric approach not only permits inference about changing firing rates within individual trials, but also tracks the evolution of firing rates over the course of a single session. This permits trials to be understoo d not as independent cases, but instead as a continuum that unfolds over the dur ation of a session. This procedure also bypasses longstanding difficulties surr ounding bandwidth selection. We use this procedure to investigate real-time changes in firing rate, revealing how single neurons change their behavior thro ughout

initial training, rather than as a result of training that was performe d at some prior time. This lets us identify the precise moments in a session at which tuni ng functions emerge, differentiating baseline firing from the tuned firi ng that reflects learning. We demonstrate this procedure on recordings from cells in p arietal area LIP in monkeys during a transitive inference task. In each session, subjects were presented with never-before-seen photographic stimuli, and learned how those stimuli were ordered using trial and error. This per mits modeling of response accuracy over the course of a session, based on the firing r ate. Insofar as neurons become tuned to task features (such as stimulus pos ition and order), we are able to show the timing and magnitude of changes i n tuning within the session. When used in concert with temporally consistent tr ial structures, this procedure enables a host of hitherto uninvestigated quest ions about learning processes to be investigated.

Title: Comparison of classical and operant conditioning using behavior and electrophysiology during auditory learning tasks

Authors: *M. GOLDSCHMIDT[1,2], A. KOLODZIEJ[1,2], A. SCHULZ[1], F. OHL[1,2,3];
[1]Leibniz Inst. For Neurobio., Magdeburg, Germany; [2]Otto von Guericke Univ., Magdeburg, Germany; [3]Ctr. for Behavioral Brain Sci., Magdeburg, Germany

Abstract: To obtain a more fundamental understanding of the role and the mechanism of cortico-striatal interaction underlying learning, two different forms of learning will be compared: A classical conditioning paradigm (fear conditioning) and an instrumental conditioning paradigm (avoidance learning). The planned approach provides a scenario to investigate the phenomenon of Pavlovian-instrumental transfer (PIT), a process where in the first phase an association is made between a conditioned stimulus (CS) and an unconditioned stimulus (US) by classical conditioning and in the second phase there is a transfer from classical to instrumental. Therefore, we designed a combined learning experiment with male C57BL/6J and NMRI mice. In this experiment one group of animals was trained initially in a modified fear conditioning paradigm and subsequently in a customized two-way active avoidance paradigm, and a second group in a reversed order. To discover possible similarities and differences between these two basic learning scenarios we will use behavioral analyses like scoring of freezing during fear conditioning, recording of hit-rate and false-alarm-rate during avoidance conditioning. In

addition to the behavioral experiments, simultaneous electrophysiological recordings of local field potentials from auditory cortex and ventral striatum will be obtained from the awake behaving animals. This approach allows dissociating the specific functions of these two behavioral brain structures and their interplay in classical and instrumental conditioning.

Title: Cortical learning and moudulation of mesoscopic cortical activity patterns in the Mongolian gerbil

Authors: ***K. TAKAGAKI**[1], G. ARIAS-GIL[2], M. T. LIPPERT[2], F. W. OHL[2];
[1]Leibniz Inst. for Neurobio., Magdeburg, Germany; [2]Leibniz Inst. for Neurobiology, Magdeburg, Magdeburg, Germany

Abstract: Transcranial DC (tDC) stimulation has been known to modulate human sensation since the early 1960s. Recently, there is a resurgence of this method, and many recent studies have documented that tDC modulates human learning. Besides the basic neuroscience applications in learning and memory, tDC is also considered to be a promising treatment modality for everything from stroke rehabilitation (modulation of plasticity) to depression (modulation of mood), due to both its ease of application and its global modulatory effects. However, very little is known about the effects of tDC on the neocortex, and how these neocortical effects lead to changes in learning and memory. We investigate the mechanisms of these effects on learning and memory, both on the behavioral scale, using a cortically-dependant auditory discrimination task in Mongolian gerbils, and on the mesoscopic physiology scale using electrocorticography and voltage-sensitive dye imaging.

Title: A head-fixed behavioral paradigm for studying whisker-mediated object recognition in mice

Authors: *C. RODGERS, A. KHANNA, P. CALAFATI, R. M. BRUNO;
Columbia Univ. Med. Ctr., New York, NY

Abstract: Rodents rely on whisker-mediated touch to explore their environment. By sweeping their whiskers across objects, similar to the way in which we palpate objects with our fingertips, rodents can identify object location, texture, and shape. The "novel object recognition" task, widely used in psychiatric research, challenges freely moving rodents to identify unfamiliar objects; however, it is typically unclear what sensory modality and strategy they use to do so. In contrast, head-fixed behavioral paradigms for studying rodent somatosensation are generally used to study object location and texture, not shape. Therefore, we have developed a head-fixed behavioral paradigm for studying object recognition that is amenable to modern imaging and recording techniques. Preliminary results indicate that mice are able to identify objects differing along a single tactile dimension in their whisker field. We ensure that mice do not usual visual cues by training them in total darkness. Trimming off all the whiskers reduced performance to chance, demonstrating that mice indeed use their whiskers to perform this task. This paradigm is useful for examining the circuit activity underlying object recognition and how it relates to processing in other sensory systems.

Title: Neuron-specific mechanisms for unilateral learning and bilateral memory recalls

Authors: *J. H. WANG[1], R. FAN[2], L. CHEN[2], Z. GAO[1];
[1]The Inst. Biophysics, Beijing, China; [2]Bengbu Med. Col., Bengbu, China

Abstract: After sensory signals and operative skills are learnt by unilateral limb, they are retrieved in bilateral limbs, such as the hand-writing can be performed by both hands after learnt by a hand. This unilateral learning toward bilateral memory is critical for both-side limbs to be coordinate in response to the environmental changes. In terms of cellular mechanism for this unilateral learning to bilateral memory, the plasticity of the corpus callosum that connects two cerebral hemispheres is presumably involved. We aim to examine how the corpus callosum plasticity initiates the recruitment and refinement of different cortical neurons to encode the unilateral learning toward bilateral memory. To study cell-specific mechanisms, the mouse glutamatergic neurons were genetically labeled by yellow fluorescent protein and GABAergic neurons were green fluorescent protein. AAV-SynaptoTag-Cherry (a gift from Tom Shudoff) was injected into the barrel cortex corresponding to the training side of whiskers to trace its distribution in the contralateral side and the synapse formation under confocal cell imaging. Electrophysiological recordings in two sides of the barrel cortices *in vivo* were used to analyze how their neurons encode associative signals. Whole-cell recordings in the brain slices were used to assess plasticity in neuronal spiking and synaptic transmission. Pairing stimuli to mouse unilateral whiskers and olfaction led to odorant-induced motion in the bilateral whiskers and their motion frequencies were higher in the training side than non-training side. In the mice of expressing this bilateral signal retrieval, the axon innervation between both sides of the barrel cortices was strengthened and new synapses between them were formed. The neurons in both sides of the barrel cortices became able to process the newly learnt odor signal besides innate whisker signal. Their encoding patterns in response to two associative signals were different. The barrel cortical excitatory neuronal units were functionally increased, and the inhibitory neuronal units were decreased. The fact that the bilateral memory recalls are induced by unilateral learning indicates that the learning by the unilateral side leads to memory formation in the bilateral cortices. The new synapse formation and neuron-specific recruitment constitute the bases for both sides of the cortical neurons to process the odor and whisker signals for their associative storage and distinguishable retrieval in unilateral learning toward bilateral recalls.

Title: Regulation of goal-directed behavior by nucleus accumbens glutamate signaling

Authors: *J. M. BARKER[1], J. CHANDLER[2];
[1]Psychiatry, [2]Med. Univ. of South Carolina, Charleston, SC

Abstract: The ability to flexibly regulate behavior is impaired in a number of neuropsychiatric disorders, including addiction. This loss of behavioral flexibility may involve a transition from goal-directed actions, where rewards are sought for their reinforcing properties, to habitual behaviors which are not performed in relationship to their outcome. Response strategy selection is mediated in part by corticostriatal circuitry. Previous research has implicated the infralimbic PFC (IL) in the expression of habitual reward seeking; loss of IL function restores goal-directed action in rodents that have acquired habitual reward seeking. Extinction learning has implicated IL projections to the nucleus accumbens shell (NAcS) in the regulation of reward seeking, but the downstream target of IL projections that mediate habitual behavior have not yet been assessed. Our recent research has implicated glutamate signaling in the NAcS in the expression of habitual behavior. In particular, we observed that mGluR2/3 agonism in the NAcS restores goal-directed reward seeking after the development of habitual behavior. To investigate the role of IL projections to the NAcS, we are utilizing a pharmacogenetic strategy. In particular, a virus expressing the inhibitory DREADD under control of the CAMKII promoter, which restricts expression to glutamatergic neurons, was injected into the IL. Findings indicate that inhibition of IL glutamatergic projections by agonism of the inhibitory DREADD prevent the expression of habitual behavior. This pharmacogenetic strategy is being employed to test the hypothesis that IL projections selectively to the NAcS are critical for habitual reward seeking.

Title: Ontogenetic changes in anterior cingulate cortical activity during trace eyeblink conditioning

Authors: *M. E. ELKIN, J. H. FREEMAN;
Univ. of Iowa, Iowa City, IA

Abstract: The ontogeny of trace eyeblink conditioning is believed to be dependent upon maturation of forebrain structures such as the anterior cingulate cortex (ACC) and hippocampus. (Goldsberry et al., 2015, J. Neurosci., 35:4238). Although neuronal responsiveness in the ACC during trace eyeblink conditioning has been studied in adults, there is a paucity of research concerning its role in the developing animals. The goal of the current study was to examine the development of neuronal activity in the ACC while developing rats were trained in trace eyeblink conditioning. We implanted moveable tetrodes in rat pups on postnatal days (P) 17, 19, 22 and 29. The rat pups were given one of day rest and then trained on trace eyeblink conditioning twice a day for three days, for a total of six sessions. Trace eyeblink conditioning involved presentation of a 250 ms tone conditioned stimulus CS, followed by a 500 ms stimulus-free trace interval which terminated in a 25 ms periorbital shock unconditioned stimulus (US). The rate of acquisition of trace conditioning increased across age groups. The spontaneous firing rate of ACC neurons also increased as a function of age. During conditioning trials there was a substantial developmental increase in the percentage of ACC neurons responsive to individual trial events (i.e., the CS, trace interval, US) and combinations of trial events from the first paired training session. The results indicate that the ACC undergoes developmental changes in neuronal coding of trial events.

Title: Anterior cingulate cortical control in visual attention

Authors: *J. KIM, E. A. WASSERMAN, L. CASTRO, J. H. FREEMAN;
Psychological and Brain Sci., Univ. of Iowa, Iowa City, IA

Abstract: The dorsal anterior cingulate cortex (dACC) has been proposed to control selective attention. However, the mechanisms of how dACC neuronal firing and theta rhythms contribute to visual attention have not been examined. In the current study, dACC neuronal activity was

recorded from multiple tetrodes while the rat performed a dACC-dependent visual attentional task using a touchscreen apparatus. On every trial, the rats were required to attend to the task-relevant visual stimulus while ignoring a task-irrelevant stimulus. Neuronal spike activity and theta were analyzed during task event periods (i.e., pre-trial, cue-onset, cuing/maintenance, and choice button selection). Both spike activity and theta power decreased during correct trials. Specifically, the spike activity was inhibited during the initial cuing phase for task-relevant stimulus selection and theta power was suppressed in the middle of cuing for maintaining the task information. Cross-correlation analysis showed that spike firing preceded theta in the pre-trial and maintenance periods when the rat made correct choices, whereas theta preceded spikes on the incorrect trials. Also, coherence in the correct trials was higher than incorrect trials during the maintenance period. Lastly, there was higher phase synchrony between dACC spikes and theta during the pre-trial period of the correct trials. The results show that dACC activity should be orchestrated in time and phase before cue-onset for the successful performance. The synchronized dACC activity leads the suppression of both dACC and theta during the correct selection and maintenance of task information. The results suggest that inhibited, yet synchronous, dACC firing is necessary for rodent visual attention tasks.

Title: Ontogeny of hippocampal CA1 activity during somatosensory trace eyeblink conditioning

Authors: *M. E. GOLDSBERRY, J. KIM, J. H. FREEMAN;
Univ. Iowa, Iowa City, IA

Abstract: Trace eyeblink conditioning (EBC) involves the association of a conditioned stimulus (CS) with an unconditioned stimulus (US) over a stimulus-free trace interval. The inclusion of this trace interval necessitates the involvement of late-developing forebrain structures such as the hippocampus and medial prefrontal cortex. Until recently, it was believed that development of these structures was the rate-limiting factor in the developmental emergence of trace EBC. Indeed, hippocampal neuronal activity shows an age-related increase in both complexity and task responsiveness during trace EBC. However, recent work from our laboratory suggests that sensory system development may also play a role. Training with the earlier-developing somatosensory system results in an earlier emergence of trace EBC in rats. Whereas learning

with a tone CS does not develop until postnatal day (P) 24, vibration-trained pups show robust levels of learning as early as P21. This suggests that the development of sensory input to the hippocampus may influence the development of trace EBC. The goal of the current study was to examine the activity of CA1 pyramidal cells during the acquisition of trace EBC with an early-developing CS modality. Rat pups were trained on P17-19, P21-23, and P24-26 while neuronal activity was recorded with a custom-built four-tetrode drive. Training consisted of two sessions per day, for a total of six sessions of somatosensory trace EBC. As seen in auditory trace conditioning, CA1 neurons responded to a number of trial events. However, the proportion of responsive neurons was significantly greater in pups trained with a vibration CS. The source of this difference appeared to occur in the proportion of neurons that were responsive during the trace interval. Pups trained with a vibration CS had a greater number of CA1 cells that showed increases in activity during the stimulus-free trace interval. Moreover, the magnitude of neuronal responding was greater in pups trained with a vibration CS. Peaks in magnitude were evident both at CS onset and at the beginning of the trace interval. These findings suggest that sensory input to the hippocampus may be playing a role in the development of trace EBC.

Title: Amygdala and prelimbic neuronal activity during retention of fear conditioning in developing rats

Authors: *K. L. BROWN, J. H. FREEMAN;
The Univ. of Iowa, Iowa City, IA

Abstract: Pavlovian fear conditioning has been used extensively to identify developmental changes underlying learning and memory. *In vivo* tetrode recording of neuronal activity has yielded important insights into developmental changes underlying associative motor learning [Ng and Freeman (2012), The Journal of Neuroscience, 32, pp. 6841-6850; Goldsberry, Kim, and Freeman (2015), The Journal of Neuroscience, 35, pp. 4238-4247], though *in vivo* recordings have yet to be applied to fear conditioning in developing rats. The present study is the first to use *in vivo* tetrode recordings during fear conditioning in developing rats. Postnatal day (P) 17 or 24 rats received presentations of white noise conditional stimuli (CS) and floor shock unconditional stimuli (US) in context A. Learned fear to the CS was measured by freezing to presentations of

the CS-alone in context B. Short-term retention was robust and comparable in rats at both age groups that had received paired (but not unpaired) CS-US presentations at training. However, long-term retention was robust only for P24 rats. Preliminary findings indicate robust, short-latency CS-related neuronal activity in the amygdala at testing in rats at both ages that had received paired CS-US training. In contrast, longer-latency CS-related prelimbic neuronal activity was evident only in rats that had received paired training on P24. These findings provide the basis for novel investigations into the mechanisms underlying developmental changes in memory retention and retrieval.

Title: Amygdala modulation of cerebellar learning

Authors: *S. J. FARLEY, J. H. FREEMAN;
Dept of Psychological and Brain Sci., The Univ. of Iowa, Iowa City, IA

Abstract: We examined the mechanisms underlying amygdala modulation of cerebellar learning. Rats were trained in a cerebellum-dependent associative motor learning task, delay eyeblink conditioning, while the central nucleus of the amygdala (CeA) was inactivated bilaterally. Training trials consisted of a pure tone conditioned stimulus (CS) paired with a periorbital stimulation unconditioned stimulus. Multiple tetrode recordings were collected from the cerebellar anterior interpositus nucleus during training sessions in rats given muscimol or vehicle infusions into the CeA. Profound deficits in learning and learning-related neuronal activity during acquisition and retention were observed in rats with amygdala inactivation compared to controls. After the inactivation phase during acquisition, rats were able to reach the same learning criterion as the control group. Short-latency neuronal responses never developed in rats originally trained during amygdala inactivation, but were robust in the controls. Monosynaptic projections from the CeA and parts of the auditory CS input pathway were investigated with anterograde and retrograde axonal tracers. An axonal projection from the CeA to the lateral basilar pontine nuclei was identified. Collectively, these findings suggest that the amygdala may gate auditory CS input to the cerebellum through projections to the pontine nuclei during associative motor learning.

Abstract: Background: In human addicts and rat models, environmental stimuli in contexts associated with previous drug use can provoke relapse to drug seeking. Specific patterns of sparsely distributed neurons, called neuronal ensembles, have been recently hypothesized to encode learned associations between these drug-associated contexts and drug effects. Methods: We trained male and female rats to self-administer ethanol in context A, extinguished drug-reinforced responding in a distinct context B and assessed context-induced reinstatement under extinction condition in context A or B (control group). After reinstatement test, rats were anesthetized and perfused with phosphate-buffered saline (PBS) and 4% paraformaldehyde; brain were remove and coronal sections from prefrontal cortex (PFC) and nucleus accumbens (Acc) were cut. We determined the proportion of dorsalmedial prefrontal cortex (dmPFC) neurons expressing Fos during the reinstatement test by double-labeling for Fos and the neuron-specific protein (NeuN). Results: On test day, re-exposure to the ethanol-associated context (context A) reinstated ethanol seeking behavior in rats (active lever presses=34.78 ± 6.32; n=14 rats), but not reinstated in the rats exposed to the extinction context (context B) (active lever presses=16.61 ± 2.59; n=14). We also observed a tendency of increase (p=0.08) in fos activation in rats exposed to context A (fos/mm2=60,6 ± 9,3; n=5) compared with rats exposed to context B (fos/mm2=38,9 ± 6,6; n=6). Double-labeling for Fos and NeuN indicated that only a small proportion of neurons were activated. In the dmPFC, Fos was expressed in 6,4 ± 0.4% and 5,6 ± 0.86% of all neurons after exposure to the contex A and B, respectively. Conclusions: Our results demonstrate that context-induced reinstatement of ethanol seeking and indicate that dmPFC may be involved in this behavior; meanwhile more rats are necessary to confirm this trend in dmPFC. Future experiments: We will analyze by double-labeling for Fos and NeuN immunohistochemical detection the neural activation in the accumbens (core and shell) and ventral medial prefrontal cortex. Furthermore, we will determined neuronal activation in Acc

brain area projecting to CPF during etanol context-induced tests by measuring double labeling of the retrograde tracer cholera toxin subunit B (CTb; injected in Acc) with Fos.

Title: Cellular consequences of extracellular signal-regulated kinase signaling in the nucleus accumbens evoked by reward-predictive cues

Authors: M. R. MARKS[1], J. C. MAUNA[1], A. E. ANDERSON[4], *E. THIELS[1,2,3];
[1]Dept. of Neurobio., [2]Ctr. for Neurosci., [3]Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA; [4]Dept. of Pediatrics, Baylor Col. of Med., Houston, TX

Abstract: After repeated exposure to a neutral stimulus paired with a reward, animals learn that the stimulus (conditioned stimulus, CS) predicts the reward. We showed previously that extracellular-regulated kinase (ERK) increases in the nucleus accumbens (NAc) of rats exposed to a food-predicting CS, and that NAc ERK activation is required for the ability of the CS to potentiate reward-seeking behavior (Shifflet *et al.,* 2008). ERK is known to regulate a wide range of cellular and intracellular functions. A potentially relevant intracellular target is the Kv4.2 voltage-gated potassium channel; when phosphorylated by ERK, channel function is reduced and, consequently, cell excitability and neuronal firing increased (Yuan *et al.,* 2002). We previously found that exposure to a CS causes an increase in ERK phosphorylation of the K4.2 channel in the NAc. Here, we wanted to determine whether (1) exposure to a CS causes induction of immediate early genes (IEGs) in the NAc whose expression is sensitive to neuronal activity, and (2) the effect of CS exposure on IEG induction is mediated by ERK. Rats in the experimental group were trained to associate a tone with sucrose pellets; control rats were exposed to the tone only and served to measure basal IEG expression. After 5 days of associative training, all rats were exposed to the tone only (test) to assess the effect of the CS on NAc mRNA levels of the neuronal activity-sensitive IEGs *arc* and *zif268*. Some rats received infusion of the specific ERK inhibitor U0126 into the NAc on one side and vehicle solution into the NAc on the other side shortly before the test. Samples of NAc harvested immediately after the test were analyzed with real-time qPCR. We found that (1) exposure to a CS causes a 3-fold increase

in mRNA level of both *arc* and *zif268* in the NAc but has no effect on the expression of these IEGs in the visual cortex (control region), and (2) the CS-evoked increase in these IEGs' mRNA level in the NAc is abolished in the presence of U0126. These findings indicate that NAc ERK is involved in the regulation of *arc* and *zif268* by appetitive CSs. Together with our previous findings that exposure to an appetitive CS causes an ERK-dependent increase in in Kv4.2 phosphorylation and findings by others that exposure to a CS causes an increase in NAc cell firing (e.g., Day et al, 2006), it is tempting to speculate that the increase in CS-evoked ERK activation causes an increase in NAc cell firing in part through its action on the Kv4.2 channel.

Title: Rapid sucrose sensing in food-restricted mice

Authors: *M. JIN[1], R. FROUSIOS[2], H. LU[2], A. KUO[2], G. SUH[2], R. FROEMKE[2];
[1]NYU Sch. of Med., New York, NY; [2]NYU Sch. of Med., New York City, NY

Abstract: Food restriction is used in many protocols as motivation for animals to perform in behavioral tasks. Here, we offer unconditioned C57BL/6 wild-type mice the choice between two nutritionally-different solutions - sucrose or sucralose - in order to investigate the effects of food restriction on decision-making in rodents. Assays were conducted using short-term water-restricted animals to first establish baseline preferences. The mice were then placed into either food restriction or control groups, in which food-restricted mice were maintained at 80-85% of their initial body weights. In overnight, 2 hour and 1 hour preference tests, food-restricted animals exhibited higher sucrose preference indices compared to the control animals (where 100% preference indicates only drinking from one solution and 50% indicates equal sampling of both sucrose and sucralose). To determine when this preference first develops, we built digital lickometers for each solution and preference tests were performed. In just 10 min upon introduction of the two solutions, food-restricted animals averaged a 68.5% preference for sucrose ($n=11$; $p<0.01$), while control animals averaged a 56.8% preference ($n=9$). Surprisingly, preference for sucrose in food-restricted animals seems to emerge in the first 10 s of the assay, with 73.4% preference for sucrose in food-restricted animals ($n=11$; $p=0.01$) and 47.9% preference in control animals ($n=9$). These preferences were observed in both naïve and experienced animals, suggesting that sucrose preference was not entirely learned by previous

exposure to the two solutions. These results show that food restriction can powerfully control decision-making and motivated behavior based on both sensory experience (taste) and internal state (hunger).

Title: Accumbens cue reactivity and affective state in a rat model of binge eating

Authors: ***J. STAMOS**[1], N. BELLO[2], A. PAWLAK[2], A. TYLOR[2], D. QUINTIN[2], K. COFFEY[2], J. KULIK[2], M. WEST[2];

Abstract: Project Summary: Binge Eating Disorder (BED) and Bulimia Nervosa (BN) are both complex disorder with social, behavioral, and self-image components. BN is characterized by repeated binge eating (BE) episodes where the person with BN consumes larger portions of food then they normally would in a discreet period of time. These episodes are followed by unreasonable compensatory behavior which can include self-induced vomiting, excessive exercise, or fasting. BED is characterized with episodes of BE as described for BN but with no compensatory behavior. BED has also been associated with feelings of negative affect and diminished self-worth. In recent years there has been growing interest in the involvement of the Nucleus Accumbens (Nac) in eating disorders such as BN and BED. However due to the complex nature of these disorders a comprehensive animal model for either of them may not be possible. In this study we used an established rat model of BE in order to study the effects of a history of BE on Nac cue processing. Here female Sprague Dawley (SD) rats were used as subjects for the experiment. Subjects were divided into two groups: binge eating (BE) and chow control (CC). The BE group was subjected to a six week treatment where they were twice weekly allowed 30 minutes of unlimited access to a mixture of sucrose and Crisco (10% sucrose by weight). All subjects had unlimited access to standard lab chow and water. Following

treatment all subjects had a 16 microwire array surgically implanted into their right Nac. Following recovery from surgery all animals were subjected to 10 consecutive daily pavlovian sessions in which a tone cue (CS) was pared with presentation of 32% sucrose solution (US). Each session was comprised of 56 trials with a variable interval of on average one minute. Behavioral measures such as number of missed trials and approach latency were measured over days. Neural data was divided into three phases for analysis: cue processing, approach, and consumption. Neural data from each phase was compared with analogues non-cued behavior from the same trial. Furthermore, ultrasonic vocalizations (USV) were recorded during each pavlovian session and were compared to USVs recorded in a baseline session. USVs can be used to give an accurate estimation of a rat's affective state and in this context was used to see if a history of binge eating would affect the animal's affective state. Preliminary behavioral results indicate that BE rats learn the pavlovian task faster than the CC group. USV data indicates a heightened response to the pavlovian chamber compared to baseline sessions in BE animals. Analysis of neural data is still forthcoming.

Title: Performance of a cue-triggered conditioned response elicits greater neural activity in the ventral pallidum when the cue is attributed with incentive salience

Authors: ***A. M. AHRENS**, T. E. ROBINSON, J. W. ALDRIDGE;
Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: In both humans and animals there is individual variation in the degree to which reward-paired cues can bias attention towards them and trigger food- and drug-seeking behavior. These individual differences can be modeled in rats using a Pavlovian conditioned approach procedure, in which a retractable lever (the conditioned stimulus, CS) is repeatedly paired with food reward. In this procedure, some rats begin to approach and interact with the lever when it is present ("sign trackers", STs), while other rats approach the food cup when the lever is present

("goal trackers", GTs). For both STs and GTs the lever acquires predictive value; however, for STs the lever is thought to also gain incentive value, making it attractive and capable of eliciting approach. The goal of the current study was to determine whether neural activity in the ventral pallidum (VP), a mesolimbic structure that encodes the motivational value of cues, reflects the enhanced incentive motivation seen in STs compared to GTs. We used single-unit in-vivo electrophysiology to examine neural firing in the caudal region of the VP during Pavlovian conditioned approach. We used video ratings to conduct a detailed analysis of behavior in STs and GTs, and examined VP neural activity in response to behavioral events characteristic of sign- and goal-tracking, including orienting to the CS, approach to the lever or food cup, and individual instances of contact with the lever or food cup. We found that VP neurons responded to the moment immediately preceding the first contact with the intended target in each trial (the lever for STs and the food cup for GTs). These responses to initial contact were stronger in STs than GTs, both in terms of percentage of responsive neurons and the magnitude of responses. The same cells did not respond to subsequent contact events within the same trial, suggesting that these responses were not related to specific motor actions. In addition, for STs, many of the neurons that responded to lever contact also responded to the moment when rats entered the magazine to retrieve the food pellet. These results suggest that neurons in the caudal VP encode the motivational state that immediately precedes the acquisition of a desired reward, which for the STs includes both the lever itself and the food pellet. Furthermore, these results show that the intensity of this motivational state depends on the degree to which a cue acquires incentive-motivational value.

Title: Motivational activation of dopamine neurons is greater in sign-trackers compared to goal-trackers

Authors: L. FERGUSON[1], A. M. AHRENS[1], L. G. LONG[1], *J. W. ALDRIDGE[2];
[2]Psychology, [1]Univ. of Michigan, Ann Arbor, MI

Abstract: The purpose of this study is to investigate individual differences in the attribution of incentive salience to Pavlovian cues through activation of dopamine neurons. We recorded neural activity in the ventral tegmental area (VTA) in rats performing a Pavlovian approach task

(Flagel et al., 2007). In this behavioral model, a conditioned stimulus (CS) consisting of an illuminated lever is presented for 8 seconds at random intervals followed by delivery of a food reward (unconditioned stimulus, US). All animals learned the predictive nature of the cue (illuminated lever entry into cage). Rodents that preferentially approach the lever itself ("sign-trackers", STs) were compared to animals that predominantly approach the location of reward receptacle ("goal-trackers", GTs). Following training to determine phenotype, rats had tetrodes implanted for neural electrophysiological recordings in VTA. Dopamine cells were characterized by spike waveform shape and firing rate (Roesch et al., 2007) and in 8 sessions, the dopaminergic nature was confirmed by a systemic apomorphine (0.75 mg/kg) test. Electrode bundle placement was confirmed histologically. Firing rates and magnitudes of responses in relation to Pavlovian behaviors, cue presentation, and reward delivery were assessed. We identified 42 dopamine and 48 non-dopaminergic neurons. Overall, 72% of neurons were responsive (85% dopaminergic, 60% non-dopaminergic). GTs and STs both showed responses to the initial (400ms) lever presentation (CS1) and also lever retraction (CS2). However, higher firing rates were sustained during the 8s interaction period only in STs, while they interacted with the lever. Even though GTs interacted just as vigorously with the goal there was no concomitant neural activation indicating that motor differences do not account for the findings. Most responsive neurons in STs were dopaminergic (50% vs. 18%). Further, firing rate magnitudes for both dopaminergic and non-dopaminergic units rates were higher in STs. Neurons outside the VTA were not responsive to the task. These results support an important role for dopamine neurons in the attribution of incentive salience to reward predictive cues and underscore the consequences of potential differences in motivational behavior between individuals. Flagel SB et al. Individual differences in the propensity to approach signals vs goals promote different adaptations in the dopamine system of rats. Title: Effects of prior stress exposure on motivation for sucrose rewards: Possible sex differences

Authors: *E. M. ANDERSON, M. MCWATERS, Z. BOND, N. MULLEN, Z. AHMAD, L. MATUSZEWICH;
Northern Illinois Univ., DeKalb, IL

Abstract: Dysfunction of motivational systems for natural rewards has been implicated in several disorders, including depression, substance abuse, and obesity (Jones, et al., 2013; Volkow & Wise, 2005). Stress is frequently hypothesized as a contributing factor to these disorders in humans and animals. Likewise, sex differences have been found in the prevalence of motivational disorders and in the response to stress, however it is not known if stress alters motivation for sucrose rewards in a sex dependent manner. Therefore, the goal of the current research project was to better characterize the motivational changes to a natural reinforcer following chronic stress exposure in male and female rats. Adult rats were either exposed to chronic unpredictable stress (CUS) for 10 days or handled daily but received no additional stress (CON). One week following the last day of stress, rats were trained to lever press using a fixed ratio (FR) which increased across five days. The rats were then tested on a progressive ratio (PR) schedule to assess motivation for a sucrose reward. Following PR, rats were re-trained on a FR1 for a total of 10 days and then their behaviors were extinguished to 10% of the FR1 responding. The day after extinction criteria was reached, yohimbine was administered to measure stress-induced reinstatement responding. Female rats showed a significantly greater number of responses and rewards earned compared to males in the progressive ratio test ($p<.01$). Prior exposure to CUS did not have a significant influence in PR responding. When re-trained on a FR1 schedule, there was also a sex difference in responding with males making a significantly greater number of responses and earning more rewards compared to females ($p<.05$). Interestingly, female rats exposed to CUS earned a greater number of rewards overall on the FR1 compared to CON females, while males exposed to CUS earned fewer than CON males ($p<.05$). Following extinction, both male and female rats previously exposed to CUS had a significantly greater increase in yohimbine-induced reinstatement compared to CON rats ($p<.05$). Overall, the data suggests that there are sex differences in sucrose motivation, but the impact of prior CUS differs by the testing parameter. Following extinction, prior exposure to CUS in both sexes potentiated responding to the acute pharmacological stressor, yohimbine. The current findings provide insight into the motivational differences between males and females and future research will investigate whether the current findings extend to stimulants, such as methamphetamine.

Title: Reward variety effects on instrumental actions in rats

Authors: *B. HALVERSTADT, H. C. CROMWELL;
Bowling Green State Univ., Bowling Green, OH

Abstract: Humans and animals respond to diversity in food items by increasing intake and appetitive behaviors, and this observed variety effect reflects changes in the motivational value of such rewards. Previous work on the effects of food variety has posed two mechanisms by which these changes in motivation may come about. Variety may slow habituation processes by decreasing exposure to any one food item. Variety effects may be due to incentive contrast, whereby comparisons between items impact their relative value. The current work uses an experimental paradigm with more than one level of variety and a chain of two different instrumental actions in series, rather than a single type of operant response, to expand on what is known about how reward variety affects motivational processes. This study also adds predictive cues about impending outcomes, allowing examination of the potential impact of factors such as preference. We investigated rats' responses to qualitative reward variety presented in different contexts. We used three flavors of sucrose rewards to test rats' patterns of operant responding in three contexts: no, low, and high variety (one, two and three flavors, respectively). We compared response patterns across no, low and high variety contexts, and we compared responses in no variety contexts presented before and after a variety context. We also tested rats' response patterns when predictive cues about upcoming outcomes were added to these conditions. We paired a distinct tone cue to each of the three flavors, which signaled the flavor of the upcoming reward. This study aimed to examine how variety influences motivation. If variety is intrinsically rewarding it would boost the motivational value of all outcomes presented in a variety context irrespective of the original value of any individual outcome. We predict that rats will exhibit a general invigoration of responding in variety compared to no variety contexts, and that the degree of responding will be related to the level of variety (low vs high). If variety is rewarding due to some relative comparison process, it would differentially boost or diminish the value of individual outcomes relative to others when presented in a variety context. We expect that predictive cues about impending outcomes will provide short-term indicators of variety that influence responding based on comparisons to the other outcomes, and that this differential responding may be related to flavor preference. The results of this study have meaningful implications for deepening our understanding of motivational processes in general, as well as for informing potential clinical approaches to dietary disorders.

Title: Chromatin remodeling and gene induction in sign and goal-tracking rats

Authors: *E. HARVEY, K. GUARDADO, J. OCHOA, P. KENNEDY;
Univ. of California Los Angeles, Los Angeles, CA

Abstract: Recent work has identified individual differences in the attribution of incentive salience to discrete and contextual stimuli. When trained in the same Pavlovian appetitive procedure, some animals exhibit approach to a conditioned stimulus while others approach the site of reward delivery. These animals are characterized as sign-trackers and goal-trackers, respectively. Differences between sign- and goal-trackers extend to other behaviors; goal-trackers exhibit stronger context-induced renewal of drug-seeking (Saunders et al., 2014) and greater freezing response to shock paired contextual stimuli (Morrow, Maren, & Robinson, 2011), while sign-trackers undergo more severe discrete cue-induced reinstatement of drug-seeking (Saunders and Robinson, 2011) and exhibit greater cue-conditioned fear (Morrow, Maren & Robinson, 2011). The molecular mechanisms supporting the acquisition and expression of one type of memory over another - contextual versus discrete cue salience - remain largely unknown. Chromatin remodeling can facilitate or suppress memory formation through bidirectional regulation of plasticity related genes (Cortes-Medoza et al. 2013). To investigate chromatin regulation of gene expression in incentive memory formation and behavioral bias, we first trained rats to asymptote in a Pavlovian Conditioned Approach (PCA) procedure known to induce varying expression of sign- and goal-tracking behavior. We then assessed histone modifications associated with transcriptional activation and repression and the induction of activity and plasticity related genes across brain regions implicated in discrete cue and context learning.

Title: Age-related differences in licking microstructural indices of incentive motivation and hedonic impact in rats

Authors: *I. A. MENDEZ[1], N. P. MURPHY[1], S. B. OSTLUND[2], N. T. MAIDMENT[1]; [1]Psychiatry and Biobehavioral Sci., UCLA, Los Angeles, CA; [2]Anesthesiol. and Perioperative Care, UCI, Irvine, CA

Abstract: Analysis of licking microstructure may be used to discern the incentive properties from the hedonic impact of food rewards. Specifically, the number of licking bouts a rat voluntarily engages in reflects incentive motivation for food, whereas the average length of bouts once engaged, reflects hedonic properties. While age-dependent differences in food consumption have been reported, the specific processes (i.e. incentive versus hedonic) driving these differences are unclear. To this end, licking microstructure during consumption of sweet solutions was studied in adult (20 weeks old) and aged (21 months old) rats under sated and hungry conditions. Animals were trained to lick for a 0.01% concentration of the non-caloric sweetener, saccharin, under sated conditions. Following training, microstructural licking responses to varying concentrations of saccharin (0.005%, 0.01%, 0.02%, and 0.04%) and sweetened condensed milk (2.5%, 10%, 25%, 50%) were studied under sated and hungry (12 hr food deprivation) conditions using a lickometer. Aged rats emitted significantly fewer licking bouts for 0.01% saccharin during training and across a range of saccharin concentrations while sated, indicating a motivational deficit. When hungry, significantly fewer bouts of licking were again observed in aged rats. In addition, a significant interaction between age and concentration was observed for mean bout length, with aged rats emitting shorter bouts, but only for the 0.005% saccharin concentration. When sweetened condensed milk was used, aged rats exhibited significantly fewer bouts of licking and shorter bout lengths across all concentrations when tested sated. Despite generally attenuated licking, aged rats displayed significantly higher locomotor activity than adult rats across all tests. Together, these findings suggests that the motivational, and in some cases, hedonic impact, of caloric and non-caloric food rewards are attenuated in aged rats. Understanding how aging impacts incentive motivation and reward palatability may inform development of targeted cognitive-behavioral and pharmacological therapies for age-dependent impairments in reward seeking and taking behavior.

Title: Bidirectional value coding in the habenula projecting pallidum is essential for optimal decision-making

Authors: *M. STEPHENSON-JONES, S. AHRENS, M. PENZO, A. VAN HUIJSTEE, K. YU, B. LI;
Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: The ability to weigh information about rewarding and aversive stimuli and choose appropriate behavioral actions is essential for survival. Brain circuits including the basal ganglia and the mesocorticolimbic dopamine system subserve such behavioral choice. Recent findings have indicated that the lateral habenula (LHb), and its input from the habenula-projecting globus pallidus (GPh) play a key role in conveying negative motivational signals that can suppress dopaminergic activity and lead to aversion. However, neurons in the GPh and LHb are also inhibited by reward and silencing the LHb is rewarding in mice. While this suggests that the GPh-LHb circuitry may integrate reward and aversive information, how these signals are used to guide behaviour is unknown. To address this question we recorded from GPh neurons, while mice associated different sounds with rewarding and aversive outcomes. As in primates, expectation of an aversive stimulus led to an increase in neuronal firing, while expectation of a rewarding stimulus caused a decrease in neuronal firing. In both cases the neuronal responses were graded depending on the expected magnitude of reward or punishment. Consequently individual GPh neurons can integrate appetitive and aversive stimuli, to bidirectionally encode value. To determine the functional consequence of these firing rate changes we optogenetically activated the GPh selectively during a probabilistic switching task. Activating this pathway decreased the value of an action and led to switching during the task. This suggests that the GPh neurons may encode how “bad” an action is through an increase in firing. Indeed selectively reducing the glutamatergic drive onto these neurons, by blocking synaptic trafficking of GluR4-containing AMPA-Rs, decreased the ability of mice to integrate negative feedback and led to aberrant perseverance in the task. In contrast, optogenetic inhibition of these neurons was sufficient to drive reward-like behavior and increase the value of an action. This suggests that these neurons may also encode how “good” an action is through a decrease in firing. Indeed reducing the GABAergic input to these neurons, by selectively ablating the GABAA receptor γ2 subunit, impaired the ability of mice to integrate positive feedback from rewards. Together our results show that GPh neurons bidirectionally encode the expected value of an action. Without these bidirectional changes mice may not be able to use either positive or negative information to guide behaviour, suggesting that the GPh represents a key node where information of opposing valence is combined to generate a unified value code.

Title: Examining the involvement of the serotonin 2c receptor in goal-directed motivation

Authors: *M. BAILEY[1], V. WINIGER[4], C. MEZIAS[5], C. WILLIAMSON[2], P. BALSAM[5], E. SIMPSON[3];

Abstract: Behavioral assays that isolate distinct components of motivation have determined that patients with schizophrenia and depression often display normal hedonic reactions in the moment, but have a reduction in the willingness to work for goals due to altered effort-reward computations. To date, however, there are no effective pharmacological treatments for specifically alleviating this reduction in willingness to work. Here we describe experiments using mice to explore a potential pharmacological treatment for amotivation. We have employed our battery of operant behavioral tasks to determine what specific aspects of motivation may be enhanced by treatment with a functionally selective 5-HT2c receptor ligand (SB242084). In addition to two widely used assays of motivated behavior, the progressive ratio and the effort based choice task, we also developed a progressive lever hold-down task in which the bar must be continuously depressed for progressively longer durations to obtain reward. This novel assay of motivation differentiates between increases in responding caused by generalized hyperactivity from those produced by increased motivation. SB242084 increases responding on a progressive-ratio schedule of reinforcement in both male and female wild type mice. SB242084 also increases willingness to work in an effort-based choice paradigm. Finally, this increase in responding is not due to hyperactivity because SB242084 also increases how long subjects will hold a lever down to earn rewards, but did not impact efficiency (rewards/lever press) in our progressive lever hold-down assay. Further, a series of experiments using the progressive ratio determined that the drug acts in an acute manner, and the behavioral effects can be reinstated repeatedly as multiple administrations of the drug over time lead to behavioral increases of the same magnitude. Our results suggest that targeting the 5-HT2c receptor can have a selective impact on effort-reward computations underlying action. This manipulation can be used for investigating the neural mechanisms underlying the specific aspects of motivation disrupted by disease.

Title: Optogenetic dissection of neuroanatomical and psychological components underlying amygdala-mediated incentive motivation

Authors: *S. M. WARLOW[1], M. J. F. ROBINSON[2], K. C. BERRIDGE[1];
[1]Psychology, Univ. of Michigan, Ann Arbor, MI; [2]Wesleyan Univ., Middletown, CT

Abstract: We have previously shown that optogenetic excitation of central amygdala (CeA) causes an intensely narrowed preference for a laser-paired sucrose reward over an alternative identical sucrose reward. Similarly, CeA excitation causes an intense preference for laser-paired cocaine over an identical cocaine reward. Here, we aimed to separately examine these effects neuroanatomically and psychologically. We first neuroanatomically assessed if the laser control of cocaine preference is localized to CeA and not to basolateral amygdala (BLA), similar to the sucrose produced localization. Second, we psychologically assessed which of the three psychological components contained in our instrumental preference test contributes most to CeA's laser control of preference: 1) Pavlovian incentive salience ('wanting' the CS) 2) Instrumental habit reinforcement (Stimulus-response habits) or 3) Sucrose/cocaine outcome enhancement (making it a more valued reward). Preliminary findings suggest that the CeA focused preference may be driven more by incentive salience than the other two components. Overall, these tests may help advance our understanding of how excessive motivation in various pathologies is directed towards a single target.

Title: Optogenetic manipulation of posterior paraventricular thalamic circuits alters chocolate intake

Authors: *K. URSTADT, D. A. ALI, E. R. GRANT, N. M. RABAH, K. C. BERRIDGE; Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Prior studies implicate the posterior paraventricular thalamus (pPVT) in controlling food intake; those data show that pPVT lesions and inhibition with muscimol increase intake. Paradoxically, pPVT excitation with orexin A also increases intake. Therefore, we sought to explore how optogenetic excitation or inhibition of the pPVT may similarly alter intake of normal chow and highly palatable food. Two groups of four adult Long Evans rats received pPVT microinjection of adeno-associated viruses coding for channelrhodopsin or halorhodopsin, and optic fiber implants were aimed at the pPVT, central amygdala (CeA), and nucleus accumbens shell (AcbSh). Rats were tested for one hour in an open field chamber with access to water, chocolate fragments, and chow. Yellow laser-mediated inhibition of the pPVT increased chocolate intake (10.3 +/- 0.8 g) relative to intake without laser (6.4 +/- 1.1 g; p = .049), but blue laser-mediated excitation of the pPVT did not significantly alter intake. Excitation of pPVT to AcbSh projections suppressed chocolate intake (0.9 +/- 0.9 g) relative to intake without laser (4.0 +/- 0.0 g; p = .023), but inhibition of this projection did not significantly alter intake. Manipulations of pPVT to CeA projections did not significantly alter intake. Chow intake remained unchanged in all tests. These data suggest that 1. pPVT optogenetic inhibition may mimic the appetitive effects of muscimol microinjections, and that 2. excitation of the pPVT to AcbSh circuit suppresses appetitive behavior.

Title: Junk-food enhances calcium-permeable AMPAR transmission in the nucleus accumbens and cue-induced motivation

Authors: *M. F. OGINSKY, R. C. DERMAN, C. W. NOBILE, C. R. FERRARIO; Univ. of Michigan, Ann Arbor, MI

Abstract: Foods with high sugar and fat content ("junk-foods") are readily available and contribute to obesity. Recent work in people and rodents shows that diet-induced obesity is associated with alterations in brain circuits that mediate reward and motivation. For example, exposure to food-cues increases the fMRI BOLD signal in the nucleus accumbens (NAc) more strongly in obese vs. non-obese people. This enhanced NAc response may be driven in part by glutamate transmission, as AMPARs provide the main source of excitation to the NAc, and AMPARs play critical roles in the incentive-motivational properties of reward-paired cues. Furthermore, the NAc activity mediates cue-induced motivation in non-obese rats, and we recently showed that cue-induced motivation is enhanced in rats susceptible to obesity. These data suggest that alterations in AMPAR function in the NAc may contribute to enhanced motivation for food-cues in obese individuals. However, no studies have examined the effects of diet-induced obesity on NAc AMPAR-transmission, nor is it clear whether interactions between predisposition and consumption of "junk-food" produce different neurobehavioral adaptations in susceptible individuals. Therefore, we examined the effects of "junk-food" exposure on NAc AMPAR-mediated transmission, AMPAR-expression, and cue-induced motivation in obesity-prone (OP) and obesity-resistant (OR) rats. We found that junk-food exposure followed by a deprivation period (14 d) enhanced CP-AMPAR transmission in the NAc core of OP rats. Interestingly, this diet manipulation did not produce differential weight gain in OP vs. OR rats, suggesting that the induction of CP-AMPARs was not due to weight gain per se. Consistent with our observations in selectively bred rats, outbred rats that gained weight during junk-food exposure showed greater increases in NAc GluA1, but not GluA2, surface protein expression compared to rats that did not become obese on the same diet. Together, these data suggest that consumption of "junk-food" enhances NAc CP-AMPAR transmission in susceptible individuals. This differs somewhat from cocaine-induced up-regulation of CP-AMPARs, which requires extended intravenous cocaine exposure and a longer drug free period (~21 d). Additionally, CP-AMPARs mediate cue-induced cocaine-seeking, but their role in motivation for food-cues related to obesity has not been examined. Our preliminary studies show that consumption of "junk-food" enhances cue-induced approach. We are currently investigating the contribution of enhanced CP-AMPAR function to increased cue-induced motivation after "junk-food" exposure.

Title: Optogenetic activation of the central amygdala generates addiction-like preference for reward despite adverse consequences

Authors: *M. J. ROBINSON[1], R. L. TOM[2], A. AHUJA[2], H. MANIATES[2];
[1]Psychology, [2]Neurosci. & Behavior, Wesleyan Univ., Middletown, CT

Abstract: Drug and behavioral addictions are characterized by focused pursuit of a single reward above all others. Motivation to pursue reward has frequently been associated with structures in the mesolimbic dopaminergic system. The amygdala interacts with key structures in this pathway, including the nucleus accumbens, ventral tegmental area, and substantia nigra, suggesting that it plays a role in reward processing and generating motivation. In this study, we explored how stimulation of the central amygdala (CeA) via optogenetic activation of channelrhodopsin-2 (ChR2) modulates choice, causing specific rewards to be almost compulsively preferred. Rats were trained on an operant task in which they could choose to respond on either of two levers to receive a sucrose pellet. One of the two levers was paired with laser stimulation of the central amygdala upon receipt of the pellet. Rats developed an almost exclusive preference for the laser-paired reward over the otherwise equal unpaired reward. We found that this preference for stimulation-paired reward persists even when a much larger sucrose reward is offered as an alternative, or when this preferred reward is paired with adverse consequence in the form of an electric footshock. We also found that optogenetic activation of the central amygdala does not generate a preference when it is not paired with reward, suggesting that this activation increases the value of reward but is not independently rewarding. Our findings suggest that the central amygdala is involved with assigning increasing value to reward and generating narrowly focused motivation to seek out reward. These results may indicate that mesocorticolimbic dysfunction, particularly in the CeA, can bias motivation and desire to generate addiction-like behavior, a desire that will persist in the face of more rewarding alternatives and adverse consequences.

Title: 'Liking' and 'wanting' for a sweet reward in rodents maintained on a prenatal and lifetime junk food diet

Authors: *E. N. LESSER[1], S. J. MI[2], A. ARROYO-RAMIREZ[2], M. J. F. ROBINSON[2];
[1]Wesleyan Univ., Oak Park, IL; [2]Neurosci. & Behavior, Wesleyan Univ., Middletown, CT

Abstract: Obesity rates have shown a dramatic global increase in the last few decades. The increase in availability, palatability and advertising of high-sugar and high-fat junk foods is largely to blame for this trend. The result is a well-documented ever-growing population of overweight and obese individuals. The greatest risk, however, may be for the escalating number of children born to obese and overweight parents and exposed to a junk food diet even before birth. Excessive exposure to junk food from birth may negatively impact typical brain development and disrupt the functioning of motivation and reward pathways. In this study we investigated the effects of a junk food diet composed of chocolate chip cookies, peanut butter, potato chips and chocolate milk powder on cue-motivated behavior, or 'wanting', as well as the effects of diet on hedonic 'liking' for sweet tastes. Tests were carried out in three offspring populations that were exposed to a mash of human junk food, standard chow, or both. All animals were exposed to the assigned diet prenatally through the mother and maintained on the diet throughout life. Properties of 'wanting' for food-paired cues were examined using a conditioned place preference paradigm and Pavlovian conditioned approach (autoshaping). While each group showed a conditioned place preference for a context paired with junk food, the shift in preference appeared to be greatest for chow-fed animals. Similarly, cues predictive of sucrose delivery appeared to elicit less cue-directed behaviors in animals chronically exposed to junk food. Finally, 'liking' was assessed using a taste reactivity paradigm. Animals fed a standard chow diet showed increasing pleasure responses with greater concentrations of sucrose solution (1%, 3%, 9%). In contrast, animals exposed to a junk food diet displayed a blunted sensitivity to increasing concentrations of sucrose, showing similar amounts of 'liking' responses to each sucrose solution. Because the animals maintained on a junk food diet did not gain significantly more weight than the standard chow animals, these findings suggest that there may be neural differences in 'liking' and 'wanting' systems produced by a junk food diet that does not dependent on weight gain.

Title: Optogenetic stimulation versus inhibition of orbitofrontal and insular cortical hotspots on hedonic and motivated behaviors

Authors: *D. C. CASTRO, K. C. BERRIDGE;
Psychology, Univ. of Michigan, Ann Arbor, MI

Abstract: Recently, our lab has found two novel hedonic hotspots in the cortex where mu opioid or orexin receptor agonist microinjections cause enhanced 'liking' reactions to the taste of sucrose. One of these hotspots is located in rostromedial orbitofrontal cortex (OFC) and the other is localized to caudal insular cortex (IC). Here, in the OFC or IC hotspots, we further probed the nature of these new hotspots by optogenetically stimulating neurons infected with either channelrhodopsin (ChR2) or halorhodopsin (NpHR3.0). After four weeks of incubation, rats were tested on taste reactivity, food intake, self stimulation, operant place preference, and social interactions tests with laser administration. These tests may further our understanding of whether these novel hotspots use generally excitatory or inhibitory mechanisms, and whether their hedonic amplification abilities transfer to other reward-related behaviors.

Title: Counteracting hyperpolarization mediated motivation with optogenetic depolarization in the nucleus accumbens shell

Authors: *S. L. COLE, C. I. COLMENERO, N. A. MOSTOVOI, K. C. BERRIDGE;
Univ. of Michigan, Ann Arbor, MI

Abstract: The nucleus accumbens (NAc) shell has been heavily implicated as a site capable of mediating multiple aspects of motivation. One popular hypothesis is that NAc-mediated motivations are produced by inhibition of NAc GABAergic neurons, subsequently disinhibiting downstream targets, such as the lateral hypothalamus, ventral pallidum, and ventral tegmental area, from tonic inhibition, to motivate behaviors. For example, DNQX, an AMPA-glutamate receptor antagonist produces intense eating when injected into the rostral NAc shell. Here, we tested whether the mechanism of DNQX-generated motivation is through passive inhibition of the NAc, by combating DNQX microinjections with optogenetic stimulation. Consistent with previous studies, we demonstrate that DNQX microinjections produce intense eating behavior.

Further, we show that channelrhodopsin (ChR2) depolarization of NAc neurons at the site of microinjection is capable of abolishing DNQX-induced feeding. These findings demonstrate that NAc hyperpolarization is necessary for DNQX-mediated motivation and indicates that NAc inhibition is a key mechanism in motivated behavior.

Title: Functional connectivity of a brain network is disrupted in children with obesity while viewing high-calorie foods

Authors: *B. A. CHODKOWSKI[1], K. D. NISWENDER[2,3], R. L. COWAN[1];
[1]Psychiatric Neuroimaging Program, Dept. of Psychiatry, [2]Div. of Diabetes, Endocrinol. and Metabolism, Dept. of Med., Vanderbilt Univ. Sch. of Med., Nashville, TN; [3]Tennessee Valley Healthcare Syst., Nashville, TN

Abstract: Background: Both central and peripheral signals drive healthy feeding behavior. However, little is known about functional brain differences in childhood obesity. Ubiquitous exposure to images of food strongly influences eating behavior and may contribute to overeating (drive), reduced ability to control eating (executive control), and subsequent obesity. We hypothesize that a disruption in functional connectivity among brain regions associated with reward, drive, and control contributes to obesity. **Methods:** We probed functional connectivity during a food-cue functional magnetic resonance imaging (fMRI) task via psychophysiological interaction (PPI) analysis. PPI analyses assess the change in functional connectivity between two brain regions during a change in psychological state. We acquired fMRI data from 34 children (16 girls; age = 10.3 (±1.3)). Subjects viewed images of nature, food, and a white crosshair on a black background. The psychological context for our PPI analysis contrasted brain activity while viewing high calorie images vs. low calorie images. For the physiological part of our PPI analysis, we separately investigated two pairs of regions: (1) amygdala and nucleus accumbens (NAc); and (2) anterior cingulate cortex (ACC) and NAc. The NAc, the hub of our network, is associated with reward. The amygdala is associated with motivation and incentive (drive); the ACC is associated with response inhibition (executive control). **Results:** We found differences in PPI between healthy-weight and obese children. Among healthy-weight children, as drive PPI

increases, executive control PPI increases ($p \leq 0.01$; $R^2 = 0.37$). Among children who are obese, as drive PPI increases, executive control PPI decreases ($p \leq 0.03$; $R^2 = 0.27$). The slopes of the regression for each group are statistically significantly different ($p \leq 0.0009$; $F = 13.60$). **Conclusions:** Our results show that for healthy-weight children, as the PPI functional connectivity between a drive-associated region and NAc increases, so too does the functional connectivity between a control-associated region and NAc increase. This positive relationship between drive and control connectivity suggests that healthy weight is maintained when control keeps pace with drive. However, for children who are obese, as PPI drive increases, PPI control decreases, suggesting a loss of control. We show that a reward-related brain network is disrupted in children with obesity.

Title: Examining the reliability of frontal alpha asymmetry both within a day and between consecutive days

Authors: *R. A. HICKS, W. E. MCILROY;
Kinesiology, Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Measurement of EEG frontal alpha asymmetry (FAA) has been suggested to provide information about processing of affect. More specifically, left frontal activity is suggested to correspond with approach motivation while right frontal activity is suggested to correspond with avoidance motivation. Consequently, it is implicated as a potential biomarker for depression risk. The long-term focus of this line of work is to determine if state changes evoked by bouts of exercise modulate affect and depression. However, as an important first step it is necessary to confirm the test-retest reliability of FAA over short term intervals. Reliability of FAA has been shown to be modest over periods of a week or greater but the test-retest reliability in short-term conditions has yet to be established. The objective of this study is to quantify the test-retest reliability of FAA both within a day and between consecutive days. Young healthy adults underwent 4 sessions of EEG collection in the morning and afternoon of two consecutive days. EEG collection occurred in a sound proof booth after a 10-minute quiet period. EEG collection consisted of eight 1-minute collections alternating eyes open or eyes closed in two randomized counterbalanced orders (COOCOCCO or OCCOCOOC). EEG data was referenced to linked

mastoid montage. FAA was calculated as the alpha power (8-12Hz) differences between right and left frontal electrodes. Preliminary results show no effect of daytime or significant changes in FAA between days. Participants had a positive FAA value on average suggesting relatively greater left frontal activity. Intraclass correlations show that across the 4 measurements, FAA has acceptable test-retest reliability (> 0.6) when measured within two consecutive days. FAA appears to be a reliable measure in short-term intervals (within and between days). This provides a necessary background on which to evaluate short term state dependent changes, specifically evoked by exercise, on FAA to inform understanding about neurophysiologic links between exercise and (depression) affect.

Title: The role of the mirror system in the audio and visual perception of emotional hand actions

Authors: ***L. MCGARRY**[1,2,3], R. RAMSAY[2], F. A. RUSSO[3], E. S. CROSS[2];
[1]Psychology, Brain and Mind Institute, Univ. of Western On, London, ON, Canada; [2]Psychology, Bangor Univ., Bangor, United Kingdom; [3]Psychology, Ryerson Univ., Toronto, ON, Canada

Abstract: Background: Neural simulation of other people's emotional movements has been hypothesized to underlie our capacity for empathy. Research suggests that the human mirror system (MS) is activated to a greater extent during (a) visual observation of emotional vs. non-emotional body actions, and (b) auditory observation of emotional vs. non-emotional vocalizations. Questions remain regarding how the MS responds during auditory perception of emotional vs. non-emotional nonvocal actions. In addition, it is not clear whether top-down processes play a role in MS engagement. The current fMRI study examined emotional facilitation of the MS towards hand movements in auditory and visual modalities while manipulating top-down engagement. Methods: The current study employed a 2 (Modality: auditory, visual) x 2 (Judgment type: emotional, non-emotional) x 2 (Stimulus type: emotional, non-emotional) factorial design. A localizer task was employed at the beginning of each fMRI session in order to isolate voxels involved in the auditory or visual perception, as well as execution, of hand actions in every participant. Participants observed a series of emotional or non-emotional hand actions (eg., crumpling up a sheet of paper angrily, or calmly turning a book

page), presented via vision or audition. In one condition, they were asked to judge whether the action they just observed was emotional or neutral in nature. In another condition, they made non-emotion based judgments of whether the action they just observed was completed using one hand or two hands. Analysis: A MS-localizer mask was created using a conjunction analysis of brain activity elicited during the localizer task. This consisted of activity involved in viewing and execution, as well as hearing and execution, of hand movements ((Execute ∩ Hear) ∪ (Execute ∩ View)). Effects of the experimental manipulations were then analysed within this mask. Results: There was greater activation towards emotional vs. neutral stimuli in several MS areas, including the inferior frontal gyrus (IFG) towards visual stimuli, and the IFG and supramarginal gyrus towards auditory stimuli. In addition, the auditory modality induced greater responsiveness to positive emotions, whereas the visual modality induced greater responsiveness to negative emotions. The top-down manipulation elicited enhanced MS activation during non-emotional judgments (number of hands required to complete an action). Results suggest that emotional movements facilitate MS functioning, while task manipulations involving simulation may also affect MS responsiveness.

Title: Early reward-related activity depends on cue salience in LIP but not in the amygdala

Authors: *M. L. LEATHERS[1,2], C. OLSON[1,2];
[1]Ctr. for the Neural Basis of Cognition, Carnegie Mellon Univ., Pittsburgh, PA; [2]Dept. of Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: In monkeys choosing between rewards and penalties, neurons in parietal area LIP respond strongly to cues associated with both large rewards and large penalties (Leathers and Olson, Science 338: 132-5, 2012). In contrast, neurons in the amygdala respond strongly only to cues associated with large rewards (Leathers and Olson, Program No. 206.12, Neuroscience

2014 Abstracts). These observations suggest that firing in LIP reflects cue salience, as determined by association with a potent positive or negative outcome, whereas firing in the amygdala represents cue value. To test this idea, we trained monkeys to make value-based decisions using cues that could not acquire differential associative salience. On every trial, the monkey chose, with a delayed saccade, between a "safe" cue predictive of moderate reward and an "ambiguous" cue predictive either of large reward or of no reward. The ambiguous cue was a morph containing subtly different proportions of a high-value parent image and a low-value parent image. Choosing the ambiguous cue yielded the outcome associated with the more heavily weighted parent image. We manipulated the discriminability of the ambiguous cues so as to maintain the rate of correct choices at 75%. Under this manipulation, cues signaling large reward and no reward were physically so similar to each other that to identify either required allocating voluntary attention to it. This precluded early automatic capture of attention by the cue associated with large reward. Accordingly, we predicted that early activity correlated with the size of the predicted reward would be attenuated in LIP but not in the amygdala. The key analysis concerned trials in which the monkey chose an ambiguous cue placed in the response field. Across these trials, the only factor that varied was the identity of the ambiguous cue, which predicted either large reward or no reward. In LIP, the population signal reflecting predicted reward-size was weak and late. The fraction of individual neurons carrying a statistically significant reward-size signal was no greater than expected by chance. In the amygdala, the population signal reflecting predicted reward-size was stronger and earlier. The fraction of individual neurons carrying a statistically significant reward-size signal was significantly greater than expected by chance. These results support the view that neuronal activity in LIP reflects cue salience whereas neuronal activity in the amygdala encodes cue value.

Title: Neural responses to emotionally expressive faces are modulated by attention in amnestic mild cognitive impairment

Authors: *L. MAH[1,2], A. TANG[1,3], N. D. ANDERSON[1,4,2], N. P. L. G. VERHOEFF[2], B. G. POLLOCK[2,5];
[1]Rotman Res. Institute, Baycrest, Univ. of Toronto, North York, ON, Canada; [2]Dept. of Psychiatry, Univ. of Toronto, Toronto, ON, Canada; [3]Dept. of Psychology, McMaster Univ.,

Hamilton, ON, Canada; [4]Dept. of Psychology, Univ. of Toronto, Toronto, ON, Canada; [5]Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

Abstract: Neuropathological changes due to Alzheimer's disease (AD) begin years before cognitive symptoms manifest. Although the earliest abnormalities occur within limbic structures that support both emotion and memory, their impact on emotional processing in preclinical AD is poorly understood. We report preliminary results of a functional magnetic resonance imaging (fMRI) study which compared neural responses to emotionally expressive faces amongst individuals with amnestic mild cognitive impairment (aMCI), a prodromal stage of AD, cognitively normal (CN) older adults, and individuals diagnosed with late-life depression (LLD). We predicted group differences in prefrontal-limbic neurocircuitry that mediate emotion regulation. Twelve non-depressed aMCI (M age= 72; SD= 7.1), 9 LLD (M age= 70; SD= 7.1), and 10 CN (M age= 70; SD= 4.9) were scanned using fMRI at 3T while viewing images of faces with happy, sad, fearful, or neutral expressions. Subjects were instructed to attend to and rate either an affective or physical aspect of faces. Functional neural activity was analyzed using Partial Least Squares (McIntosh et al., 1996, Neuroimage 3, 143). Structural equation modeling was used to assess group differences in effective connectivity between the amygdala and ventral anterior cingulate cortex (vACC). A group x rating task x emotion interaction in fMRI data was found. Independent of task condition, greater amygdalar reactivity was observed to happy expressions in CN, and to sad faces in LLD. In contrast, patterns of functional neural activity in response to emotional faces were modulated by task condition in aMCI. aMCI subjects showed greater amygdalar reactivity to happy expressions when attending to a physical aspect of faces, but to sad expressions when attending to an affective aspect of faces. In the latter condition, aMCI was characterized by decreased effective connectivity between the amygdala and vACC relative to CN. These preliminary data are compatible with the hypothesis that the earliest stages of AD may be characterized by alterations in emotional processing. These changes may include greater amygdalar neuroplasticity, as suggested by attentional modulation of amygdalar responses to emotion in aMCI, but not in either CN or LLD. Further work on the role of amygdalar neurocircuitry in the pathogenesis and treatment of AD is warranted.

Title: Deep brain stimulation of the mesolimbic system induces cortical responses in limbic and sensorimotor areas in monkeys

Authors: *M. SUZUKI[1,2], T. ISA[3,2], Y. NISHIMURA[3,2,4];
[1]Dept. of Developmental Physiol., Natl. Inst. for Physiological Sci., Okazaki, Japan; [2]Dept Physiol Sci., Grad. Univ. Advanced Studies (SOKENDAI), Okazaki, Japan; [3]Dept. of Developmental Physiol., Natl. Inst. For Physiological Sci., Okazaki, Japan; [4]JST-PRESTO, Tokyo, Japan

Abstract: Depression is one of major psychiatric disorders. Previous studies have reported that individuals with depression have dysfunction of the ventral striatum (VSt). The VSt plays a critical role in processing reward and reward-motivated behavior. Moreover, deep brain stimulation (DBS) of the VSt has been investigated clinically for the novel treatment of individuals suffering from treatment-resistant depression. However, neural mechanism underlying the therapeutic benefit of mesolimbic-DBS remains largely obscure. Furthermore, although the VSt receives dopaminergic inputs related to reward information from the ventral midbrain, such as the ventral tegmental area (VTA) and the medial substantia nigra pars compacta (mSNc), there are few studies that investigating the effect of DBS of the ventral midbrain. To clarify the effect of DBS of the VSt or the ventral midbrain on the cortical activity, electrical stimulation was delivered to the VSt or ventral midbrain (100-500 μA x 3 at 300 Hz)in two monkeys sedated with ketamine. Evoked-cortical responses in the frontal cortical areas including the sensorimotor cortex (SMC) and limbic cortex such as the orbitofrontal cortex (OFC) and evoked responses in upper limb muscles were recorded simultaneously with electrocorticogram and electromyogram, respectively. DBS of the VSt induced neural response in the OFC but not in the SMC. In contrast, DBS of the ventral midbrain induced responses not only in the OFC but also in the SMC, especially in the primary motor cortex (M1). Evoked response in the SMC was stronger than that in the OFC. In addition, DBS of the ventral midbrain induced muscle responses in upper limb muscles. The onset latencies of the evoked muscle responses were longer than those of muscle responses evoked by stimulation of M1. This result suggested that ventral midbrain could modulated the excitability of the descending motor pathways from M1. The present study has provided the idea to understand the neural mechanism underlying therapeutic DBS to the mesolimbic system. DBS of the VSt modulates neural interaction between the VSt and limbic cortex. DBS of the VTA/mSNc modulates both the limbic and motor cortex. Because DBS of the VTA/mSNc directly affects not only limbic area but also descending motor pathways, clinical application of DBS of the VTA/mSNc could be considered for not only treating the mood disorder but also for facilitating the recovery of deficits in the motor system.

Title: Psychostimulant drug administration markedly increases visual stimulus seeking behavior in calorie-restricted rats; underlying neural mechanisms

Authors: *A. TALISHINSKY, S. IKEMOTO;
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: Administration of psychostimulant drugs augments goal-directed responses, especially in calorie-restricted animals. Our lab has previously demonstrated that chronic calorie-restriction interacts synergistically with D-amphetamine to potentiate visual stimulus-seeking behavior in rats. Recent work has shown that calorie-restriction affects the sensitivity and responsiveness of the mesolimbic dopamine and serotonin pathways. Continuing with this work, we found that chronic calorie restriction increased visual-stimulus seeking potentiated by the psychostimulant methylphenidate, and decreased sensitivity to the selective serotonin reuptake inhibitor (SSRI) fluoxetine in methylphenidate-potentiated visual-stimulus seeking in rats. To further characterize the neural circuitry underlying the interaction of calorie-restricted physiological state and psychostimulant drug action, we have begun using DREADD-mediated neuronal inhibition of brain regions upstream of the mesolimbic dopamine system, including the medial prefrontal cortex and the basolateral amygdala. Our results suggest that chronic calorie restriction alters behavioral responsiveness to both psychostimulants and SSRIs. Potentiated visual stimulus seeking behavior in calorie-restricted rats may be dependent upon input from the basolateral amygdala. Future work will aim to characterize the involvement of specific BLA efferents in potentiating visual stimulus seeking behavior.

Title: Adiponectin in the prefrontal cortex regualtes depression-related behaviors through AdipoR1

Authors: *J. LIU, M. GUO, H. LI, D. ZHAO, J. LIU, X.-Y. LU;
Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: Our previous studies have demonstrated that levels of circulating adiponectin, an adipocyte-derived hormone, are reduced in a chronic social defeat stress model of depression and adiponectin-deficient mice are susceptible to developing depression-like behaviors. Furthermore, we have shown that central administration of adiponectin produces antidepressant-like effects. These results support that adiponectin regulates depressive behaviors via a central mechanism (Liu et al., PNAS, 2012). The neural circuits underlying the actions of adiponectin, however, have not been identified. The expression of adiponectin receptor 1 (AdipoR1) in the prefrontal cortex (PFC) suggests a role of this brain area in mediating the functional effects of adiponectin. In this study, we generated mice lacking AdipoR1 specifically in the PFC and found that these mice displayed depressive-like phenotypes including behavioral despair and anhedonia. Infusion of adiponectin into the PFC produced antidepressant-like effects. These results suggest that the PFC is a functional target of adiponectin and AdipoR1 in this brain area mediates adiponection effects on depression-related behaviors.

Title: PVN magnocellular AVP system signals motivation through suppressing LHb functional output during multifaceted stress coping

Authors: *L. ZHANG, V. S. HERNANDEZ;
Physiology, Medicine, Natl. Autonomous Univ. of Mexico, Mexico City, Mexico

Abstract: The presence of arginine-vasopressin (AVP) containing axons and terminals in lateral habenula (LHb) has long been observed. However, the origin, neurons acted upon, and

functional implications of these projections have been unclear. To address these questions, we used anatomical/immunohistochemical methods, *in vitro* whole-cell recording in LHB, and *in vivo* extracellular single-unit and local field potential (LFP) recordings. These findings were contextualized by juxtacellular labeling and reconstruction of both hypothalamic AVP neurons in paraventricular nucleus (PVN), and medial division of lateral habenular complex in rat. Additionally, we employed two behavioral tests, live-predator exposure (LPE) and forced swimming test (FST), to test for fear and learned helplessness respectively. Here, we show that a direct vasopressin-containing glutamatergic pathway, from AVP-MNN axon collaterals, selectively targets the medial-LHb GABAergic interneuron recorded and juxtacellularly labeled *in vivo*. At the electron microscopy level, AVP+ dense-core vesicles co-localized with small-clear vesicles at synaptic active zone suggesting AVP plays a role in synaptic transmission. Activation of this pathway by physiological osmotic stress led to a sharp increase in theta power recorded LHbM *in vivo* and a significant reduction of psychomotor deficits during innate fear and learned helplessness processing. Fos expression overall in the LHb was significantly reduced. These finding suggest that the magnocellular AVP containing glutamatergic pathway exerts powerful inhibition in the LHb to promote motivational behavior during a multifaceted stress coping.

Title: Contribution of the medial thalamus to social and non-social behavior

Authors: *E. BONNEMA, Y. CHUDASAMA;
Dept. of Psychology, McGill Univ., Montreal, QC, Canada

Abstract: There is substantial evidence that disturbances in learning and memory are associated with a damaged mediodorsal (MD) thalamus (for review, see Mitchell and Chakraborty, 2013, Front. System Neurosci, 9:00037). On account of its strong afferent input from the central nucleus of the amygdala, the MD thalamus has also been implicated in the expression of fear-related emotions. For example, rats with MD lesions have been observed to freeze more in aversive situations (Vanderwolf, 1967, Physio and Beh, 2:339), and mice with MD lesions show increased anxiety in the elevated plus maze (Chaveau et al., 2005, Behav Brain Res, 156:215). The MD thalamus also sends a direct projection to the ventral and orbital prefrontal cortex

known to mediate emotional responses to socially significant stimuli (Beer et al., 2006, J Cog Neursci, 18:871). Unfortunately, there has been no systematic attempt to understand how the MD thalamus contributes to social aspects of emotion. We thus set out to explore the effect of MD thalamic lesions on social emotional behaviour. A group of Long-Evan rats received bilateral excitotoxic lesions of the MD thalamus through *N*-methyl-D-aspartate (NMDA) injections, or received sham control surgery. We then tested the rats on a variety of tasks to measure social and non-social emotional behaviours. First, we found anxiety levels to be in the normal range as both shams and MD-lesioned rats spent similar amounts of time in the open arms of the elevated plus maze (shams: 70.5 seconds, MD: 68.8 seconds). Second, we found that the MD lesions did not affect sociability measures because, like the sham controls, rats with MD lesions readily approached and interacted with a familiar rat (shams: 103.6 seconds, MD: 81.6 seconds) or a stranger rat (shams: 97.2 seconds, MD: 95.8 seconds). However, when the familiar and stranger rats were replaced with familiar and novel objects, rats with MD lesions exhibited a preference for familiar objects (familiar: 162.9 seconds, novel: 53.9 seconds), whereas the sham control rats explored familiar and novel objects for similar amounts of time (familiar: 75.7 seconds, novel: 82.1 seconds). These preliminary data indicate that although rats with MD lesions are sensitive to objects that have never been encountered before, and thus avoid them, they nonetheless readily interact socially with rats, even if those rats are complete strangers. Further analyses and studies will explore the nature of the object avoidance behaviour and the type of behaviours that constitute social interactions.

Title: Social facilitation of foraging effort in domestic chicks: functional contribution of the descending pathway from arcopallium to midbrain tegmentum

Authors: *X. QIUHONG[1], T. MATSUSHIMA[2];
[1]Grad. Sch. of Life Sci., [2]Fac. of Sci., Hokkaido Univ., Sapporo, Japan

Abstract: Social facilitation denotes an increment of individual activity that occurs in the presence of one or more conspecifics (Crawford 1939). Since pioneering psychological reports (Zajonc 1965, Clayton 1978), however, the underlying neural mechanisms has rarely been

studied. Ogura and Matsushima reported at the SfN2014 meeting that electrolytic lesion of the midbrain tegmental area resulted in a partial suppression of facilitation, whereas the selective depletion of catecholaminergic neurons by 6-OHDA micro-infusion failed to reproduce the lesion effect. It is thus suggested that some tegmentum pathways other than the ascending dopaminergic projections may be responsible. Arcopallium (Arco, previously archistriatum) is a candidate, as it constitutes one of the major telencephalic descending efferents in the tegmentum. Arco constitutes a heterogeneous structure with multiple functional roles in behavioral control. Arco is assumed to play a "limbic" function (Saint-Dizier et al. 2009, Phillips & Youngren 1971). Arco is also critical for sensori-motor controls (Zeier & Karten 1971), particularly the spatial working memory of sound localization (Knudsen & Knudsen 1996). Furthermore, Arco is involved in the cost-based decision making (Aoki et al. 2006). In this study, we examined effects of bilateral electrolytic lesion to Arco on social facilitation. Chicks were trained in an I-shaped maze equipped with a pair of feeders at both terminals, and grains of millet were delivered at variable intervals. The maze was composed of two parallel lanes separated by a transparent wall. A subject chick was initially placed in one lane and tested in isolation; subsequently it was paired with a companion chick in the parallel lane. Finally the companion was removed and the subject chick was tested in isolation again. Chicks actively shuttled between the two feeders and foraged the delivered food. Pairing significantly increased the running distance, and the increase was supposed to represent the social facilitation. We compared among 3 groups of chicks, (1) Arco lesion, (2) nidopallim lesion control, and (3) sham lesion control, and found that a significant suppression of the social facilitation occurred in the group (1). In all of the chicks in group (1), we also found an increase in κ value (number of pecks per unit gain), suggesting an impaired sensori-motor coordination. The foraging effort in the isolate condition was also suppressed in some chicks, but not significantly. We therefore conclude that (i) descending pathway from Arco to tegmentum plays a critical role in social facilitation, and (ii) Arco is responsible for other functions such as sensori-motor coordination.

Title: Prosubiculum rather than subiculum heavily projects to medial prefrontal cortex, amygdala, ventral striatum, bed nucleus of the stria terminalis and hypothalamus in mouse

Authors: *S.-L. DING, J. W. PHILLIPS;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: Hippocampal formation (HF) plays important roles in motivation, emotion, reward, drug addiction, stress, anxiety and fear. Anatomically these functions have been attributed to subiculum (Sub) and/or hippocampal CA1 region with less consideration of the prosubiculum (ProS). The ProS was originally designated by Lorente de No to the region located between the Sub and CA1 but it has not commonly been used in modern literature on rodent HF. However, a recent comprehensive analysis has revealed that there indeed exists a unique ProS in rodents, as is seen in monkeys and humans. In order to explore connectional evidence for differential functions of the ProS and Sub in mouse the present study investigated and compared the target regions of these two HF subregions defined by unique gene markers. After the anterograde tracer rAAV was injected into intermediate and ventral ProS, heavily labeled axon terminals were observed in the medial prefrontal cortex [mainly infralimbic cortex (IL)], lateral entorhinal cortex, distal CA1, anterior olfactory nucleus (AON), lateral part of lateral septal nucleus (LSN), ventral striatum (VS: nucleus accumbens and olfactory tubercle), amygdala, bed nucleus of the stria terminalis (BNST), anteromedial and paratenial nuclei of the thalamus, and many hypothalamic regions. Much less terminal labeling was detected in AON, amygdala, BNST, and hypothalamus after dorsal ProS injections. In contrast to ProS injections, rAAV injections in the Sub resulted in heavily labeled axon terminals in a different set of brain regions including medial entorhinal cortex, area 29 of the retrosplenial cortex, pre-/para-subiculum, area prostriata, medial LSN, medial mammillary nucleus, anteroventral, laterodorsal and reuniens nuclei of the thalamus. In summary, the present study revealed distinct projections of the ProS and Sub with the former having wider spread projections. The middle and ventral ProS predominantly target the IL, VS, amygdala, BNST and hypothalamus, regions critical for motivation, emotion, reward, drug addiction, stress, anxiety and fear. The Sub mainly projects to the regions important for procession of spatial information such as medial entorhinal cortex, area 29, pre-/para-subiculum, medial mammillary nucleus, anteroventral nucleus of the thalamus. These results also call for careful localization of the ProS and Sub in lesion, injection, stimulation and recording studies in rodents. A detailed comparison of the connectivity between the ProS and Sub will be presented.

Title: The hippocampus projects to bed nucleus of the stria terminalis but not the central amygdala nucleus in primate

Authors: J. IOURINETS[1], *J. L. FUDGE[2];
[1]Neurosci., Univ. of Rochester, Rochester, NY; [2]Dept of Neurobio. and Anat., Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: The bed nucleus of the stria terminalis (BNST) and central nucleus (CeN) of the amygdala are opposite poles of the 'central extended amygdala', a macrostructure that is best known for its role in responses to aversive stimuli. The extended amygdala is most extensively studied in rat, where afferent inputs to the lateral BNST and CeN are quite similar. Despite this, behavioral and lesion studies suggest differences in lateral BNST and CeN function, with the lateral BNST required for long-lasting fear responses evoked by unconditioned stimuli and contextual cues, whereas the CeN is more involved in immediate fear responses and consolidation of conditioned stimuli. Comparatively little information has been obtained in the nonhuman primate. To help clarify afferent systems to the lateral BNST and CeN, we first focused on hippocampal inputs. Small injections of retrograde tracers were placed in the BNST and CeN, and the distribution of labeled cells in the hippocampus was charted. Results were confirmed with anterograde injections into the hippocampus. BNST injections resulted in a very restricted but dense distribution of labeled cells in rostral CA1' of the hippocampus, mostly anterior to the dentate gyrus. Surprisingly, none of the CeN injections resulted in labeled cells in the hippocampus. None of the anterograde injections in the hippocampus resulted in labeled fibers in the CeN, and only one injection, in the rostral CA1', issued labeled fibers into the BNST. We then analyzed direct hippocampal-BNST and hippocampal-CeN data together with our previous work on hippocampal-amygdala projections and amygdala-extended amygdala projections. Combined tracing studies indicate that the BNST differs from the CeN in receiving direct hippocampal inputs, while the CeN receives only indirect hippocampal influence through amygdala-CeN pathways. In higher species, the rostral hippocampus, including uncal CA1', is greatly expanded. In humans, this region is associated with autobiographical memory storage and retrieval. Our data suggests that autobiographic information from the past is channeled directly to the BNST, perhaps shaping long-lasting responses in conditions such post-traumatic stress disorder, where cues originate in personal memory. Conversely, our anatomic data indicate that in primates, CeN responsivity is largely shaped by direct amygdala inputs, suggesting a greater role in responses to stimuli presented in the 'here-and-now'.

Title: Subgenual anterior cingulate area 25 corticocortical connections and their interface with distinct classes of inhibitory neurons

Authors: *M. JOYCE, H. BARBAS;
Hlth. Sci., Boston Univ., Boston, MA

Abstract: Cortical area 25 (A25) is located in the ventral and posterior aspect of the subgenual anterior cingulate region. A25 is a limbic type of cortex with less elaborate laminar structure than the six-layered eulaminate areas. Converging evidence suggests that A25 may have a role in emotional regulation and may contribute to the pathology of mood disorders. Using neural tracers in the rhesus monkey, we investigated the largely unexplored corticocortical projections to A25 to study how it interfaces with areas associated with emotion and cognition. Numerous projection neurons directed to A25 were found in the neighboring ventromedial prefrontal cortex (VMPFC) and anterior cingulate cortex (ACC), both of which are linked to emotion and its expression. Some neurons projecting to A25 were also found in the frontal pole (area 10). There were no significant projections from other dorsolateral prefrontal areas, which are associated with cognition. Outside of the frontal lobe, a significant number of neurons directed to A25 were found in the entorhinal cortex, anterior auditory association cortices, and the anterior insula, an area that is associated with interoceptive function. These findings reveal that A25 receives the strongest input from the VMPFC and ACC, which are involved in emotion and are part of the default mode network (DMN), a resting state network that becomes active when subjects are not engaged in specific tasks. In humans, the DMN is thought to become engaged during internal modes of cognition, e.g., when one reflects on the past or plans for the future. We also analyzed the laminar density of functionally distinct inhibitory neurons in A25 based on expression of the calcium-binding proteins Parvalbumin (PV) and Calbindin (CB). CB neurons were significantly denser than PV neurons, and were found mostly in the superficial layers of A25. PV neurons were distributed equally across the superficial and deep layers of A25. The laminar organization of CB and PV neurons in A25 provide information on the interface of pathways with different inhibitory systems in A25, which may be relevant for the switch between task-dependent and default modes of processing.

Title: Consumption of food calorically high in fat alters reward circuitry and increases "craving-like" behaviors over periods of abstinence

Authors: *R. A. DARLING[1], T. BROWN[2], P. DINGESS[3];
[1]Univ. of Wyoming, Laramie, WY; [2]Sch. of Pharm., [3]Neurosci., Unversity of Wyoming, Laramie, WY

Abstract: Sensory cues indicative of palatable food rewards have been shown to induce a motivational craving state. This can trigger unhealthy eating behaviors. In rats, craving may be assessed by measuring their response on a lever for cues previously associated with a reward. Craving has been shown to increase in intensity progressively over time for such rewards as cocaine and sucrose. The increased craving behavior manifests in rats as an enhancement in lever responding to contingent cues (light and tone) after extended abstinence periods and subsequently coined, *incubation of craving*. Our lab has previously observed an incubation of craving effect in response to a high-fat reward (HF) following 2 h access training sessions. However, this effect was also observed in our standard chow controls. Previous literature has shown a difference in neuroadaptations following 6 h extended-access compared to 2 h access. Therefore, we repeated our experiments with 6 h training sessions. We tested rats for their responses to the contingent cues following 30 days of abstinence (CE30) from HF. Our results indicate that lever pressing for HF increases from one day of abstinence (CE1) to CE30 (44.3 ± 4.9 vs. 79.3 ± 10.4, $p<0.05$, n=15). In the 6 h training paradigm, cues paired with standard chow pellets do not incubate to the same magnitude as the high-fat group but the relative magnitude of incubation was comparable between the two dietary conditions (24.0± 2.9 vs. 58.6 ± 5.2, $p<0.05$, n= 16). Current ongoing experiments are being conducted to evaluate whether there are differences in structural and synaptic plasticity, which parallel the changes in craving behavior. We conclude that extended-exposure to cues paired with HF undergo an incubation of craving effect, which may contribute to maladaptive food seeking behaviors.

Title: Mapping of monosynaptic cannabinoid type 1 receptor inputs into dopamine neurons of the ventral tegmental area

Authors: *V. KASHTELYAN[1], C. A. MEJIAS-APONTE[3], M. MORALES[3], J. F. CHEER[1,2]; [1]Dept. of Anat. and Neurobio., [2]Dept. of Psychiatry, Univ. of Maryland Sch. of Med., Baltimore, MD; [3]Intramural Res. Program, Neuronal Networks Section, Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: The mesolimbic dopamine (DA) pathway is critically involved in reward-seeking and appetitive behaviors. It originates in the ventral tegmental area (VTA) of the midbrain and projects rostrally to provide profuse DA innervation to terminal regions, in particular the nucleus accumbens. Impaired DA release within the mesolimbic system is a hallmark of schizophrenia, depression and drug abuse. The activity of DAergic cells in the VTA is potently modulated by the endocannabinoid system (ECS). The ECS influences neuronal activity through presynaptic inhibition of neurotransmitter release. The cannabinoid type 1 receptor (CB1R) is the main receptor involved in this signaling pathway. Here, we identify afferents that control firing of DAergic cells in the VTA by means of signaling at CB1Rs. Using DAT::Cre transgenic mice, we first injected two AAV viruses into the VTA. The viruses infected DA cells with an avian retroviral receptor, the mammalian rabies glycoprotein and a fluorescent tag. Mice were later transduced with a pseudorabies virus in which the rabies glycoprotein has been removed and replaced with a fluorescent protein. The pseudorabies binds specifically to DA cells expressing the avian retroviral receptor and utilizes the rabies glycoprotein in DA cells to infect cells that form monosynaptic, classical synapses with DA neurons. Once we identified monosynaptic inputs to DA neurons in the VTA, we performed a combination radioactive in-situ hybridization and immunohistochemistry experiment. We were able to visualize cells that were infected by the pseudorabies virus and cells that express CB1R mRNA. For each brain region in which we found rabies infected cells, we performed a cell count of the pseudorabies infected neurons and the pseudorabies neurons expressing CB1R mRNA to determine the ratio of afferents to DA neurons that are and are not under the control of the ECS. Our results identify discreet populations of VTA DA afferents that signal through the ECS. This confirms that VTA DA neurons are under the control of multiple input regions, which can engage ECS signaling to change activity patterns of dopamine neurons in an activity-dependent negative feedback fashion.

Title: Intra-Accumbens blockade of tyrosine-related kinase B (TrkB) receptors using ANA-12 modulates emotional behaviors and biochemical signaling following a repeated stress regimen in male Wistar rats

Authors: *H. PLAMONDON, I. AZOGU;
Dept Psychol, Univ. Ottawa, Ottawa, ON, Canada

Abstract: Elevated levels of brain-derived neurotrophic factor (BDNF) and its primary receptor, tyrosine-related kinase B (TrkB) in the nucleus accumbens (Nac) shell have been reported following stress, which has been linked to anxiogenic and pro-depressive mood. Recently, the selective TrkB antagonist, ANA-12, was developed which prevents the binding activation of TrkB by BDNF, thus inhibiting processes downstream of TrkB signaling. Four groups of male Wistar rats (n=10 /group) were implanted with guide cannulas in the NAc shell and treated with ANA-12 or vehicle to assess the effects of repeated stress on the activity of BDNF/TrkB in the mesolimbic system, and whether the inhibition of this system can affect anxiety and motivational behaviors. They underwent a ten-day repeated stress/no stress regimen, in which stress regimen involved alternating restraint and forced swim stressors. Rats were later tested in the elevated plus maze, social interaction test, and the forced swim test. In addition, post mortem levels of CRH and vGluT2 within the PVN and BLA regions, as well as Orexin A and ΔFosB in the LH, perifornical area and CA3 of the hippocampus were determined. Findings show that ANA-12 significantly reduced anxiety-like behavior in the EPM and increased social interaction in stressed animals. However, both stress groups performed uniformly in measures of swimming and immobility in the forced swim test. Immunohistochemical results show decreased CRH and vGluT2 following repeated stress in the parvocellular portion of the PVN and in the BLA in ANA-12 stressed rats. Of interest, ANA-12 had intrinsic actions to increase orexin A-ir and Fos B-ir, to the same levels as that observed in the vehicle-treated stress rats. Notably, ANA-12 when injected in stressed rats restored orexin-A and Fos B levels to that found in control (non-stressed) animals. Overall, these data suggest that ANA-12 represent a good tool in understanding the effects of TrkB activation within the mesolimbic system following repeated stress exposure.

Title: Grey matter differences are predicted by variation in the ADRA2b gene

Authors: *M. R. EHLERS[1], D. J. PALOMBO[2], D. J. MUELLER[3], A. K. ANDERSON[4], R. M. TODD[1];
[1]Psychology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Boston Univ., Boston, MA; [3]Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada; [4]Cornell Univ., Ithaca, NY

Abstract: A common genetic polymorphism in the ADRA2b gene, which codes for the noradrenergic α2b receptor, has been found to predict individual differences in emotional processing in humans. Previous research suggests that the deletion variant has *in vivo* effects similar to that of a noradrenergic antagonist putatively leading to increased extracellular norepinephrine. Deletion carriers have been shown to have greater emotional enhancement of memory than noncarriers and a higher susceptibility to intrusive memories following trauma (de Quervain et al., 2007). During memory encoding deletion carriers show higher amygdala activation (Rasch et al., 2009) and greater attentional bias for emotionally salient stimuli (Todd et al., 2013). ADRA2b deletion carriers also perceive emotional stimuli as more perceptually vivid, an effect driven by increased activation of valuation network hubs proposed to be directly modulated by locus coeruleus noradrenergic activity. That is, in deletion carriers emotionally enhanced vividness is associated with greater activity in the amygdala and ventromedial prefrontal cortex (VMPFC), which modulate visual cortex activity (Todd et al., 2015). Given the accumulating evidence for a role of the ADRA2b polymorphism in affective processing, we hypothesized differences in cortical and subcortical grey matter volume between deletion carriers and noncarriers. In the present study Caucasian participants were recruited from the University of Toronto as part of a collaborative study investigating genetic influences on attention and memory. Participants were 18 - 35 years old and screened for a history of brain injury, learning disabilities and psychopathology. Saliva samples were collected in order to genotype participants for ADRA2b as well as other genes linked to influences of emotion on attention and memory. T1-weighted magnetic resonance images were obtained for a subset of participants. Structural scans of 72 participants (37 deletion carriers) were subjected to cortical and subcortical segmentation using FreeSurfer. Results revealed larger amgydala volume for ADRA2b deletion carriers compared to noncarriers. This anatomical difference provides a putative neural mechanism for deletion carriers' advantage in emotionally enhanced perception and memory reported in the literature. In addition, grey matter volume in other key nodes of valuation networks was investigated. The results demonstrate that individual variations in norepinephrine availability are not only associated with altered affective processing, but are also reflected in anatomical differences.

Title: Caudal nucleus accumbens core inactivation results in decreased appetitive motivation and increased aversive motivation in response to conditioned cues

Authors: *L. M. HAMEL, T. THANGARASA, R. ITO;
Univ. of Toronto, Toronto, ON, Canada

Abstract: The nucleus accumbens is a site of integration of positively and negatively valenced information and action selection. Differentiations in valence processing have been found along the rostrocaudal axis of this structure, in assessments of both unconditioned motivation and in approach-avoidance decision making in response to conditioned cues. A previous study revealed that disruption of activity in the caudal accumbens core via a GABA receptor agonist resulted in a bias toward aversion in response to conflicting cues signaling both reward and punishment. In the current study we sought to determine whether this finding was mediated by enhanced avoidance, diminished approach motivation, or a combination thereof. Rats were trained to associate visuo-tactile cues with appetitive sucrose, aversive foot-shocks and neutral outcomes. In order to assess motivation in response to conditioned cues, separate tests were conducted which measured exploratory preference for the arms containing the appetitive versus neutral cues, and the aversive versus neutral cues. Animals receiving GABA receptor agonists in the caudal core region spent a decreased proportion of time in the aversive arm as compared with control animals, as well as a decreased proportion of time in the appetitive arm as compared with controls. The results suggest that the caudal nucleus accumbens core mediates both appetitive and aversive motivation in response to conditioned cues, and that the behaviour observed after inactivation of this region during decision-making tasks likely results from a composite of effects on the processing of both valences.

Title: The role of lateral habenula orexin signaling in aggressive behavior

Authors: *M. FLANIGAN[1], H. ALEYASIN[1], S. GOLDEN[2], M. HESHMATI[1], M. PFAU[1], G. HODES[1], S. RUSSO[1];
[1]Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Natl. Inst. of Drug Abuse, Baltimore, MD

Abstract: The neuropeptides orexin-A and orexin-B are produced from the precursor peptide pre-pro orexin solely by neurons in the lateral hypothalamic area (LHA) and have been implicated in a broad spectrum of behaviors including reward, arousal, and response to stress. Developmental knockouts of the pre-pro orexin gene display attenuated defense responses when presented with an intruder mouse, suggesting that the orexin system may be important in aggressive behavior. To investigate the role of orexin in aggression, we first measured expression of orexin peptide and its receptors throughout the brain in aggressive and non-aggressive CD1 mice following exposure to an intruder mouse. Aggressors displayed marked increases in orexin signaling between the LHA and the lateral habenula (lHb), a brain region implicated in the motivational components of aggression. Acute I.P. injection with 30 mg/kg EMPA, a brain-penetrant selective orexin receptor 2 (OxR2) antagonist, significantly decreased aggression. AAV-shRNA-mediated knockdown of OxR2 in the lHb also decreased aggression, further strengthening the importance of OxR2 in this behavior and providing a previously undefined behavioral role for orexin signaling in the lHb.

Title: Differences in regulation of medial vs. lateral dopamine neurons in rodents by lateral habenula and infralimbic prefrontal cortex: relevance to the chronic mild stress model of depression

Authors: *J. L. MOREINES[1,2], Z. OWRUTSKY[1], A. A. GRACE[1];
[1]Dept. of Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Med. Scientist Training Program, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA

Abstract: Although serotonin has been classically associated with major depressive disorder (MDD) emerging data from both clinical and animal model studies have implicated the dopamine (DA) system in the reward and motivational impairments core to the disorder. Specifically, we found in two models of MDD a significant down-regulation in DA neuron population activity that correlated with depression-like symptoms. Human studies have also implicated two other regions in the pathophysiology of MDD, Brodmann Area 25 (homologous to rodent infralimbic prefrontal cortex, ILPFC) and the lateral habenula (LHb). In this study, we explored how the ILPFC and LHb may contribute to the down-regulation of DA neurons in the unpredictable chronic mild stress (UCMS) model of depression. We performed single-unit extracellular recordings of identified ventral tegmental area (VTA) DA neurons from anesthetized rats following LHb or ILPFC pharmacological activation. We then assessed whether inactivation of the ILPFC or LHb in animals that previously underwent 5-7 weeks of the UCMS (which features a hypodopaminergic phenotype) would restore normal DA system population activity in this model. We found that activation of either ILPFC or LHb in normal rats potently suppressed VTA DA neuron population activity, albeit in different patterns. ILPFC activation primarily affected medial VTA DA neurons, whereas LHb activation had a greater effect on central and lateral VTA DA neurons. Similarly, in rats that underwent UCMS (which impacts primarily medial VTA DA neurons), only ILPFC inactivation restored VTA DA neuron population activity to normal levels, whereas LHb inactivation had no restorative effect on DA neuron population activity. These data suggest that the ILPFC and LHb might regulate different subpopulations of DA neurons within the mesolimbic DA system. This striking pattern of differential modulation could explain the unique restorative capacity of ILPFC inactivation in reversing abnormal DA system hypoactivity in the widely used UCMS animal model of MDD. More generally, these results suggest that in humans, abnormal activity in BA25 vs. the LHb may drive different types of dopamine-related pathological states in patients with MDD.

Title: Rewarding effects of pain relief require endogenous opioid activity in anterior cingulate cortex

Authors: *E. NAVRATILOVA, C. QU, N. LAUDE, C. KRAMER, D. MESKE, E. LEMISTER, J. Y. XIE, X. YUE, M. HEIEN, F. PORRECA;
Univ. of Arizona, Tucson, AZ

Abstract: Clinical and preclinical investigations suggest that relief of pain engages brain emotional and motivational circuits. Relief of pain may thus be considered as a reward. We have shown previously in rodent pain models that relief of pain with non-opioid treatments (e.g., peripheral nerve block or spinal clonidine) activates the mesolimbic dopaminergic reward circuit and elicits relief-motivated behavior (conditioned place preference, CPP). Blockade of dopaminergic signaling in the nucleus accumbens (NAc), part of the reward circuit, prevents pain relief induced CPP. Furthermore, endogenous opioid signaling in the anterior cingulate cortex (ACC), an area encoding pain aversiveness, is required for both pain relief induced CPP and NAc dopamine release. Whether systemically administered analgesics such as gabapentin (Neurontin), used clinically for the treatment of neuropathic pain, produce their pain relieving effects by stimulating release of endogenous opioids in the ACC is not known. In this study, we used male Sprague Dawley rats with spinal nerve ligation (SNL) as a model of chronic neuropathic pain and investigated behavioral and neurochemical consequences of pain relief following intravenous administration of gabapentin. Pain relief motivated behavior was evaluated using the conditioned place preference (CPP) paradigm. Dopamine release in the NAc was assessed in freely moving animals using *in vivo* microdialysis. To measure endogenous levels of opioid neurotransmitters (methionine- and leucine-enkephalin) in the ACC, we developed an online-preservation method for improved microdialysis recoveries and quantification of these peptides by Mass Spectrometry. Our studies demonstrate that in rats with neuropathic pain, gabapentin reversed SNL-induced tactile hypersensitivity, produced CPP and elicited release of dopamine in the NAc. Blockade of opioid signaling in the ACC prevented both gabapentin-mediated CPP and dopamine efflux in the NAc. Preliminary assessments of endogenous opioid levels indicate altered opioid neurotransmitter activity in the ACC of neuropathic rats. These findings provide support for a critical role of endogenous opioid activity in the ACC in chronic pain states. Release of endogenous opioids in the ACC appears to be a general mechanism for relief of pain unpleasantness and for rewarding/motivational features of pain relief. Selective engagement of brain cortical opioid circuits may allow the identification of new molecular targets and development of novel therapies to alleviate pain. Supported by DA034975. The authors have no conflict of interest.

Title: Impulsive action and impulsive choice are distinct behavioral components with different underlying neural substrates

Authors: *K. M. NAUTIYAL[1,2], S. WANG[2], M. M. WALL[2], P. D. BALSAM[2,3], C. BLANCO[2], R. HEN[2];
[1]Neurosci., Columbia Univ., New York, NY; [2]Psychiatry, Columbia Univ. and New York State Psychiatric Inst., New York, NY; [3]Psychology, Barnard Col., New York, NY

Abstract: Impulsivity is a core feature of many psychiatric disorders including substance use disorder, pathological gambling, attention deficit hyperactivity disorder, and personality disorders. Acting without forethought and the inability to withhold responding are two behavioral phenotypes of impulsive behavior that are referred to as impulsive choice and impulsive action, respectively. The degree to which impulsive choice and impulsive action represent distinct or related subcomponents of impulsivity is unknown, as is the extent to which they have overlapping neural substrates. In order to test the hypothesis that impulsive action and impulsive choice represent dissociable behavioral constructs with distinct neural circuits, we collected a number of behavioral measures of impulsivity in a single cohort of mice. We included mice with whole-brain knockdown of serotonin 1B receptor (5-HT1BR) expression given its known role in modulating impulsivity from human gene association studies and animal models. Using a tetracycline operator (tetO)/tetracycline-dependent transcriptional silencer (tTS) system, we investigated the effect of both whole-life knockdown and adult-rescue of 5-HT1BR. The absence of 5-HT1BR expression caused increased impulsivity in the differential reinforcement of low-rate responding (DRL) and Go/No-Go operant paradigms, representing a

deficit in impulsive action. Interestingly, this was reversed with adult rescue of the receptor. However, there was no significant effect of 5-HT1BR expression on the discounting rate in the delayed discounting (DD) or probabilistic discounting (PD) operant tasks used as measures of impulsive choice. Further analysis using an exploratory factor analysis (EFA) revealed a good-fitting two-factor model with the latent factors representing impulsive action and impulsive choice (RMSEA<0.001, CFI=1.0, TLI=1.1). Specifically, DRL and Go/No-Go measures loaded onto one factor, while DD and PD loaded strongly onto the other. Loadings of all indicators were >0.4 and the two factors were not significantly correlated. Finally, a multiple indicator multiple causes (MIMIC) analysis revealed that 5-HT1BR expression and sex were significant covariates in the two-factor model. Male mice had significantly higher levels of impulsivity on both factors, while 5-HT1BR knockdown resulted in significantly increased impulsivity in the impulsive action factor only. Overall, the data support the conclusion that impulsive action and impulsive choice are distinct behavioral phenotypes with dissociable biological influences.

Title: What is novel about the "deep frontal nucleus"?

Authors: *D. ROBY, K. P. PARSLEY, D. S. ZAHM;
Pharmacol. and Physiological Sci., St. Louis Univ., Saint Louis, MO

Abstract: A dense cluster of round and ovoid neurons in the deep frontal lobe of the rat becomes uniformly and intensely labeled following injections of retrograde tracer into the ventral tegmental area (VTA), consistent with the accumulation of dense, fine gauge labeled axons in the VTA after the cluster is injected with anterograde tracer (Soc Neurosci Abstr 442.05, 2014). This aggregation of neurons, tentatively called the deep frontal nucleus (DFN), sits astride the rostralmost tip of the accumbens and the anterior commissure just in front of it. Its pyriform shape (in frontal sections) stems from structures that bound it medially, laterally and below - respectively, the deep layer of the infralimbic cortex (IL), fornix minor and subependymal sheath of the olfactory ventricle. Despite being wedged between the IL, medial orbital and dorsal peduncular areas of frontal cortex, DFN neurons appear to be not pyramidal - suggesting non-cortical character. Here we addressed whether the efferent projections of the DFN differ from

those of cortical structures abutting it by injecting the DFN with one anterogradely transported axonal tracer, either Phaseolus vulgaris-leucoagglutinin or biotinylated dextran amine, and, in the same subjects, injecting adjacent cortical areas with the other tracer. Series of cases with injections into only the DFN or nearby cortex were also evaluated. Labeled outputs from both the DFN and IL in the present material resembled those earlier reported for IL (Hurley et al., JCN 308:249-76, 1991), which included to piriform and agranular and dysgranular insular cortex, olfactory tubercle, accumbens, ventromedial caudate-putamen, preoptic region and lateral and posterior hypothalamus, thalamic reuniens, submedius and paraventricular nuclei, VTA, substantia nigra compacta, periaqueductal gray, laterodorsal tegmental nucleus and parabrachial nucleus. However, labeling in piriform and insular cortices and their extensions into the temporal lobe were much denser and widespread after DFN as compared to IL injections, which produced anterograde labeling that was everywhere more patchy and focal and extended densely into some areas, such as the supramammillary region, not innervated by DFN. In contrast, olfactory bulb was labeled after DFN but not IL injections. Thus, despite clear similarities in distributions of DFN and IL outputs, their general character differs. Nowhere is this more striking than in the VTA, to which the DFN sends an exceedingly fine gauge, dense projection that, in the immunofluorescence image, starkly contrasts with coarser, sparser projections from the IL. We anticipate that EMs in preparation will further this distinction.

Title: Evidence of functional connectivity between the nucleus accumbens and ventral pallidum in hedonic processing

Authors: *C. CHAN[1], D. S. WHEELER[2], R. A. WHEELER[2];
[2]Biomed. Sci., [1]Marquette Univ., Milwaukee, WI

Abstract: The nucleus accumbens (NAc) and its major output target, the ventral pallidum (VP), are both involved in reward learning and hedonic processing. Rewarding gustatory stimuli generally reduce the firing rates of NAc neurons while increasing the firing rates of caudal VP neurons, leading to the proposal that rewarding stimuli disinhibit the VP by reducing GABA-ergic input. However, we have observed considerable regional heterogeneity in the encoding of

rewarding and aversive stimuli in the VP. Here we examined the firing patterns of anterior VP neurons during exposure to palatable and unpalatable stimuli, as well as following the drug-induced devaluation of palatable stimuli. In this design, an otherwise palatable saccharin solution elicits a negative affective state as it comes to predict cocaine administration. Adult male rats, implanted with stainless steel microwires for electrophysiological recordings, were intraorally infused with a 0.15% saccharin solution (0.2 ml delivered over 6 sec/trial for 45 trials) that predicted a cocaine injection (20 mg/kg, ip). Rats received daily taste-drug pairings for 7 days. On the test day, rats were presented with the cocaine-predicting saccharin and VP neuronal activity was recorded. Unlike reports of recordings in the posterior VP, most phasically active neurons recorded in the anterior/mid VP reduced firing rate in response to a palatable gustatory stimulus. Interestingly, these responses are also modulated by NAc activity. To examine this functional relationship we pharmacologically inhibited the NAc and measured the neural activity of VP neurons while rats were presented with palatable stimuli. Adult male rats were implanted with guide cannulas in the NAc, bilateral chronic stainless steel microwires for electrophysiological recordings in the VP, and intraoral catheters for sucrose delivery. Following NAc microinfusion of the GABAA agonist muscimol, GABAA antagonist bicuculline or vehicle, animals were intraorally infused with a 20% sucrose solution (0.2 ml/trial for 20 trials) to assess hedonic responses. Then animals were allowed to nosepoke for the same sucrose solution at a FR1 schedule to assess motivated behavior. Consistent with prior investigations, VP activity encoded rewarding taste stimuli, and this encoding was altered by pharmacological manipulations of the VP. These results characterize a functional connectivity from the NAc to VP that modulates the encoding of rewarding taste stimuli. Ongoing studies are further characterizing the heterogeneity of responses in the VP by contrasting these results with more posterior VP recordings.

Title: A rabies virus based approach to map serotonergic neurons innervating different brain structures

Authors: *M. PASQUALETTI[1,2], A. BERTERO[1,2], A. BIFONE[2];
[1]Univ. of Pisa, Pisa, Italy; [2]Ctr. for Neurosci. and Cognitive Systems, Inst. Italiano di Tecnologia, Rovereto, Italy

Abstract: Serotonergic neurons are part of one of the most widely distributed neural systems in the mammalian brain (Lauder and Bloom, 1974). Serotonergic neurons form the raphe nuclei in the brain stem, and are organized in distinct nuclei (B1-9) that project to the whole central nervous system. Consistently with such a broad innervation, serotonin is involved in a wide range of physiological processes including the control of appetite, sleep, memory, mood, stress and sexual behavior (Veenstra-Vanderweele et al, 2000). Several studies using anatomical tracing methods and anterograde viral tracers have led to the hypotheses of a topographic organization of the serotonergic system, with different projections from the caudal, median/central and dorsal raphe neurons to specific target districts in the rostral brain (Muzerelle et al. 2014). Experimental evidence suggests that clusters of serotonergic neurons within the raphe nuclei may have distinct functional properties, but the complex organization of serotonergic neuron projections remains poorly understood. The aim of the present study is to map at a finer scale the organization of serotonin neurons projecting to different target areas, thus contributing to understanding the functional role of specific serotonergic neuronal subpopulations. To this end, we used a Tph2::GFP knock-in mouse model, in which serotonergic neurons are clearly labeled by the expression of GFP (Migliarini et al, 2013), and the retrograde recombinant rabies viral tracer to map the serotonergic neurons innervating different brain structures. Moreover, we developed a conditional GFP expressing mouse model, in which the reporter is maintained under the transcriptional control of the Tph2 gene and activated upon an flp mediated somatic recombination, to map the organization of serotonergic neuron subgroups sharing common targets in the brain.

Title: Anatomical characterization of GABAergic projections to the mouse rostromedial tegmental nucleus

Authors: J. L. THOMPSON[1], *T. C. JHOU[2];
[1]Med. Univ. of SouthCarolina, Charleston, SC; [2]Med. Univ. of South Carolina, Charleston, SC

Abstract: The rostromedial tegmental nucleus (RMTg) is a recently characterized brain structure necessary for encoding aversive stimuli and promoting avoidance behaviors. The magnitude of presynaptic glutamate release onto RMTg neurons is implicated in promoting avoidance or inhibiting responding to aversive and appetitive stimuli, respectively. However, it is unknown if RMTg neurons receive GABAergic inputs from distal regions, and if they are implicated in the inhibition of RMTg neurons seen during the presentation of reward-predictive cues. Here, we sought to characterize GABAergic inputs to the RMTg by retrogradely labelling RMTg afferents in VGAT-cre mice crossed to ZsGreen. We injected CTB (0.2%, 74 nL) unilaterally into the mouse RMTg (from bregma, mm; AP: -4.1ML: +1.1, DV (from skull): -4.75, at a 10 degree angle). Brains were sectioned and immunolabeled for fluorescent CTB using a biotinylated secondary antibody and fluorescent streptavidin. Analysis of CTB-labeled neurons were restricted to slices containing the hypothalamus. Several retrogradely labeled neurons negative for Vgat were observed in the lateral and medial regions of the hypothalamus, lateral habenula, and zona inserta as previously reported. Cells colabeled for Vgat and CTB were also found in these regions. A considerable portion of colabelling was found throughout the lateral hypothalamus, near the border of the premammillary nucleus and dorsal to the fornix. We observed the highest density of RMTg-projecting GABAergic neurons in the ventral portion of the zona inserta near the border of the lateral hypothalamus. Although the full extent to which GABAergic neurons project to the RMTg is unclear, a significant portion of RMTg-projecting neurons in hypothalamic regions appear to be GABAergic. How this population of neurons controls behaviors regulated by the RMTg remains to be elucidated.

Title: *In vivo* recording, identification and reconstruction of adult mouse ventral tegmental area (VTA) GABAergic neurons

Authors: *C. A. GONZALEZ-CABRERA[1], T. MONTERO[2], P. HENNY[2];
[1]Dept. de Anatomia, Facultad De Medicina Univ. Católica De Chile, Santiago, Chile; [2]Anatomia Normal, Pontificia Univ. Católica de Chile, Santiago, Chile

Abstract: GABAergic neurons of the ventral tegmental area (VTA) intermingle with dopaminergic neurons and, according to previous evidence, can regulate the activity of dopaminergic neurons through local projections. The present work aims to describe the innervation that VTA GABAergic neurons provide to neighbour dopaminergic neurons. In anaesthetised adult male mice, we recorded and labeled VTA single neurons using the juxtacellular technique. Following brain fixation and histological processing, neurobiotin-labeled neurons were identified as GABAergic by the presence of the vesicular inhibitory amino-acids transporter (VIAAT, also known as VGAT) in local axon terminals. We then examined appositions established between neurobiotin-labeled boutons and tyrosine hydroxylase positive (TH+) structures, and confirmed those contacts as synaptic using further staining for the scaffolding protein gephyrin. Preliminary results show that VTA GABAergic neurons leave axon collaterals in the VTA and that they intermingle with TH+ structures. By extending this analysis in a larger number of neurons, as well as to other type of local synaptic afferents (e.g. glutamatergic), this project aims to define the microcircuitry of the VTA.
