Title: Characterizing GABAergic interneuron deficit in Holoprosencephaly

Authors: *A. GILANI, J. LIBIEN;
Pathology, SUNY Downstate Med. Ctr., Brooklyn, NY

Abstract: Normal brain function requires an intricate balance of excitation and inhibition. Local interneurons that secrete GABA contribute the major inhibitory input to pyramidal neurons in the cerebral cortex. Cortical inhibitory interneurons show great diversity in their synaptic connectivity, electrophysiological properties and peptide content and may perform distinct functions in the cortical circuit. Not surprisingly, alterations in GABAergic function have been implicated in various psychiatric and neurological conditions, most notably in epilepsy, schizophrenia, and autism. In spite of their potential significance, GABAergic interneurons have been seldom studied in postmortem neuropathological examination of pediatric developmental disorders. A previous study (Fertuzinhos et al, Cerebral Cortex September 2009) showed that in Holoprosencephaly, a neurodevelopmental disorder with incomplete separation between the right and the left hemisphere, specific populations of GABAergic interneurons are reduced. The majority of cortical GABAergic interneurons are produced in the ganglionic eminence (GE), a neuroproliferative zone overlying the future basal ganglia. To further characterize interneuron deficit in Holoprosencephaly, we used immunohistochemical markers that label interneurons produced in the medial (Sox 6) and caudal (COUP-TFII, Calretinin) divisions of the GE. Preliminary results in a small set of fetal human brains with lobar holoprosencephaly indicate a complete absence of Sox 6+ neurons and an abnormal distribution of COUP-TFII and Calretinin+ neurons. These data indicate that different GABAergic proliferative zones are differentially affected in cases of Alobar Holoprosencephaly.

Title: Determining the impact of Zika virus on neural stem cells and mature neurons

Authors: *O. V. LOSSIA[1,2,3], M. T. OCEAN[2], E. D. PETERSEN[2,1], B. SRINAGESHWAR[1,3], U. HOCHGESCHWENDER[2,1], G. L. DUNBAR[1,5,4,3], M. J. CONWAY[2], J. ROSSIGNOL[2,3,1]; [1]Neurosci., [2]Col. of Med., [3]Field Neurosciences Inst. for Restorative Neurosci., [4]Psychology, Central Michigan Univ., Mount Pleasant, MI; [5]Field Neurosciences Inst., Saginaw, MI

Abstract: The recent emergence of Zika virus (ZIKV) has been linked to severe nervous system abnormalities in infants, such as microcephaly, and the autoimmune disorder, Guillain-Barré, in adults. The World Health Organization predicts that by the end of this year three to four million people will be infected with the Zika virus, a virus now known to be transmitted by mosquitoes and through sexual contact in humans. Very little is known regarding the basic biology of this virus and its implications in the developing brain, fueling the need to investigate the interactions of ZIKV with neural cells. So far, studies have shown that ZIKV affects the morphology and survival of neural stem cells and neural progenitor cells. In our study, we sought to assess the effect of ZIKV on neural stem cells (NSCs) and mature neurons using liquid chromatography-tandem mass spectrometry (LC-MS/MS) and multielectrode arrays (MEAs), respectively. We were able to determine the impact of infection on the secreted proteome "secretome" of NSCs as well as how the infection impacts the neuronal firing capabilities of mature neurons. Our results show that the ZIKV strain of African lineage is able to replicate in mouse NSCs and leads to a significant downregulation in secretion of proteins into the extracellular environment. These studies provide mechanistic detail on how ZIKV impacts the differentiation, survival, development, and function of neural stem cells and neuronal cultures. *Support for this study was provided by the College of Medicine, the Field Neurosciences Institute, and the John G. Kulhavi Professorship in Neuroscience at CMU.*

Title: Apoptotic signaling through p75NTR in response to BDNF requires Rab5 and JNK activity

Authors: *C. A. CABEZA, C. ESCUDERO, F. BRONFMAN;
Pontificia Univ. Católica De Chile, Santiago, Chile

Abstract: Introduction: During the development of the sympathetic nervous system, the p75 neurotrophin receptor (p75NTR) triggers apoptosis upon binding to BDNF. Apoptotic signaling through p75 requires activation of the stress kinase, JNK that increases the regulated receptor proteolysis in response to pro-apoptotic ligands. The cleavage facilitated ubiquitination of the DNA binding protein NRIF, a zinc finger protein that interacts with the intracellular domain of p75, resulting in nuclear translocation of NRIF. Moreover, this leads a second wave of activation of JNK. All this is required for a long-term apoptotic signaling of p75. Rab5 regulates the trafficking of receptors by regulating early endosomes dynamics. Results of our lab have shown that p75 transiently interacts with the Rab5 positive endosomes in sympathetic neurons (SCGs) and accumulates in other endocytic organelles. Our aim was to clarify the role of Rab5 positive endosomes on p75 signaling and the relevance of JNK in retrograde apoptotic signaling of p75. **Material and Methods:** We used SCGs prepared from postnatal day one rats. We over-expressed a constitutively active (Rab5CA) or dominant negative (Rab5DN) Rab5 mutants in 6 DIV SCGs and then we treated with BDNF for 30 hrs. We evaluated NRIF translocation and cleaved caspase-3. Moreover, we used compartmentalized culture of SCGs to evaluate JNK activation in axons. In addition, we used SP600125 a JNK inhibitor to evaluate the role of this kinase in the internalization and apoptotic signaling of p75. **Results:** When a Rab5CA mutant was expressed, p75 was accumulated in Rab5 positive organelles and we observed an increase nuclear translocation of NRIF in response to BDNF. Nevertheless, when Rab5 activity was down regulated by expressing a Rab5DN a down-regulation of NRIF nuclear translocation and cleavage of caspase-3 was observed in response to BDNF. Moreover, we evaluated the retrograde activation of JNK by BDNF. Inhibition of JNK activity by SP600125 decreases the internalization and apoptotic signaling of p75. **Discussion:** Our results suggest that although p75 transiently interacts with Rab5 positive endosomes, this interaction is required for BDNF-mediated NRIF nuclear translocation and cleavage of caspase-3. In addition, we determine a new role of JNK in the internalization and retrograde apoptotic signaling of p75.

Title: Ventricular zone disassembly and delamination of radial glia progenitors triggers alpha-beta hydrolase domain containing 4 (ABHD4)-mediated cell death in the embryonic neocortex

Authors: *Z. LÁSZLÓ[1,2], Z. LELE[1], Z. BALOGI[1], A. DORNING[1], G. SIMON[3], S. SHU-JUNG HU[4], K. MACKIE[4], B. CRAVATT[3], I. KATONA[1];

[4]Psychological and Brain Sci., Gill Inst., Bloomington, IN

Abstract: Epithelial-mesenchymal transition (EMT) of epithelial cells and delamination of the non-radial glia-fated daughter cells after asymmetric divisions in the embryonic cortex share several common features. It is presently unclear however, whether an anoikis-like protective apoptosis is also present in the developing cortex and if there is, how non-radial glia-fated daughter cells escape it during their migration? Here, we demonstrate that interference with classic cadherin-dependent adherens junction function in radial glia progenitor cells initiates disassembly of the ventricular zone. In turn, this leads to the abnormal dispersion of Pax6-positive cells into the SVZ, and halts proper cell migration into the cortical plate due to an elevated caspase-dependent cell death response in the electroporated area. Prior studies suggested that endocannabinoid signaling controls cell migration in the developing neocortex, and that cannabinoid ligands regulate cell death processes in various *in vitro* models. Notably, we found that *Abhd4*, a serine-hydrolase, which functions as an N-acyl-phosphatidylethanolamine (NAPE) lipase, and produces a precursor lipid for the biosynthesis of the endocannabinoid anandamide, is highly and specifically expressed in the ventricular zone during cortical development. In addition, expression of *Abhd4* (but not of its hydrolase-dead point mutant version) induces apoptosis *in vitro* in the immortalized neuroepithelial modell NE-4C cells, as well in the generally apoptosis-resistant HEK293 cells. Furthermore, in utero electroporation of Abhd4 into the lateral ventricles triggers a similar cell death response. Most

importantly, however, we also found that loss of Abhd4 eliminates increased neocortical cell death induced by breaking up cadherin connections between radial glia cells. Together, these results demonstrate that Abhd4 is a necessary and sufficient proapoptotic member of the pathway between ventricular zone disassembly due to adherens junction disruption and caspase-dependent apoptosis.

Title: Angiopoietin-1 is essential for zebrafish embryonic neurogenesis

Authors: *Y.-C. CHEN, V. MARCHICA, T. S. MARTINS, P. PANULA;
Univ. of Helsinki, Helsinki, Finland

Abstract: Angiopoietin-1 (*angpt1*) is a selective endothelial cell growth factor that binds to its receptor Tie2 and regulates vessel development and vascular stabilization. Besides its crucial role in angiogenesis, it also acts as a proneurogenic peptide involved in neuronal differentiation and affects the brain size in fish. How angpt1 regulates neurogenesis is still largely unknown. The present study focuses on the role of angpt1 during zebrafish development. By quantitative PCR (qPCR), the transcripts of *angpt1*, *angpt2b* and *tie2* were detected at one-cell stage and showed a robust expression at the prim-5 stage (24 hours post-fertilization). The spatiotemporal patterns showed that these angiogenic factors were expressed in the eyes, heart, hypochord and aortic arch arteries in the head and trunk. To elucidate the function of angpt1, we investigated a zebrafish mutant, *angpt1*^{sa14264}, carrying a nonsense mutation resulting in a stop codon at Q261. The *angpt1*mutant embryos showed a smaller size of head and body length compared with the wild type-like siblings, and exhibited cardiac edema, embryonic CNS hemorrhage, poor blood circulation and blood accumulation in the pericardial sac. They did not survive beyond 5 dpf. Additionally, at 3 dpf, a significant reduction of *tyrosine hydroxylase 1* transcript was detected in *angpt1*-deficient fish; however, the mRNA level of *tie1*, *angpt2b*, *tyrosine hydroxylase 2* and *histidine decarboxylase* were unaffected. These results demonstrate that lack of angpt1 leads to aberrant embryonic brain and cardiovascular development.

Title: Microglial morphology during cortical development

Authors: *J. '. KEITER[1], V. MARTINEZ-CERDEÑO[2], S. NOCTOR[2];
[1]UC Davis, Vacaville, CA; [2]UC Davis, Davis, CA

Abstract: Microglia are resident macrophages of the brain and colonize the cerebral cortex during early development. Recent evidence demonstrates that microglia shape brain development and that disrupting microglial function during early development may be a factor in neurodevelopmental diseases such as Schizophrenia and Autism. The functional role(s) of microglia in the normally developing brain are not well understood. In the healthy adult cerebral cortex microglia are distributed evenly throughout the grey matter of the cerebral cortex, and the cells have a relatively small soma with many finely ramified processes. Microglia displaying this morphology have traditionally been termed 'resting' cells. In contrast, after damage like injury or stroke, and in neuropathological conditions microglia take on an 'activated' morphology characterized by a large soma and a few thick processes, or an amoeboid shape. Activated microglia concentrate in regions of injury or pathology and are a hallmark of pathology. Interestingly, recent work has shown that as microglial cells begin colonizing the normally developing brain they concentrate in distinct regions including cellular proliferative zones, and display the activated morphology that is characteristic of pathology in the adult brain. We have found that microglia display distinct morphological profiles within different structures of the developing cerebral cortex. Here we map out the distribution of microglial cells in the developing brain and correlate morphology with cell location. We show that microglia in the subventricular zone (SVZ) of the developing cerebral cortex are more likely to exhibit an amoeboid shape. Microglia in the SVZ have a large soma, and few short thick processes. In contrast, microglial cells closer to the ventricle in the ventricular zone have a smaller soma and more elaborate processes than microglia in the SVZ. We also note that amoeboid microglia lacking any processes are found in discrete structures. The few microglia that are located within

the developing cortical plate exhibit a “rod” like shape and a radial orientation. Correlating microglial cell morphology with location in the developing brain may offer clues to the varied functions associated these cells in the developing cortex.

Title: Mediation of autophagic cell death by type 3 ryanodine receptor (RyR3) in adult hippocampal neural stem cells

Authors: *K. CHUNG, E.-J. JEONG, H. PARK, H.-K. AN, S.-W. YU;
Daegu Gyeongbuk Inst. of Sci. & Technol., Daegu, Korea, Republic of

Abstract: Cytoplasmic Ca^{2+} actively engages in diverse intracellular processes from protein synthesis, folding and trafficking to cell survival and death. Dysregulation of intracellular Ca^{2+} levels is observed in various neuropathological states including Alzheimer’s and Parkinson’s diseases. Ryanodine receptors (RyRs) and IP_3 receptors (IP_3Rs), the main Ca^{2+} release channels located in endoplasmic reticulum (ER) membranes, are known to direct various cellular events such as autophagy and apoptosis. Here we investigated the intracellular Ca^{2+}-mediated regulation of survival and death of adult hippocampal neural stem (HCN) cells utilizing an insulin withdrawal model of autophagic cell death. Despite comparable expression levels of RyR and IP_3R transcripts in HCN cells at normal state, the expression levels of RyRs — especially RyR3 — were markedly upregulated upon insulin withdrawal. While treatment with the RyR agonist caffeine significantly promoted the autophagic death of insulin-deficient HCN cells, treatment with its inhibitor dantrolene prevented the induction of autophagy following insulin withdrawal. Furthermore, CRISPR/Cas9-mediated knockout of the RyR3 gene abolished autophagic cell death of HCN cells. This study delineates a distinct, RyR3-mediated ER Ca^{2+} regulation of autophagy and programmed cell death in neural stem cells. Our findings provide novel insights into the critical, yet understudied mechanisms underlying the regulatory function of ER Ca^{2+} in neural stem cell biology.

Title: Exposure of embryonic Xenopus laevis to organophosphate pesticides during development leads to disruption of the cholinergic nervous system

Authors: ***M. BRYSON**[1], F. WATSON[1], E. FRADINGER[2], T. HOLDER[1], M. QUELLHORST[1];
[1]Biol., Washington and Lee Univ., Lexington, VA; [2]Whittier Col., Whittier, CA

Abstract: Organophosphate pesticides (OPs), a subset of acetylcholinesterase-inhibiting chemicals, are widely used to protect crops, homes and businesses from insects. Despite a US ban on residential use of organophosphates, widespread use of these pesticides continues in large scale agriculture. Developing countries have no pesticide restrictions and rely heavily on OPs residentially as well as agriculturally. Because it is difficult to mitigate exposure to these pesticides, it is important to understand both the short and long term effects of exposure to these compounds. Here we examine the effects of chlorpyrifos exposure on the sensory neurons of developing *Xenopus laevis* over a 21-day period. At concentrations above 0.1 μM, we observed reduced survival by day 4. At concentrations above 1 μM, nearly all tadpoles died by day 6. We examined two subpopulations of sensory neurons, dorsal root ganglia and Rohon-Beard neurons, and show increased defects in neural migration at developmental stages 33, 47, and 52. Chlorpyrifos exposure leads to decreased neuronal growth coupled with large scale neural migration defects. Rohon-Beard neurons fail to develop in a linear fashion within the dorsal spinal column, especially in stage 33 tadpoles. Exposure levels of 5 μM and above lead to more severe neural migration defects such that Rohon-Beard neurons often reside outside the spinal column. Dorsal root ganglia neurons also show irregular neural patterns at these higher concentrations. To assess the level of apoptosis, we use Acridine Orange. Preliminary data shows apoptosis occurs within the external skeletal muscle of the tadpoles. This pesticide-induced cell death increases with increasing chlorpyrifos concentrations. Our results provide evidence that OPs have profound neurological effects in developing vertebrates and ongoing studies will investigate and provide a more complete analysis of sensory neuron defects caused by OP exposure.

Title: Mutant SOD1 species induce toxicity in astrocytic cultures: bystander effects occur in a continuum of astrogliosis

Authors: ***R. D. O'SHEA**[1], N. WALLIS[2], C. L. LAU[2], M. A. FARG[3], J. D. ATKIN[4,3], P. M. BEART[2];
[1]La Trobe University, Dept. of Physiology, Ana, La Trobe University, Australia;
[2]Neurodegeneration, The Florey Inst. of Neurosci. and Mental Hlth., Parkville, Australia;
[3]Biochem., La Trobe Univ., Bundoora, Australia; [4]Biomed. Sci., Macquarie Univ., North Ryde, Australia

Abstract: Astrocytes contribute to the death of motor neurons via non-cell autonomous mechanisms of injury in amyotrophic lateral sclerosis (ALS). Since mutations in the gene encoding Cu/Zn superoxide dismutase (SOD1) underlie the neuropathology of some forms of familial ALS, we explored how expression of mutant SOD1 proteins affected the biology of murine astrocytes in culture. Primary cultures of astrocytes were established from forebrains of C57BL6 mouse pups (postnatal day 1.5; at least n=3 independent cultures), and were subcultured after 10 days into 48-well plates (1 x 10^4 cells/cm^2) and maintained until confluent. Cells were transfected with constructs expressing wild-type SOD1-EGFP, A4V SOD1-EGFP or G85R

SOD1-EGFP, using Transfast according to the manufacturer's instructions. 72 h after transfection, astrocytes expressing A4V SOD1-EGFP displayed impaired mitochondrial activity (~45%, MTT assay) and L-glutamate transporter activity (~25%, [^{3}H]-D-Aspartate uptake), relative to those transfected with wild-type SOD1-EGFP. Astrocytes transfected with A4V SOD1-EGFP also demonstrated altered F-actin and Hoechst staining, indicative of cytoskeletal and nuclear changes, while altered GM130 labelling suggested fragmentation of Golgi apparatus. SOD1 inclusion formation shifted from discrete to "clumpy" over 72 h. A4V SOD1-EGFP more rapidly produced inclusions than G85R SOD1-EGFP and formed more "clumpy" aggregates. A4V SOD1-EGFP, but not wild-type SOD1-EGFP, exerted a substantial, time-dependent effect on GFAP expression, and ~60% of astrocytes were stellate and hypertrophic at 72 h. Spreading toxicity was inferred, since at 72 h ~80% of bystander cells exhibited hypertrophy and stellation. This evidence suggests that mutant SOD1-containing astrocytes release destructive species that alter the biology of adjacent astrocytes. This panoply of mutant SOD1-induced destructive events favours recruitment of astrocytes to non-cell autonomous injury in ALS.

Title: Disruption of nuclear bodies causes activation of DNA damage and repair pathways

Authors: *A. KANNAN[1], K. BHATIA[2], L. GANGWANI[2];
[1]Neurosci., Texas Tech. Univ. Hlth. Sci. Ctr., El Paso, TX; [2]Neurosciences, Texas Tech. Univ. of Hlth. Sci. Ctr., El Paso, TX

Abstract: Nuclear bodies are membraneless subnuclear organelles rich in RNAs and proteins involved in various nuclear processes, including RNA biogenesis (maturation and splicing), stress response, transcription and DNA replication. Integrity of many nuclear bodies such as gems, Cajal bodies (CBs), histone locus bodies (HLBs), promyelocytic leukaemia (PML) bodies is essential for the normal functioning of mammalian cells. Each nuclear body carry out specific function and disruption of these sub-nuclear bodies leads to pathological conditions with human diseases such as neurodegenerative disorders, including spinal muscular atrophy (SMA). SMA is

an autosomal recessive disease caused by the low levels of full length survival motor neuron (SMN) protein. Zinc finger protein ZPR1 interacts with SMN and is required for the accumulation of SMN in nuclear bodies. The interaction of ZPR1 with SMN is disrupted in SMA and SMN fails to accumulate in gems and CBs in cells derived from SMA patients. The severity of SMA disease correlates negatively with the number of SMN containing nuclear bodies. In this study, we have investigated the effect of the low levels of ZPR1 and SMN on the integrity of sub-nuclear bodies such as CBs, HLBs and PML bodies identified by the signatory proteins p80 coilin, LSM11 and PML respectively in cultured cells. Knockdown of ZPR1 and SMN was achieved by using antisense oligonucleotides and RNA interference (RNAi) respectively. We show that the reduced expression of ZPR1 or SMN causes disruption of Cajal, HLB and PML nuclear bodies and marker proteins p80 coilin, LSM11 and PML are mislocalized. We examined the effect of disruption of these nuclear bodies on transcription, replication and integrity of genomic DNA. We report that the disruption of ZPR1 or SMN containing nuclear bodies results in fragmentation of DNA and activation of DNA damage and repair pathways proteins such as γH2AX, 53BP1, pATM, pATR and pDNAPKc. Results from the present study show that the disruption of sub-nuclear bodies causes activation of DNA damage and repair pathways that leads to defects in transcription and DNA replication. This finding suggests that DNA damage may contribute to neurodegenerative disorders, including SMA.

Title: Mechanisms underlying C9orf72 associated toxicity in a *C. elegans* model of disease

Authors: ***S. T. LAMITINA**[1], J. OOSTEN[1], C. SNOZNIK[1], U. PANDEY[2], P. RUDICH[3]; [1]Dept of Pediatrics and Cell Biol., [2]Dept of Neurol., [3]Dept of Pediatrics and Cell Biology, Grad. Program in Cell Biol., Childrens Hosp. of Pittsburgh of UPMC, Pittsburgh, PA

Abstract: Amyotrophic lateral sclerosis (ALS) is a rapidly progressing age-related neurodegenerative disease that affects ~30,000 Americans. ALS causes degeneration of the

upper and lower motor neurons, leading to paralysis. Currently, there are no effective treatments for ALS and only ~50% of patients survive beyond three years after diagnosis. A recently discovered expanded hexanucleotide repeat in the first intron of the C9orf72 gene is the most common known genetic cause of familial and sporadic ALS. The repeat expansion is not thought to cause disease through alteration of C9orf72 function. Rather, the expanded repeat is transcribed in both sense and antisense directions to produce repeat-containing RNAs that are then translated in multiple reading frames to yield up to five distinct dipeptide repeat proteins. This unusual mode of translation is termed Repeat Associated-non-ATG (RAN) translation. It is controversial whether the expanded repeats cause ALS through RNA toxicity, RAN translated dipeptide toxicity, or both. Using codon-varied transgenes, we created a 'dipeptide-only' model in the nematode *C. elegans* to better understand the mechanisms of dipeptide toxicity. The arginine rich dipeptides, PR and GR, were toxic in *C. elegans* when expressed in multiple cell types, including motor neurons. This toxicity was dependent on both the length of the dipeptide as well as its subcellular localization. Genetic inhibition of the insulin pathway, a conserved regulator of ageing, delayed age-onset toxicity caused by PR dipeptides, suggesting that physiological age rather than chronological age is a determinant of PR toxicity. Currently, we are performing RNAseq and using unbiased forward and reverse genetic screens to identify modifiers or arginine-containing dipeptide toxicity. Defining these modifiers will allow us to determine potential mechanisms for dipeptide toxicity and may lead to new disease biomarkers and/or therapies.

Title: The divergent neuroprotective capacities of *Drosophila* Nmnat in C9orf72 ALS/FTD

Authors: *K. O. RUAN[1], R. ZHAI[2], T. LLOYD[1];
[1]Dept. of Neurol., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Dept. of Mol. and Cell. Pharmacol., Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: Nicotinamide mononucleotide adenylyltransferase (NMNAT) is a conserved enzyme in the NAD synthetic pathway. It has also been identified as an effective and versatile neuroprotective factor. However, it remains unclear how healthy neurons regulate the dual

functions of NMNAT and achieve self-protection under stress. My previous study has shown that *Drosophila Nmnat* (*DmNmnat*) is alternatively spliced into two mRNA variants, RA and RB, which translate to protein isoforms with divergent neuroprotective capacities against spinocerebellar ataxia 1 (SCA1)-induced neurodegeneration. Isoform PA/PC translated from RA is nuclear-localized with minimal neuroprotective ability, and isoform PB/PD translated from RB is cytoplasmic and has robust neuroprotective capacity. Under stress, RB is preferably spliced in neurons to produce the neuroprotective PB/PD isoforms. The results indicate that alternative splicing functions as a switch that regulates the expression of functionally distinct DmNmnat variants. Neurons respond to stress by driving the splicing switch to produce the neuroprotective variant and therefore achieve self-protection.I am now applying this concept to the study of C9orf72. In this study, I will explore three questions: (1) whether the divergent neuroprotective capacities of NMNAT isoforms also occur in C9orf72 ALS/FTD; (2) whether the protection is cell autonomous; and (3) whether this neuroprotective effect is cell-type specific.

Title: Temporal and spatial expression pattern of miRNA and protein expression in peripheral nerve injury

Authors: *V. YEROKHIN, S. DAS, K. MILLER;
Oklahoma State Univ. Ctr. For Hlth. Scienc, Tulsa, OK

Abstract: Peripheral nerve injury (PNI) affects approximately 20 million Americans annually, costing the healthcare system over $150 billion each year. Although current therapies attempt to promote nerve regeneration, only 50% of persons fully regain motor and sensory function, while others retain poor motor control and suffer from life-long, debilitating neuropathic pain. Injured peripheral axons can regenerate, but this is rarely complete due to the slow rate of regeneration. Clearly, a new therapeutic approach for accelerating peripheral nerve regeneration is needed. Although miRNA and anti-miRNA therapy has proved fruitful in normalizing dysregulated protein expression in other diseases, clinical use of this therapeutic modality in pain and PNI has yet to be realized. The absence of translational application of miRNA therapeutics stems mostly

from our limited understanding of the molecular mechanisms underlying nerve injury and regeneration. Because nerve regeneration requires a complex coordination of finely regulated events, understanding these molecular mechanisms is key for designing an effective bio-pharmacological intervention. In this study, we present novel findings of spatial and temporal expression of miRNA let-7a and 23b post-PNI, and elucidate their relationship with Nerve Growth Factor (NGF) and Glutaminase (GLS) expression. Three experimental and three sham surgery groups of male, Sprague-Dawley (SD) rats (n=6 per group) underwent sciatic nerve crush (SNC). The animals were euthanized and the sciatic nerve (SN), the dorsal root ganglia (DRG) and the spinal cord (SC) at the level of SN innervation (L4-L6 levels) were collected at 3 time points: 1) 24 hours (Group 1), 2) 4 days (Group 2) and 3) 7 days (Group 3) post-injury. The SN proximal to, at the location of, and distal to the site of injury was collected. Protein and miRNA expression was measured using Western Blot and RT-PCR. A sham surgical control group (n=6 per group) was paired to each experimental group. The SN was visualized, but not crushed in the sham surgery group. We observed differential expression of the miRNAs and proteins at the different sites following SNC (SN, SC and DRGs). Furthermore, we observed an inverse relationship between the miRNA let-7a and 23b and NGF and GLS expression, respectively. Finally, the differential expression followed a temporal trend. To our knowledge, this study is the first to assess miRNA let-7a and 23b and NGF and GLS expression in sciatic nerve injury model. As such, we provide a novel insight onto possible therapeutic targets in *vivo* for improving functional outcome following nerve injury.

Title: The daily pattern of adult neurogenesis in zebrafish

Authors: *A. STANKIEWICZ[1], V. AKLE[2], L. YU[1], I. ZHDANOVA[1];
[1]Anat. and Neurobio., Boston Univ. Sch. of Med., Boston, MA; [2]Univ. de los Andes, Bogota, Colombia

Abstract: The majority of physiological processes follows a circadian pattern and is under direct or indirect control of the intrinsic clock. To investigate whether adult neurogenesis in diurnal

vertebrates, like human, follows a circadian pattern, and the timing of specific phases of the cell cycle, we used zebrafish as a model, in view of its robust circadian clock system, diurnality, and abundant adult neurogenesis. We employed real-time RT-PCR (qPCR) analysis of mRNA expression for D, E, A2 and B2 cyclins involved in specific phases of the cell cycle, and immunohistochemical analysis of markers for S-phase (BrdU and EdU) and G2/M phase (pH3) of the cell cycle. The results demonstrated the presence of a robust daily rhythm of cell proliferation in adult brain and determined that while many cells can repeat the cell cycle the following day, a large proportion of neuronal progenitors can cycle with longer than 24h periods. The number of neuronal progenitors dividing on any given day remains stable, with BrdU/EdU pulse-chase studies revealing gradual decline in the number of older neuronal progenitors being compensated by the emergence of new cells, and reflecting the neuronal stem cell activity. This is a powerful model to determine optimal timing for pharmacological and physical interventions that can promote adult neurogenesis, and to characterize time-dependent adverse impact of diverse agents on adult neurogenesis.

Title: Alterations in human hippocampal neurogenesis predict progression from mild cognitive impairment to Alzheimer's disease

Authors: A. MARUSZAK[1], T. MURPHY[1], A. DOUIRI[2], A. J. NEVADO[3], B. LIU[3], C. DE LUCIA[1], J. PRICE[1], S. LOVESTONE[3], *S. THURET[1];

Abstract: Introduction: We hypothesized that Alzheimer's disease (AD) systemic milieu (blood/serum) modulates hippocampal neurogenesis (HN). The systemic environment is a

recognized modulator of HN and carries factors implicated in AD. Increasing evidence has demonstrated that adult HN plays an essential role in learning and memory. In addition, altered HN is an early hallmark of AD. Given that HN occurs in one of the earliest affected brain structures in AD, the gradual impairment of memory and learning observed during the disease progression might be linked to changes in HN.
We aimed at establishing how the systemic environment influences HN in AD using an in vitro assay of human hippocampal neurogenesis. Our goal was also to apply our assay in predicting conversion from mild cognitive impairment (MCI) to AD.
Materials and Methods: Human multipotent hippocampal progenitor cell line HPC0A07/03C was exposed to human serum from 1) individuals with MCI that converted to AD (MCI converters) and 2) individuals that were initially diagnosed with MCI but did not develop any disease (MCI non-converters). Serum from each annual follow-up visit was used to model changes in HN with disease progression. Statistical analyses involved linear mixed effects models for repeated measures and stepwise logistic regression.
Results: We determined that decreased proliferation, increased neurogenesis and increased cell death are signatures of disease progression towards conversion to AD. Proliferation of HPC0A07/03C cells in the presence of serum from MCI converters leads to significantly higher proliferation rate and apoptotic cell death as compared to the effects of serum from MCI non-converters. In addition, exposure to serum during both proliferation and differentiation of the HPC0A07/03C cells is associated with increased levels of newborn neurons and elevated apoptotic death when serum donors were MCI converters as compared to MCI non-converters. Finally, we built a statistical model predicting the likelihood of conversion from MCI to AD at baseline. Among the predictors of conversion are education and baseline assay readouts (proliferation rate, average cell count during proliferation, cell death during differentiation). The ROC curve shows that our model is very good at discriminating (AUC=0.9675) who will develop AD, with 92.11% converters correctly classified and 94.12% MCI non-converters correctly discriminated.
Conclusion: Our data highlights the importance of the systemic environment for HN in AD and our assay could be used as a biomarker of disease progression and conversion to AD.

Abstract: The cerebral cortex plays a key role for higher-order cortical functions and is traditionally viewed as a non-neurogenic region. However, it remains controversial whether continuous, transient, or no neurogenesis occurs in the adult cerebral cortex. A microcircuit of sensory input from cortical layer IV is projected to layer II-III that in turn drives layer V. Excitation of excitatory neurons in layer II-III is controlled by fewer GABAergic interneurons, providing a rationale for why newborn layer II-III interneurons should contribute to cortical plasticity. Similar to other neurogenic regions, expression of neuroblast markers in cortical layer II-III is regulated by enriched environment, stress, and injuries. Using flow cytometry, we confirmed the presence of neuroblasts antigens in cortical layer II-III of adult mice. Using bromodeoxyuridine (BrdU) pulse-chase and genetic fate-mapping experiments, we demonstrate that glial fibrillary acidic protein-positive astrocytes can give rise to layer II-III neuroblasts during adulthood. Adult-born layer II-III neuroblasts differentiated into GABAergic interneurons in mice. Patients diseased from non-brain related disorders and pulsed with BrdU displayed significant numbers of BrdU+ cells in layer II-III of the cerebral cortex. In conclusion, we identify limited numbers of astrocyte-derived neuroblasts in the adult brain. Identifying cortical astrocytes as a novel source of immature neurons and GABAergic interneurons has wide-spread implications for cortical plasticity, regeneration and brain repair.

Title: Multilevel regulation of neural stem cell proliferation and self-renewal by Pros1

Authors: *T. BURSTYN-COHEN[1], K. ZELENTSOVA[1], Z. TALMI[1], G. ABBOUD-JARROUS[1], T. SAPIR[2], T. CAPUTCHA[1];
[1]The Hebrew Univ., Jerusalem, Israel; [2]Dept. of Mol. Genet., Weizmann Inst. for Sci., Rehovot, Israel

Abstract: Revealing the molecular mechanisms underlying neural stem cell self-renewal is a major goal towards understanding adult brain homeostasis. The self-renewing potential of Neural stem cells (NSCs) must be tightly regulated to maintain brain homeostasis. We find the expression of the anticoagulant Protein S (PROS1) in adult hippocampal NSCs, and show that genetic ablation of *Pros1* in neural progenitors increased both NSC proliferation and self-renewal. Mechanistically, we identified the upregulation of Bmi-1 signaling to cell-autonomously promote NSC self-renewal in *Pros1*-ablated cells. Rescuing *Pros1* expression restores Bmi-1 signaling, and reverts the proliferation and enhanced self-renewal phenotypes observed in *Pros1*-deleted cells. Enhanced proliferation in Pros1-deleted NSCs was found to be mediated through dysregulated Notch1 signaling. Our study uniquely uncouples between increased NSC proliferation and depletion of the NSC pool, due to concomitant increased self-renewal. By manipulating PROS1 expression, we provide a novel model in which both Notch1 and Bmi-1 pathways are dysregulated, allowing to investigate the balance between these two key pathways, and their impact on adult neurogenesis. We provide a first indication that the balance between Bmi-1 and Notch signaling pathways is important, and may lead to new outcomes. Conclusion: We identify PROS1 as a novel regulator of NSC biology. PROS1-deleted NSCs are affected at multiple levels: quiescence/proliferation, self-renewal/differentiation and daughter-cell fate determination. Our findings provide novel insight into maintaining brain homeostasis.

Heart Inst. and Ctr. for Neurosci. Res., Children's Natl. Med. Ctr., Washington, DC

Abstract: Many patients suffering from severe/complex congenital heart disease (CHD) display significant neurodevelopmental deficits and subnormal cortical development associated with reduced cerebral oxygenation during fetal life and early infancy. Due to technical/ethical barriers, the cellular mechanisms underlying cortical dysmaturation and function in CHD remain elusive and hinder therapeutic advances. Therefore, novel models utilizing gyrencephalic species to recapitulate subnormal cortical brain development in CHD will be essential in determining the cellular mechanisms underlying brain dysmaturation. We have developed a neonatal porcine hypoxia model to address these key issues. Magnetic resonance imaging (MRI) revealed that chronic hypoxia reduced cortical volume and folding of the frontal cortex. Under normal physiological conditions, we found that the porcine subventricular zone (SVZ) shares unique anatomical/structural similarities with the human SVZ; including nearly identical laminar

organization with an astrocyte ribbon. In addition, we identified a subregion of the SVZ with an abundance of multipotent neural stem progenitor cells (NSPCs) that supply the frontal cortex with newborn neurons during early postnatal development. *In vivo* cell labeling demonstrated that chronic hypoxia limits the contribution of SVZ-derived neurons to postnatal cortical development. Finally, a decrease in the number of immature neurons was displayed within the frontal cortices with no changes in apoptosis. These findings suggest that chronic hypoxia reduces the generation of neuronal producing NSPCs in the SVZ which delays/impairs corticogenesis. Since the SVZ generates neural NSPCs capable of replenishing damaged neurons and glia in the brain throughout the human lifespan, novel therapies designed to protect or replenish SVZ-derived NSPCs may restore cortical growth and improve neurological function in patients born with CHD.

Title: Calorie restriction modulates intrinsic and niche factors in the aging murine subventricular zone

Authors: *D. M. APPLE[1], R. SOLANO FONSECA[2], S. MAHESULA[2], E. KOKOVAY[2]; [1]Dept. of Cell. and Structural Biol., Univ. of Texas Hlth. Sci. Ctr. San Antonio, San Antonio, TX; [2]Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX

Abstract: The normal aging process in the brain results in increased susceptibility to damage from brain insults like stroke, inflammation, and degeneration. Calorie restriction (CR) can improve physiological markers of health during aging, including extending lifespan and protecting against age-related damage to the brain. The largest source of neural stem cells in the adult brain is the subventricular zone (SVZ). We sought to determine the effect of long-term CR on neurogenesis and the neural stem cell niche in the SVZ of young and aged mice. Here, we

show that aged mice fed standard control chow have fewer SVZ-derived neurons in the olfactory bulb, indicating that aging impairs neural stem cell function. Long-term CR preserved neural stem cell function and resulted in a significant increase in neurogenesis in aged mice compared with *ad libitum*- fed controls. Confocal imaging and fluorescent staining of SVZ wholemounts revealed an increase in both the total number and reactivity of microglia in the aged control mouse, suggesting increased inflammation in the neural stem cell niche during aging. Remarkably, these age-related inflammatory markers were not observed in the long-term CR aged mice, which appeared no different from young control and young CR mice included in the study. We observed a protective effect of CR on aging related dysregulation of vascular-associated chemoattractants important for stem cell activity. However, CR did not protect against rarefaction of the SVZ vasculature in the aged brain. Altered proliferation profiles in the aged SVZ have suggested a change in cell fate determination, and CR maintains the expression of lin28a, a modulator of stem cell differentiation that declines in the aged brain. The maintenance of lin28a levels in the aged SVZ by CR suggests a potential mechanism by which CR protects the SVZ neural stem cell population in the aging brain.

Title: The effects of a proprietary spearmint extract on neurogenesis rates in rat hippocampal neurons

Authors: *B. A. FONSECA, K. A. HERRLINGER;
Kemin Human Nutr. and Hlth., Des Moines, IA

Abstract: Decreases in cognitive performance due to aging, stress and/or sleep deprivation can often be associated with specific changes in the brain. An area of the hippocampus known as the dentate gyrus is one of the few areas in the adult human brain that can produce new neurons throughout the lifespan, a process called neurogenesis. Aging, stress and/or sleep deprivation are suggested to decrease the rate of neurogenesis through reduced activity in the dentate gyrus resulting in a corresponding reduction in cognitive performance in healthy adults. Neumentix™

Phenolic Complex K110-42 is a natural extract derived from spearmint containing greater than 66 phenolic constituents that has been shown to improve working memory after 90 days of supplementation in healthy adults with age associated memory impairment. One reason for the observed improvements with Neumentix was hypothesized to be an increase in the rates of neurogenesis in the dentate gyrus of the hippocampus. Therefore, the purpose of this study was to determine if Neumentix could enhance neurogenesis in rat hippocampal cells at physiologically relevant concentrations in a cell culture assay. Four concentrations of Neumentix were tested on primary hippocampal cells treated with the test item, vehicle, or fibroblast growth factor, for a total of 48 h. Digital images were analyzed for the % of Bromdesoxyuridine (BrdU) positive neurons compared to the total number of neurons. Cells, which were labeled by BrdU, NeuN and 4',6-diamidino-2-phenylindole (Dapi), were classified as proliferating neurons. Neurons were defined as cells positive for NeuN and Dapi. Analyses showed that primary embryonic hippocampal neurons responded differentially to various concentrations of Neumentix. Overall, there was a treatment effect as determined by one-way ANOVA ($p=0.0169$). A Fisher's LSD pairwise comparison showed the treated cultures in the lowest dose group (0.02083 mg/L Neumentix) displayed significantly greater levels of neurogenesis than vehicle treated cultures ($p=0.0228$) indicating that Neumentix may support working memory by acting to increase rates of neurogenesis in the adult hippocampus.

Title: Effects of the Smoothened antagonist MRT-83 on adult neural stem cells quiescence and activation

Authors: L. TIROU[1], M. DAYNAC[1], H. FAURE[1], L. GAUTHIER[2], M.-A. MOUTHON[2], F. BOUSSIN[2], *M. RUAT[1];
[1]NeuroPSI, UMR9197, CNRS, Gif Sur Yvette, France; [2]CEA DSV iRCM SCSR Lab. de Radiopathologie, Fontenay-aux-Roses, France

Abstract: Neural stem cells (NSCs) from the subventricular zone (SVZ) of the lateral ventricle are implicated in adult neurogenesis and brain repair. The Sonic Hedgehog (Shh) pathway is important for regulating adult NSC proliferation, but its roles on particular NSCs (quiescent vs.

activated) and the neurogenic population of the SVZ, are not known (Ruat et al, *Top Med Chem*, 2015). Using immunofluorescence and FACS techniques to distinguish all SVZ neurogenic populations, including quiescent vs activated NSCs, we dug out the role of Shh pathway on the maintenance of adult neurogenesis. We observed that, in adult transgenic Fluorescence Ubiquitination Cell Cycle Indicator (FUCCI)-Green mice that allow tracking the S-G2/M phases with green fluorescence (Sakaue-Sawano et al, *Cell*, 2008), proliferating quiescent NSCs (qNSCs) and activated NSCs (aNSCs) are increased 3 days after intraventricular Shh injections. This effect is specific to qNSCs and aNSCs and not their progeny, the transit amplifying cells or immature neuroblasts. Then, we investigated whether a pharmacological blockade of the Shh pathway could modify the cell proliferation effect observed above. Treatment with the Smo antagonist MRT-83 (1µM) (Roudaut et al*, Mol Pharmacol*, 2011) reduced the number and size of neurospheres *in vitro*, thus mirroring *in vitro* data with Shh. The number of proliferating qNSCs and aNSCs from the SVZ populations was decreased 3 days after intraventricular injection of MRT-83, although not significantly for aNSCs. Thus, blocking of the Shh pathway *in vivo* does not alter significantly NSCs proliferation at short term, which might be related to the low basal expression of the pathway in SVZ cells as investigated by qRT-PCR of *Gli1-3*. Experiments are in progress to further investigate the role of the Shh pathway on qNSCs and aNSCs using a genetic mouse model of Shh activation through the conditional deletion of the Shh receptor Patched in NSCs using the GLAST marker (Ferent et al, *Stem Cell Reports*, 2014). These data contribute to explore how Shh orchestrates the balance between qNSCs and aNSCs in the SVZ with important implications for understanding adult neurogenesis under normal homeostatic conditions or during injury.

Title: Deep brain stimulation regulates diet-responsive hypothalamic neurogenesis in young adult male rats

Authors: *M. P. MEDINA[1], J. SOTELO[2];
[2]Exptl. Neurol. Unit, [1]Inst. Nacional De Neurologia Y Neurocirugia, Ciudad DE Mexico, Mexico

Abstract: Tanycytes of the median eminence are neurogenic progenitors that responds to changes in weight gain and metabolism. In this study we assessed the effects of lateral hypothalamic area (LHA) deep brain stimulation (DBS) on the neurogenesis rate of median eminence tanycytes in a well-characterized rodent model of obesity. We used high frequency DBS to stimulate LHA of male young rats (P45) subjected to high-fat diet (HFD). Tungsten electrodes were implanted within LHA using stereotaxic coordinates, fixed to the skull and connected to subcutaneous pulse generators. Generator parameters were initially adjusted before implantation and included biphasic rectangular pulses of 130 Hz, 60us pulse duration and 1 V of amplitude. Animals received a scheme of daily continuous DBS stimulation during 30 consecutive days. During the first 15 days of LHA DBS, animals were administered with BrdU I.P. injections in order to measure the hypothalamic proliferation rate. Rats were perfused after physical assessments for immunohystochemical staining. Control sham animals showed a significant higher increase in weight gain compared to stimulated partners. Food intake was consistently pronounced in sham animals subjected to HFD compared to animals in ON state with LHA stimulation. Only sham animals with HFD showed differences in weight gain and food-intake when compared to controls with normal chow. BrdU expression in tanycytes within the median eminence was markedly modified by DBS scheme in ON stimulation rats only. Neuronal proliferation rate was positively correlated with gain weight. Interestingly, newborn neurons were positive for POMC and Neuropeptide Y, and were physiologically reactive to intraperitoneal leptin injections. In conclusion, LHA DBS modifies feeding behavior by modulating neuronal proliferation rates within hypothalamic neurogenic niches.

Title: PINK1-deficient mice show impaired hippocampal neurogenesis and mitochondrial and cell signaling defects in adult neural stem cells

Authors: ***H. BUELER**, S. K. AGNIHOTRI;
Harbin Inst. of Technol., Harbin, China

Abstract: Parkinson's disease (PD) is characterized by a severe movement disability and several non-motor symptoms, including depression, anxiety and cognitive impairments in a sizeable proportion of patients. The latter symptoms are also typical features of affective disorders and have been associated with deficits of adult hippocampal neurogenesis (AHN). Despite of this, studies of neurogenesis in models of PD and, in particular, the importance of mitochondria for AHN are limited. Mutations in the mitochondrial kinase PINK1 cause recessive familial PD. PINK1 and Parkin cooperate to protect neurons against oxidative stress, maintain mitochondrial integrity and promote the selective degradation of depolarized mitochondria through mitophagy. Here we show that adult hippocampal neural stem cells (aNSC) lacking PINK1 display mitochondrial dysfunction and impaired AKT signal transduction, associated with decreased proliferation of aNSC in culture and in the hippocampus of PINK1-deficient mice. Moreover, doublecortin-positive neurons in the dentate gyrus of PINK1-deficient mice show abnormal dendritic morphology and their maturation is impaired. Our results link impaired mitochondrial function and AKT signaling in aNSC with abnormal AHN in a model of recessive Parkinsonism. Taken together, these studies suggest that mitochondrial and cell signaling defects - in particular in PD patients with PINK1 mutations - may lead to abnormal mood and cognition through impairments of AHN. Targeting mitochondria and metabolism of adult NSC to increase neurogenesis in the hippocampus may be a promising strategy for the treatment of affective disorders and the mitigation of related symptoms in PD and other neurodegenerative conditions.

Title: Regulation of adult neurogenesis in the mouse SGZ by Kv1.1

Authors: S.-M. CHOU[1], C. LI[2], H.-Y. CHEN[1], L. JAN[2], *S.-B. YANG[1];
[1]Inst. of Biomed. Sci., Academia Sinica, Taipei, Taiwan; [2]Howard Hugh Med. Inst. Univ. of California San Francisco, San Francisco, CA

Abstract: In mammals, the sub-granular zone (SGZ) in the dentate gyrus is one of a few brain regions that exhibit extensive adult neurogenesis. The SGZ neurogenesis is tightly regulated by a balance between cell proliferation and apoptosis to keep the total number of neurons constant in

the SGZ. Although the molecular mechanisms that regulate adult neurogenesis have been studied extensively, the role of ion channels and membrane excitabilities in modulating adult neurogenesis remain to be precisely elucidated. Recent studies have found that mice lacking functional Kv1.1 channels have enlarged brain due to excessive adult neurogenesis in the SGZ; however, the molecular and cellular mechanisms by which Kv1.1 suppresses adult neurogenesis are still largely unexplored. We found that, using mosaic analysis with double markers (MADM) in adult mouse SGZ, neurons lacking functional Kv1.1 were more abundant than wild-type neurons that produced from the same progenitor cells; in contrast, astrocytes lacking Kv1.1 did not exhibit proliferation advantage over the wild-type astrocytes. Next, we recorded from Fezf2-GFP expressing neural progenitor cells that were not coupled by gap junctions in the brain slice, and we found a subset of these neural progenitors had a more depolarized potential in the Kv1.1 knockout background. Lastly, we found daily injection of GNF5837, a pan-TrK antagonist, suppressed the over-population of neuronal progenitor cells in the Kv1.1 knockout mice. Our data suggest that Kv1.1 regulates adult neurogenesis in the SGZ in a cell-autonomous manner, as Kv1.1 hyperpolarizes the neuronal progenitor cells and suppresses BDNF-Trk signal in the SGZ.

Title: Programming of stress-sensitive neurons via NRSF-dependent epigenetic mechanisms by neonatal experience promotes emotional resilience

Authors: *A. SINGH[1], J. MOLET[3], S. JIANG[2], A. KOROSI[4], J. L. BOLTON[1], Y. NOAM[1], K. SIMEONE[5], J. COPE[1], A. MORTAZAVI[2], T. Z. BARAM[1];

Abstract: Resilience to stress-related emotional disorders is governed in part by early-life experiences. Here we demonstrate experience-dependent reprogramming of stress-sensitive hypothalamic neurons, which takes place through modification of neuronal gene expression via epigenetic mechanisms. Specifically, we found that augmented maternal care reduced glutamatergic synapses onto stress-sensitive hypothalamic neurons and repressed expression of the stress-sensitive gene, *Crh*. In hypothalamus *in vitro,* reduced glutamatergic neurotransmission recapitulated the repressive effects of augmented maternal care on *Crh*, and this required recruitment of the transcriptional repressor REST/NRSF. Increased NRSF binding to chromatin was accompanied by repressive epigenetic changes *in vitro* and *in vivo*. ChIP-Seq analyses of NRSF targets identified gene networks that, in addition to *Crh*, contributed to the augmented care-induced phenotype, including diminished depression and anxiety. Together, these findings provide the first causal link between enriched neonatal experience, synaptic refinement, and induction of epigenetic processes within specific neurons. They uncover a novel mechanistic pathway from neonatal environment to emotional resilience.

Title: Brain-5, a novel regulator of activity-dependent cellular plasticity and synaptic integration in the adult brain

Authors: *C. K. MCCLARD[1,2,3,4], M. KOCHUKOV[1,2,4], I. HERMAN[1,3,5], Z. LIU[1,4,6], L. HUANG[1,4,7], J. ORTIZ-GUZMAN[1,4,5], D. COLCHADO[8], B. R. ARENKIEL[1,2,4,5,7]; [2]Dept. of Genet., [3]Med. Abstract: The discovery of ongoing neurogenesis in the adult mammalian brain has prompted efforts to investigate the mechanisms of this astonishing plasticity. The mouse olfactory bulb (OB) features lifelong neuronal integration and thus serves as an ideal model system to examine how new cells rewire the adult brain. We discovered a local population of interneurons in OB that secretes the neuropeptide corticotropin releasing hormone (CRH) onto developing neurons, which in turn upregulate expression of the CRH receptor (CRHR1) as they mature. Genetic experiments showed that signaling by local CRH-secreting interneurons is required for normal rates of survival of developing neurons, and is both necessary and sufficient for production of synaptic machinery in development. CRHR1 is a G_S protein-coupled receptor that transcriptionally activates the receptor-expressing cell in the presence of its ligand. We hypothesize that in the adult brain, local CRH binds to CRHR1 to initiate cell-intrinsic programs of survival and synaptogenesis. To determine the identity of these transcriptional programs, we profiled gene expression changes associated with CRHR1 activity in developing neurons of the OB. We found that local CRH signaling dynamically regulates expression of the brain-specific Homeobox-containing transcription factor Brain-5 (BRN5). To test whether expression of BRN5 suffices to enhance normal levels of survival or synaptogenesis, we targeted developing neurons in the adult OB to overexpress BRN5. Neurons that overexpressed BRN5 displayed a higher propensity toward survival and exhibited greater success at recruiting strong functional synaptic connections in the olfactory circuit than controls. Conversely, loss of BRN5 during neuronal development reduced the number of excitatory connections onto adult-born neurons of the OB. These findings suggest that the transcriptional programs directed by BRN5 downstream of local CRH signaling influence neuronal survival and functional development. Together, our studies reveal a novel regulatory pathway by which local neuropeptidergic signaling in the adult brain activates specific genetic programs to govern cell and circuit plasticity.

Title: Neonatal hyperoxia leads to neurobehavioral impairment in adult mice by impairing synaptic plasticity and increasing inflammation in the hippocampus

Authors: *M. RAMANI[1], N. AMBALAVANAN[1], L. MCMAHON[2];
[1]Pediatrics, [2]Cell Develop. and Intergrative Biol., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: Background: Very preterm infants are at high risk (30-40%) for developing neurodevelopmental impairment (NDI) even in the absence of obvious brain injury. Many preterm infants with a relatively uncomplicated neonatal intensive care course have poor executive and memory function later in life. The etiology of NDI in children born preterm without apparent brain parenchymal injury is unknown. We recently showed that adult mice exposed to neonatal hyperoxia had deficits in spatial and recognition memory associated with smaller hippocampal volumes. Oxygen is known to increase inflammation and causes cell death in developing brain. Long-term changes in the strength of synapses (long-term potentiation) are critical for the formation and maintenance of memory. We hypothesized that neonatal hyperoxia exposure results in neurobehavioral impairment by (a) deficits in long-term potentiation and/or (b) increase in inflammation. **Methods**: C57BL/6 mouse pups (n = 2 litters per condition; at least 10/group) were exposed to hyperoxia (85% oxygen) or air, from postnatal day 2 to 14 (P2-P14; roughly corresponding from very preterm equivalent to early infancy in human brain development) and then returned to air. We assessed neurobehavioral assessment (14 weeks of age), long-term potentiation studies (6 weeks of age) and hippocampal IL-1β mRNA levels (P14). **Results**: In adult mice, neonatal hyperoxia induced spatial navigation deficits and increased exploratory behavior (Figure A, B, C). Young adult mice (6 weeks of age) exposed to neonatal hyperoxia had deficits in long-term potentiation (Figure D). Neonatal hyperoxia increased hippocampal IL-1 β mRNA levels (Figure E). **Conclusion**: Oxygen exposure during the critical developmental period of the brain increases hippocampal IL-1 β, leading to permanent impairment of long-term potentiation and results in neurobehavioral impairment. This model suggests therapeutic strategies that target the hyperoxia-induced hippocampal inflammation may potentially be of benefit in the prevention of neurodevelopmental impairment in preterm infants.

Title: Ependyma derived CCN1 promotes progenitor cell proliferation and neurogenesis in the adult SVZ

Authors: ***Q. SHEN**;
Tsinghua Univ., Beijing, China

Abstract: In adult rodents, the subventricular zone (SVZ) is the largest germinal zone, where new neurons are continuously generated and migrate to the olfactory bulb. Type B neural stem cells (NSCs) in this region give rise to type C transit amplifying cells, which, after several rounds of division, turns into migrating neuroblasts. Apart from various intrinsic mechanisms, this neurogenic process is under tight spatial and temporal control of niche factors. Exploring important factors regulating neural stem cell behavior offers great value for treating nervous system diseases. CCN1 is an extracellular matrix protein, belonging to the CCN family. It is abundant in various cancers. Here we find that CCN1 is specifically expressed by the ependymal cells, the important niche cells in the SVZ, and binds to neural stem and progenitor cells. Conditional ablation of the gene in ependymal cells impairs cell proliferation as well as neurogenesis which involves decreased AKT phosphorylation. In vitro overexpression of CCN1 dramatically increased cell proliferation and decreased neural differentiation. We are interested in exploring the underlying mechanisms as well as increasing our knowledge on adult brain development. We hope that this could be beneficial to neural stem cell therapy and neurological diseases.

Title: Diazepam binding inhibitor (DBI): a novel protein for the induction of postnatal neurogenesis in the spinal cord?

Authors: L. NEW, E. TEDFORD, J. SMITH, J. HEE, J. DEUCHARS, *S. A. DEUCHARS; Univ. of Leeds, Leeds, United Kingdom

Abstract: The ependymal cell (EC) layer surrounding the central canal (CC) of the postnatal mammalian spinal cord is considered a neurogenic niche, proliferating extensively after injury and contributing to the development of the glial scar. Understanding the niche, its microenvironment, and how its proliferative behaviour may be manipulated is essential if we are to harness endogenous mechanisms to aid spinal repair. This study examines ways in which GABA and its opposing ‘partner’ DBI may contribute to the balance of proliferation vs. relative quiescence of the ECs. To determine the effects of GABA on spinal cord proliferation, GAD67-GFP mice (4-6 weeks n=3), which have reduced GABA levels as a result of replacing one allele of GAD67 with GFP, and wild type (WT) C57Bl/6 (4-6 weeks n=3) mice were injected I.P with

the thymidine analogue 5-Ethynyl-2'-deoxyuridine (EdU). Animals were anaesthetised (60mg/kg pentobarbital I.P) and perfused transcardially with 4% paraformaldehyde. The thoracolumbar spinal cord was sectioned (40μm) and post hoc fluorescent detection of EdU was performed. EdU+ve cells were counted (n=3 N=36) at both the CC and the grey and white matter. For immunohistochemical (IHC) investigation of DBI and its 'mitochondrial receptor' TSPO in the spinal cord, tissue from WT C57Bl/6 mice (4-6 weeks, n=9 and 15±2 days, n=3) was prepared as above. Tissue was processed for DBI immunoreactivity (IR) and double labelling fluorescence IHC for other cellular markers including; glial fibrillary acid protein, neuN, panQKI, nestin, sox2, Iba1, CD24, S100β. GAD67-GFP mice were used to identify cerebrospinal fluid contacting cells (CSF-cCs). GAD67-GFP animals, which have significantly lower levels of ambient spinal GABA compared to control, (assessed by HPLC $P < 0.05$), exhibited greater levels of proliferation than WT animals at both the CC (0.2778 ± 0.1099 vs. 3.361 ± 0.3589 cells $P < 0.0001$) and across the spinal cord (11.28 ± 1.811 vs. 35.17 ± 2.846 cells, $P < 0.0001$) This is likely due to the reduction in ambient GABA, thus releasing inhibition on proliferation. In both adult and juvenile animals, intense DBI IR was detected within the EC layer. A lack of colocalisation of DBI with GFP in GAD67-GFP mice suggests that DBI is absent from CSF-cCs, whereas sox2, a neural stem cell marker labelling ECs, colocalised with DBI at the CC. These results suggest that DBI is found in the spinal EC population. The EC layer is also TSPO IR. Further experiments will seek to link the two complementary players GABA and DBI together, exploring the ways in which DBI can be used to modulate GABAaR, and therefore influence proliferation and differentiation of ECs within the spinal cord.

Title: Early-life sevoflurane exposure targets microRNAs and excitatory-inhibitory balance

Authors: D. LIN[1], J. LIU[2], J. COTTRELL[2], *I. S. KASS[1];
[1]Anesthesiol. and Physiol. and Pharmacol., [2]Anesthesiol., SUNY Downstate, Brooklyn, NY

Abstract: Introduction:
During early brain development, the intricate regulations of neurons include, gene expression, morphology and circuitry establishment within/between regions. Failure to fine-tune these spatiotemporal regulations could have long lasting functional consequences later on in life. Previously, our lab has shown that P7 sevo treated mice have social behavior and cognition deficits later on in life. Subsequently, we identified specific brain microRNAs (miRNAs) to be associated with early-life sevo treatment.
Methods:
Postnatal day 7 (P7) C57/BL6 male pups were exposed to 2-2.3% sevo in a 40% oxygen (O2) 60% nitrogen (N2) gas mixture for 2 hours. The expression of brain miRNAs was examined using the nCounter miRNA Expression Assay (Nanostring Technologies) and validated using Real-Time PCR (BioRad). Morphology experiments were done by using cell cultures from 7 days in vitro (DIV) primary cortical neurons. Paired-pulse extracellular recording was conducted on CA 1 region of the hippocampus slices.
Results:
miRNA profiling from P7 brains identified differentially expressed miRNAs as a result of sevo treatment. We further validated expression changes of miRNA 15a from the hippocampus and miRNA 145 from the whole brain by RT-PCR. At the morphological level, we observed a reduction in axonal growth (as indicated by axon specific GFP) and dendritic branching (as indicated by dendritic specific protein Map 2) after application of miRNA 145 inhibitor in 7 DIV. At the electrophysiological level, paired-pulse tests showed adult sevo treated group has a trend toward increased inhibition compared to control. The opposite was observed in P7 sevo treated groups, a trend toward increased facilitation was shown when recorded at P7 and P10.
Conclusions:
P7 sevo-associated miRNA 145 is critical for early brain development such as dendritic branching and axonal growth. Furthermore, after P7 treatment, hippocampus neurons showed increased excitatory responses when measured at P7 and P10. We are in the process of examining the roles of miRNAs in neuronal excitation/inhibition balance. Our understanding on the role of miRNAs has provided us one of the putative mechanisms of early-life sevo induced neuronal toxicity.

Title: Neurovascular ligand-receptor systems modulate post-stroke neurogenesis and angiogenesis

Authors: *N. ABDULJAWAD, A. J. BRUMM, M. MACHNICKI, S. T. CARMICHAEL; Neurol., Univ. of California Los Angeles, Los Angeles, CA

Abstract: Ischemic stroke initiates a process of tissue repair that includes the development of new blood vessels (angiogenesis) and the proliferation of neural progenitor cells (NPCs). Previous work has shown that NPCs born in the subventricular zone (SVZ) after stroke localize to angiogenic blood vessels in damaged tissue (peri-infarct), forming a neurovascular unit in which angiogenesis modulates neurogenesis. However, the blood vessel-secreted trophic factors that mediate this targeted migration and neurogenesis remain unknown. Whole-genome expression profiling of peri-infarct vasculature and stroke-responsive neuroblasts 7 days post-stroke, the time point at which post-stroke angiogenesis and neurogenesis reach their peak, reveals upregulation of four ligands of interest in angiogenic vascular cells, along with upregulation of their respective receptors in stroke-responsive neuroblasts: colony stimulating factor 1 (CSF1), thymic stromal lymphopoietin (TSLP), protein S alpha (PROS1), and Wnt5a. To investigate the effects of these molecular signaling systems on post-stroke angiogenesis and neurogenesis, two in vitro culture systems were used. Primary NPCs, isolated from the adult mouse SVZ and expanded as neurospheres for 2 passages, and mouse cerebrovascular endothelial cells (MCVECs) were transduced with lentivirus designed to either overexpress or knockdown each ligand. NPC and MCVEC proliferation in response to each treatment was measured using EdU DNA synthesis assays. NPC differentiation following treatment was measured through immunocytochemical phenotyping of NPCs. Finally, MCVEC development was measured using tube formation assays. Data from these assays are currently being quantified. Results will provide insight into novel molecular signaling systems that potentially regulate endothelial cell and neural progenitor cell function after stroke in vivo.

Title: The study of sonic hedgehog signaling pathway in development of cerebellar granule cells

Authors: *X. JIAO, N. ASHTARI, K. BAILEY, M. R. BALAEI, S. GHAVAMI, M. DEL BIGIO, H. MARZBAN;
Human anatomy and cell science, Univ. of Manitoba, Winnipeg, MB, Canada

Abstract: Introduction: The cerebellum is responsible for motor control and cognitive functions. The cerebellar cortex can be divided into three layers consist of different cell types, such as granule cells (gcs), Purkinje cells (Pcs) and Bergmann glial cells. During the development, the granule cell precursors arise from the cerebellar rhombic lip and initially migrate rostrolaterally in subpial stream pathway of the cerebellar primordium to form the external germinal zone (egz). Thereafter, the granule cell precursors radially proliferate and then move to granule layer (gl) and differentiate into mature gcs. In this process, sonic hedgehog (Shh) secreted by Pcs is an important promoter of granule cell precursors proliferation. A lysosomal acid phosphatase 2 (Acp2) mutant mouse (*nax*) shows a significant gcs reduction in the cerebellum. We hypothesize that the Shh signaling pathway is interrupted by the Acp2 mutation and causes cerebellar gc neurodevelopmental disorders.
Methods: We used the *nax* and the wild-type sibling mice as control in this study. *In vivo* and *in vitro* immunohistochemistry and Western-blotting are used to detect the molecular expression.
Results: In *nax* mouse the number of gcs is greatly reduced compared with wild-type sibling mice. The Shh expression is down regulated from P12, while the expression of Pax6 by gc precursors in the external germinal zone is down regulated at around P7 and it is maybe due to the decreased number of gcs. The immunostaining shows reduced expression of N-Myc which is an essential downstream effector of Shh pathway in *nax* MEF cells. N-Myc expression is less from P10 to P18 in *nax* as compared to control.
Conclusion: The absence of Acp2 impacts on the gcs proliferation prior to the Shh to cease gcs proliferation during cerebellar development. The significant reduction in the proliferation and probably differentiation of gcs in *nax* mouse reveals that the Shh signalling pathway in gcs is interrupted by Acp2 mutation and causes cerebellar gc neurodevelopmental disorders.

Title: Meninges are a niche for neural precursor cells

Authors: I. DECIMO[1], V. BERTON[1], A. PINO[1], S. DOLCI[1], M. MARCHETTO[1], F. PARI[1], *G. F. FUMAGALLI[1], F. BIFARI[2];

Abstract: Brain and skull developments are tightly synchronized allowing the cranial bones to dynamically adapt to the brain shape. Meninges are the stromal tissue that represent the physical interface between brain and skull. Meningeal cells produce trophic signals necessary for normal corticogenesis and bone development. Different cell populations have been described in meninges including cells that can function as endosteum of the cranial vault. Recently, we and other groups described the presence in meninges of a cell population endowed with neural differentiation potential *in vitro* and, after transplantation, *in vivo*. However, whether meninges may be a niche for neural progenitor cells during embryonic development to adulthood is not known. In this work we provide the first description of the distribution of neural precursor markers in rat meninges during development up to adulthood. We describe that meninges share common properties with the classical neural stem cell niche: i) meninges are unexpected highly proliferative tissue; ii) they contain cells expressing neural precursor markers such as nestin, vimentin, SOX2 and DCX and iii) meningeal tissue is enriched with extracellular matrix components (fractones) known to bind and concentrate growth factors. This study underlines the importance of meninges as a potential niche for endogenous precursor cells during development and in adulthood.

Title: Hilus of the hippocampus possess progenitor cells of oligodendrocytes and neurons in the adult brain

Authors: *J. PACHECO-ROSADO[1], Y. GARCÍA-MARTÍNEZ[2], L. FLORES-PÁEZ[2], K. B. SÁNCHEZ-HUERTA[3];
[1]Escuela Nacional de Ciencias Bio, Ciudad DE Mexico, Mexico; [2]Fisiología, Inst. Politécnico Nacional, Mexico City, Mexico; [3]Lab. de Neurociencias, Inst. Nacional de Pediatría, Mexico city, Mexico

Abstract: Adult neurogenesis results in the generation of new neurons or glia cells in the subgranular zone (SGZ) of the dentate gyrus. This process involves both cell populations that dynamically switch between pools of proliferative and quiescent cells, and cells that definitely leave the cell cycle to maturate into neurons or glia cells. Interestingly, the hilus of the hippocampus also has proliferative cells whose mitotic activity responds to environmental signals. It has been shown that seizures or hypothyroidism affect the number of proliferative cells in this region. However, the impact of these changes is poorly understood; since the lineage of proliferative cells and their differentiation process is still unknown. The aim of this work was to characterize the population of proliferative cells present in the hilus of the hippocampus. For this, male Wistar rats (90 days old) were administrated with BrdU (6 times, every 2 hours). Twenty four hours after the last injection, the animals were anesthetized and perfused. Brains were dissected and dorsal hippocampus was serially sectioned. Slices were processed for immunofluorescence. The total number of proliferative cells (BrdU+), precursor cells (Sox2+/BrdU+); neural restricted progenitor cells (NRPs; DCX+/BrdU+); oligodendrocytes progenitor cells (OPCs; NG2+/BrdU+); and proliferative mature astrocytes (PMA; S100β+/BrdU+) were quantified **i**n the hilus and **i**n the SGZ. The results showed that approximately 77% of proliferative cells were precursor cells in both regions studied. Interesting, in the hilus OPCs proliferation (57%) is favored over NRPs (42%); while in the SGZ, NRPs proliferation (66%) is favored over OPCs (10%). Finally, it was found that mature astrocytes do not proliferate in either SGZ or hilus. These results demonstrate the presence of OPCs and NRPs in the hilus of the hippocampus and suggest that this region contributes to the formation of oligodendrocytes and neurons in the adult brain.

Title: Differential expression of Gas1 in neural stem cells and in cancer stem cells

Authors: N. AGUIRRE-PINEDA, E. BAUTISTA, J. HERNÁNDEZ, *J. V. SEGOVIA-VILA; Cinvestav-IPN, Mexico 07300 DF, Mexico

Abstract: Growth Arrest Specific 1 (Gas1) is a pleiotropic molecule linked to the outer cell membrane by a glycosylphosphatidylinositol (GPI) anchor. Because of its high structural similarity with the glial cell line derived neurotrophic family receptors (GFRαs), Gas1 is capable of inducing cell cycle arrest and apoptosis of glioma cell lines and of primary cultures of human gliomas by inhibiting the intracellular signaling pathway mediated by GDNF. On the other hand, Gas1 acts as a co-receptor for the morphogen Sonic Hedgehog (SHH) enhancing its signaling. Moreover, Gas1 is expressed in the developing mammalian brain, specifically in progenitor cells, thus indicating a role in the proliferation and differentiation of neural cells. In an effort to understand the function(s) of Gas1 in the neural stem cell (NSC) population we sought to determine its expression in both cancer stem cells (CSC) obtained from the glioma cell lines C6 and U87 MG and in stem cells isolated from primary cultures of the subgranular zone of the hippocampus and the subvbentricular zone of the mouse brain. CSC and NSC were isolated from free floating gliomaspheres and neurospheres, respectively, and characterized by the expression of specific markers, including CD133, nestin, Sox2 and GFAP. We determined by RT-PCR and immunocytochemistry that healthy NSC express Gas1, but that Gas1 is no longer found in CSC. These results indicate that Gas1 has an important role in the control of the cell cycle of NSC and that this regulation is lost in CSC.

Title: Characterization of Met receptor tyrosine kinase-expressing serotonergic neurons

Authors: *H.-H. WU[1], R. KAST[2], P. LEVITT[1];
[1]Children's Hosp. Los Angeles, Los Angeles, CA; [2]Neurosci. Grad. Program, USC, Los Angeles, CA

Abstract: There is increasing awareness that the brain serotonin system as a unified system is actually far more complex functionally and structurally. Specific subsets of raphe neurons have different connectivity patterns, electrophysiological properties, and molecular profiles. However molecule profiles that define specific subpopulation are not well studied. We demonstrated that, from late gestation to adulthood in the mouse, MET receptor tyrosine kinase (MET) is specifically expressed in a remarkably small subset of 5-HT neurons that includes the classic B6 subgroup in the dorsal raphe nuclei (DRN). Detailed mapping from embryonic day 16 to postnatal day 14 reveals that MET is expressed almost exclusively in the caudal part of DRN as a paired nucleus situated just below the aqueduct, corresponding to the B6 subgroup. Small population of MET+ neurons is also found in subset of median raphe (B5) 5-HT neurons. Remarkably, the location of MET-expressing 5-HT neurons (5-HT^{MET+}) in the developing rhesus monkey brainstem is highly conserved. This group of unique 5-HT neurons may thus function in a conserved fashion across species. In mice, conditional deletion of *Met* only in the 5-HT neurons causes social behavioral deficits. The connectivity of 5-HT^{MET+} neurons involved in mediating social behavior, and the impact of deleting *Met* on the circuitry of this 5-HT subgroup, is unknown. We set to further characterize this 5-HT^{MET+} subgroup by 1) analyzing its molecular signature using public available database and by 2) determination of their target sites on the forebrain. Using developing mouse brain database in Allen Brain Atlas we found 14 genes, including 4 neurotransmitter/neuropeptide receptors and 2 potassium channels, expressing in the DR region exhibiting a B6-specific manner. Tract tracing experiments shows that almost all the 5-HT axons innervated ventricular/subventricular regions are MET+. Gene expression of candidates is being evaluated in WT and *Pet-1*^{Cre} x *Met*^{fx} mice.

Abstract: Adult neurogenesis is a continuous process of addition of new neurons into the nervous system after birth. Newly born neurons in the dentate sub granular zone integrate with dentate gyrus granule neurons and play a role in learning and memory. Adult neurogenesis declines in an age dependent manner in albino rats. However pattern of adult neurogenesis in pigmented Dark Agouti (DA) rats is not known. Objective of the present study was to explore the pattern of neurogenesis at different ages in DA rats and compare it with age matched Wistar rats. DA rats aged 1, 2,4,6,8 and 10 months were euthanized with CO_2 and perfused with saline followed by 4% paraformaldehyde. Brains were dissected and processed for doublecortin (DCX, marker for new neurons) immunostaining. Number of newly born neurons in the dentate gyrus were quantified. Unfixed hippocampal tissues were used for Western blot analysis of DCX content. Hippocampal tissues from age matched Wistar rats were processed in the similar way for comparison. Data were analyzed with one way ANOVA and Bonferroni's test. Neurogenesis declined progressively in both DA and Wistar rats. Number of new neurons in the dentate gyrus of 1 month and 2 months old DA rats were similar to each other as well as to age matched Wistar rats($p>0.05$). However neurogenesis commenced to decline as early as 4 months in DA rats as number of new neurons significantly less in them compared to age matched Wistar rats ($p<0.05$). At 6, 8 and 10 months of age, neurogenesis further declined in DA rats compared to Wistar rats ($p<0.01$). Neuronal count data was supported by Western blot analysis for DCX content in the hippocampus. In conclusion, extent of adult hippocampal neurogenesis in DA rats is significantly less and declines at an earlier age than in Wistar rats. Mechanism, cause, and functional implications of such a decreased neurogenesis at an early age needs to be explored further.

Title: Assessment of single nucleotide variants in genes encoding eif2α kinases in autism simplex families

Authors: *A. G. VOROBYEVA[1], E. KLANN[1], I. IOSSIFOV[2], T. E. DEVER[3];
[1]Ctr. for Neural Sci., New York Univ., New York, NY; [2]Cold Spring Harbor, cold Spring Harbor, NY; [3]NIH, Bethesda, MD

Abstract: Autism spectrum disorder (ASD) is a heritable neurodevelopmental disorder characterized by the early onset of social and communication deficits, repetitive behaviors, and cognitive inflexibility. Multiple lines of evidence suggest that dysregulated translational control is one molecular mechanism underlying ASD neuropathology. Exome sequencing of Simplex families with a child affected by autism revealed numerous heritable and *de novo* autism-associated single nucleotide variations (SNVs) within genes encoding for proteins responsible for maintaining translational homeostasis. We assessed three affected genes; *EIF2AK2, EIF2AK3* and *EIF2AK4*, which encode protein kinase R (PKR), PKR-like ER kinase (PERK), and the evolutionarily conserved general control nonderepressible 2 (GCN2) kinase, respectively. All three kinases are activated under conditions of cellular stress, which results in phosphorylation of eIF2 on its α subunit. Phosphorylated eIF2α terminates global protein synthesis and enhances the translation of mRNAs containing 5'UTRs with unread open reading frames, including the transcription factor ATF4. We hypothesized that heritable and *de novo* missense and nonsense ASD-associated SNVs in genes encoding the eIF2α kinases would alter their protein structure and kinase function, and would significantly dysregulate global protein synthesis leading to abnormal development and cognitive function. We discovered that multiple ASD-associated SNVs in eIF2α kinases result in altered kinase activity as measured by changes in eIF2α phosphorylation and global protein synthesis levels. Consistent with our hypothesis, PERK and GCN2 haploinsufficient mice display atypical cognitive function and ASD-like behaviors. All together our findings suggest that impaired PKR, PERK and GCN2 function occurs in multiple individuals with ASD.

Title: Functional analysis of the autism gene SHANK3 using iPSCs-derived models of neural development

Authors: *S. GONG[1], L. SHI[2];
[1]Room 819 The Second Sci. and Technol. Buildin, Guangdong, China; [2]Jina Univ., Guangzhou, China

Abstract: Multiple genetic studies have implicated significant roles of exonic deletions in genes coding for pre-postsynaptic complex, such as neurexins, neuroligins and scaffolding protein SHANKs, in the susceptibility to autism spectrum disorders (ASDs). Most previous studies on autism candidate genes were based on animal models or cultured neurons, which do not represent patient-specific models of neurodevelopment. Here we assess the feasibility using urine-derived induced pluripotent stem cells (iPSCs) to build patient-specific models of neural development, and study the functional effects of SHANK3 knockdown. Two inhibitor systems (SB431542, Drosomophorin) were used to induce human urine-derived iPSCs into neural stem cells (NSCs). We then introduced shRNA targeting SHANK3 into NSCs by lentivirus to model SHANK3 deletion, then investigated dynamic activity of developing neuron cells using live cell microscope. We collected fixed cells to analyze the dendrite length and number of branches of early stage neurons, and identified dysregulated molecular pathways by transcriptome sequencing. Urine-derived iPSCs and NSCs can be differentiated into neurons and astrocytes in our in vitro culture system in a highly reproducible manner. After shRNA targeting SHANK3 was introduced into NSCs, SHANK3 expression decreased ~50%. We observed abnormal dynamic activity of neurite outgrowth after SHANK3 KD in the beginning of neural development, where neurites develop into axons much earlier than control. We also found that both the total dendrite length of neuron and the number of branches decreased substantially after SHANK3 knockdown, especially the number of secondary branches. Our results demonstrated that decreased SHANK3 expression affects the fate of neural development, especially axon growth. Our study also suggested that urine can be a feasible and sustainable source for non-invasive collection of patient-specific iPSCs for building in vitro models of neural development.

Title: aberrant mitochondrial autophagy in autistic mouse models

Authors: *H. LI;
Columbia Univ. Med. Ctr., New York City, NY

Abstract: Autism spectrum disorders (ASD) are genetically heterogeneous, but different ASD genes may cluster into a smaller number of pathways, including the protein kinase mammalian target of rapamycin (mTOR). mTOR is a key molecule that regulates protein homeostasis by promoting protein synthesis and inhibiting macroautophagy (autophagy thereafter), a homeostatic degradation process whereby cellular protein and organelles,e.g. damaged mitochondria, are engulfed by autophagosomes, digested in lysosomes and recycled to sustain cellular metabolism. We recently discovered that autophagy deficiency in response to aberrant mTOR hyperactivation contributes to the synapse pathology of ASD. While the precise mechanism driving autophagy-related pathology remains obscure, mitochondrial dysfunction is likely a critical precipitating factor and a downstream mediator of the cellular and physiological responses to faulty autophagy. Here, we examined the effect of mTOR hyperactivation on mitochondrial autophagy (mitophagy) in both Tsc2+/- and Fmr1X-Y ASD mouse models, both of which exhibit excessive mTOR activity. Removal of damaged mitochondria through autophagy requires two steps: induction of general autophagy and priming of damaged mitochondria for selective autophagic recognition. We found impaired general autophagy in both Tsc2+/- and Fmr1X-Y mutant mouse brains, demonstrated by decreased LC3-II and increased p62 protein levels. We analyzed the content of autophagy receptor proteins, including Nbr1, Bnip3, Optineurin and p62, on mitochondrial fraction of each mouse line. These are cargo-recognizing molecules which bind to the surface of damaged mitochondria and regulate the recruitment of the autophagy machinery to the damaged mitochondria, a process called mitochondrial priming. Compared to control mice, both Fmr1X-Y and Tsc2+/- mutants showed a decrease in mitochondria-bound autophagy receptor proteins Bnip3 and p62, suggesting impairment in mitochondrial priming. Our results indicate that mitochondria autophagy is downregulated in both Tsc2+/- and Fmr1X-Y ASD mouse brain due to both reduced autophagy induction and impaired mitochondrial priming.

Title: Identifying a neural circuit of social behavior in an autism mouse model Identifying a neural circuit of social behavior in an autism mouse model

Authors: *J. J. WALSH, G. A. BENDOR, R. C. MALENKA;
Psychiatry, Stanford Univ., Stanford, CA

Abstract: There is an urgent need for effective treatment strategies for autism spectrum disorder (ASD), with a prevalence rate of more than 1 in 100. One of the most common genetic variations found in ASD is a copy number variation (CNV) on human chromosome 16, accounting for approximately 0.5-1% of all ASD cases. While several brain regions have been implicated in ASD, such as the dorsal raphe (DR) and nucleus accumbens (NAc), the neural circuit mechanism and the projection specific pathway underling social impairment in ASD is largely unknown. Studies have implicated the serotonergic system (5HT) in the pathophysiology of ASD, with 5HT neurons in the dorsal raphe (DR) sending projections throughout the forebrain.
Through the use of optogenetic and viral-mediated gene transfer approaches, we found that activation of non-specific, as well as 5HT specific DR neurons and their projection to the NAc increased sociability. Conversely, inhibition of the DR 5HT neurons and their projection to the NAc decreased sociability. Utilizing a mouse line with a conditionally inactive 16p11.2 chromosomal segment, we determined that whole brain deletion and DR specific deletion of 16p11.2 decreased sociability, Furthermore, this deficit was reversed through optogenetic activation of the DR following 16p11.2 deletion, demonstrating the critical nature of DR 5HT activity in social interactions. Future studies will assess how 16p11 deletion in DR 5-HT neurons affects the physiology of these cells and the circuits in which they participate.

Title: Altered action of 5-HT2a receptor ligands in the 16p11.2 deletion syndrome mouse.

Authors: C. PANZINI[1], *K. G. COMMONS[2];
[1]Boston Children's Hospital/Harvard Med., Boston, MA; [2]Anesthesia, Children's Hosp, Harvard Med., Boston, MA

Abstract: In humans the 16p11.2 deletion syndrome is caused by a loss of a chromosomal segment that encodes about 25 genes. This microdeletion results in variable deficits and features of autism, developmental delay and intellectual disability are common. Mouse models of 16p11.2 deletion syndrome have been developed and these animals have several behavioral abnormalities and are typically hyperactive. Serotonin neurotransmission has long been associated with autism, yet it remains poorly understood if altered serotonin neurotransmission could represent a common deficit in autism generated by distinct genetic or environmental factors. In this study, we studied the function 5-HT2A receptors in 16p11.2 deletion mice (Del) and their wild-type (WT) littermates (Jackson Labs B6129S-Del(7Slx1b-Sept1)4Aam/J; Horev et al., PNAS 2011). To evaluate the status of 5-HT2 receptors we administered the agonist, DOI, and measured head twitch and ear scratch response, both mediated by 5-HT2A receptors. We found that Del mice are relatively insensitive to DOI compared to their WT siblings. Next we examined the effects of the 5-HT2A antagonist M100907. This was done in the context of acute stress (swim), as this stimulus is known to activate the serotonin system. Typically rodents exhibit active coping or escape-directed strategies when initially exposed to the swim, and with time, active coping is gradually replaced by passive coping (floating). This pattern of behavioral adaptation in the swim is evident in WT siblings over a 15 min time-course. However, Del mice are more active initially, and they perseverate with an active coping strategy throughout the test. Immunolocalization of the immediate early gene product Fos showed the relative engagement of the lateral septum and prefrontal cortex and during this task. In WT mice, 0.01 mg/kg M100907 administered prior to the swim test had no significant effect on coping strategy. However dramatically in Del mice 0.01 mg/kg reduced active coping throughout the test, and partially restored the adaptive shift from active to passive strategy, attenuating the behavioral deficit in comparison to their WT siblings. In addition Del mice were hypersensitive to the effects of M100907 on Fos expression compared to WT mice. These effects correlated with regional and cellular distribution of 5-HT2A receptors. Taken together these data reveal alterations in 5-HT2A receptor function in the mouse model of 16p11.2 deletion syndrome.

Abstract: Mutations and deletions of the transcription factor *FOXP1* are causative for autism spectrum disorder (ASD) and intellectual disability (ID). Previous work has shown that whole-brain *Foxp1* conditional knockout mice (cKO) display ASD-related phenotypes, and we have identified the brain-region specific transcriptional program of Foxp1 in *Foxp1* heterozygous mice. However, the circuit-specific contribution of Foxp1 to ASD and ID-related phenotypes remains to be determined. In order to answer this question, we crossed *Emx1.Cre*$^{+/-}$ mice with *Foxp1*$^{flox/flox}$ mice to generate *Foxp1* cKO (*Foxp1*^{cKO}) mice with loss of Foxp1 specifically in the pyramidal neurons of the neocortex and hippocampus. Using immunohistochemistry and histology, we find morphological abnormalities in the neocortex and hippocampus of *Foxp1*^{cKO} mice. Correlated with these findings, *Foxp1*^{cKO} mice display alterations in ASD-related behaviors, including deficits in hippocampal-based learning and memory. Future experiments will focus on identifying the molecular and cellular mechanisms underlying these phenotypes.

Title: The association between genetic polymorphisms of methionine cycle enzymes and autism in Jordan

Authors: *O. K. HALHOULI[1], M. F. ALKHOUJAH[1], M. ELDAHABI[2], L. ALZGHOUL[2]; [2]Dept. of Physiol. and Biochem., [1]Univ. of Jordan - Fac. of Med., Amman, Jordan

Abstract: Autism spectrum disorder (ASD) is a pervasive developmental disorder characterized by disturbances in social interactions, verbal and non-verbal communication, as well as restricted and repetitive patterns of interest and behavior. Despite the high prevalence of ASD, its etiology and pathophysiology are still largely unknown and heterogeneous. In the last couple of decades, thousands of studies investigating the etiology of ASD have been published and several environmental as well as genetic factors proposed to be associated with ASD when compared to controls. Methionine cycle is an important metabolic cycle in the body, not only because it is the main source for sulfur-containing amino acids, but it also provides the cells with several metabolites that are vital for many cell functions, such as the methylation process and antioxidant activity. Recently, several studies have proposed an association between the pathophysiology of ASD and the alteration in methionine metabolism including increased concentrations of homocysteine (Hcy), decreased DNA methylation, and increased oxidative stress. Genetic studies have demonstrated that genetic polymorphisms in several enzymes functioning in the cycle may alter it. For example, C677T polymorphism of the methylene-tetrahydrofolate reductase (MTHFR) gene coding the enzyme responsible for the conversion of 5,10-methyleneTHF to the 5- methyleneTHF, leads to a 60% decrease in the activity of the MTHFR enzyme and an increase in homocysteine levels, especially in people with low levels of B vitamins. Likewise, genetic polymorphisms of the enzyme methionine synthase reductase (MTRR) and cystathionine b-synthase (CBS) genes, which are also enzymes involved in the methionine cycle may alter the cycle and hence increase the risk of ASD. **Therefore, the goal of this study was to examine the association between the genetic variations in the enzymes of methionine metabolic cycle with ASD.** To do that, the presence of the most common polymorphisms of MTHFR, MTRR, and CBS genes was tested using PCR-RFLP method and compared between 1) a group of Jordanian autistics, 2) their unaffected siblings, and 3) unrelated health controls. Our preliminary data demonstrates a higher frequency of polymorphisms in the

mentioned genes in autistics compared to the unrelated controls. These data indicated that genetic polymorphisms which lead to alteration in the methionine cycle may increase the risk of ASD.

Title: The effect of treatment with a partial 5-HT_{1A} receptor agonist on grooming behavior in Shank3 mice

Authors: *J. DUNN, M. E. RAGOZZINO;
Psychology, Univ. of Illinois At Chicago, Chicago, IL

Abstract: Restricted interests and repetitive behaviors (RRBs) are a core diagnostic criteria in autism spectrum disorder (ASD). Phenotypic expression of RRBs encompasses a range of behaviors from motor stereotypy to cognitive rigidity. To date there lacks effective treatments to alleviate various RRBs expressed in ASD. Mouse models of syndromic forms of autism offer an approach to understand the underlying pathophysiology and test potential treatments to alleviate RRBs in ASD. Loss of the SHANK3 gene has been identified as the cause of a monogenic form of autism. Deletion of the SHANK3 gene in mice leads to repetitive behaviors, e.g. self-grooming, that are comparable to that observed in ASD. Therefore, the Shank3$^{tm2Gfng/J}$ (Shank3) mouse can be used to test possible treatments to alleviate RRBs in ASD. A recent study found that a partial 5-HT_{1A} receptor agonist reduces irritability in ASD. It is possible that a similar treatment may also alleviate RRBs in ASD. Therefore, the present study investigated whether the partial 5-HT_{1A} receptor agonist, tandospirone, is effective in reducing self-grooming behavior in male Shank3 mice. Thirty minutes prior a self-grooming test mice received an intraperitoneal injection of sterile water, 1.0 or 3.0 mg/kg tandospirone. Grooming behavior was measured for 10 minutes in an empty plastic cage. As previously reported, Shank3 null mice exhibited elevated grooming behavior. Preliminary results indicate that treatment with tandospirone at the 1 and 3 mg/kg dose reduced grooming behavior in Shank3 null mice. The preliminary results

raise the possibility that treatment with a partial 5-HT_{1A} receptor agonist may be effective in treating RRBs in ASD.

Title: Expression of mutant DISC1 in Purkinje cells increased their spontaneous activity, leading to behavioral phenotypes consistent with aspects of autism spectrum disorders

Authors: *A. V. SHEVELKIN[1,2], B. N. ABAZYAN[2], C. YANG[2], O. A. MYCHKO[2], T. J. KAJSTURA[2], J. C. TRONCOSO[2], D. J. LINDEN[2], M. V. PLETNIKOV[2];
[1]P.K.Anokhin Inst. Norm Physiol, Moscow, Russian Federation; [2]Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Disrupted-In-Schizophrenia-1(DISC1) and its variants have been associated with neurodevelopmental disorders, including schizophrenia and autism spectrum disorders (ASD). Purkinje cells (PC) are neurons with highest expression of DISC1 in the brain. In order to explore the role of DISC1 in cerebellar physiology and associated ASD-relevant behaviors, we generated a mouse model of inducible and selective expression of dominant-negative form of DISC1 (truncated mutant human DISC1) in PC of anterior lobuli of the cerebellum (II-V and internal side of VI).
We measured the volume of the cerebellum and PCs in mice at postnatal day 21 and assessed the behavioral phenotype in male and female mice of 3-7 months of age using a series of tests relevant to schizophrenia and ASD, including novelty-induced activity, elevated plus maze, Y maze, object and place recognition, fear conditioning and rotarod. Mutant DISC1 male but not female mice demonstrated abnormal social interaction, hyperactivity and deficient novel object recognition, with no group differences in elevated plus maze, spontaneous alteration or spatial recognition in Y maze.
Neither the total number of PC nor the volume of the cerebellum were significantly altered in mutant DISC1 mice. No up-regulation of cellular markers of inflammation was observed in

mutant mice. Whole-cell patch clamp and loose patch recordings in brain slices found larger amplitude and increased frequency of mEPSCs and spontaneous spiking in PCs, but no changes in intrinsic excitability, R_{input} and paired-pulse ratio in mutant DISC1 mice.
Our findings indicate that mutant DISC1 might alter physiology of PC to lead to cognitive and social abnormalities in mice. This may have the potential to advance our knowledge of the role of DISC1 in maturation and function of the cerebellum related to neurodevelopmental disorders.

Sch., Nashville, TN; [10]Psychiatry, Columbia Univ., New York, NY; [11]Florida Atlantic Univ. Brain Inst., [12]Col. of Med., Florida Atlantic Univ., Boca Raton, FL

Abstract: Autism Spectrum Disorder (ASD) is a heterogeneous disorder spanning a variety of symptoms involving sensory processing, repetitive behaviors, as well as, deficits in communication and social interactions. The neuromodulator serotonin (5-HT) is known to play an important role in normal brain development and has been implicated in perceptual and behavioral abnormalities in ASD. In fact, 5-HT has been considered a biomarker for ASD in about ~ 25-30% of all cases (Cook, 1990; Veenstra-VanderWeele and Blakely, 2012). Using a mouse model of ASD expressing a human coding variant in the 5-HT transporter (SERT, *SLC6A4*), the present study set out to characterize potential changes in cytoarchitecture and

connectivity patterns of cortical sensory regions that might be linked to alterations in serotonin availability during development. The Gly56Ala substitution mutation at the N-terminus has been shown to produce a hyperactive SERT, clearing away more 5-HT than in the wild type form. With SERT being transiently expressed in thalamocortical axons during embryonic development, our initial analysis examines the anatomical effects of altered 5-HT clearance on the distribution of thalamocortical axons in the adult. Additionally since previous work showed that there is a greater concentration of SERT in projections deriving from unisensory thalamic nuclei than from multisensory nuclei (Lebrand et al., 1996), we expected that differential effects on thalamocortical development might be observable in different regions of cortex depending on their thalamic input source. Primary visual cortex (V1) and multisensory region V2L were subsequently selected for analysis. Utilizing the presence of vesicular glutamate transporter 2 (VGluT2) as a proxy to investigate thalamic projections to these areas, our data reveals a significant difference in the distribution of thalamocortical terminals in the adult knock in (KI) mice. KIs exhibited more broadly distributed VGluT2-positive terminals beyond layer IV in V1 but not in V2L compared to wildtype littermates (129S4/S6). Specifically, thalamic terminals appeared to encroach into supragranular layers suggestive of less precise targeting. Furthermore, since no differences were observed in V2L, alterations in 5-HT availability during development may preferentially impact unisensory regions, potentially leading to unisensory processing deficits. This change may have cascading effects shaping, for example, integration of visual sensory cues with other sensory signals further explaining some of the observable symptoms in ASD.

Title: The neurodevelopment of the autistic brain: longitudinal changes of brain connectivity in Fmr1KO and CNTNAP2-KO mice models

Authors: *V. ZERBI[1], M. MARKICEVIC[1], G. D. IELACQUA[2], M. RUDIN[2], N. WENDEROTH[1];

[1]Neural Control of Movement Lab, ETH Zurich, Zurich, Switzerland; [2]Inst. of Pharmacol. and Toxicology, Univ. Zurich, Zurich, Switzerland

Abstract: Motivation. During the postnatal stages the development of functional brain circuits depends critically on the genetic background as well as on neuronal activity driving the formation of new synapses. Alterations of genes regulating migration and synapse formation during development can therefore cause neurodevelopmental disorder like Autism spectrum disorder (ASD). However, how abnormal development at the cell level impacts on functionality at the circuit level is currently unknown. Here we use *Fmr1*KO and *CNTNAP2*-KO mice, two well-established mouse models for ASD, to comprehensively characterize the brain circuits that show delayed or abnormal development in these mice when compared to wild type controls. **Experimental setup.** *Fmr1*KO mice, *CNTNAP2*-KO mice and respective wild type control littermates are longitudinally evaluated during early development (juvenile stage 30 days post-natal, adolescent stage 60 days post-natal, adult stage 120 days post-natal). At each stage, we performed MRI scanning to evaluate structural and functional connectivity changes. The dataset are acquired on a 7T Bruker scanner, equipped with a transmit-receive mouse brain cryogenic coil. Well-established protocols are applied to sedate and monitor mice during the MRI acquisition[1]. Rs-fMRI time series is acquired using gradient echo EPI sequence (2000 repetitions, TR=1s). Thereafter, a multi-shell diffusion-weighted sequence is applied (90 directions, b-values ranging 0-3000). Brain connectivity will be analyzed focusing on specific neural networks. Diffusion-weighted data will be modeled as tensor (DTI) as well as constrained spherical deconvolution (CSD), followed by global tractography[2]. Rs-fMRI will be cleaned from artifacts and analyzed using several established methods[1,3], including independent component analysis (ICA), total correlations and network dynamics analyses. **Expected output and impact.** We will test whether neuroimaging connectivity biomarkers are sufficiently sensitive for detecting differences between the neuro-phenotype of the different mouse models already at young age. This longitudinal experiment will further reveal how circuit development of the autistic brain deviates from normal dynamics depending on the genetic background. This study will provide new insights relevant for developing neuroimaging biomarkers for early diagnosis and monitoring of ASD in human patients. [1] Zerbi, V., et al. NeuroImage 123, 11-21, (2015). Title: Spontaneous beta oscillations: an electrophysiological biomarker of Dup15q syndrome

Authors: *S. S. JESTE[1], J. FROHLICH[2], R. SANKAR[3], P. GOLSHANI[4];
[1]Psychiatry, UCLA Hlth. Syst., Los Angeles, CA; [2]Dept. of Psychiatry, [3]Pediatrics and Neurol., [4]Neurol. and Psychiatry, UCLA, Los Angeles, CA

Abstract: Duplications of 15q11.2-q13.1 (Dup15q syndrome) account for 1-3% of autism spectrum disorder (ASD) and also confer a high risk for intellectual disability (ID) and epilepsy. The duplicated region includes three γ-aminobutyric $acid_A$ receptor ($GABA_AR$) subunit genes. Case reports have identified spontaneous beta oscillations (SBOs) in clinical electroencephalogram (EEG) recordings from children with Dup15q syndrome. SBOs resemble beta activity induced by drugs that modulate $GABA_A$, suggesting upregulation of $GABA_AR$ subunit genes.

We measured SBOs from resting-state EEG recordings of children with Dup15q syndrome (n = 11) and compared these recordings to age-matched typically developing (TD) children (n = 9) and age-and-IQ-matched children with nonsyndromic ASD (n = 10). No children in the study were taking benzodiazepine or similar drugs known to induce beta activity. Relative power in delta, theta, alpha, beta1, beta2, and gamma bands was computed for 9 regions of interest and analyzed using repeated measures analysis of variance (ANOVA), with multiple testing corrected for using false discovery rates (FDR). In a larger cohort (n = 27) of children and adults tested across two sites, we examined age, duplication type, and epilepsy status as predictors of beta power using simple linear regressions.

Resting beta1 (12 – 20 Hz) and beta2 (20 – 30 Hz) power was significantly ($p < 0.05$, FDR corrected) stronger in Dup15q syndrome as compared with both control groups. Effect sizes for comparisons of beta2 power as measured with Cohen's d were as follows: d = 1.73, Dup15q – ASD; d = 1.63, Dup15q – TD. Beta2 power was significantly predicted by epilepsy status in Dup15q syndrome ($R^2 = 0.17$, $p < 0.05$).

SBOs are a biomarker of a genetically distinct subgroup of children within the autism spectrum. Quantification of this biomarker could improve diagnosis, prognostication, and measurement of target engagement and outcomes in clinical trials, a model that can inform similar investigations

in the quickly expanding number of high-risk genetic syndromes associated with neurodevelopmental disorders.

Title: Regulatory small non-coding RNAs in the superior temporal sulcus and primary auditory cortex brain regions of Autism Spectrum Disorders display sexual dimorphism

Authors: *B. STAMOVA[1], B. P. ANDER[2], A. OMANSKA[3], F. R. SHARP[2], C. M. SCHUMANN[3];
[1]MIND Institute-Wet Lab., UC Davis Sch. of Medicine, Dept. of Neurol., Sacramento, CA;
[2]Neurol., [3]Psychiatry and Behavioral Sci., UC Davis Sch. of Med., Sacramento, CA

Abstract: Autism spectrum disorders (ASD) are neurodevelopmental disorders which display social interaction deficits and repetitive behaviors. ASD is sexually dimorphic and more prevalent in boys than girls. Sexually dimorphism in ASD neuropathology has been reported. Thus we investigated whether there is molecular sexual dimorphism in the ASD brain transcriptome. We focused on small non-coding RNAs (sncRNA, including miRNA), which are a major class of regulatory RNAs. We investigated two brain regions: the superior temporal sulcus (STS) and primary auditory cortex (PAC). STS is an association cortex involved in social perception, joint attention, face perception and speech perception and is implicated in ASD. PAC is a primary sensory cortex modulating auditory processing.
We aimed to identify:1) sexually dimorphic and regionally dysregulated sncRNA expression in STS and PAC in postmortem male and female human brains of ASD compared to TD controls; and 2) potentially affected pathways based on predicted sexually-dimorphic dysregulated miRNA targets.
Affymetrix miRNA 3.0 arrays were run on 34 samples (5 ASD Female, 5 ASD Male, 2 TD Female, 6 TD Male; two brain regions – STS, PAC; 4-58 years of age; two of the 18 subjects had only one brain region available). Mixed Regression Model was used to identify sexually dimorphic differentially expressed sncRNA ($p<0.005$, $|\text{fold-change}|>1.2$).
There were 27 and 9 sexually dimorphic sncRNA in ASD STS and PAC, respectively, and 85 sexually dimorphic sncRNA regionally dysregulated in ASD between the two brain regions. Based on the predicted targets of the dysregulated miRNAs, there were many more immune pathways over-represented (Benjamini-Hochberg corrected $p<0.05$) in female (70) than in male (14) in the regional STS vs PAC comparison, with 12 immune pathways in common between male and female. A number of pathways with targets of sexually dimorphic miRNAs have been implicated in ASD, such as axonal guidance, PI3K/Akt Signaling. Moreover, in the common pathways in male and females, there were a number of different mRNA predicted targets. Sexually dimorphic sncRNA expression in ASD brains may contribute to ASD pathophysiology. Even though common pathways may be affected in male and female, different branches of these pathways may be aberrant in the two sexes, which highlights
the necessity for sex-specific treatment and prevention. This study also highlights the importance of the immune system in ASD, and its sexually dimorphic nature. Future studies will need to confirm these findings.

Title: Ube3a and seizures impair sociability by down-regulating autism network gene Cbln1 in VTA

Authors: *D. C. STOPPEL, V. KRISHNAN, Y. NONG, M. A. JOHNSON, E. OZKAYNAK, I. NAGAKURA, M. SILVA, M. J. S. NADLER, S. PETERSON, E. M. KASPER, F. MOHAMMAD, R. ARNAOUT, M. P. ANDERSON;
Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: Increased gene copies of *UBE3A* underlie the autism-related behavioral traits observed in individuals with maternally inherited 15q11-13 triplications (idic15). Here we demonstrate that restricting excess UBE3A to the nuclear compartment impairs sociability by repressing the expression of Cbln1, a key node in an autism gene network of interacting proteins that transsynaptically bridges NRXN and GRID family members that are frequently deleted in autism. *Cbln1* mRNA is negatively regulated by neuronal activity and we show that chemically induced epileptic seizures synergize with *UBE3A* dosage to impair sociability through an Ube3a-dependent mechanism that involves glutamatergic neurons located in the ventral tegmental area (VTA). Deleting Cbln1 in VTA glutamate neurons disrupts social behavior by weakening glutamatergic synaptic transmission. Finally using chemogenetics, we demonstrate that normal glutamatergic synaptic transmission emanating from VTA is necessary and sufficient for intact social behavior.

Title: OTUD7A is a novel candidate driver gene of neurodevelopmental abnormalities in 15q13.3 microdeletion syndrome

Authors: *B. K. UNDA[1], M. UDDIN[2], S. WHITE[1], N. HOLZAPFEL[1], V. KWAN[1], N. MURTAZA[1], A. FORSINGDAL[3], J. NIELSEN[3], K. HOPE[1], S. W. SCHERER[2], K. SINGH, L8S 4L8[1];

Abstract: Copy number variations (CNVs) are chromosomal deletions or duplications that confer high risk for many neuropsychiatric conditions. The 15q13.3 CNV microdeletion is associated with high risk for epilepsy, intellectual disability, schizophrenia and autism spectrum disorder (ASD), and most reported cases are heterozygous for this deletion. However, the neurodevelopmental abnormalities underlying the clinical phenotypes and the gene(s) driving these phenotypes remain unknown. To study this CNV, we are utilizing a heterozygous 15q13.3 microdeletion mouse model that displays characteristic behavioural features of 15q13.3 syndrome, including epilepsy, increased stereotyped behaviour and deficits in spatial learning and memory. RNA-sequencing and gene set enrichment analysis (GSEA) of cortical brain tissue from WT and heterozygous mice revealed that differentially expressed genes are highly enriched in forebrain development. We next analyzed postnatal neuronal morphology, which revealed alterations in dendritic arborization and dendritic spine morphology in excitatory cortical pyramidal neurons. Additionally, preliminary biochemical experiments revealed a decrease in post-synaptic density fraction proteins with a concomitant increase in presynaptic fraction proteins in heterozygous mice, further suggesting that synaptic connectivity may be altered in 15q13.3 heterozygous mice. To understand the pathophysiology of 15q13.3 microdeletion

syndrome, we dissected candidate driver genes using whole-genome sequencing (WGS) and brain-critical exon analysis of human transcriptome data. WGS of ASD quartet families identified 4 *De Novo* variants in one of the genes within the deletion, OTUD7A. OTUD7A is also the only gene within the deletion containing a brain-critical exon that is highly enriched in the brain, suggesting a novel role for this gene in brain function. GSEA of human protein expression data revealed that genes that are highly co-expressed with OTUD7A are highly enriched in pathways involved in synaptic connectivity. Additionally, preliminary biochemical experiments showed that OTUD7A is localized to the post-synaptic density of neurons in the mouse brain, further supporting a role for OTUD7A in synaptic connectivity. Future work will focus on further elucidating the role of OTUD7A and associated pathways in brain development and determining whether loss of OTUD7A can account for the observed synaptic defects in the mouse model.

Title: Loss of lateral asymmetry in the brain of mouse models of autism

Authors: *J. ELLEGOOD[1], B. C. DARWIN[1], M. C. VAN EEDE[1], R. M. HENKELMAN[1,2], J. P. LERCH[1,2];
[1]Mouse Imaging Ctr., Hosp. For Sick Children, Toronto, ON, Canada; [2]Med. Biophysics, Univ. of Toronto, Toronto, ON, Canada

Abstract: Background - Lateral asymmetry in the brain is common in most biological systems. Differences in that asymmetry can provide insight into functional and/or behavioural variations in the population. Studies have shown asymmetry differences in autism compared to typically developing controls. Previous work on the mouse highlights several regions of asymmetry in the mouse brain (Spring et al. 2010), including the striatum, hippocampus, and areas within the

thalamus and cortex. **Objectives** - Using 26 different mouse models related to autism as a representative sample of an autistic population, we hypothesized asymmetry differences compared to wild-type (WT) would be found in the autistic population that would be indicative of functional and/or behavioural variations. **Methods** - In total 593 mouse brains were examined from 26 different mouselines related to autism (Ellegood et al. 2015). Imaging was performed using pre-established methods (Lerch et al. 2011). Acquisition images were flipped/mirrored along the midline axis and registered, first to the original image and then all together. Comparisons were made between the flipped and original image to assess asymmetry and across mouselines. Baseline asymmetry was established using 76 C57Bl6/J mice. Areas of significant voxelwise asymmetry were used to form regional asymmetry networks. 11 different areas were identified, and mean effect size differences in asymmetry were calculated in those 11 areas for the WT and mutant in each of the 26 models. Significant differences between the WT and mutant group were calculated using a linear model and multiple comparisons were controlled for using False Discovery Rate (FDR). **Results and Discussion** - Of the 11 regional networks/areas that were examined we found a loss in lateral asymmetry in 5 areas. The strongest losses were found in areas in the hypothalamus and thalamus (p=0.01, FDR=11%) as well as a corpus callosum to motor cortex network (p=0.01, FDR=11%). Additional losses of asymmetry were found in a memory network involving the striatum, hippocampus and amygdala (p=0.03, FDR=13%), and a brainstem network (p=0.03, FDR=13%). The models with the strongest asymmetry loss in those 5 areas were *Cntnap2*, *Nl3*, *En2*, XO and BTBR in that order. The loss of asymmetry in the corpus callosum to motor cortex network could be related to functional deficits as several lines have motor abnormalities (e.g. *En2*, *Gtf2i, Mecp2* etc.). Similarly the loss of asymmetry in the memory network may be related to cognitive deficits in several lines (e.g. *Shank3*, 15q11-13, *Cntnap2* etc.). Overall, we found specific areas where normal lateral asymmetry was lost in the brain of autism related mouse models.

Abstract: Genome-wide association studies (GWAS) have identified many genomic loci associated with the risk of schizophrenia and autism, and additional sequencing efforts are in progress for bipolar disorder and ADHD. The field has a need for strategies to mine this wealth of genetic information to understand disease etiology and progression and to inform treatment strategies. One major obstacle is that the cellular and anatomical substrates of neurodevelopmental disorders are largely not known. We propose that new knowledge of the affected neurons and circuits can be gained by determining whether genomic loci mutated in patients are enriched for genes and pathways characteristic of specific neuronal populations. This requires a more comprehensive understanding of neuronal subtype-specific molecular profiles than currently available. To this end, we are building a critical resource of gene expression data from multiple subtypes of projection neurons isolated from the murine neocortex and, in parallel, from human cortex at both fetal and adult stages.
The approach we used to label neurons does not require genetic labeling and is thus particularly valuable for large-scale transcriptomic studies in human samples, as it allows for the simultaneous isolation of multiple neuronal classes from the same tissue sample. As the number of neuronal classes profiled grows, this type of resource will provide a platform to interface GWAS data with neuronal class-specific expression profiles to facilitate the identification of the classes of neurons most likely affected and to clarify the developmental timing of disease susceptibility.

Title: Matrix metalloproteinase 9 overexpression recapitulates neurophysiological changes induced by early exposure to valproic acid in a Xenopus tadpole model for neurodevelopmental disorders

Authors: *E. J. JAMES, J. PARK, C. D. AIZENMAN;
Brown Univ., Providence, RI

Abstract: Prenatal exposure to valproic acid (VPA), a commonly prescribed antiepileptic medication, is known to greatly increase risk for autism and other neurodevelopmental disorders (NDDs). Prior experiments in our lab had shown that early developmental exposure of Xenopus tadpoles to VPA resulted in behavioral and electrophysiological abnormalities consistent with various NDDs. The etiology of autism, and NDDs, is hypothesized to arise from misexpression of synaptic proteins that function to stabilize, maintain, and refine synapses. Matrix metalloproteinase 9 (MMP9), an endopeptidase involved with synaptic refinement, has been associated with various NDDs, and microarray and qPCR data from our lab revealed that chronic exposure of tadpoles to VPA, caused significantly altered expression MMP9 mRNA in the CNS. Knocking out MMP9 expression, in a Fragile X mouse model, has been shown to rescue the Fragile X phenotype. Here we find that pharmacological inhibition of MMP9 activity recues neurophysiological and behavioral abnormalities induced by early developmental exposure to VPA. Although these findings highlight the potential role of MMP9 in neurodevelopmental disorders it remains unknown if dysregulation of MMP9 is sufficient to cause the abnormalities observed with VPA exposure. Thus, we overexpressed MMP9 in the optic tectum of developing tadpoles and conducted electrophysiological recordings from tectal neurons. We found that MMP9 overexpression caused increased synaptic transmission, elevated network connectivity and excitability, and reduced intrinsic cell excitability. These results recapitulate the observed effects of VPA on the developing neural circuit and suggest a shared mechanism by which genetic, epigenetic, and environmental risk factors may induce neurodevelopmental disorders.

Title: Reduced mGluR5 binding activity and mRNA expression following astrocytes activation

Authors: *T. LEE[1,2], K. J. GREGORY[4], M. DOTTORI[2], C. PANTELIS[3,1,2], A. CHRISTOPOULOS[4], I. P. EVERALL[1], E. SKAFIDAS[2,1], G. CHANA[2,1];
[1]Dept. of Psychiatry, [2]Ctr. for Neural Engin., [3]Melbourne Neuropsychiatry Ctr., The Univ. of Melbourne, Melbourne, Australia; [4]Fac. of Pharm. and Pharmaceut. Sci., Monash Univ., Melbourne, Australia

Abstract: Alterations in excitatory glutamatergic signalling together with increased astrocytic activation and neuroinflammation have been observed in the brain of individuals with autism spectrum disorder (ASD). Within the ASD brain, the metabotropic glutamate receptor 5 (mGluR5) has been found to be downregulated in expression in the DLPFC, with mGluR5 modulators having the potential for clinical benefit for syndromic ASD. At the glutamatergic tripartite synapse, astrocytes play an important role in regulating the pre- and post-synaptic glutamate receptors as well as intercellular glutamate levels. Within the ASD brain elevated levels of excitatory amino acid transporters (EAAT1 and EAAT2) and glia fibrillary associated protein (GFAP) have also been found. For this investigation we utilised human primary foetal and adult human astrocytes to investigate astrocytic glutamatergic signalling in response to a neuroinflammatory insult. Primary human foetal and adult astrocytes were exposed to Polyinosinic:polycytidylic acid (Poly I:C) [100ng/ml] for 24 hours and 1 week to induce acute and chronic activation states. Following on we assessed levels of pro-inflammatory cytokines using enzyme-linked immunosorbent assay (ELISA), mRNA expression of glutamatergic and astrocytic markers using qPCR, and mGluR5 binding activity via [3H] methoxyPEPy radioligand binding assay. Astrocytes exposed to poly I:C showed elevated levels of pro-inflammatory cytokines IL-6 and Rantes versus controls. We also observed a reduction of mGluR5 binding activity in cells exposed to Poly I:C, together with a reduction in mRNA expression of GRM5 (p<0.05), and the main CNS glutamate transporter EAAT2 (p<.001), as well as increased expression of mGluR5 downstream element SHANK3 (p<.001). Finally, we observed a reduction in mRNA expression of the astrocyte cytoskeletal markers ALDH1L1 (p<.005) and GFAP (p<.005). Our findings demonstrate that during astrocytic activation mGluR5 signalling is reduced and is accompanied by a reduction in EAAT2 expression that is suggestive of a reduced capability to clear extracellular glutamate. These findings point to reduced mGluR5 signalling in the ASD potentially associated with abnormal astrocyte functioning and an increased vulnerability to glutamate mediated excitotoxicity, however further post-mortem work is required to confirm this. Our findings of reduced GFAP are to an extent counterintuitive following Poly I:C exposure but may not be reflected at the protein level. Conversely, reduced GFAP and ALDH1 may represent a decrease in structural astrocytic proteins that are indicative of a reduced capacity to carry out normal functioning.

Title: Alteration of Purkinje cells by autism-inducing drugs, and recovery effects with bumetanide or oxytocin administration in developing rat cerebellum

Authors: S. NAKAJIMA[1], T. TOMIDA[1], K. IKAI[1], *Y. FUETA[2], S. UENO[2], N. HOZUMI[1], Y. SEKINO[3], S. YOSHIDA[1];
[1]Dept. Envrn. and Life Sci., Toyohashi Univ. Technol., Toyohashi, Japan; [2]Univ. Occupational/Environmental Hlth., Kitakyushu, Japan; [3]Natl. Inst. of Health. Sci., Tokyo, Japan

Abstract: Autism, a severe neurodevelopmental disorder, becomes increased in young age. In human patients, cerebral and cerebellar developmental abnormalities are reported. Especially, reduction in size and number of Purkinje cells in cerebellum is revealed in both the postmortem human studies and some drug-administrated adult animals. Several chemicals are known to play some roles in onset of autism . Valproate (VPA) is one of the candidates of inducer of autism. Chlorpyrifos (CPF), an organophosphorus agent, is also known as an autistic inducer likewise VPA. In this study, we investigated cerebellar cytological and behavior changes in development with some drug administrations. VPA is known as a HDAC inhibitor. The effects of other HDAC inhibitors, suberoylanilide hydroxamic acid (SAHA), and MS-275, were also investigated. Additionally, CPF or tributyltin (TBT) were tested. Each drug was administrated to embryonic day 16 p.o. (VPA; 600mg/kg, MS-275; 4mg/kg, CPF; 4.3mg/kg, and TBT; 20mg/kg of mother weight, respectively) or i.p. (suberoylanilide hydroxamic acid, SAHA; 50mg/kg of mother weight).
In cerebellar development, the soma of Purkinje cells form a single layer and elongate their dendrites with synapses during the first two weeks. In VPA-administrated rat, we have observed the elongation of Purkinje cell dendrites started earlier and reached all over the molecular layer even in P12. It was observed also in SAHA, or CPF administrated rat, while in MS-275, or TBT administrated rats, it was not. The behavior of VPA- or CPF-administrated animals was observed as same as control animals in the first week, however, VPA-administrated became differentiated from others in the second week. MS-275, or TBT-administrated animals showed unique behavioral development.
After the facilitation of Purkinje cell development in these drugs in the first week, excess gyrus in cerebellar lobules, especially in lobe V to VII, was formed in the second week. During the

developmental progress, this excess gyrus was eliminated with some Purkinje cells.
Recently, some recovery effects from autism with bumetanide, or oxytocin administration have been reported. We investigated the neuronal effects of these drugs to the VPA-induced autistic model animals. We suggest that drug-induced autistic model rat would become useful to evaluate the recovery effect of a drug.

Title: Lifelong trajectory of human amygdala neuronal development is disrupted in autism

Authors: *T. A. AVINO, N. BARGER, M. VARGAS, M. D. BAUMAN, D. G. AMARAL, C. M. SCHUMANN;
Psychiatry & Behavioral Sci., UC Davis MIND Inst., Sacramento, CA

Abstract: The amygdala is a complex cluster of nuclei located in the rostral portion of the temporal lobe. It plays a prominent role in modulating socioemotional processing, yet little is known about the postnatal neuronal development of this structure in humans. Understanding these developmental processes is critical for untangling a number of neuropsychiatric disorders that have been associated with amygdala dysfunction such as anxiety disorder, depression, and autism spectrum disorder (ASD). Structural and functional imaging studies have demonstrated an altered age-related growth trajectory and activation of the amygdala across the lifespan in individuals with autism. The cellular substrates of these lifelong alterations are not well understood. We performed a stereological analysis of neuron number and size in subregions of the amygdala utilizing postmortem tissue from 50 human brains (28 ASD, 22 Typical) representing the largest study of its kind to date. In typical development, the number of neurons in the amygdala increases with age from childhood through adulthood by 23% in the basal nucleus and 15% in the accessory basal nucleus. In contrast, individuals with autism on average show an initial 15% increase in neuron number during childhood in the basal, accessory basal, and central nuclei relative to age-matched typically-developed brains. This initial increase is followed by a pronounced reduction in neuron number in autism with increasing age in all

amygdala subregions, including lateral, basal, accessory basal, and central nuclei, such that by adulthood there is, on average, a 17% decrease relative to the typical adult brain. These findings provide the first evidence of the normal pattern of lifelong neuronal development and maturation in the postnatal human amygdala and demonstrate that these typical processes are disrupted in autism, resulting in an age-related loss of neurons across amygdala nuclei in adults with ASD.

Title: Abnormal phosphorylation of AMPA receptor subunit GluR1 in the basolateral amygdala of the valproic acid-exposed rat model of autism following extinction learning

Authors: *S. H.-M. CAVALIER[1], K. GRIFFIN[2], A. ALVAREZ-DIEPPA[2], C. MCINTYRE[2]; [1]Univ. of Texas At Dallas, Dallas, TX; [2]Univ. of Texas at Dallas, Dallas, TX

Abstract: This work compares the expression of synaptic plasticity-associated protein GluR1, a subunit of the AMPA receptor, in the basolateral complex of the amygdala (BLA) in the valproic acid (VPA) rat model of autism spectrum disorder vs. saline-treated controls, after fear conditioning and extinction. Fear extinction is a process in which a conditioned fear response is suppressed by the formation of a new memory that competitively opposes the fear-association. The BLA plays a vital role in extinction of conditioned fear response and is heavily modulated by reciprocal connections with the infralimbic cortex (IL). Because extinction is a form of new learning, it involves both memory acquisition and consolidation and is therefore dependent on the cellular and molecular processes that mediate synaptic plasticity. Extinction of conditioned fear is impaired in rats prenatally exposed to VPA. Fear extinction learning in neurotypical animals promotes increased GluR1 synaptic expression in the IL and extinction learning related to cocaine withdrawal promotes increased synaptic GluR1 in the IL and decreased synaptic GluR1 in the BLA; however, little is known about the molecular and synaptic state of the BLA in VPA exposed rats, and how potential synaptic dysfunction in this region might contribute to extinction impairment. To examine the effect of prenatal exposure to VPA on the expression of synaptic GluR1 in the BLA, 500 mg/kg VPA or saline were injected (i.p.) to pregnant dams on embryonic day 12.5. Two month-old male offspring were subjected to auditory fear-conditioning followed 24 hours later by extinction training. VPA exposed rats showed extinction deficits when tested on day three ($F(1,14)=12.89$; $p=0.003$). Animals were sacrificed 45 minutes following retention testing. Tissue punches were taken from the BLA for western blot analysis of phosphorylated GluR1 at the Ser831 and Ser845 sites. No difference in phosphorylated levels of GluR1 at Ser831 was seen. Expression levels of phosphorylated GluR1 at the Ser845 site were significantly increased in the BLA of VPA exposed rats compared to saline controls ($t(15)=2.13$; $p=0.02$). Phosphorylation of Ser845 is associated with increased GluR1 subunit synaptic trafficking, which could alter the ion selectivity of resultant AMPARs and affect plasticity. These results indicate that the VPA animal model of ASD presents normal acquisition but impaired extinction memory consolidation, and suggest that this impairment is associated with abnormal AMPA receptor subunit trafficking in the BLA.

Title: Dysregulated protein synthesis in autism and fragile X syndrome patient iPSC-derived neural progenitor cells

Authors: ***N. RAJ**, G. J. BASSELL;
Cell Biol., Emory Univ., Atlanta, GA

Abstract: Autism spectrum disorders (ASDs) are complex neurodevelopmental disorders characterized by stereotyped behaviors, and impairments in social interaction and communication. While a majority of autism is idiopathic, several genetic and environmental factors have been shown to be involved in its diverse etiology and symptoms, posing a serious challenge to the development of therapeutic strategies. Many symptoms of idiopathic autism are also seen in other neurodevelopmental disorders, suggesting that these symptoms may converge upon a unifying molecular nexus – the phosphoinositide-3 kinase (PI3K) pathway. PI3K is a key regulator of signaling and protein synthesis and is implicated in several monogenic forms of autism including fragile X syndrome (FXS), the most common known genetic cause of autism. We have recently shown that a prefrontal cortex-selective genetic knockdown of the PI3K catalytic subunit, p110β, rescues specific cognitive deficits in a FXS mouse model. We have also found that a p110β subunit selective inhibitor ameliorates the increased protein synthesis rate in synaptoneurosomes from the *Fmr1* knockout mouse model and human FXS patient cells. Dysregulated protein synthesis has been shown to be a key feature of several neurodevelopmental disorders; however our knowledge of the molecular pathogenesis in human neurons has, until recently, been largely limited to studies conducted in post-mortem tissue from patients. In this study, we extend our investigation of the therapeutic value of targeting overactive PI3K signaling in fragile X syndrome and autism to a more translationally relevant model, using human patient induced pluripotent stem cells (iPSCs). Using both BONCAT and a flow cytometry-based assay in multiple control and patient iPSC-derived neural progenitor cells (NPCs) to measure novel protein synthesis, we have found that patient-derived NPCs exhibit increased global protein synthesis compared to control NPCs. Furthermore, treatment with a

p110β inhibitor reduced the exaggerated protein synthesis rate in FXS patient-derived NPCs. Thus, this work suggests that patient iPSC-derived neural progenitor cells recapitulate molecular phenotypes seen in the mouse model, and can be used as valid model for critical pre-clinical testing and comparison of therapeutic strategies.

Title: Neurobiological basis of Oxytocin on pro-social behaviors

Authors: ***G.-Y. WU**[1,2], Y.-J. HO[1], Z.-Y. HU[1], Q.-W. HUO[1], G. CHEN[2];
[1]Sch. of Life Science, South China Normal Univ., Guangdong, China; [2]Penn State Univ., State College, PA

Abstract: The neuropeptide, oxytocin has attracted tremendous attention as potential therapeutic treatment for various social deficits in recent years. However, the neurobiological basis of oxytocin on pro-social behaviors is still poorly understood. Here we report an activity-dependent regulation of oxytocin receptor (OXTR) stability and trafficking in cultured neurons. When neuronal activity is increased, the steady-state level of OXTR is rapidly increased by up-regulation of protein synthesis and down-regulation of ubiquitin-proteasome (UPS)-dependent degradation. Conversely, when neuronal activity is decreased, the steady-state level of OXTR is decreased by up-regulation of receptor internalization and UPS-dependent degradation. Furthermore, we have established a stable multi-site *in vivo* recording system of single-unit spikes from different brain regions simultaneously, permitting better exploring relevant neuronal circuitry underlying oxytocin's effect on pro-social behavior. In a preliminary study, we found that intravenous application of oxytocin alters neuronal firing pattern from continuous into burst activities in several brain regions implicated in social circuitry. We are currently exploring how this is relevant to social behaviors, and determining the molecular mechanisms underlying OXTR trafficking and degradation.

Title: Maternal immune activation disrupts synaptic pruning in the mouse offspring brain

Authors: *L. FERNÁNDEZ DE COSSÍO GÓMEZ, A. GUZMAN, G. N. LUHESHI;
Douglas Mental Hlth. Univ. Institute, McGil, Verdun, QC, Canada

Abstract: Background: Environmental challenges to the maternal immune system during pregnancy increase the likelihood of neurodevelopmental disorders, such as Autism, appearing in the progeny. While previous studies show that the mother's inflammatory response is implicated, how inflammation during pregnancy can disturb brain development remains unknown. Microglia, the brain's resident immune-cells, have been recently shown to be critically involved in normal brain development, shaping connections between neurons by pruning superfluous synaptic spines. Objective: To show that maternal immune activation (MIA) alters microglia's spine pruning function and lead to behavioral disturbances. Methods: Using our established mouse model of MIA induced by bacterial Lipopolysaccharide (LPS), we quantified spines and assessed alterations in some molecular signals involved in pruning, within the offspring's brain. Additionally we assayed the offspring's behaviour during development. Results: Prenatal LPS resulted in a significant increase in the number of spines in dentate gyrus neurons. In addition, we show reduced hippocampal expression of fractalkine and its microglial receptor (CX3CR1), which are involved in mediating the pruning process. In both cases these changes were only noted in the male offspring of LPS challenged dams. Interestingly, C3, a compliment protein involved in tagging spines for microglia pruning, was less expressed in male pups independent of treatment. We further found an LPS effect in the offspring's duration of ultrasonic vocalizations. Conclusions: Our results provide an early indicator that microglial function is altered in the brain of maternally challenged progeny and that the effects in the brain appear to be specific along sex lines. In addition, we find early-onset alterations in communication in the offspring of infected mothers, a hallmark of disorders like Autism.

Title: Zinc and Shank regulation of AMPAR during neuronal development

Authors: ***H. T. HA**[1,2], S. A. KIM[2], C. C. GARNER[3], J. R. HUGUENARD[2];
[1]Neurosci., [2]Neurol. and Neurolog. Sci., Stanford Univ., Palo Alto, CA; [3]German Ctr. for Neurodegenerative Dis., Berlin, Germany

Abstract: Autism Spectrum Disorders (ASDs) affects 1 out of 68 children in the US. Despite the growing number of diagnosed children worldwide, the underlying biological mechanisms are unknown, and there are no effective medications. Mutations in the **Shank family of proteins** are a highly prevalent and penetrant genetic risk factor for ASDs given their role as essential scaffolding molecules at synapses. While the genetic heritability of autism is high, environmental factors (such as prenatal **zinc deficiency**) might promote the onset and manifestation of ASDs. Considering the role of the zinc ion as a signaling molecule in the brain and its ability to bind and activate Shank3, it could offer a potential mechanism for gene/environment interaction. Identifying specific downstream targets of zinc deficiency and *Shank* mutations will facilitate the development of new treatments for ASDs. One such potential molecule implicated in previous Shank and zinc studies is **AMPAR** (the major group of glutamate receptors in the nervous system). *Here, we ask how zinc, Shank and their interaction regulate AMPAR* by using a combination of electrophysiology and imaging approaches in dissociated neuronal culture. We found that AMPAR-mediated synaptic current is strengthened by zinc addition during early synaptic development, particularly relevant since ASDs manifest at a young age when the brain is highly vulnerable to genetic mutations or environmental insults. The effect of zinc on AMPAR activity is subunit-specific, suggesting the involvement of this signaling pathway in particular phases of plasticity. Interestingly, Shank2 and Shank3 display different synaptic expression pattern over neuron development, which hints at their potential contribution to the developmental dependence of AMPAR's zinc sensitivity. This work demonstrates that zinc regulates the function of AMPAR early in development potentially through its interaction with Shank3. It also

identifies modulation of AMPAR function as a potential therapeutic strategy for autism patients with history of prenatal zinc deficiency.

Title: Regulating ERK signaling improves vocal communication in a mouse model of autism

Authors: ***N. CHENG**, M. KHANBABAEI, E. HUGHES, K. MURARI, J. M. RHO;
Univ. of Calgary, Calgary, AB, Canada

Abstract: Language delays and deficits have been considered a defining feature of autism spectrum disorder (ASD). Currently, only co-morbid manifestations of the disorder can be alleviated, but not the core symptoms. Notably, the most common genetic linkages to ASD include ones that alter the extracellular-signal-regulated kinase (ERK) pathway. Here, we hypothesized that ERK signaling is dysregulated in ASD and that interventions aimed at normalizing this pathway can alleviate the core symptoms of the disorder. We tested this hypothesis in the BTBR mouse model because it robustly exhibits all of the core behavioural features of ASD. We found that the levels of both active MEK and ERK proteins were significantly increased in the neocortex of juvenile (postnatal day 35, or P35) BTBR mice compared with age-matched B6 animals. To test if pharmacological inhibition of ERK signaling would mitigate ASD-like behaviour in BTBR mice, we injected i.p. both B6 and BTBR mice from P24 to P35 with U0126 (12.5 mg/kg/day), a highly selective and potent MEK inhibitor. Using liquid chromatography-tandem mass spectrometry, we first confirmed that the concentration of U0126 in neocortex homogenate after i.p. injection was above its IC_{50}. In addition, i.p. injection of U0126 reduced pERK levels in the neocortex of BTBR mice. Behavioural testing revealed that while U0126 treatment did not affect body weight or motor activity of either BTBR or B6 animals compared with vehicle-injected controls, it increased the number of ultrasonic vocalizations (USVs) emitted by BTBR mice during male-female encounters, without altering the average duration, peak frequency, or maximum amplitude. Further analysis showed that similar to what has been reported in neonatal mice, USVs in juvenile B6 mice were mostly clustered into strings of calls separated by relatively long pauses.

In contrast, the USVs from BTBR mice showed only modest string organization, with larger proportion of calls not associated with a string structure, as well as fewer total number of strings and calls per string during the test. U0126 treatment increased the proportion of calls associated with string structure and the total number of strings emitted from BTBR mice. Thus, U0126 treatment improved both the volume and structure of vocalizations from BTBR mice. In addition, we also examined the effect of U0126 treatment in the 3-chamber sociability assay, and found that the BTBR mice showed a trend toward improvement. Together, our data indicate that regulating ERK signalling ameliorates deficits in vocal communication of the BTBR model of ASD, suggesting that targeting this pathway could have potential therapeutic benefit.

Title: Maternal plasma fetal neuronal exosomes: a non-invasive tool to interrogate in-utero neuronal injury

Authors: *L. GOETZL[1,2,3], E. J. GOETZL[4], N. MERABOVA[3], E. LAURETTI[3], G. TATEVOSIAN[3], D. MARTIROSYAN[3], N. DARBINIAN[3];
[1]Shriners Hosp. Pediatric Res. Ctr., Temple Univ. Sch. of Med., Philadelphia, PA; [2]Obstetrics & Gynecology, [3]Ctr. for Neural Repair and Rehabilitation, Shriners Hosp. Pediatric Res. Ctr., Lewis Katz Sch. of Med. at Temple Univ., Philadelphia, PA; [4]Univ. of California, San Francisco, CA

Abstract: **Introduction**: We have recently reported that fetally derived neuronal exosomes (FNEs) can be isolated from maternal plasma and their proteins analyzed as a non-invasive method for evaluating fetal neurodevelopment. We have also found that, in some cases, response to a toxin such as ethanol (EtOH) results in more dramatic reductions in markers of synaptic function and neuronal survival in FNEs than in paired fetal synaptosomes (SYNAPs). This may be due to homeostatically reduced loading of these key proteins into exosomes to preserve levels in damaged neurons. We hypothesized that biomarker levels would remain highly correlated between FNEs and paired SYNAPs. **Methods:** We performed an IRB-approved, matched case-

control study in women 9 -19 weeks' gestation (GA). Heavy EtOH cases were compared to controls matched for GA and fetal gender (n=10/group). Maternal plasma exosomes were precipitated (ExoQuick) and the fetal subset enriched (anti-Contactin-2/TAG1 streptavidin bead absorption). Synaptosomes (SYNPs) were prepared from fetal brain tissue and protein levels quantified by ELISA. **Results**: The majority of markers of synaptic function and neuronal survival showed moderate to strong correlation between protein level in SNYPs and FNEs (**Table 1**). We previously identified SNP, REST, NG and Synapsin-2 as highly discriminatory in FNEs with little or no overlap between cases and controls. Three of these 4 most promising biomarkers had highly significant FNE-SNYP correlations. SNYP NG may correlate poorly due to its post-synaptic role. **Conclusions**: These results represent additional evidence that developing neurons release exosomes into the fetal circulation from where they are able cross the placenta into the maternal circulation. Our novel methods for isolating FNEs from maternal plasma provide potentially clinically relevant biomarkers of acute and/or chronic neurotoxic exposures between 9 and 19 weeks GA. Both EtOH and viral infections may ultimately result in fetal microcephaly through an imbalance between progenitor cell production/differentiation and cell death. Therefore FNE-based assays may ultimately prove useful in predicting microcephaly in an earlier gestational age window than fetal ultrasound and magnetic resonance imaging.

Table 1. Correlations between Median Protein Levels in FNEs and SYNAPs (Spearman's ρ, non-parametric)

Marker	Rho	p value
Synaptophysin (SNP)	0.61	0.004
Synaptotagmin-2	.008	0.98
Restriction element-1 silencing transcription factor (REST)	0.55	0.01
Growth Associated Protein 43 (GAP43)	0.18	0.44
Neurogranin (NG)	0.21	0.38
Synaptopodin	0.47	0.04
Brain-derived neurotrophic factor (BDNF)	0.56	0.01
Synapsin-2 total	0.86	<0.001

Title: Mmp-9 deletion rescues developmental abnormalities in the auditory cortex of fragile x syndrome mouse model

Authors: *S. AFROZ[1], T. WEN[1], S. REINHARD[2], K. TAPIA[1], K. RAZAK[2], I. ETHELL[1]; [1]Biomed. Sci., [2]Psychology, Univ. of California Riverside, Riverside, CA

Abstract: Fragile X Syndrome (FXS), a leading genetic cause of autism and intellectual disability, is characterized by language deficiencies, impaired social reciprocity and auditory processing deficits. The Fmr1 knockout (KO) mice replicate most of these FXS-associated auditory deficits which are likely the result of an impaired excitatory-inhibitory (E/I) balance due to reduced excitatory drive onto inhibitory cells, a reduced number of PV interneurons or increased firing rate of excitatory neurons and their high firing probability during UP states in KO mice. In this study, we analyzed the density of parvalbumin (PV)-positive inhibitory interneurons in developing auditory cortex of KO mice. We also investigated the formation of perineuronal nets (PNNs), which are thought to regulate the functions of PV interneurons. We found a significant increase in PV cell density in both wt and KO mouse auditory cortex from P14 to P60. PNN formation was also observed during the same period with a major increase in PNN-positive cell density at P21 and P30. PNNs were mostly observed in layer 4 but not layers 2/3 or 1 of the auditory cortex. Further analysis showed lower PV cell density, PNN density, and lower numbers of PV cells enwrapped with PNNs in layer 4 of KO mice as compared to WT animals at P21 but not P30. Matrix metalloproteinase-9 (Mmp-9), a protein that is a target of Fmrp transcriptional regulation, also regulates enzymatic cleavage of the extracellular matrix, in particular PNNs around PV-positive interneurons. We found abnormally high Mmp-9 levels in the developing auditory cortex of KO mice which may explain impaired PNN formation observed at P21. We therefore investigated the effect of full and partial deletion of Mmp-9 and found a restoration of PV and PNN cell density in the auditory cortex of Fmr1/mmp-9 double KO mice at P21. Density of PV/PNN positive neurons and the percentage of PV cells enwrapped with PNN was also restored to WT levels. We further investigated whether irregular PV cell maturation in the KO contributed to auditory cortex deficits by analyzing the expression of neuropeptide Y (NPY), a marker that is expressed in immature PV cells. We found increased expression of NPY in PV cells in the KO auditory cortex and an increased propensity of NPY cells to be enwrapped by PNNs at P30, which was not observed in wt or double KO mice. These

findings indicate that elevated Mmp-9 levels may be responsible for the abnormal development and maturation of PV/PNN in the auditory cortex of Fmr1 KO mice leading to impaired excitatory-inhibitory balance and the development of auditory processing deficits. This work was supported by grants from FRAXA Research Foundation and NIH 1U54HD082008.

Title: Time-delimited MET receptor tyrosine kinase signaling controls glutamatergic circuits formation and refinement in the developing forebrain

Authors: ***X. MA**[1], Z. LU[2], G. LI[2], L. ZHANG[2], M. PIECHOWICZ[2], J. WU[3], S. QIU[2]; [1]Dept. of Basic Med. Sci., The Univ. of Arizona Col. of Med., Phoenix, AZ; [2]Univ. of Arizona COM-PHX, Phoenix, AZ; [3]Barrow Neurolog. Inst., Phoenix, AZ

Abstract: The human *MET* gene encodes the MET receptor tyrosine kinase, which a replicated risk for autism spectrum disorder (ASD) and is implicated in the structural and functional brain development. *MET* plays a pleiotropic role in embryogenesis and modifies a large number of neurodevelopmental events. In the mouse forebrain, MET expression in the dorsal pallium is turned on at late embryonic stage, peaks during the first two postnatal weeks, and precipitously down-regulated after the third postnatal week. Our previous works suggest that MET signaling controls synaptogenesis and the time of maturation in the developing hippocampus and the prefrontal circuits. Here, using a transgenic mouse model with controllable MET over-expression, we show that continued MET expression after the third postnatal week in mouse forebrain leads to excessive neurite growth, and profuse generation of small, immature dendritic spines. These morphological and functional impairments may be caused by enhanced neurite growth, and/or impaired dendrite/spine developmental pruning. In addition, two photon in vivo imaging in MET over-expression neurons suggest impaired synapse pruning. Therefore, normal time-delimited MET signaling, particularly the timely downregulation of MET expression is critical in regulating the timing of neuronal growth, glutamatergic synapse maturation and cortical circuit function. Dysregulated MET signaling may lead to pathological changes in

forebrain maturation and connectivity, and thus contribute to the emergence of neurological symptoms associated with ASD.

Title: Synaptic protein interaction network analysis of seven autism mouse models

Authors: ***S. E. SMITH**[1], A. A. WILLIAMS[2], E. A. BROWN[2], S. C. NEIER[3], A. G. SCHRUM[3];
[1]Ctr. for Integrative Brain Res., [2]Seattle Childrens Res. Inst., Seattle, WA; [3]Mayo Clin., Rochester, MN

Abstract: Autism genetic studies have identified multiple genetic risk factors with protein products localizing to the glutamate synapse. Moreover, mouse models of autism often show disruptions of glutamatergic transmission and excitatory/inhibitory balance, even when the gene product under study is not localized to the synapse. These data suggest that impaired glutamatergic transmission may be a central component of many different genetic and environmental causes of autism. To test this 'synaptic hypothesis of autism', we have assembled a quantitative multiplex immunoprecipitation (QMI) assay to measure dynamic protein-protein interaction networks at the glutamate synapse in mouse models of autism. The QMI assay immunoprecipitates a given protein onto a microbead substrate, and quantifies the abundance of co-immunoprecipitated proteins in shared complexes using fluorescently tagged antibodies read by a flow cytometer. Using this principle, we can simultaneously measure 100+ binary protein combinations of autism-linked and related gene products using Luminex addressed beads. We have analyzed seven independent genetic and environmental mouse models of autism and quantified the differences in the synaptic protein interaction network in the hippocampus and frontal cortex. Our results show that when one synaptic protein is genetically altered (e.g. Shank3), the abundance of other, seemingly unrelated protein complexes is affected (e.g. a complex containing Homer1 and PSD95). By comparing protein network changes in different mouse models using graph-theory-based techniques, we are beginning to identify a set of

proteins in shared complexes that are altered in multiple models of autism. We predict that a better understanding of both levels of individual protein abundance and, critically, the amount of interaction among synaptic proteins, will enable the identification of convergent molecular pathways shared among different models of autism and allow the classification of biologically relevant sub-groups of the disorder.

Title: S100B protein accumulation alters intracellular trace metal homeostasis and affect autism associated signaling cascades in the central nervous system

Authors: *S. HAGMEYER[1], J. S. CRISTÓVÃO[2], T. M. BOECKERS[3], C. M. GOMES[2], A. M. GRABRUCKER[4];
[1]WG Mol. Analysis of Synaptopathies, Neurol. Department, Neurocenter of Ul, Univ. Ulm, Ulm, Germany; [2]Chem. and Biochem. Dept., BioISI – Biosystems & Integrative Sci. Inst., Lisbon, Portugal; [3]Inst. for Anat. and Cell Biol., Ulm, Germany; [4]WG Mol. Analysis of Synaptopathies, Neurol. Dept., Neurocenter of Ulm University, Ulm, Germany, Inst. for Anat. and Cell Biol., Ulm, Germany

Abstract: An increasing number of studies have reported the implication of an altered trace metal homeostasis, in particular abnormal zinc and copper levels, in several neurological disorders including Autism Spectrum Disorders (ASD) and Alzheimer´s disease (AD). This non-genetic risk factor may unfold not only in response to nutritional deficiencies, but may also be caused by the occurrence of abnormal accumulations of trace metal binding proteins that induce local changes in trace metal homeostasis. S100B, an EF hand calcium binding protein of the S100 protein family, has been recently reported to be prone to aggregation. S100B is mostly expressed in the brain where it accounts for 0.5% of soluble proteins and mainly exists as a homodimer. Besides its calcium-binding property, S100B proteins also bind two zinc ions per dimer. Elevated serum levels of S100B have been reported in cases of ASD as well as AD, both disorders that also show alterations in metal ion homeostasis and neuro-inflammation. Taken this into account, we investigated the effects of abnormal S100B protein aggregates on neuronal metal ion homeostasis and down-stream effects on synapse formation, composition and function

at different developmental stages in *in vitro* cell culture systems and *in vivo* in mouse models. We could show that S100B binds zinc under physiological conditions *in vitro*. After the exposure of neurons to elevated levels of dimeric or tetrameric S100B, indeed intracellular zinc levels were affected. Rescue experiments confirmed that the effects were caused directly by zinc-binding to S100B. The reduction in zinc levels leads to impaired postsynaptic scaffold formation affecting proteins of the SHANK family, such as SHANK2 and SHANK3 *in vitro*. SHANK2 and SHANK3 proteins have previously been identified as candidate genes for ASD. Intriguingly, a dysregulation of S100B has been reported in other cases of ASD. We conclude that an altered trace metal homeostasis can be caused by abnormal protein aggregations of S100B and might lead to synaptic dysfunction.

Title: Pericyte initiation of Intussusceptive (splitting) angiogenesis in the postmortem cortex of autism spectrum disorder

Authors: *X. F. JIA, E. C. AZMITIA, Z. T. SACCOMANO, K. N. LATCHA;
biology, New York Univ., New York, NY

Abstract: Autism Spectrum Disorder (ASD) is a pervasive developmental disorder. We previously detected persistent angiogenesis in ASD brains that had many of the characteristics of intussusceptive angiogenesis (IA; Azmitia et al, 2016). We now report on further studies aimed at exploring the details of this form of splitting angiogenesis that involves proliferating pericytes and recruitment of precursor endothelial cells. The present work used postmortem brains of 10 children/young adults with ASD and their age matched controls. Specific mouse monoclonal antibodies against membrane-associated proteins selected for study were Ulex Europaeus Agglutinin lectin (UEA-1) (Vector Laboratories, Burlingame, CA), CD34 (Abcam Cambridge, MA) and nestin (Millipore, Temecula, CA). UEA-1 showed pleiotropic binding of endothelial cells, while nestin identified proliferating pericytes and CD34 labeled precursor endothelial cells. The cellular labeling of vascular cells was found in all layers of the gray and white matter of the

STC in both pre-capillary arterioles and capillary vessels. We confirmed our previous observation of nestin labeling pericytes seen principally in ASD brains of all ages (2.8-28 years) but only in young controls (<2.1 years). UEA-1 labeling endothelial cells in both ASD and control brains, however, compared to control brains where the staining along the fiber length of endothelial cells was homogenous, in ASD brains branch points (nodules) were more heavily stained at all ages (control: 2.1-30 years, ASD: 2.8-28 years). CD34 labeling endothelial cells were seen principally in ASD brains of all ages (2.8-28 years) but only in young controls (<2.1 years). As seen with UEA-1, the CD34 label showed a non-homogeneous distribution of the label along the fiber length. In ASD brains, CD34 labeling along the fiber was especially dense at branch points, thin branches and terminal endpoints of the vessel. In cortex from autism patients, co-localization of proliferating pericytes (nestin) and endothelial cells (UEA-1) in branching blood vessels were identified, whereas in control brains only UEA-1 labeling was seen throughout cortex Interestingly, we documented pericyte vessels devoid of endothelial cells branching off both large arterioles and capillaries in ASD. These results are in support of previous in vitro studies (Nehls et al., 1992; Balabanov. 1998; Otani et al., 2000; Witmer et al., 2004) suggesting an important role of proliferating pericytes in leading and recruiting precursor endothelial cells in the formation of intussuceptive angiogenesis.

Title: Microbial reconstitution reverses maternal diet-induced social and synaptic deficits in offspring

Authors: *S. A. BUFFINGTON[1,2], G. VIANA DI PRISCO[1,2], J. F. PETROSINO[3,4], M. COSTA-MATTIOLI[1,2];

Abstract: Maternal obesity during pregnancy has been associated with increased risk of neurodevelopmental disorders, including autism spectrum disorder, in offspring. Here we report that maternal high fat diet (MHFD) induces a shift in microbial ecology that has a negative impact on offspring social behavior. Social deficits and gut microbiota dysbiosis in MHFD offspring are prevented by co-housing with offspring of mothers on a regular diet (MRD) and transferable to germ-free mice. In addition, social interaction induces synaptic potentiation (LTP) in the ventral tegmental area (VTA) of MRD, but not in MHFD offspring. Moreover, MHFD offspring had fewer oxytocin immunoreactive neurons in the hypothalamus. Using metagenomics and precision microbiota reconstitution, we identified a single commensal strain that corrects oxytocin levels, LTP, and social deficits in MHFD offspring. Our findings causally link maternal diet, gut microbial imbalance, VTA plasticity and behavior, and suggest that probiotic treatment may relieve specific behavioral abnormalities associated with neurodevelopmental disorders.

Title: Greater amygdala spine density in young ASD brains

Authors: *R. K. WEIR[1], M. D. BAUMAN[2], C. M. SCHUMANN[2];
[1]Univ. of California, Davis, Sacramento, CA; [2]UC Davis MIND Inst., Sacramento, CA

Abstract: The amygdala, a medial temporal lobe structure implicated in social and emotional regulation, undergoes an aberrant growth trajectory in individuals with autism spectrum disorder (ASD), which includes precocious growth early in childhood followed by cell loss in adulthood. The goal of this study is to determine if the aberrant amygdala growth in children with ASD may be attributable to alterations in neuronal dendritic morphology.
Tissue from 34 postmortem human brains (age range 4-46) was assembled from the NIH NeuroBioBank at the University of Maryland, the BEARS program at UC Davis MIND Institute, Autism BrainNet and the Harvard Brain Tissue Resource Center. Blocks of amygdala tissue approximately 1.5x1.5x0.5cm were excised from the temporal lobe and neurons were visualized

using a modified Golgi-kopsch staining technique. After dehydration and embedding in parlodion, 150µm sections were cut on a sliding microtome. 10 lateral nucleus neurons per case were selected (fully impregnated, central within the slice and free from obscurities) to be traced using Neurolucida software (MBF Biosciences). Spine counts were collected from one dendrite per neuron. Measures of dendrite morphology such as total dendritic length, segment count and spine density were analyzed using Neurolucida Explorer and statistical analyses conducted in SPSS.
The success of Golgi-kopsch staining in post-mortem human tissue was in line with previous studies (Rosoklija et al., 2014) allowing complete data collection from 13 TD and 14 ASD cases. There was a positive correlation between total dendritic arborization and age in both TD and ASD amygdala. There was no difference in dendritic arborization between diagnostic groups. However, spine density was significantly different between diagnostic groups across age ($F_{(3,26)}$=4.36, P=0.014). Younger cases (≤16 years old) of ASD have a greater spine density than TD controls. While spine density remains relatively constant in the amygdala into adulthood in TD, there is a significance decrease in spine density as people with ASD age.
This study shows a clear difference in spine density between young ASD and TD cases, which possibly represents an underlying difference in amygdala innervation or pruning mechanisms in ASD brains that may contribute to social and emotional impairments into adulthood.

Title: Deletion of CTNNB1 in inhibitory circuitry contributes to autism-associated behavioral defects

Authors: *F. DONG[1], J. JIANG[1], C. MCSWEENY[1], D. ZOU[1,2], L. LIU[1,3], Y. MAO[1];
[1]Biol., Penn State Univ., University Park, PA; [2]First Affiliated Hospital, Guangxi Med. University,, Nanning, China; [3]Dept. of Chem. and Biology, Col. of Science, Natl. Univ. of Def. Technol., Changsha,, China

Abstract: Mutations in β-catenin (CTNNB1) have been implicated in cancer and mental disorders. Recently, loss-of-function mutations of CTNNB1 were linked to intellectual disability (ID), and rare mutations were identified in patients with autism spectrum disorder (ASD). As a key regulator of the canonical Wnt pathway, CTNNB1 has an essential role in

neurodevelopment. However, the function of CTNNB1 in specific neuronal subtypes is unclear. To understand how CTNNB1 deficiency contributes to ASD, we generated CTNNB1 conditional knockout (cKO) mice in parvalbumin interneurons. The cKO mice had increased anxiety, but had no overall change in motor function. Interestingly, CTNNB1 cKO in PV-interneurons significantly impaired object recognition and social interactions and elevated repetitive behaviors, which mimic the core symptoms of patients with ASD. Surprisingly, deleting CTNNB1 in parvalbumin-interneurons enhanced spatial memory. To determine the effect of CTNNB1 KO in overall neuronal activity, we found that c-Fos was significantly reduced in the cortex, but not in the dentate gyrus and the amygdala. Our findings revealed a cell type-specific role of CTNNB1 gene in regulation of cognitive and autistic-like behaviors. Thus, this study has important implications for development of therapies for ASDs carrying the CTNNB1 mutation or other ASDs that are associated with mutations in the Wnt pathway. In addition, our study contributes to a broader understanding of the regulation of the inhibitory circuitry.

Title: Protocadherin 19 downregulation affects cortical development and autism-related behaviors in rats.

Authors: *A. W. CWETSCH[1], L. PERLINI[1], S. BASSANI[2], M. PASSAFARO[2], L. CANCEDDA[1];
[1]Dept. of Neurosci. and Brain Technologies, Inst. Italiano Di Tecnologia, Genova, Italy; [2]Dept. of BIOMETRA, CNR Inst. of Neurosci., Milan, Italy

Abstract: Epilepsy and mental retardation limited to females (EFMR) is a genetic disorder caused by mutations in the protocadherin 19 (PCDH19). The clinical characteristics of EFMR include seizures, fever sensitivity, as well as varying degree of intellectual disability and autistic behaviors. PCDH19 has been implicated in cell adhesion and cell-cell interactions *in vitro*, but its

role during *in vivo* development has not been characterized yet. Here, we found that PCDH19 expression is increased during early development while fading in adulthood in the rat hippocampus and cortex. By three-electrode *in utero* electroporation coupled with RNA interference (siRNA), we downregulated PCDH19 expression in pyramidal neurons migrating to both somatosensory or motor cortex *in vivo*. We found that PCDH19 siRNA-treated animals presented ectopic positioning of neurons. Furthermore, PCDH19 siRNA-treated animals also showed an impaired morphology. Moreover, we found that downregulation of PCDH19 *in utero* in the somatosensory cortex resulted in decreased number of ultrasonic vocalizations in pups at P9. We are currently investigating the physical and functional interaction of PCDH19 with other adhesion molecules and signaling pathways previously implicated in autism. These data suggest that PCDH19 has a crucial role in the correct development of the cortex *in vivo* that may relate to autism-related behaviors in PCDH19-downregulated animals.

Title: Autism animal model exhibits abnormal norepinephrine innervation and increased stress circuit activity following forced swim.

Authors: *J. W. LUNDEN[1], M. GENESTINE[2], C. C. PENG[3], V. MIRABELLA[1], S. PREM[1], J. MILLONIG[1], E. DICICCO-BLOOM[1];

Abstract: Autism spectrum disorder (ASD) is a pervasive neurodevelopmental disorder characterized by impairments in social interaction and the presence of repetitive/restricted behaviors. The neural patterning transcription factor En2 is involved in development of the embryonic mid-hindbrain region where monoamine neurons emerge, and has been associated with ASD. Our previous studies indicate that En2 knockout (KO) mice exhibit abnormalities in

social interaction, depression related tasks (forced swim), fear conditioning and spatial learning, all associated with diminished hippocampal neurogenesis, norepinephrine (NE) levels, and NE fiber innervation. While these deficits in neurogenesis and NE systems suggest abnormalities in the stress system, nothing is known about NE fiber innervation and neural activity in other limbic regions (amygdala and paraventricular nucleus of the hypothalamus, PVN), and responses to acute stress. To examine this issue, postnatal day 60-70 wild type (WT) and KO mice (N=3-6/genotype) were assessed for protein levels of NE transporter (NET) and tyrosine hydroxylase (TH, the rate-limiting enzyme for NE biosynthesis) using western blotting. Immunohistochemistry was used to quantify NET positive fibers in the amygdala and PVN as well as c-fos expression before and after swim stress. En2 KO mice exhibited a 1.7-fold increase in TH protein levels ($p<0.02$) and 1.5-fold increase in NET levels ($p<0.002$) in the amygdala compared to WT controls. NET fiber counts were also increased, by 2.6-fold in the basolateral amygdala ($p<0.004$) and 1.7-fold in the PVN ($p<0.016$) in KO mice. Finally following swim stress, KO mice exhibited a 2.25-fold increase in c-fos in the PVN ($p<0.006$), while there were no changes in the ventral hippocampus. These observations indicate that NE fiber innervation is increased in some En2-KO limbic system regions, a result that contrasts with reduced NE fibers in the dorsally localized hippocampus. We tentatively conclude that region-specific dysregulation of NE fibers in the En2-KO leads to increased PVN and decreased hippocampal neural activities that in turn impact depression-related tasks, fear conditioning, and social interactions. More broadly, these studies of a neurodevelopmental animal model are defining a surprising array of monoamine system abnormalities in the forebrain that may be a consequence of disordered early development of hindbrain regulatory pathways.

Title: Decreased expression of β_2 subunit of $GABA_A$ receptor in the hippocampus and cerebellum in a rat model of autism

Authors: *A. PUIG-LAGUNES[1], E. VELASCO-CERCAS[2], I. ZAMORA-BELLO[2], A. PUIG-NOLASCO[3], R. TOLEDO-CÁRDENAS[2], C. PÉREZ-ESTUDILLO[2], C. MORGADO-VALLE[2],

Abstract: Gamma-aminobutyric acid (GABA) is the main inhibitory neurotransmitter in the brain; its fast inhibitory action is mediated through $GABA_A$ receptors ($GABA_A$-R). Several studies in patients with autism spectrum disorder (ASD) have demonstrated abnormalities in $GABA_A$-R expression in different brain areas. Alterations in the GABAergic neurotransmission have also been reported in experimental models of ASD. This evidence suggests that a dysregulation in this system could be involved in ASD pathogenesis. The main goal of this study was to evaluate the expression of β_2 subunit of the $GABA_A$-R ($GABA_A$-R β_2) in the hippocampus and cerebellum from developing rats prenatally exposed to valproic acid (VPA). Wistar pregnant females were injected with VPA (600 mg/Kg, i.p.) during the twelfth embryonic day (E12); control rats were injected with saline solution. On the fourteen postnatal day, rats from VPA (3 females and 11 males) and control (7 females and 7 males) groups were anesthetized, perfused with 4% phosphate-buffered paraformaldehyde and 40-µm-thick brain sections were obtained at the level of the dorsal hippocampus (coronal sections) and the cerebellar vermis (sagittal sections). Colorimetric immunohistochemistry was performed in order to detect $GABA_A$-R β_2 in CA1, CA2, CA3 fields (oriens, pyramidal and radiatum strata) and dentate gyrus (granule layer and hilus) from hippocampus, as well in the ten lobes of the medial vermis (molecular and granular layers). Presence of $GABA_A$-R β_2 in the brain was determined semi-quantitatively by a densitometrical analysis. Results showed a significant reduction of $GABA_A$-R β_2 inmunoreactivity in the pyramidal layer of CA2 region in the VPA group compared with the control group. A similar decreased was detected when VPA males were compared with control males. No statistical differences in $GABA_A$-R β_2 expression were observed between experimental groups at any lobe from cerebellar vermis. Nevertheless, VPA females had lower $GABA_A$-R β_2 inmunoreactivity in the molecular layer of lobes III and IX and in the granular layer from lobes IV and IX compared with control females. Furthermore, VPA females showed a lower $GABA_A$-R β_2 expression in the granular layer from lobes I, III, IV and X and in the molecular layer from lobes II, III, V and X in comparison with VPA males. These data demonstrate that prenatal exposure to VPA reduces the expression of $GABA_A$-R β_2 in the hippocampus and support that a GABAergic dysfunction could be implicated in the pathogenesis of ASD. Additionally, prenatal VPA exposure produces changes in cerebellar $GABA_A$-R β_2 expression depending on the gender.

Title: Epilepsy in toll like receptor 3, 7, 9 deficient mice

Authors: *J. CORDERO, O. ARIAS-CARRION;
Unidad de Trastornos del Movimiento y Sueño, Hosp. Gen. Dr. Manuel Gea Gonzalez, Ciudad DE Mexico, Mexico

Abstract: The role of the innate immune system in the defence against exogenous pathogens is well established. In contrast, its role in the central nervous system needs further investigation. Immunological analysis revealed that mice with a triple deficiency of the nucleic acid recognizing Toll-like receptor (TLR)-3, 7 and 9 lose control of endogenous retroviruses of the MuLV type in the hematopoietic system. Surprisingly, we noticed that a significant number of these triple TLR deficient mice exhibited spontaneous seizures. Although disorders of the innate immune system have been implicated in the etiology of epilepsy, convincing evidence for a causal role has yet to be reported. Like most patients with epilepsy TLR379 deficient mice appear behaviourally normal between seizure episodes. Here, we show that cFos, an immediate early gene that is upregulated by seizures, was up regulated in the hippocampus. This suggests that these mice experience seizures that involve temporal structures, e.g. hippocampus. Therefore, these mice may prove to be a novel model of temporal lobe epilepsy, providing insight into the mechanisms underlying the role of viral infections or impaired innate immunity in neuronal diseases, such as epilepsy.

Title: Protocadherin-19 downregulation affects the surface expression of associated $GABA_A$Rs and increases seizure susceptibility in rats

Authors: S. BASSANI[1], L. GEROSA[1], A. CWETSCH[2], L. CANCEDDA[2], *M. PASSAFARO[3]; [1]CNR -Institute of Neurosci., Milan, Italy; [2]Dept. of Neurosci. and Brain Technologies, Inst. Italiano di Tecnologia, Genova, Italy; [3]DTI-CNR-IN Sect Cell, Milan, Italy

Abstract: PCDH19-Female Limited Epilepsy (PCDH19-FLE) is a debilitating neurological condition characterized by early onset seizures, intellectual disability and autistic features. PCDH19 (Xq22) encodes for the cell-adhesion protein protocadherin-19 (pcdh19) whose function is largely unknown. Our data indicate that PCDH19 is highly expressed in the rat brain, especially in the cortex and hippocampus. Consistent with a cell-adhesion role, pcdh19 is expressed on the plasma membrane and is recruited at cell-cell contacts in cultured hippocampal neurons. Furthermore, pcdh19 shows a synaptic distribution and pcdh19 levels affect the expression of synaptic markers, suggesting pcdh19 involvement in neuronal wiring. By yeast two-hybrid screening we found that pcdh19 interacts with the alpha1 subunit of the $GABA_A$ receptor ($GABA_A$R). Pcdh19 and $GABA_A$R coimmunoprecipitate in neurons and pcdh19 shRNA-mediated downregulation reduces $GABA_A$R surface expression, suggesting the involvement of pcdh19 in $GABA_A$R trafficking. Consistently with a GABAergic defect, pcdh19 shRNA-mediated downregulation *in vivo* by *in utero* electroporation affects neuronal migration and morphology. Furthermore rats expressing pcdh19 shRNA in the hippocampus show higher susceptibility to-pentylentetrazol-induced seizures at postnatal day 7 (P7) compared to control animals. We hypothesize a role for PCDH19 in the regulation of neuronal excitability both at the circuit level, through its adhesive properties, as well as at the cell-autonomous level, through the regulation of $GABA_A$R trafficking and hence inhibitory transmission.

Title: Heightened neuronal network excitability in a mouse model of CDKL5 disorder

Authors: *M. YENNAWAR[1], H. SUN[2], Z. ZHOU[2], F. E. JENSEN[2];
[1]Pharmacol., [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: CDKL5 disorder frequently appears as a pattern of neurological deficits including severe early-life epilepsy, intellectual disability, and autism. It results from loss-of-function mutations in cyclin dependent kinase-like 5 (CDKL5), a kinase that is enriched in the brain and upregulated postnatally. The onset of seizures and intellectual disability in CDKL5 disorder occur during a developmental period where the excitation-inhibition (E-I) balance is already shifted to favor excitation. Normally, heightened excitation during this time facilitates synaptogenesis and neural circuit formation. However, when this sensitive balance is dysregulated it can result in epilepsy and autism. To understand alterations in the E-I balance in CDKL5 disorder, we investigated neuronal network activity and plasticity during development a CDKL5 knock-in (KI) mouse model using slice electrophysiology. The CDKL5 KI mouse model is based off of a human mutation that causes truncation of the protein in the kinase domain, rendering the protein nonfunctional. The mice are grossly similar to their WT litter mates although their weights are significantly lower than WT at postnatal day (P)21 ($n=14$, $p=0.0176$). Slice recordings for all experiments were done at CA3-CA1 synapses. At P21, input-output curves obtained from CDKL5 KI and WT litter mates indicate that CDKL5 KI mice have significantly greater network excitability ($n=10$, $p<0.0001$). Additionally, after a repetitive stimulation paradigm (20 pulses, 100 Hz), the CDKL5 KI mice exhibited heightened short-term plasticity. There was no difference in paired pulse facilitation at P21, indicating that presynaptic function is not altered in CDKL5 KI mice. No animals were observed to be spontaneously seizing. These results show that CDKL5 KI mice have significantly elevated network activity and heightened plasticity due to alterations in postsynaptic function. Ongoing studies are evaluating differences in excitatory and inhibitory postsynaptic receptor expression and function.

Title: Synaptic dysfunction in Sanfilippo Syndrome: the affects of lysosomal heparan sulfate accumulation on the cell surface glycocalyx

Authors: *C. WRIGHT DWYER[1], S. L. SCUDDER[2], Y. LIN[1], L. DOZIER[2], N. J. ALLEN[3], G. N. PATRICK[2], J. D. ESKO[1];
[1]Cell. and Mol. Med., [2]Neurobio., Univ. of California San Diego, LA Jolla, CA; [3]Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: Sanfilippo Syndromes, MPSIII A-D, result from deficits in lysosomal enzymes that specifically degrade heparan sulfate, a type of sulfated glycosaminoglycan. In humans, MPSIII typically presents during early childhood following a period of developmental delay, accompanied by hyperactivity and autistic-like social behaviors. The appearance of these behaviors in MPSIIIA mouse models arises by the third postnatal week. Heparan sulfate accumulation and lysosomal expansion occurs in the developing MPSIIIA brain. In fact, excitatory synaptic function is reduced in the cerebral cortex of developing MPSIIIA mice, which correlates with the onset of behavioral symptoms. Current work is focused on ascertaining the mechanism causing reduced excitatory synaptic function in the developing MPSIIIA brain. MPSIIIA mice exhibit synaptic deficits and behavioral phenotypes similar to mice deficient in heparan sulfate biosynthesis, suggesting changes in extracellular heparan sulfate may cause synaptic dysfunction in the developing MPSIIIA brain. Our work investigates the role of heparan sulfate fine structure on excitatory synaptic function and contributions to synaptic pathology in MPSIIIA mice.

Abstract: Working memory capacity, a critical component of executive function, developmentally expands from childhood to adulthood. This developmental process halts its upward trajectory during adolescence and increasingly lags behind toward adulthood in individuals with autism spectrum disorder (ASD), suggesting that this process is functionally relevant to the developmental trajectory of neuropsychiatric disorders. However, the cellular and neuronal substrates contributing to this process are not understood. As duplication/triplication of human chromosome 22q11.2 is one of the copy number variants (CNVs) consistently and robustly associated with developmental neuropsychiatric disorders, we used this genetic variant as an entry point to delve into the cellular substrates for this developmental atypicality. Using a region- and cell-specific gene expression approach, we over-expressed catechol-O-methyl-transferase (COMT) or Tbx1, two 22q11.2 CNV-encoded genes, in adult neural stem/progenitor cells in the hippocampus of C57BL/6J mice. Mice were tested for spontaneous alternation in a T-maze, a measure of spatial working memory, at either 1 month or 2 months of age. Following behavioral analysis, mice were sacrificed and the location of gene-transduced cells within the granule cell layer of the hippocampal dentate gyrus was examined. In a separate experiment, cells were taken from the hippocampus of C57BL/6J mice and cultured and passaged to isolate adult neural stem/progenitor cells. Cells in culture were then tranfected with plasmid carrying either COMT or Tbx1, and the rate of proliferation and apoptosis was examined. Mice increased working memory capacity from 1 to 2 months of age, corresponding to adolescence to young adulthood. Over-expression of COMT in adult neural stem/progenitor cells reduced the maximum working memory capacity at 2 months, but not at 1 month of age. Similarly, over-expression of Tbx1 in the same cell population at 2 months reduced working memory capacity. Moreover, over-expression of COMT or Tbx1 reduced the rate of migration of progenies of adult neural stem/progenitor cells in the hippocampus granule cell layer. When COMT or Tbx1 was over-expressed in adult neural stem/progenitor cells *in vitro*, their proliferation was reduced without elevating the rate of apoptosis. Our data provide evidence for the novel notion that elevated levels of these 22q11.2 genes deter the typical developmental maturation of working memory capacity via an altered rate of proliferation--and migration of progenies--of adult neural stem/progenitor cells in the hippocampus.

Abstract: A major consequence of premature birth is the early loss of the placenta and its hormonal contributions to development. Less dramatic, but more common, placental dysfunction also alters placental endocrine function, including the placental progesterone derivative allopregnanolone (ALLO). ALLO, a critical neurosteroid that acts as a potent $GABA_A$ receptor allosteric modulator, has been implicated in many neurodevelopment processes (neurogenesis, outgrowth, and survival, synapse stabilization). ALLO may also be neuroprotective: It inhibits toxin-induced cell death, protects against excitotoxicity, and increases in vivo in response to immune challenge and hypoxia. Although ALLO can be produced de novo in fetal brain, the major source of fetal ALLO is the placenta. Despite the importance of placental ALLO, until now, limited tools were available for direct investigation of the effects of placental ALLO alterations on neurodevelopment and behavior. We therefore generated a mouse model in which ALLO production is suppressed only in the placenta using a placenta-specific lentiviral knockdown of the enzyme responsible for ALLO production, 3αHSD. In this model, we showed a specific reduction in the number of cortical intermediate progenitor cells in the subventricular zone, validating the importance of placental ALLO production. We have now produced a new mouse model (*AKR1c14*$^{fl/fl}$), with LoxP sites surrounding the *AKR1c14* gene site (encoding 3αHSD) allowing inexpensive, efficient and flexible ALLO manipulation. Upon crossing with a placenta-specific Cyp19-CRE mouse, we show that recombination occurs in placenta but not brain, and *AKR1c14* mRNA is significantly reduced in placenta but not in brain. We also show a compensatory increase in Cyp11a1 (the rate-limiting enzyme in all neurosteroid synthesis from cholesterol) in both brain and placenta in the *AKR1c14*$^{fl/fl}$. This increase has been observed in preeclamptic human placentas, supporting use of this mouse as a preclinical model. We are currently investigating the effects of 3αHSD knockout on developing and adult cortical phenotypes and on behavior. ALLO and its synthetic analogs will be used to target developmental and behavioral deficits. Better understanding of the role of placental ALLO may

lead to therapeutic treatments to improve developmental outcomes in high-risk fetuses and infants.

Title: Elucidation of the molecular mechanisms of cognitive impairment in Bardet- Biedl syndrome

Authors: ***N. HAQ**[1], C. SCHMIDT-HIEBER[2], M. HÄUSSER[2], P. BEALES[1], S. CHRISTOU-SAVINA[1];
[1]Genet. and Genomic Med., ICH, London, United Kingdom; [2]Wolfson Inst. for Biomed. Res., London, United Kingdom

Abstract: Bardet-Biedl syndrome (BBS) is a genetically heterogeneous, autosomal recessive disorder. The phenotype includes severe retinal degeneration, early onset obesity, cognitive impairment, polydactyly and renal malformation. Approximately half of all individuals with Bardet-Biedl syndrome experience developmental disabilities ranging from mild impairment or delayed emotional development to severe mental retardation. Investigation of BBS proteins prove to be undeniably important to the field of molecular genetics and molecular biology as it led to emergence of a new class of human disorders, the ciliopathies, disorders of primary cilia. Cilia, a membranous antenna like organelle, were found on almost all cells including neurons. It is believed now that primary cilia is involved in various cellular functions by modulating cell signalling via specialised receptors integrated into its membrane that includes somatostatin receptor 3, melanin-concentrating hormone receptor 1, serotonin receptor 6, dopamine receptor type 5. Loss of BBS proteins has been proved to be vital for the function of cilia. Recent MRI study in patients affected with BBS revealed a high rate of unilateral or bilateral hippocampal dysgenesis as well as reduced volume of hippocampus. Specifically Bbs4 models reveal ventriculomegaly of the lateral and third ventricles, thinning of the cerebral cortex and reduced volume of hippocampus. Our study aims to investigate the mechanisms of how loss of ciliary Bbs proteins leads to cognitive impairment and learning difficulties. We hypothesise that impaired neuroplasticity may contribute to development of cognitive impairment in BBS.

Despite the varied genetic and nongenetic factors that contribute to intellectual disability, this condition has been consistently associated with changes in dendrite and dendritic spine structure. We have analysed the morphology of dentate gyrus of hippocampal neurons and have found 50% reduction in dendritic spine density across the whole dendritic tree. We have also found that loss of spines is not restricted to hippocampus but affects other brain structures such as frontal cortex and basolateral amygdala. Interestingly, we have found that the spine loss occurs within the first 3 postnatal weeks and it results from the increased autophagy and impaired mTOR signalling during this period. Notably, aerobic exercise can partly reverse this "loss of spine" phenotype in BBS mice models.

Abstract: RASopathies are a family of related syndromes caused by perturbations in the RAS/RAF/MEK/ERK signaling cascade that typically exhibit neurological deficits, such as intellectual disability, motor delay, and epilepsy. The precise role of aberrant ERK/MAPK signaling or mutation-specific alterations in nervous system pathogenesis remains poorly understood. RASopathy mutations in upstream MAPK components, such as *Nf1*, *Shp2/Ptpn11*, and *Ras* have been well-studied, whereas less is known about the precise deficits associated with downstream mutations. Here, we assessed the contributions of a Noonan Syndrome-linked,

RAF1 gain-of-function mutation, *Raf1*$^{L613V+/-}$, to cellular and behavioral phenotypes in the mouse forebrain. We report that *Raf1*$^{L613V+/-}$ mutants do not exhibit a significantly altered number of NEUN/RBFOX3-labeled neurons in the cortex. In contrast, we observed a statistically significant increase in the number of GFAP^{+} astrocytes in the adult mutant cortex and hippocampus. No significant changes in the number of activated microglia labeled with IBA1 were noted. OLIG2^{+} oligodendrocytes were increased in number in the adult cortex but not in the hippocampus, providing evidence that responses to RAF1 mutations are region-specific. Analysis of myelin sheath thickness in the corpus callosum revealed no change in average g-ratio or the proportion of myelinated to unmyelinated axons. To better understand the behavioral ramifications of altered nervous system development, we tested learning and memory in *Raf1*$^{L613V+/-}$ mutants using the Morris water maze and cued fear conditioning. Significant changes in locomotor or anxiety-like behavior were not detected. However, following five days of Morris water maze testing, we found that *Raf1*$^{L613V+/-}$ mutants performed better than controls by exhibiting decreased swim distance to the hidden platform by day three. In fear conditioning, mutants and controls showed similar increases in freezing to tone during three tone-footshock pairings. Following exposure to cued fear conditioning, mutants exhibited a significant increase in freezing to tone 24 hrs later and impaired extinction to tone when compared to controls. Overall, these data suggest that the observed alterations in forebrain glial development are not sufficient to diminish learning in *Raf1*$^{L613V+/-}$ mutants and highlight the importance of mutation-specific mechanisms in the RASopathic nervous system.

Title: Mutation in a tubulin gene reveals a novel model of leukodystrophy

Authors: *I. D. DUNCAN[1], A. B. RADCLIFF[1], J. J. MORAN[2], J. P. SVAREN[2];
[1]Dept Med. Sci., [2]Dept Comp Biosci, Univ. Wisconsin Sch. Vet Med., Madison, WI

Abstract: The *taiep* rat is a well characterized autosomal recessive mutant that has a unique myelin disorder with early hypomyelination followed by severe demyelination of white matter in the brain and certain tracts of the spinal cord. We have shown that a unique disturbance of

oligodendrocytes occurs with the progressive accumulation of microtubules (MTs) in the cell body and processes leading to a defect in the transport of MBP mRNA. In addition, changes in the polarity of MTs in oligodendrocyte processes has been suggested to disrupt myelination and the maintenance of the myelin sheath.
Previous mapping studies on the taiep rat had identified a candidate interval for the causative gene on chromosome 9. Since the defect was observed in oligodendrocytes, it seemed likely that the gene may be regulated by the Sox10 transcription factor, which is required for multiple facets of oligodendrocyte development. Therefore, gene expression profiling data and Sox10 binding site maps in rat spinal cord by ChIP-seq were used to identify candidate causative genes in the chromosome 9 interval. From this analysis, one primary candidate gene was selected, Tubb4a, since point mutations in this gene have been identified in humans with a white matter disorder. Sequencing cDNA from taiep spinal cord identified a homozygous mutation in Ala353 in the Tubb4a gene, which was absent in wild type littermates. Mutations in flanking residues (352 and 354) have been found in humans with MRI evidence of hypomyelination. The affected residue is positioned within the binding interface between beta-tubulin and alpha-tubulin.
Mutations in the Tubb4 gene in humans result in an incompletely characterized leukodystrophy known as Hypomyelination and Atrophy of the Basal Ganglia and Cerebellum (H-ABC). The *taiep* rat may provide an ideal model in which to study the putative CNS changes in this rare human disorder.

Title: Evaluation of visual motion perception ability in mice with knockout of the dyslexia candidate susceptibility gene Dcdc2

Authors: *P. A. PERRINO[1], A. R. RENDALL[1], J. J. LOTURCO[2], R. H. FITCH[1];
[1]Behavioral Neurosci., [2]Physiol. and Neurobio., Univ. of Connecticut, Storrs, CT

Abstract: Dyslexia is a common neurodevelopmental disorder, affecting over 3 million individuals per year in the US. Dyslexia is characterized by difficulties in learning to read and write despite typical intelligence and educational opportunity. The etiology indicates a strong but complex genetic basis, with heritability estimates ranging from 40% to 80%. Although the neurobiological and genetic mechanisms underlying dyslexia remain poorly understood, several dyslexia candidate risk genes have been identified. One of these candidate risk genes - doublecortin domain containing 2 (*DCDC2*) - has been shown to play a major role in neuronal migration, as well as cilia function. Disruption of these functions during neurodevelopment could contribute to the dyslexic phenotype. At a behavioral level, variants of *DCDC2* have been associated not only with dyslexia *per se*, but also intermediate phenotypes such as impairments in phonological processing and working memory. To further explore the relationship between *DCDC2* and dyslexia, a genetic knockout (KO) of the rodent homolog of *DCDC2* (*Dcdc2*) was created. Initial studies showed that cortical pyramidal neurons from *Dcdc2* KO mice exhibit increased excitability and decreased temporal firing precision (Che et al., 2015). Behavioral assessments also showed that *Dcdc2* KOs display deficits in auditory processing, as well as working memory (Truong et al., 2015). These findings parallel observations from the clinical population. More recently, a specific mutation in *DCDC2* has been strongly linked to deficits in motion perception - a skill subserving reading success. It has been suggested that the decreased temporal precision of AP firing and spontaneous NMDAR-mediated activity in KO mice may contribute to the link between *DCDC2* and motion perception deficits. Since motion perception skills have not yet been assessed in the *Dcdc2* KO mouse model, the current study was designed to evaluate the association between *DCDC2* and motion perception. Specifically, we developed a novel motion perception task based on published human assessments, utilizing touchscreen technology and operant conditioning in a modified Pairwise Discrimination task. Subjects were exposed to visual stimuli known as Gabors (adjusted for mouse vision to provide higher contrast and longer display), as used to assess individuals with dyslexia. Our overall goal was to replicate the clinical finding that *DCDC2* plays a role not only in auditory processing and working memory, but also in visual motion perception. Abnormalities in these processes could relate to impairments in the acquisition of reading skills.

Title: Behavioral and neuroanatomical evaluation of the Ts2-neo mouse model of Timothy syndrome, a rare genetic disorder associated with autism spectrum disorders

Authors: *A. R. RENDALL, A. L. FORD, P. A. PERRINO, R. H. FITCH;
Psychology - Behavioral Neurosci., Univ. of Connecticut, Storrs, CT

Abstract: Autism Spectrum Disorders (ASD) is a set of neurodevelopmental disorders characterized by a complex behavioral phenotype, encompassing deficits in social and cognitive domains. Accepted core symptoms are heterogeneous, and range from atypical social interactions and language impairments to repetitive behaviors. To date, causal mechanisms underlying ASD remain poorly understood, but likely include a complex combination of polygenic and environmental risk factors. The genetic influence in ASD is strong, with heritability rates ranging from 70-90%, however over 1,000 risk genes have been identified making the underlying genetic architecture complex. One of these genes, calcium voltage-gated channel subunit alpha1 C (*CACNA1C*) has been recently associated to ASD. Specifically, a single *de novo* missense mutation to the 8A exon of *CACNA1C* gene, which codes for the voltage-gated L-type Ca2+ channel (Cav1.2), results in a rare disorder known as Timothy syndrome (TS) (Splawski et al. 2004). TS is strongly associated with cardiac arrthytmias, ASD and neurological dysfunction such as language impairments, seizures and intellectual disability. A genetically engineered knock-in mouse with a heterogeneous TS2 (G406R) mutation in the L-type calcium channel containing a neomycin resistance cassette was developed to study. This mouse model (Ts2-neo) provides us with a platform to investigate the role of calcium channel inactivation and calcium signaling related to brain development and ASD. Previous behavioral studies that examined Ts2-neo mice found that these animals exhibit normal general health and anxiety level but, display restricted respective behavior, altered social behavior and ultrasonic vocalizations as well as enhanced tone-cued and contextual memory following fear conditioning (Bader et al., 2011). The purpose of the current study is to further behaviorally characterize Ts2-neo mice by assessing their performance on a wide variety of paradigms. Results indicate that the loss of Ca.V1.2 inactivation in this mouse model affects motor learning, auditory processing, social and repetitive behaviors but does not have an impact on spatial learning and memory. These results further validate the role of CaV1.2 channels are playing in ASD and support prior work done with this model. Following behavioral examination, all subjects' brains were extracted and underwent a neuroanatomical Nissl-stain assessment of various white matter and cortical structures.

Title: Disrupted Cav1.2 L-type calcium channel function and expression alters behavior and ascending serotonin system activity

Authors: *D. G. EHLINGER[1,2,3], C. M. PANZINI[2,3], K. G. COMMONS[2,3];
[1]Dept. of Anesthesia, Boston Children's Hosp/Harvard Med. Sch., Boston, MA; [2]Boston Children's Hosp., Boston, MA; [3]Harvard Med. Sch., Boston, MA

Abstract: Human genetic variation in the gene *CACNA1C* altering expression of the Cav1.2 L-type calcium channel (LTCC) has been strongly associated with enhanced risk for the development of neuropsychiatric disorders including major depression, bipolar and schizophrenia. Furthermore, a missense mutation (G406R) of the Cav1.2 LTCC that results in reduced channel inactivation associated with Timothy Syndrome has been modeled in the TS2-neo mouse model of autism spectrum disorders (ASD). Here, we ask whether alterations in Cav1.2 LTCC function and expression influence a common neural circuit in the ascending serotonin (5HT) system. First, we assessed 5HT system abnormalities in the TS2-neo mouse. Following an acute stressor (forced-swim), behavioral analyses and immunofluorescent co-labeling of Tph2 and C-Fos reveals that TS2-neo mice exhibit enhanced active coping behavior, enhanced 5HT neuron activity, and altered 5HT1A-dependent feedback inhibition in both caudal and rostral subregions of the dorsal raphe nucleus (DRN). These alterations are accompanied by enhanced 5HT and 5HIAA content in forebrain regions including the orbitofrontal cortex, dorsal striatum and dorsal hippocampus. Next, we sought to determine whether temporally controlled knock-out of 5HT neuron Cav1.2 LTCCs also produces behavioral alteration and changes in 5HT neuron activity. To this end, we crossed Tph2-icre/ERT2 mice with Cav1.2-loxP/Ai14-TdTomato mice (Tph2-Cav1.2KO). Following tamoxifen treatment, preliminary results suggest that Tph2-Cav1.2KO mice display altered behavior on the forced-swim and open-field paradigms. Additional behavioral characterization and analysis of 5HT neuron activity within the DRN will provide context regarding these deficits. Collectively, our results suggest that disruptions of Cav1.2 LTCC function in the TS2-neo mouse and Cav1.2 LTCC expression within 5HT neurons may alter a common neural circuit in the ascending 5HT system. This

provides a potential neurological mechanism through which alterations in the gene *CACNA1C* may enhance risk for development of a broad range of psychiatric and developmental disorders.

Title: Ablation of arx in mature interneurons impaired network functions via disruption of calcium homeostasis in the mouse hippocampus

Authors: D. J. JOSEPH[1], A. J. MCCOY[1], R. RISBUD[1], *J. G. JACKSON[2], E. D. MARSH[1,3]; [1]Neurol., [2]Neurosci., Children's Hosp. of Philadelphia, Philadelphia, PA; [3]Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Transcription factors (TFs) establish molecular codes that orchestrate the assembly of neural circuits. The Aristaless Related homeobox (*Arx*) protein is a TF within such regulatory network controlling early stages of GABAergic interneurons development. However, *Arx* remains expressed in mature interneurons, suggesting a divergent, yet unknown, function. We previously showed that postnatal ablation of *Arx*, in interneurons, resulted in abnormal EEG, altered synaptic transmission, and impaired long term plasticity (LTP) in the hippocampus. Here, we begin to investigate the molecular basis for the synaptic impairments induced by postnatal ablation of *Arx*.

We temporally controlled *Arx* expression by crossing a floxed *Arx* mouse ($Arx^{fl/fl}$) with a tamoxifen-inducible Cre^{ER}- mouse, resulting in complete loss of *Arx* 30 days after injection. To identify the mechanisms by which *Arx* impaired synaptic transmission and plasticity, we targeted intracellular Ca^{2+} handling given its implication in limiting plasticity at CA2 synapses. We reasoned that if achieving and maintaining homeostatic Ca^{2+} levels are the factors limiting LTP expression, then elevation of external Ca^{2+} or chelation of excess intracellular Ca^{2+} could reverse these deficits and rescue LTP. To that end, we recorded field excitatory postsynaptic potentials (fEPSPs) at the CA1 synapse in response to Schaffer collaterals (SC) stimulation in $Arx^{+/y}$ and $Arx^{-/y}$; Cre^{ER} mice in normal recording solution or in solution containing high extracellular Ca^{2+}

or BAPTA-AM. We measured the input-output (I/O) coupling of fEPSPs to assess synaptic transmission under those recording conditions. To measure LTP, baseline fEPSPs were recorded for 30 min in normal recording solution or in high Ca^{2+} or BAPTA-AM for the last 5 min of baseline recordings and post-tetanus fEPSPs were recorded in normal conditions.
Our results demonstrated that *Arx*$^{-/y}$; Cre^{ER} mice had reduced LTP and perfusion with higher external [Ca^{2+}] during induction partially restored CA1 LTP to *Arx*$^{-/y}$ slices. This restoration of CA1 LTP in *Arx*$^{-/y}$; Cre^{ER} mice was also noted when Ca^{2+} influx was partially blocked by reducing the extracellular Ca^{2+}/Mg^{2+} ratio. Application of BAPTA-AM partially attenuated the impairment in I/O coupling of fEPSP and completely restored CA1 LTP to *Arx*$^{-/y}$ slices.
Our results suggest that the cellular machinery required for LTP expression remains intact following loss of *Arx* but this postnatal loss of *Arx* resulted in elevation of postsynaptic Ca^{2+} that limits SC-CA1 LTP. These data suggest that modulation of Ca^{2+} buffering capacity may be temporally targeted for therapy in patients with *Arx* mutations and more broadly in epilepsy.

Title: EphrinA5$^{-/-}$ mice display behavioral abnormalities and exhibit altered striatal organization and synaptic function

Authors: *L. F. KROMER[1], R. WURZMAN[2], S. VICINI[3], J. G. PARTRIDGE[3];
[1]Dept Neurosci, Georgetown Univ. Med. Ctr., Washington, DC; [2]Dept. of Neurol., Univ. of Pennsylvania Perelman Sch. of Med., Philadelphia, PA; [3]Pharmacol. and Physiol., Georgetown Univ. Med. Sch., Washington, DC

Abstract: Disruptions in striatal organization and dysfunction in corticostriatal circuits are implicated in multiple neurodevelopmental spectrum disorders, such as OCD, ADHD, and autism. Currently, we have limited understanding of the molecular and cellular events that

contribute to the development of shared versus unique neuropsychiatric behaviors associated with these disorders. To address this issue, we have begun studying mice with Eph receptor or ephrin deletions (E/E) as models for investigating how disruptions in the function of cell-cell signaling molecules that regulate neuronal migration, axon guidance, and synaptogenesis produce corticostriatal circuit abnormalities and spectrum disorder behavioral endophenotypes. During development, E/E expression is tightly regulated temporally and regionally in striatum (matrix neurons express EphA4 and matrisome neurons express EphA7 receptors) and cortex (EphA7 is highly expressed in specific cortical subregions). Moreover, there is an inverse correlation in the topographic organization of corticothalamic and corticostriatal axons expressing high levels of ephrinA5 with thalamic and striatal regions expressing high EphA7 levels. Although mice with ephrinA5 gene deletions have abnormal corticothalamic and thalamocortical projections, it is not known whether there are disruptions in corticostriatal projections or what behavioral abnormalities these mice exhibit. Thus, the present study behaviorally characterized ephrinA5$^{-/-}$ mice and examined whether these mice have altered striatal compartment organization and corticostriatal synaptic function. Using immunohistochemical procedures, we determined that ephrinA5$^{-/-}$ mice possess a normal striosome/matrix organization but exhibit expansion of the matrisome compartment compared to controls. Behavioral analyses indicated that ephrinA5$^{-/-}$ mice exhibit hyperactivity in both the open field and elevated plus maze and have impaired learning in the Morris water maze and accelerating rotarod task. Using whole-cell voltage clamp and traditional stimulating techniques in acute brain slices from BAC-*drd2*-eGFP:ephrinA5$^{-/-}$ mice, we detected several measures of synaptic transmission that differed between control and ephrinA5$^{-/-}$ mice. This included the ratio of AMPA- and NMDA-mediated components of synaptic transmission on spiny projection neurons and glutamate release probability. Together, these results support a developmental role for ephrinA5 in striatal organization and corticostriatal synaptic functions involved in regulating important cognitive and motor behaviors affected in neurodevelopmental spectrum disorders.

Title: Deletion of the NR2A subunit of NMDAR increases susceptibility to redox dysregulation causing long-term impairment of prefrontal parvalbumin interneurons and perineuronal net.

Authors: *P. STEULLET[1], R. CARDIS[2], J.-H. CABUNGCAL[3], K. Q. DO[3];
[1]Ctr. For Psychiatric Neuroscience, CHUV, Lausanne-Prilly, Switzerland; [2]Ctr. For Psychiatric Neuroscience,, [3]Ctr. For Psychiatric Neurosci., Lausanne Univ. Hosp., Lausanne-Prilly, Switzerland

Abstract: De-novo mutations in GRIN2A gene, coding for the NR2A subunit of NMDA receptors (NMDAR), are linked to developmental brain disorders such as mental retardation, epilepsy, autism, and schizophrenia. A large scale GWAS study has revealed GRIN2A as a risk gene for schizophrenia. NR2A plays a critical role during early postnatal brain development as it undergoes an increase in expression in parallel with a decrease in expression of NR2B. While administration of general NMDAR antagonists during the second postnatal week affects durably prefrontal parvalbumin interneurons via oxidative stress, specific NR2A antagonists also impact the maturation of these neurons. The goal of the study was to assess the effect of a lack of NR2A (GRIN2A KO) on parvalbumin interneurons in the medial prefrontal cortex, and whether the observed anomalies of this type of interneurons in GRIN2A KO mice are the consequence of an enhanced susceptibility to redox dysregulation. While the number of parvalbumin immunoreactive (IR) neurons and the perineuronal net (PNN) surrounding many of these interneurons were normal in young adult (P60) KO mice, the PNN was less developed in young (P20) KO compared to WT mice. This suggested a delayed maturation of the PNN in GRIN2A KO mice. In both ages, KO mice had the tendency to display higher immunoreactivity for 8-oxo-dG (an oxidative stress marker) than age-matched WT mice. Our primary findings revealed a susceptibility to redox dysregulation in GRIN2A KO mice. Indeed, an additional oxidative challenge (dopamine uptake inhibitor, GBR12909) applied during early postnatal life (P10-P20) significantly increased oxidative stress in KO but not WT mice. GBR12909-treated KO mice had also a decreased number of parvalbumin-IR neurons and a further weakening of the PNN. These effects were prevented by a treatment with the antioxidant, N-acetylcysteine. The expression of sulfiredoxin 1 (from the peroxiredoxin system) and the modulatory subunit of glutamate-cysteine ligase (from the glutathione system) were significantly reduced in KO compared to WT mice, suggesting that antioxidant capacities were weakened in mice lacking NR2A. Early postnatal oxidative challenge had long term consequences in KO mice as it led to oxidative stress, reduced number of parvalbumin-IR neurons, and abnormal PNN at early adulthood (P60). Moreover, an early-life treatment with GBR12909 reduced the power of fast oscillatory activity in prefrontal slices of adult KO but not WT mice. Altogether, these indicate that functional impairment of NR2A-containing NMDAR confers a susceptibility to redox dysregulation, which can have long term impact on parvalbumin interneuron networks.

Title: Loss of oligophrenin-1 in medial prefrontal cortex leads to age-dependent synaptic dysfunction

Authors: *T. KROON, H. MANSVELDER, R. M. MEREDITH;
VU Univ., Amsterdam, Netherlands

Abstract: Oligophrenin-1 (OPHN1) is a Rho GTPase-activating protein whose dysfunction leads to syndromic intellectual disability. Absence of OPHN1 has been shown to affect synaptic function and morphology of dendrites and spines in cultured neurons, as well as in acute hippocampal slices. However, little is known about the effect of OPHN1 on other regions of the brain. Furthermore, it is not known whether the role of OPHN1 at the synapse depends on the developmental stage of the animal. The medial prefrontal cortex (mPFC) is involved in decision making and social behaviour, making it a promising target for the study of neurodevelopmental disorders. To study the effect of OPHN1 dysfunction throughout development, we assessed synaptic function in mPFC slices from OPHN1 knockout mice at several ages using whole-cell electrophysiology. We find a reduction of both glutamatergic and GABAergic synaptic transmission that is dynamic and dependent on age, indicating that OPHN1 functions in a developmentally regulated manner.

Title: Do neuroanatomical abnormalities in Pax6-deficient mice change as a function of age?

Authors: *M. K. GRANT[1], A. M. BOBILEV[2], K. K. JOHNSON[1], K. HEKMATYAR[3], J. D. LAUDERDALE[1];
[1]Cell. Biol., [2]Neurosci., [3]Bio-Imaging Res. Ctr., Univ. of Georgia, Athens, GA

Abstract: The *PAX6* gene encodes a highly conserved transcription factor required for various aspects of anatomical and functional development of the eye and brain. Heterozygous loss-of-function mutations in *PAX6* cause aniridia in humans and the *Small eye* trait in rodents. Although aniridia is best known as a panocular eye disorder, the condition has a number of structural and functional abnormalities in the brain. Previous studies of patients with aniridia using structural magnetic resonance imaging (MRI) have shown changes in interhemispheric connectivity, grey matter volume, and accelerated age-related cortical thinning. The full scope of neuroanatomical changes in humans, and the conservation of these changes in model organisms remain poorly understood. We predicted two major contributors to the changes in adult brain structure and function: 1) structural changes that occur as a result of altered development, and 2) structural changes in brain regions that require PAX6 for maintenance throughout adulthood. The current study evaluated neuroanatomical consequences of Pax6 haploinsufficiency using the PAX6$^{Sey\ Neu/+}$ mouse model to distinguish between developmental and age related changes across the lifespan. This study employed MRI using a 7T Agilent system to acquire structural brain images using 3D T2 weighted fast spin echo sequences. Thirty-two mice (16 PAX6$^{Sey\ Neu/+}$, 16 wild-type littermates; 50% age 4-5 months, 50% 12-13 months, outbred background) underwent MRI scans under isofluorine (TR/TE 400/44 msec, nt=4). Following in vivo imaging, animals were euthanized following approved protocols, and their brains sectioned for histological comparison. PAX6$^{Sey\ Neu/+}$ mice 4-5 months old show significant volume increases in grey matter in the medial olfactory bulb, cerebral cortex, midbrain, and cerebellum. Increases in white matter volume were seen in the posterior corpus callosum forceps, arbor vitae, dorsal hippocampal commissure, and cerebellum. Comparisons to histological sections show that MRI grey matter changes reflect abnormalities in restricted cell layers in several brain regions, particularly in the medial olfactory bulb and dentate gyrus of the hippocampus. White matter changes reflect overall differences in tract size. In addition, preliminary results comparing age groups suggest changes in specific brain structures are exacerbated in older PAX6$^{Sey\ Neu/+}$ mice, indicating that disruption of Pax6-dependent maintenance functions in the adult brain leads to an accelerated aging phenotype. Overall, this model provides a comparison for human aniridia towards identifying conserved neuroanatomical consequences of PAX6 deficiency.

Title: Gnas imprinted gene, a new player connecting neurodevelopment, sleep and cognition

Authors: *C. GARCIA-GARCIA, E. BALZANI, C. CHIABRERA, E. ALBANESI, L. CANCEDDA, V. TUCCI;
Inst. Italiano di Tecnologia, Genova, Italy

Abstract: Recent evidence has pointed out that imprinted genes, which exert fundamental roles in embryonic development, are also important in the regulation of sleep and cognitive processes in adulthood. Moreover, sleep abnormalities and cognitive defects are hallmarks of several neurodevelopmental disorders, suggesting that neurodevelopment is a pivotal time window for the formation of sleep and cognition. However, the link between developmental mechanisms and sleep remains largely unknown. Recently, our group has demonstrated that loss of imprinting in the GNAS locus dramatically affects sleep physiology and cognitive functions in mice. GNAS main product, Gαs, codifies for the G protein α-subunit, essential for the generation of intracellular second messenger cAMP. In order to further understand the role of Gαs in neural development and sleep formation, we knocked down its expression with 3-electrode intrauterine electroporation in mice hippocampus and frontal cortex during development. Our results demonstrate that Gαs is involved in pyramidal neuron morphology and migration during neurodevelopment. Specifically, Gαs knocked down neurons are characterized by more and longer branches; while the 20% of them are misplaced in the stratum radiatum of the hippocampus and the layer I of the frontal cortex. Moreover, we discovered that Gαs downregulation during development has also a modulatory effect on sleep and memory consolidation later in life. Specifically, Gαs downregulation in hippocampal neurons leads to a detrimental effect in NREM quality, and dramatically reduces the contextual freezing response of these animals following fear conditioning. Overall, this work provides new insights into the link between genomic imprinting, neurodevelopment, sleep and cognition.

Title: Effects of Transient P7 DISC1 signalling disruption on LTP in the prefrontal cortex

Authors: *N. R. HARDINGHAM[1], K. FOX[2];
[2]Sch. of Biosci., [1]Cardiff Univ., Cardiff, United Kingdom

Abstract: DISC1 has been identified as a schizophrenia risk factor and has an important role in brain development. We have used a transgenic mouse that expresses a fragment of the DISC1 c-terminal (DISC1-cc) and acts as a dominant negative when activated for 24-48 hours by a single injection of tamoxifen. Transient activation of the mutant protein at P7 results in schizotypic behaviour in the mouse (Li *et al*, 2007) and a loss of experience dependent plasticity and LTP in layer 2/3 of adult barrel cortex (Greenhill et al 2015) Schizophrenia has been strongly linked to dysfunction in the prefrontal cortex with both functional and structural deficits documented. Therefore we set out to investigate whether following P7 disruption of DISC1 signalling, synaptic plasticity is similarly affected in the prefrontal cortex to the barrel cortex. We recorded from layer 3 neurons in medial prefrontal cortex, stimulating the hippocampal input in a modified coronal slice. We used two protocols to induce LTP, a theta burst protocol, consisting of trains of 5 pre-synaptic stimulations followed by 5 post-synaptic spikes at a frequency of 20Hz and an HFS protocol consisting of trains of presynaptic stimulation at 50Hz. We applied dopamine chronically or acutely; either perfusing slices in ACSF containing 3μM dopamine or used a spritzer to apply a 10s puff of 50μM dopamine at the end of the theta burst protocol. Using a low concentration of picrotoxin (2.5 μM or 5μM) in addition to the 3μM dopamine produced significant LTP in wild types (143 ± 78% change in mean amplitude) but not in DISC1-cc mice following P7 DISC1 disruption (15 ± 16% change in mean amplitude, effect of genotype $p<0.001$). Dopamine was necessary for induction of LTP in WTs (change in mean amplitude = 3 ± 24% in absence of dopamine). Our results suggest that development of LTP in adult prefrontal cortex requires normal DISC1 function at P7, in common with barrel cortex. The lack of adult LTP cannot be explained by an alteration in the inhibitory system, as the impairment in LTP is present in DISC1-cc mice in the presence of a GABA antagonist, which in turn implicates the deficit in the function of the excitatory synapses.

Title: Engrailed-2 is a cell-autonomous regulator of proliferation and survival in cultured hippocampal neural stem cells

Authors: *M. DURENS[1], S. CHUNG[2], E. DICICCO-BLOOM[2];
[1]Rutgers Univ. - Busch Campus, Piscataway, NJ; [2]Rutgers Robert Wood Johnson Med. Sch., Piscataway, NJ

Abstract: En2 is a transcription factor with canonical function in mid-hindbrain development. Its roles in cerebellar patterning are well-studied, and gene deletion (En2-knockout, En2-KO) produces diverse cerebellar defects. However, almost nothing is known about En2 function outside the mid-hindbrain, despite several studies finding low-level expression in forebrain areas including hippocampus. Significantly, En2-KO mice display deficits in forebrain-related behaviors including spatial memory, fear conditioning, and social interaction. En2-KO hippocampus exhibits structural deficits including reduced weight, size, and neuron number. At P21, En2-KO dentate gyrus contains 17% less granule cells, and exhibits 2-fold increase in neural stem cell (NSC) proliferation and 70% increase in cell death. While we showed decreased monoamine innervation contributes to these defects, we hypothesize that En2 expression in hippocampus also contributes to dysregulated neurogenesis. This study examines possible cellular roles for En2 in hippocampal NSC development by using neurosphere cultures. To define cell-autonomous effects, dissociated cells from P7 En2 wild-type (WT) and KO mice were incubated in defined media with EGF and FGF until neurospheres formed. We assessed neurosphere size and number, and markers of proliferation (BrdU) and apoptosis (cleaved-caspase3, pyknosis). We detected expression of En2 mRNA in (WT) but not KO-derived neurospheres. Expression was also detected through immunostaining of an En2-LacZ reporter. Consistent with the heterogeneous composition of neurospheres, the LacZ reporter was only detected in a subset of cells, whose identity is being defined by double labeling with neural markers Sox2, Tbr2, and Tuj1. Compared to WT spheres, KO spheres exhibit a 22% increase in diameter ($p<0.01$), as well as 2-fold increases in proliferation ($P<0.005$) and apoptosis ($p<0.05$), consistent with the phenotype observed in dentate gyrus in vivo. The majority of proliferating cells (~90%) in both genotypes were Sox2+ suggesting that En2 may have a role in maintaining

quiescence of NSCs or promoting differentiation. Overall, these studies suggest En2 expression plays a cell-autonomous role in regulating proliferation and survival in hippocampal NSCs. In turn, these findings in culture prompt further investigation in vivo, where there is absence of En2-LacZ signal, and no apparent evidence of mRNA by in situ hybridization. More broadly these observations suggest that En2 may influence hippocampal development and function through both cell autonomous and non-cell autonomous mechanisms.

Title: Cerebellar corticogenesis in the lysosomal acid phosphatase (acp2) mutant mice; purkinje cell neurodevelopmental disorder

Authors: *N. ASHTARI[1], X. JIAO[2], M. RAHIMI BALAEI[2], K. BAILEY[2], S. GHAVAMI[2], H. MARZBAN[2];

Abstract: Introduction: A mouse mutant called *nax* (naked-ataxia); resulting from a spontaneous mutation in Lysosomal Acid Phosphatase (*Acp2*) gene shows severe cerebellar defects and neuronal degeneration in its cerebellum. Cerebellum is a brain region important for motor control and cognition. In the *Acp2* mutant mouse, three layer cortex (Granule cells (gcs), Purkinje cells (Pcs) and Molecular layer) were found to decrease significantly and monolayer Pcs turn to multi-layered Pcs that ectopically invade the molecular layer. Reelin is an important large extra-cellular signaling protein important in Pcs monolayer formation in cerebellar cortex. It is expressed by gcs and is required for Pcs distribution from the clusteric stage to establish a monolayer of Pcs between the molecular and granular layers of the cerebellar cortex. We hypothesize that the establishment of mono layered Pcs is independent to the Reelin pathway, however rely on Reelin through MAPK signaling pathway.
Methods: *Acp2* mutant mice were used for this study and molecular expression and distribution were assessed by immunohistochemistry and Western blotting.
Results: The cerebellar cortex of the *Acp2* mutant mice reveals the presence of Pcs in a randomized, dispersed manner spanning the entire molecular layer rather than a monolayer in the cerebellar cortex. The pattern of Reelin expression shows a down-regulation in both wild type and *nax* mouse, while lower amount of protein is detected in *nax* mutant at P4 (around Pc layer

formation) compared to wild type. Pcs differentiation is severely delayed in the *Acp2* mutant cerebellar cortex while the presence of Reelin is comparable with wild type during early postnatal development. It is indicative of Reelin effect during clustric stages however failed to form mono layer Pcs.
Conclusion: It is concluded that multilayer Pcs may be due to the failure of appropriate cross-talk between *Acp2* and the Reelin signaling pathway during early postnatal cerebellar development.

Title: Neurofibromin loss of function leads to increased spontaneous grooming in *Drosophila*

Authors: *L. B. KING[1], M. KOCH[1,1], K. R. MURPHY[2,4], Y. VELAZQUEZ[1,3], W. W. JA[2], S. TOMCHIK[1];
[1]Dept. of Neurosci., [2]Dept. of Metabolism and Aging, [3]SURF Program, The Scripps Res. Inst., Jupiter, FL; [4]Integrative Biol. Grad. Program, Florida Atlantic Univ., Jupiter, FL

Abstract: Neurofibromatosis I is a common genetic disorder that results in tumor formation and predisposes individuals to a range of cognitive and behavioral symptoms, including deficits in attention, visuospatial skills, learning, language development, sleep, and autism spectrum disorder-like traits. The *nf1*-encoded neurofibromin protein (Nf1) exhibits high conservation, from the common fruit fly, *Drosophila melanogaster*, to humans. *Drosophila* is a powerful model with which to investigate the signaling cascades upstream and downstream of Nf1, and exhibits similar behavioral phenotypes to mammalian models. In order to understand how loss of Nf1 affects motor behavior in flies, we combined traditional infrared beam based activity monitoring with video analysis of grooming behavior. In *nf1* mutants, spontaneous grooming was increased up to 7x. This increase in activity was distinct from previously-described dopamine-dependent hyperactivity, as dopamine transporter mutants exhibited slightly decreased grooming. In addition, we verify the utility of a published set of conditional driver lines to produce reliable and precise grooming behavior targeted towards specific body parts. Here, we use optogenetic stimulation of a red-shifted channel rhodopsin, CsChrimson, to produce grooming in an open field arena. Overall, these data suggest that loss of *nf1* results in increased

activity that is at least in part manifested as increased grooming, providing a platform to dissect the molecular genetics of neurofibromin signaling across neuronal circuits.

Title: Determining the locomotor effects and expression of thrombospondin in *Drosophila melanogaster* larva

Authors: E. LOWENSTEIN[1], *N. A. VELAZQUEZ ULLOA[2];
[1]Biochem. and Mol. Biol. Program and Dept. of Mathematical Sci., [2]Lewis & Clark Col., Portland, OR

Abstract: Thrombospondin (TSP), a gliotransmitter, has been implicated in promotion of synapse formation through binding to the $\alpha_2\delta$-1 subunit of neuronal voltage-gated Ca^{2+} channels in rat retinal ganglion cell cultures, as well as through neuroligin-1 in rat hippocampal neurons. In *Drosophila melanogaster*, $\alpha_2\delta$-3 and neuroligin-2, with functional homology to $\alpha_2\delta$-1 and neuroligin-1, promote formation of boutons at the neuromuscular junction and neuroligin-2 mutants display abnormal locomotion. Additionally, TSP has been shown to be involved in tendon adhesion in *D. melanogaster* (D-TSP). Given TSP's role in the nervous system, this study aims to utilize *D. melanogaster* to study the effects of TSP at multiple levels of action: developmental expression and associated behavioral phenotypes. Characterization of the expression of TSP in the larvae brain through whole-mount immunohistochemistry is underway, and affinity chromatography and qPCR will be used to validate the microscopy results. Preliminary locomotion analysis of D-TSP knockout larvae in open crawling chamber suggests reduced reverse crawling and turns. Future studies hope to probe the role of TSP in the *D. melanogaster* embryo and adult to understand its function within the framework of development.

Title: The effects of dopaminergic receptor ligands on the performance of nonhuman primates in a comprehensive, translational cognitive operant test battery (OTB)

Authors: *J. L. WALTERS, J. J. CHELONIS, M. P. GILLAM, J. C. TALPOS, M. G. PAULE; Natl. Ctr. for Toxicological Res. (NCTR), Jefferson, AR

Abstract: The effects of dopaminergic receptor ligands on cognitive function have been widely studied in rodents, yet limited research has assessed the effects of these compounds on cognition in nonhuman primates. Thus, the purpose of this experiment was to assess the sensitivity of the National Center for Toxicological Research (NCTR) operant test battery (OTB) to detect the effects of acute administration of dopamine (DA) receptor agonists and antagonists in rhesus monkeys. Here, we sought to determine the differential sensitivity of tasks in the NCTR OTB to manipulations of the DA system and characterize the effects of these compounds in a preclinical model with greater relevance to humans. The test battery is thought to measure aspects of motivation, learning, color and position discrimination, time estimation, and short-term memory and has been proven to be sensitive to an array of psychotropic compounds. Quinpirole (0.001-0.75 mg/kg), sulpiride (0.3-10.0 mg/kg), SCH 23390 (0.03-0.3 mg/kg), SKF38393 (0.03-3.0 mg/kg), and corresponding vehicles were administered to young adult males trained to perform the NCTR OTB, which consisted of progressive ratio, incremental repeated acquisition, temporal response differentiation, conditioned position responding, and delayed matching to sample tasks. Results revealed all four dopaminergic compounds differentially affected OTB performance. The D2/D3 agonist, quinpirole, produced the most disruptive effects, decreasing accuracies in all of the tasks with some impairments occurring at doses that did not affect response rates. The D1/D5 partial agonist, SKF38393, did not impair accuracy in any of the tasks and produced minimal effects on response rates while leaving cognitive abilities relatively intact. The D1 antagonist, SCH 23390, and the D2/D3 antagonist, sulpiride, were both found to decrease response rates while having limited to no effects on accuracies, suggesting that these compounds, at the doses given here, primarily disrupt motor behaviors while having modest or no effects on cognition. In summary, these results demonstrate that the NCTR OTB is sensitive to detecting differential effects of compounds that act at D2/D3 receptors and D1/D5 receptors, indicating that this battery is a valid tool for detecting undesirable effects associated with pharmacological manipulations of the DA system. Further, the data suggest this battery can be used to assess the

effects of current and future drugs designed to treat aspects of disorders/diseases related to DA system disruption, such as schizophrenia, Parkinson's disease, and attention deficit hyperactivity disorder. Supported by NCTR/FDA E6979

Title: Lateral septum stimulation induces and increase in GABA and dopamine extracellular levels in the rat ventral tegmental area

Authors: I. M. VEGA[1], H. E. YARUR[1], *K. GYSLING[2];
[1]Dept. of Cell. and Mol. Biol., [2]Pontificia Univ. Catolica De Chile, Santiago, Chile

Abstract: The lateral septum (LS) is involved in positive reinforcement as shown by James Olds and Peter Milner in 1954. The LS belongs to a complex limbic circuit in which the ventral tegmental area (VTA), prefrontal cortex (PFC), and the nucleus accumbens (Nac) connections play a critical role in the motivated behavior. The dysfunction of this circuit is crucial in diseases such as addiction. Dopamine (DA) is the key neurotransmitter of this circuit, and is mainly released from VTA neurons that connect the VTA with the rest of the limbic circuit, inducing and regulating motivated behavior. In this sense, the regulation of dopamine release in the VTA is critical for the activity of VTA dopamine neurons and for the functional integration of the rest of limbic system areas. In this study we performed in vivo dual-probe microdialysis to reveal the neurochemical relationship between LS and VTA, when we stimulate the LS such as Olds and Milner.We observed a significant increase in the extracellular levels of GABA and DA in the VTA after a depolarizing stimulus in the LS. We also observed that the infusion of muscimol/baclofen in LS resulted in a significant decrease in VTA GABA levels after LS stimulation but not in VTA DA levels that remain unchanged. We also studied the effect of LS stimulation after VTA infusion of bicuculline (GABA-A receptor antagonist) or CPG-52432 (GABA-B receptor antagonist). These results showed that in the presence of bicuculline in the

VTA, DA VTA levels did not increase after LS stimulation but VTA GABA extracellular levels increased.Thus, our data suggest that there is a gabaergic projection from the LS to VTA gabaergic interneurons and that its activation results in a disinhibition of VTA dopaminergic neurons. Further studies should prove if this proposed connections are involved in the positive reinforcement effects induced by LS stimulation.

Title: Sex differences in behavior and neurophysiology during reward approach and punishment avoidance

Authors: *T. G. CHOWDHURY[1], N. W. SIMON[1], R. DUTTA[2], B. MOGHADDAM[1]; [1]Dept. of Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Stanford Univ., Stanford, CA

Abstract: Men and women show different rates of diagnosis of various psychiatric illnesses. Men are more commonly diagnosed with schizophrenia and substance abuse disorders, while major depression and anxiety disorders are more common in women. These epidemiological patterns suggest that biological sex differences may underlie the gender disparities in vulnerability to psychiatric disease. To study the sex differences in the neurobiology relevant to psychiatric illnesses, we have used a novel paradigm for simultaneously testing two different motivated behaviors, namely approach and avoidance, in rats. Furthermore, we tested the effect of an experimental model of anxiety on these two. Rats are first trained on two separate tasks: (1) to perform a nose-poke action to obtain a reward and (2) to perform a lever-press action to avoid an impending foot-shock. Once the rats are trained to a criterion of >70% on these two tasks, they enter the testing phase in which both tasks are presented during the same session. This allows concurrent measurement of reward seeking and punishment avoidance. Male and female rats showed similar rates of successful reward attainment, and anxiety caused a similar reduction in correct reward trials completed in males and females. While females acquired the avoidance behavior faster than males, males showed a greater rate of shock avoidance once the behavior

was stable. In males, anxiety diminished performance on avoidance trials, while the drug had no effect in female avoidance behavior. We are currently exploring the neural correlates of these behaviors by recording from VTA dopamine neurons.

Title: Agitating dopamine d1 receptor prevents long-term special memory loss.

Authors: *J. ZHANG;
Dept. of Oriental Phamaceutical Sci., Seoul, Korea, Republic of

Abstract: Dopamine D1 receptors 1 (D1 receptors) have a function of memory improvement according to the previous studies, but it is unclear whether agitating D1 receptors can prevent memory loss or extend memory. In our study, we hypothesized whether D1 receptor agonist, SKF 38393 could prevent spatial memory loss using Barnes Maze test (BM test). We found that the acquired spatial memory through three trials per training for four days in BM test has maintained for 21 days, and the memory had begun to fade down from the 14^{th} day after training. So on the 14^{th} Day after training administration of SKF 38393 for 7 days has prevented the natural memory extinction process, and administration of the D1 receptor antagonist, SCH 23390 blocked this process. In the western blotting, administration of SKF 38393 increased the phosphorylation of PKA and CREB, which indicated that SKF 38393 ameliorated memory consolation through cAMP-PKA-CREB signaling pathway. These results suggest that dopamine D1 receptors are associated with the consolation of long-term spatial memory by cAMP-PKA-CREB signaling pathway. Abstract: The striatum is the input nucleus of the basal ganglia and is involved in goal-directed behaviors, motivation, and reward processing. Subdivided into the dorsal striatum (DStr) and nucleus accumbens (NAc), both regions are made up predominantly of medium spiny neurons (MSNs) and receive dense dopaminergic innervation from the midbrain. Despite these similarities, the DStr and NAc have different afferent and efferent connections as well as unique behavioral functions. Regional differences in dopamine release properties and reuptake have been identified using fast scan cyclic voltammetry, but it is important to understand how these differences correspond to differences in postsynaptic receptor activation in these striatal subregions. To examine how the synaptic release of dopamine activates D2-receptors on MSNs in the DStr and NAc, G-protein activated inwardly rectifying potassium (GIRK2; K_{ir} 3.2) channels were virally overexpressed in the striatum and the resulting outward currents were used as a sensor of D2-receptor activation. Optogenetic stimulation of dopamine terminals evoked robust D2-receptor mediated inhibitory postsynaptic currents (IPSCs) in GIRK2-expressing MSNs. D2-IPSCs recorded in the NAc were significantly slower than those in the DStr. Regional differences in reuptake, spillover, terminal density, and transmitter diffusion distance were examined as potential explanations for the difference in D2-IPSC kinetics. The finding that D2-IPSCs have different kinetics in the dorsal and ventral striatum may have important consequences for how D2-receptors encode dopamine signals in these striatal subregions.

Title: Altered dopamine D4 receptor dependent regulation of synaptic transmission and hippocampal circuit function in PGC-1α-/- mice

Authors: *L. BRADY, A. BARTLEY, Q. LI, L. DOBRUNZ;
Neurobio., Univ. of Alabama At Birmingham, Birmingham, AL

Abstract: GABAergic interneurons control neuronal excitability, integration, and plasticity & have been shown to be altered in various neurological diseases that have cognitive impairment as a core symptom. In schizophrenia for example, post mortem studies have consistently shown transcriptional dysregulation in GABAergic interneurons, in particular fast-spiking interneurons containing the calcium binding protein parvalbumin (PV). To model this, our lab uses mice with genetic deletion of PGC-1α, a transcriptional coactivator that has been shown to be altered in a several neurological disorders. Previous data from our lab has shown that the inhibitory/excitatory (I/E) ratio is increased in PGC-1α-/- mice at the Schaffer collateral - CA1 pathway in hippocampus, caused by enhanced inhibition and increased GABA release from interneurons. PGC-1α-/- mice also have enhanced gamma oscillation power and impaired nesting behavior, indicating hippocampal circuit dysfunction. GABAergic inhibitory synaptic transmission has been shown to be modulated by dopamine (DA) in hippocampus. In particular, DA D4 receptors have been observed to be located on PV+ GABAergic interneurons in hippocampus, and have been shown to be important for regulating gamma oscillations. Here we use PGC-1α-/- mice to investigate the interaction between dysfunction of the dopaminergic and GABAergic systems caused by interneuron transcriptional dysregulation. We find that DA has a disinhibitory effect on synaptic responses in WT and PGC-1α-/- slices, although there was no significant difference in the magnitude. We observed that blocking D4 receptors resulted in an increased field potential in PGC-1α-/- mice due to disinhibition. These data suggest that there is a tonic effect of D4 activation to enhance feedforward inhibition in PGC-1α-/- slices, which may contribute to the enhanced I/E ratio in these mice. We also found that specific D4 receptor antagonists rescued the deficit in basal synaptic transmission observed in PGC-1α-/- mice, and normalized the increased power of hippocampal gamma oscillations and the deficit in nesting

behavior. This suggests that alterations in the DA system's modulation of inhibition, through changes in D4 receptor effects, are involved in the circuit dysfunction caused by deletion of PGC-1α. These results also provide mechanistic support for atypical antipsychotics that have a higher affinity for D4 receptors, like Clozapine, in the treatment of cognitive symptoms of neurological disorders.

Title: Dopaminergic transmission in nucleus accumbens shell neurons are modulated by methylphenidate.

Authors: ***C. REYES-VAZQUEZ**, A. VÁZQUEZ-ALVAREZ, D. PINEDA-VÁZQUEZ, S. RAMOS-MEJIA, B. PRIETO-GÓMEZ;
Depto. De Fisiología, Mexico DF, Mexico

Abstract: Dopaminergic (DA) neurons from ventral tegmental area (VTA) project to both, the core and shell subregions of the Nucleus Accumbens (NAc) in these regions DA release is induced by natural stimuli as well as by drugs of abuse. DA synaptic transmission is critically involved in reward-motivated behaviors, which are altered in addiction. Also, glutamate (GLUT) is packaged and released by a subset of mesolimbic DA neurons, eliciting Excitatory Postsynaptic Currents (EPSCs) onto medium spiny neurons in NAc. There is no precise information about the modulation of GLUT release from DA midbrain terminals by Methylphenidate (MTP). Using electrical stimulation to selectively activate midbrain DA fibers, we compared the properties and modulation of EPSCs measured using whole-cell recordings in rat brain slices. Rats (18 weeks old) that showed sensitization to methylphenidate in an open-field paradigm, and naive control rats, were anesthetized with isoflurane and killed by decapitation. Brains were quickly removed, mounted, and sliced. Slice preparation and whole cell patch clamp recordings were performed using standard techniques. For electrical stimulation, a glass pipette filled with ACSF was placed in the NAc shell and a rectangular pulse (0.2 ms) was applied every 2 min. The amplitude of the current pulse (100–250 μA) was adjusted to use the minimal current needed to generate a maximal and stable response. In both groups of rats, electrically induced EPSCs were inhibited by a DA receptor D2R agonist and showed a marked paired-pulse depression that required 2 min for a full recovery. MTP depressed EPSCs

amplitude by 50% in control rats, and until 80 % in sensitized rats. But, in both groups, MTP enhanced the overall DA transmission from midbrain DA neurons. AMPA and NMDA receptor-mediated EPSCs were equally inhibited by MTP in sensitized rats, suggesting a presynaptic mechanism of action. These findings demonstrate that MTP inhibits DA and glutamate release from midbrain DA neurons via presynaptic D2R but has differential overall effects on their transmissions in the NAc. Suggesting that MTP, by blocking DA reuptake, facilitates the feedback inhibition of DA and glutamate release from these terminals.

Title: Kinetic characterization of stimulation-evoked striatal dopamine release in a 6-hydroxydopamine-lesioned parkinsonian rodent model

Authors: ***S. PAEK**, J. K. TREVATHAN, A. D. BATTON, C. D. BLAHA, A. J. BIEBER, J. L. LUJAN, K. H. LEE;
Mayo Clin., Rochester, MN

Abstract: **Background** Dopamine (DA) is an important neurotransmitter, exhibiting critical roles in neurologic function during Parkinson's disease (PD). As such, the ability to characterize DA responses to therapeutic interventions such as deep brain stimulation (DBS) has important implications for studying the pathophysiology of disease. The non-linear and time-varying dynamics of stimulation-evoked DA responses have been characterized using mathematical models of DA release in healthy anesthetized animals. However, the complex relationship between electrical stimulation and consequent stimulation-evoked DA release has yet to be characterized in a Parkinsonian animal model. Thus, this study characterizes DA responses in the striatum of 6-hydroxydopamine (6-OHDA) lesioned rats in response to medial forebrain bundle (MFB) DBS. **Methods** The MFB was electrically stimulated in urethane-anesthetized 6-OHDA lesioned male Sprague-Dawley rats using a comprehensive range of stimulation parameters.

Concurrently, striatal DA release was measured using fast scan cyclic voltammetry in combination with carbon fiber microelectrodes. Evoked responses were characterized using a multi-compartment parametric model of DA release. The resulting kinetics were then compared to the kinetic responses from healthy anesthetized rats. **Results** Preliminary data suggest that the kinetics of stimulation-evoked DA release can be described using compartmental models and that these models can describe the forward relationships between electrical stimulation parameters (i.e., stimulus pulse width and amplitude) and stimulation-evoked extracellular dopamine responses. Further analysis will determine whether these relationships are altered following 6-OHDA lesioning. **Conclusions** Characterization of DBS induced DA release in a model of PD is an important step towards understanding neurotransmitter dynamics in the context of neurologic disease and therapeutic interventions. Ultimately, this work will aid in understanding the neurochemical effects of DBS and further the development of novel therapeutic strategies.

Title: Differential dopamine potency across striatal d1 positive neurons

Authors: S. E. PEDERSEN[1], T. F. ANDREASSEN[1], J. K. DREYER[2], U. GETHER[1], *K. L. MADSEN[2];
[1]Dept. of Neurosci. and Pharmacol., Univ. of Copenhagen, Copenhagen N, Denmark; [2]Univ. of Copenhagen, Copenhagen, Denmark

Abstract: The major target of dopamine (DA) signaling is the medium spiny neurons (MSNs) located in the nucleus accumbens and the dorsal striatum of the brain. The majority of MSNs are classically categorized as belonging to either the direct or indirect pathway, defined by the expression of either D1 or D2 receptors (D1R or D2R), respectively. Sensitivity towards cortical inputs is regulated by, amongst others, DA. Local changes in DA levels have opposite effect on the direct and indirect pathways; In D1R positive neurons DA increases cAMP and protein kinase A (PKA) signaling, whereas DA leads to a decrease in cAMP/PKA signaling in D2R

positive neurons.
In this study we investigate the spatiotemporal regulation of PKA activity in striatal neurons in response to dopamine stimulation in an isolated MSN culture system. This approach allows us to study individual neurons with great temporal and spatial specificity. Using a FRET based biosensor of PKA activity (AKAR3) we are able to distinguish downstream effects of D1R activation reflected by intracellular time-dependent changes in the FRET ratio. Single neurons show significant FRET ratio changes upon stimulation with physiologically relevant concentrations of dopamine (100nM) illustrating the viability of this assay as a tool to monitor discrete signaling events in MSNs. Moreover, our data reveal a high degree of heterogeneity in the concentration-dependent PKA activation downstream of D1R in these neurons. Further, we show that D1R expression levels can modulate this observed variability in potency. Altogether, these findings illustrate the possibility of a hitherto unknown mechanism of action of DA-induced striatal signaling.

Title: ACh and opioid regulation of dopamine D2 receptor mediated transmission in striatal medium spiny neurons

Authors: *Y. CAI, A. A. MAMALIGAS, C. P. FORD;
Case Western Reserve Univ., Cleveland, OH

Abstract: In the striatum, cholinergic interneurons (ChIs) regulate dopamine (DA) release by activating nicotinic acetylcholine receptors (nAChRs) on DA terminals. However, it is unclear how post-synaptic dopamine D2 receptors (D2Rs) on medium spiny neurons (MSNs) respond to acetylcholine-mediated DA transmission. Here we compared D2R activation through two different pathways: either direct midbrain DA release or ChI evoked release. To examine this, G protein-coupled inwardly rectifying potassium channels (GIRK2) were overexpressed in striatal

MSNs while ChR2 was expressed in DA neurons in DAT-Cre mice or ChIs in ChAT-Cre mice. Optogenetic stimulation of both ChIs and DA terminals evoked D2-receptor inhibitory postsynaptic currents (D2-IPSCs) in GIRK expressing MSNs. D2-IPSCs in both cases were abolished by D2R antagonist sulpiride (400nM), however only D2-IPSCs evoked by optogenetic activation of ChIs were abolished by the nAChR antagonist DHBE (1 uM). D2-IPSCs evoked by a single electrical stimulus were reduced by ~40% by DHBE (1 uM) indicating that electrical stimulation drove the release of DA both directly from DA terminals and also by the disynaptic release from ChIs. Bursts (5 stimuli at 40 Hz) of DA terminal stimulation potentiated the amplitude of D2-IPSCs by about 20% compared with single optogenetic stimulation. Bursts of ChI stimulation (5 stimuli at 40 Hz), however, did not potentiate the amplitude of IPSCs. This was likely due to desensitization of nAChRs as a result of ChI burst firing. In addition, the opioid receptor agonist U69593 (300nM) and the opioid receptor agonist DAMGO (1uM) inhibited D2-IPSCs evoked by optogenetic stimulation of ChIs. Taken together, the data suggests synchronous activation of ChIs regulates D2R activation in the striatum and probably also indicates a differential regulation pattern of opioids on D2R activation mediated by ChIs and DA neurons

Title: Shedding light on the subunit arrangement of extrasynaptic $\alpha_4\beta_2\delta$ $GABA_A$ receptors

Authors: ***N. WONGSAMITKUL**, R. BAUR, E. SIGEL;
Univ. of Bern, Bern, Switzerland

Abstract: Extrasynaptic $\alpha_4\beta_2\delta$ $GABA_A$ receptors are considered to be an important drug target. However, subunit stoichiometry and arrangement of these receptors is difficult to establish. To predefine subunit arrangement, we constructed concatenated receptors. The δ subunit was substituted in any of the five positions in the $\alpha_1\beta_2\gamma_2$ receptor with γ_2 replaced by β_2. α_4, β_2 and δ subunits were concatenated to dimeric and trimeric subunits. Five pentameric $GABA_A$ receptors were built with two different ways from the combination of trimers and dimers, and two representative pentameric constructs were engineered. The resulting receptors were expressed in *Xenopus* oocytes and their electrophysiological and pharmacological properties were

characterized using the two-electrode voltage clamp technique. We determined GABA EC_{50} in the presence of THDOC (3α, 21-dihydroxy-5α-pregnan-20-one), sensitivity to DS2 (the δ-selective 4-chloro-*N*-[2-(2-thienyl)imidazo[1,2-a]pyridine-3-yl benzamide) and ethanol. All functional receptors were sensitive to DS2 and none of them was affected by ethanol. The subunit arrangement of $\alpha_4\beta_2\delta$ $GABA_A$ receptors seems to be flexible as the δ subunit can assume multiple positions in a receptor pentamer.

Title: Multiple sites of action of CGS 9895 on $GABA_A$ receptors

Authors: *M. C. MALDIFASSI, R. BAUR, E. SIGEL;
Univ. of Bern, Bern, Switzerland

Abstract: $GABA_A$ receptors are the main inhibitory neurotransmitter receptors in the brain and are targets for numerous clinically important drugs such as benzodiazepines, anxiolytics and anesthetics. Previously, CGS 9895 was described as a positive allosteric modulator acting through the α+/β- interface in the extracellular domain of $GABA_A$ receptors. The localization of the binding site was based on a steric hindrance approach, rather than on direct effects of point mutations. In the current study we further characterized modulation by this compound that seems to have six sites of action. We investigated $GABA_A$ receptors expressed in *Xenopus laevis* oocytes using voltage-clamp electrophysiology. We have identified the α_1Y209 residue present at this interface as a key residue for CGS 9895 modulation. Additionally, the interaction between this residue and various structural analogs was characterized, allowing tentative positioning of CGS 9895 versus α_1Y209. Not all compounds were found to be sensitive to mutations at the α_1Y209 residue. In addition, the interaction of CGS 9895 with flurazepam was characterized. Flurazepam is hypothesized to act at the same subunit interface in the extracellular domain. We also provide evidence that the $GABA_A$ receptor harbors additional modulatory sites for CGS 9895 at each of the subunit interfaces in the trans membrane domain.

Title: Competitive antagonists facilitate the recovery of α1β2γ2 $GABA_A$ receptors from desensitization

Authors: *Y. CHANG[1], X. XU[1,2], D. ROBERTS[1], G. ZHU[2];
[1]Barrow Neurolog. Inst., St. Joseph's Hosp. & Med. Ctr., Phoenix, AZ; [2]Inst. of Pesticide and Envrn. Toxicology, Zhejiang University, China, Hangzhou, China

Abstract: The continuous presence of an agonist drives its receptor into a refractory state, termed desensitization. However, it is still unknown whether a competitive antagonist can reverse the agonist-induced desensitization and facilitate receptor recovery from desensitization. In this study, we tested the hypothesis that a competitive antagonist, SR95531, can facilitate the recovery from functional desensitization of the α1β2γ2 $GABA_A$ receptor. The α1β2γ2 $GABA_A$ receptor was expressed in *Xenopus* oocytes, and receptor function was evaluated using the two-electrode voltage-clamp technique. Our results demonstrated that after termination of GABA perfusion, the GABA-response recovery was faster in the presence of SR95531. Furthermore, SR95531 co-application with GABA during the steady-state GABA-induced current caused rebound of the GABA-induced current after removal of SR95531. The SR95531 co-application-induced current rebound was much higher than the steady-state desensitization level. This SR95531-induced current rebound was time dependent and concentration dependent. The concentration dependence of the current rebound had a high potency component and a low potency component. Interestingly, these two components were similar to the two potency components of the SR95531 inhibition of the steady-state current. In addition, bicuculline exhibited a similar facilitation of desensitization recovery. Finally, our results are consistent with that SR95531 has low affinity to the desensitized receptor but high affinity to the non-desensitized receptor. In conclusion, competitive antagonists can facilitate recovery of the α1β2γ2 $GABA_A$ receptor from desensitization by two mechanisms: binding to the desensitized receptor and converting it to the non-desensitized state and binding to the resting state receptor and preventing re-desensitization.

Title: Pharmacology of the human ε subunit from the $GABA_A$ receptors

Authors: *D. C. BERTRAND[1], S. BERTRAND[1], E. NEVEU[1], M. A. ACKLEY[2];
[1]Hiqscreen, Vesenaz - GE, Switzerland; [2]SAGE Therapeut., Boston, MA

Abstract: $GABA_A$ receptors are ligand gated channels members of the family of four transmembrane domain receptors, which also comprise the nicotinic, $5HT_3$ and glycine receptors. This family includes multiple genes encoding for several individual subunits, allowing expression of a vast repertoire of functional proteins with specific physiological and pharmacological properties. In human this is readily illustrated by the observation that 19 genes encoding for distinct $GABA_A$ receptor subunits have been identified and are known to be expressed in specific areas of the brain. Further pharmacological complexity is brought by the incorporation of three or more distinct subunits in a single receptor complex. For example, $GABA_A$ receptors are typically composed of two $\alpha_{(1-6)}$, two $\beta_{(1-3)}$ and one other subunit ($\gamma_{(1-3)}$, δ, ε, π or θ) and the specific combination of subunits that make up a functional receptor can exert distinct biophysical and pharmacological properties to the channel.
In the human, the ε subunit is encoded by a 506 amino acid long sequence expressed in human on the chromosome X at location p22.33-q28 in a cluster with the gene encoding for the α3 subunit. The ε subunit shows distinct distribution in the CNS and can show plasticity in expression during certain CNS disorders. We have explored how incorporation of this subunit into GABA receptors can exert distinct properties to the receptor.
Expression of the $\alpha_1\beta_2$ subunits in *Xenopus* oocytes in a (1:1) ratio yielded functional receptors displaying an average current to GABA of 0.36 μA and an EC_{50} of 3.5 μM. Co-expression in sibling oocytes of the ε resulted in current that was around ten-fold larger and that was accompanied by an increase in sensitivity and differences in time course of the response. Moreover, these receptors were significantly distinct from other subunit combinations such as $\alpha_1\beta_2\gamma_2$. Further evidences about the incorporation of the ε in the receptor complexes are illustrated by the pharmacological signature of these heteromeric $GABA_A$ receptors.
Taking advantage of the automated HiClamp system we review the singularities of $GABA_A$ receptors that include the ε subunit.

Title: The challenge in comparing the pharmacology of agonists and modulators at alpha4beta2gamma2 and alpha4beta2delta GABAA receptors

Authors: *N. ABSALOM[1], L. H. BANG[2], M. CHEBIB[1], P. K. AHRING[1];
[1]Univ. of Sydney, Sydney, Australia; [2]Neurosearch A/S, Ballerup, Denmark

Abstract: Extrasynaptically located γ-aminobutyric acid (GABA) receptors type A are often characterized by the presence of a δ subunit in the receptor complex. These δ-containing receptors respond to low ambient concentrations of GABA or respond to spillover of GABA from the synapse to give rise to slow phasic and tonic currents. In certain brain regions such as thalamocortical neurons, tonic inhibition is estimated to represent the majority of total GABA-mediated inhibition, and has thus raised substantial interest in extrasynaptic receptors as drug targets. Unfortunately, the α4β2/3δ receptors have proven difficult to study in recombinant *in vitro* expression systems due to the inherently low current levels elicited in response to GABA. In this study, we sought to characterize the function of a range of agonists and positive allosteric modulators at α4β2δ and α4β2γ2 receptors. All the agonists tested (GABA, THIP, muscimol, and taurine) displayed between 8 and 22 fold increase in potency at the α4β2δ receptor. In contrast, the modulatory potencies of steroids (allopregnanolone, THDOC and alfaxalone), anesthetics (etomidate, pentobarbital) DS1 and DS2 were similar at α4β2δ and α4β2γ2 receptors. When evaluating modulatory efficacies, the neurosteroids and anesthetics displayed highest efficacy at α4β2γ2 receptors whereas DS1 and in particular DS2 had the highest efficacy at α4β2δ receptors. Overall, none of the tested compounds displayed significant selectivity and a great need for identifying new δ-selective compounds remains. Further, α4β2δ and α4β2γ2 receptors have such divergent intrinsic activation properties that valid comparisons of modulatory efficacies are at best challenging.

Title: Positive modulation of $GABA_A$ receptor currents by isomers of 2,6-Dimethylcyclohexanol

Authors: *A. C. HALL[1], L. COWDHURY[1], C. J. CROFT[1], S. GOEL[1], N. ZAMAN[1], A. C.-S. TAI[1], E. M. WALCH[1], K. M. SHEA[1,2], C. D. HALL[2], D. JISHKARIANI[2,3], G. G. PILLAI[3]; [1]Smith Col., Northampton, MA; [2]Univ. of Florida, Gainesville, FL; [3]Univ. of Tartu, Ravila, Estonia

Abstract: $GABA_A$ receptors meet all the pharmacological requirements necessary to be considered important targets for the action of general anesthetic agents in the mammalian brain. In a patch-clamp study, the relative modulatory effects of 2,6-dimethylcyclohexanol diastereomers were investigated on human γ-aminobutyric acid type A ($GABA_A$, $\alpha_1\beta_3\gamma_{2s}$) receptor currents stably expressed in human embryonic kidney cells (WSS-1 cells). *Cis,cis, trans,trans*; and *cis,trans* isomers were isolated from commercially available 2,6-dimethylcyclohexanol and were tested for positive modulation of sub-maximal GABA responses. Co-applications of 30 μM 2,6-dimethylcyclohexanol isomers produced a range of positive enhancements of control GABA responses with a rank order for positive modulation: *cis,cis* > *trans,trans* ≥ mixture of isomers >> *cis,trans* isomer. For example, the addition of 30 μM *cis,cis* isomer resulted in ~2-3 fold enhancement of the ~EC_{20} GABA current while the *cis,trans* isomer produced a nominal enhancement of the current.
In molecular modeling studies, the three cyclohexanol isomers bound with the highest binding energies to a pocket within the transmembrane helices M1 and M2 of the β_3 subunit through hydrogen-bonding interactions with a glutamine at the 224 position and a tyrosine at the 220 position. The energies for binding and the hydrogen bond lengths within this pocket corresponded with the relative potencies of the agents for positive modulation of $GABA_A$

receptor currents (*cis,cis* > *trans,trans* >> *cis,trans* 2,6 dimethylcyclohexanol).
In conclusion, the stereochemical configuration of the dimethylcyclohexanols is an important molecular feature in conferring positive modulation of $GABA_A$ receptor activity and for binding to the receptor, a consideration that needs to be taken into account when designing novel anesthetics with enhanced therapeutic indices.

Title: Multiple non-equivalent interfaces mediate direct activation of α1β3 $GABA_A$ receptors by propofol

Authors: ***A. S. EVERS**[1], M. M. EATON[1], A. GERMANN[1], R. ARORA[1], L. CAO[1], X. GAO[1], D. SHIN[1], A. WU[1], D. C. CHIARA[2], J. B. COHEN[2], J. H. STEINBACH[1], G. AKK[1]; [1]Anesthesiol., Washington Univ. In St. Louis, Saint Louis, MO; [2]Harvard Med. Sch., Boston, MA

Abstract: Propofol is an allosteric activator of the γ-aminobutyric acid type A ($GABA_A$) receptor. Photo-labeling studies with propofol analogues have identified potential interaction sites in the transmembrane domain of the receptor at both the "+" and "-" sides of the β subunit. We have examined the functional contributions of the putative binding sites at the β-α and α-β interfaces in direct gating of the α1β3 $GABA_A$ receptor by propofol. Electrophysiological assays were performed on human α1β3 $GABA_A$ receptors expressed in *Xenopus* oocytes, using standard two-electrode voltage clamp. Individual tryptophan mutations at the "-" side of the β3 subunit at Y143 in loop 7 of the extracellular domain, or F221 or Q224 near the extracellular end of the first transmembrane segment in the β3 subunit (βM1), or the "+" side of the β3 subunit at M286 in βM3 had a modest effect on receptor activation by propofol. Combination of β3(M286W) with

one of β3(Y143W), β3(F221W), or β3(Q224W) strongly reduced gating efficacy of propofol. Control experiments with GABA showed no systematic effect of mutations. Structural modeling revealed that the mutated residues at the "-" surface of β3 contribute to a cavity predicted to bind propofol with favorable energies, while the mutated residue at the "+" surface of β3 contributes to a distinct pocket in the transmembrane domain that binds propofol and other general anesthetics. We propose that α1β3 $GABA_A$ receptors can be activated by propofol interactions with the β-β, α-β or β-α interfaces where distinct regions control channel gating.

Title: Diphenylpyraline, a histamine receptor antagonist, acts as a $GABA_A$ receptor agonist

Authors: *D. B. WILLIAMS[1], J. J. HARP[2];
[1]Biol. Sci., Winston Salem State Univ., Winston Salem, NC; [2]Biol. Sci., Winston-Salem State Univ., Winston-Salem, NC

Abstract: Compounds derived from the antihistamine diphenylpyraline (DPP) have been demonstrated to be high affinity $GABA_A$ receptor agonists. As a result, we hypothesized that DPP itself could also be a $GABA_A$ receptor agonist. $GABA_A$ receptors consisting of α1β2 (injected 1:1 ratio) or α1β2γ2s (injected 1:1:5 ratio) subunits were expressed in *Xenopus* oocytes. GABA and DPP induced currents were measured using a two-electrode voltage clamp set at -60 mV. GABA and DPP were applied for 20-30 s (until peak current). Perfusion with a modified Ringer's was set at 5 ml/min, with drugs washed out 3-5min between applications. DPP currents were reported as the % maximum as measured by 1 mM GABA. DPP concentrations ranged from pM to μM. Dose response curves were fit to one or two site models, varying the slope; the best fit is reported. At α1β2 receptors, in the absence of GABA, DPP was a strong $GABA_A$ agonist, able to induce up to 98% of maximal current with an EC_{50} of 0.18 pM. However, higher concentrations of DPP (still no GABA) inhibited its own current, down to 24% of maximal GABA current, with an IC_{50} of 7.8 nM. At α1β2γ2s receptors, DPP alone induced current to about 60% of maximal, with a similar pM EC_{50} as the α1β2 receptors. DPP did not cause any significant antagonism of its own currents in the α1β2γ2s receptors. We conclude that DPP is a

high affinity $GABA_A$ agonist with potential antagonistic actions depending on the receptor subunit composition. These results may explain some of the side effects, such as drowsiness, of many commercially available antihistamines.

Title: Acute and chronic itch are suppressed by positive allosteric modulators of α2- and α3-$GABA_A$ receptors

Authors: *W. T. RALVENIUS[1], D. BENKE[1], M. PAGANI[1], H. JOHANNSSEN[1], U. RUDOLPH[2], H. U. ZEILHOFER[1,3];
[1]Inst. of Pharmacol. and Toxicology, Univ. Zürich, Zürich, Switzerland; [2]Dept. of Psychiatry, Harvard Med. School., Lab. of Genet. Neuropharmacology, McLean Hosp., Boston, MA; [3]Inst. of Pharmaceut. Sciences, Swiss Federal Inst. of Technol. (ETH) Zurich, Zürich, Switzerland

Abstract: *Aim of investigation:*
Loss of inhibitory dorsal horn neurons leads to chronic pruritus in mice, while acute activation of such neurons inhibits itch. We tested the hypothesis that drugs that enhance GABAergic inhibition in the dorsal horn would reduce scratching behavior in mice.
Methods:
Behavioral tests were done in wild-type mice and in $GABA_A$ receptor triple point mutated mice in which only a single $GABA_A$ receptor subtype was left diazepam (DZP) sensitive. Acute itch was induced by intradermal cheek injection of α-methyl-serotonin, histamine or chloroquine. To assess effects on chronic itch, atopic dermatitis was induced by repeated application of oxazolone. Scratching bouts were quantified as a measure of itch. We tested the anti-pruritic effects of the classical benzodiazepine agonist DZP in triple $GABA_A$ receptor point mutated mice and of the non-sedative α2- and/or α3-$GABA_A$ receptor-preferring agents TPA023B, TP003, and N-desmethyl clobazam (NDMC) in wild-type mice.
Results:
Activation of α2- and α3-$GABA_A$ receptor in the $GABA_A$ receptor point-mutated mice reduced scratching behavior in both acute and chronic itch, while α5 $GABA_A$ receptors had only minor

effects. The α2- and α3-$GABA_A$ receptor-preferring agents TPA023B, NDMC and TP003 also reduced scratching in acute and chronic itch models. Tolerance to the anti-pruritic effects did not develop after a 10-day treatment with TPA023B or NDMC. Electrophysiological recordings in spinal cord slices demonstrated that TPA023B enhances GABAergic inhibition in gastrin releasing peptide (GRP) positive dorsal neurons, which are known to be required for the relay of pruritogenic signals within the spinal cord. Finally, we show that the spinal expression patterns of MrgprA3 and GRP, markers of primary and secondary pruritoceptors, overlap with those of α2-and α3-$GABA_A$ receptors. No such co-expression was seen for α1-and α5-$GABA_A$ receptors.
Conclusion:
Our findings suggest that α2- and α3-$GABA_A$ receptors are promising targets for the development of novel antipruritic agents.

Title: De novo GABRB3 mutations disrupt $GABA_A$ receptor gating and expression and lead to Early Infantile Epileptic Encephalopathy

Authors: *C. C. HERNANDEZ[1,2], Y. ZHANG[3], N. HU[2], D. SHEN[4], W. SHEN[2], X. LIU[3], W. KONG[3], Y. JIANG[3], R. MACDONALD[2];

Abstract: *De novo* mutations in the γ-aminobutyric acid type A ($GABA_A$) receptor β3 subunit gene *GABRB3* were found in three cases, two heterozygous and one mosaic, with early infantile epileptic encephalopathy (EIEE) (Zhang Y, et al. 2015). We determined the impact of *GABRB3* mutations on $GABA_A$ receptor function and biogenesis. $GABA_A$ receptor α1 and γ2L subunits were co-expressed with wild-type and mutant β3 subunits in HEK 293T cells. Currents were measured using whole cell and single channel patch clamp techniques. Surface expression was determined using surface biotinylation and confocal microscopy. Potential structural

perturbations in mutant $GABA_A$ receptors were explored using structural simulations. We found that the EEIE-associated *GABRB3*(L170R), *GABRB3*(T288N), and *GABRB3*(A305V) mutations located along the axis between the N-terminal domain and the channel pore reduced whole cell currents by decreasing the gating of the receptor. $GABA_A$ receptors containing different mutant β3 subunits had reduced cell surface expression at different levels but without total loss of surface receptors. In addition, structural simulations predicted mutation-induced rearrangements of neighboring subunits that may underlie both assembly and channel kinetic defects of $GABA_A$ receptors, which may contribute to the pathogenesis of EEIE. Although it is difficult to predict what effect a mosaic mutation would have, our results suggest that the impact on $GABA_A$ receptors function is comparable to that of heterozygous *GABRB3* mutations. Title: Functional properties of GABArho receptors from cerebellar astrocytes

Authors: *A. PÉTRIZ[1], D. REYES-HARO[2], M. GONZÁLEZ-GONZÁLEZ[2], R. MILEDI[2], A. MARTÍNEZ-TORRES[2];
[1]Univ. Nacional Autónoma De México-Instituto, Queretaro, Mexico; [2]Cell. and Mol. Neurobio., Univ. Nacional Autónoma De México-INB, Queretaro, Mexico

Abstract: The cerebellum plays a fundamental role in fine motor control, mainly due to GABAergic neurotransmission. Differential distribution of distinct types of GABA receptors at cerebellar inhibitory synapses has been reported and seems to contribute to specific function at each type of synapses (synaptic or extrasynaptic), due to their peculiar characteristics. As neurons, glial cells express a plethora of $GABA_A$ receptor subunits.
In the present work, we assessed the expression of $GABA_A$ receptors which comprised the GABAρ subunits in $GFAP^+$ cells located in the roof of the fourth ventricle and in the granular

layer of cerebellum during early postnatal development. Immunofluorescence revealed the presence of GABAρ in $GFAP^+$ cells during postnatal development, in contrast, expression in the adult was restricted to Purkinje neurons and a subset of ependymal glial cells.
Astrocytes from cerebellum express functional $GABA_A$ which are inhibited by bicuculline (100 μM) and TPMPA (IC50, 5.9 ± 0.6 μM), indicating the presence of a GABAρ component. GABAρ subunits are assembled as homo- or heteropentamers. Co-immunoprecipitation and double immunofluorescence demonstrated protein–protein interactions between GABAρ1 and GABAα1 in the plasma membrane. Three populations of $GABA_A$ receptors in astrocytes were identified: 1) classic $GABA_A$, 2) bicuculline-insensitive GABAρ, and 3) $GABA_A$–GABAρ hybrids. Clusters of $GABA_A$ receptors were distributed in the perinuclear space and along the processes of $GFAP^+$ cells. Time-lapse microscopy showed clusters of GABAρ2-GFP were relatively immobile, with mean displacement of 9.4 ± 0.9 μm (in 30 min) and a net distance traveled of 1–2 μm (in 30 min), due mainly to diffusion directional movement or simple diffusion. Modulation of GABAρ dynamics may be a novel mechanism of extrasynaptic transmission regulating GABAergic control of $GFAP^+$ cells during early postnatal development. The relative low mobility of GABAρ2 in astrocytes together with the distribution of endoplasmic reticulum in the processes suggested the possibility of the presence of ribosomes in this space; thus we labeled the ribosomal binding proteins RpL29 and RpS5 with fluorescent tags and explored their distribution in $GFAP^+$ of cerebellum maintained in organotypic culture. We detected abundant label of both proteins in distal processes of $GFAP^+$, moreover we found all along the processes co-localization of ribosomal proteins with the endoplasmic reticulum, suggesting the possibility that synthesis of proteins may occur in these sites. Therefore, the local protein synthesis may be the mechanism by which glial cells dynamically modulate at the synapsis.

Title: Human peripheral blood mononuclear cells (PBMCs) express receptors for the neurotransmitters GABA and Glutamate

Authors: *A. BHANDAGE[1], C. HELLGREN[2], Z. JIN[1], S. KOROL[1], E. OLAFSSON[1], I. SUNDSTRÖM[2], B. BIRNIR[1];
[1]Dept. of Neuroscience, Uppsala Univ., Uppsala, Sweden; [2]Dept. of Women's and Children's Hlth., Uppsala Univ., Uppsala, Sweden

Abstract: Background: Usually neurotransmitter signalling is associated with the central nervous system (CNS). But the evidence for neurotransmitter signalling outside of the CNS is increasing. It takes place in cells of the immune system where immune cells can secrete neurotransmitters and do often express neurotransmitter receptors (1). Immune cells can also encounter neurotransmitters while travelling throughout the body. Thus, neurotransmitter signalling may have an important role in immune functions.
Aim: We examined if human peripheral blood mononuclear cells (PBMCs) can express receptors activated by GABA or glutamate and if their expression is influence by physiological conditions such as gender, pregnancy and depression.
Materials and Methods: The PBMCs were isolated by density gradient centrifugation of the EDTA blood. The mRNA expression of all subunits of GABA-A (19 subunits), GABA-B (2 subunits), ionotropic glutamate (18 subunits) receptor (iGluR) and 6 chloride transporters in the PBMCs was accessed by real time RT-qPCR and compared in four experimental groups: men, non-pregnant women, healthy pregnant women and depressed pregnant women.
Results: Most of the GABA-A and iGlu receptor subunit mRNAs were expressed in the PBMCs. Out of those, the GABA-A rho2, GluK4, GluK5, GluN2C and GluN2D subunits had higher expression level than other subunits. In pregnant women, the GABA-A delta and rho2 subunits were upregulated while in depressed pregnant women, the beta1 and epsilon subunits expression were altered (2). In depressed pregnant women, the GABA-B1 was up-regulated (2). The cotransporters NKCC1 and KCC4 were down-regulated in all pregnant women (2). Similar to GABA-A and GABA-B receptor subunits, the expression of specific iGlu receptor subunits was changed by pregnancy and depression.
Conclusions: The results are consistent with the immunomodulation of PBMCs by the neurotransmitters GABA and Glutamate and their receptors. The human PBMCs differentially express neurotransmitter receptors subunits and chloride transporters that are modified by gender, pregnancy and depression. The results indicate that cross-talk is taking place between the nervous and the immune system.

Title: Metabolic hormones modulate GABA-A receptors mediated synaptic and tonic currents in rat hippocampal and amygdala neurons.

Authors: *B. BIRNIR, S. V. KOROL, O. BABATEEN, Z. JIN;
Dept. of Neurosci., Uppsala Univ., Uppsala, Sweden

Abstract: INTRODUCTION. The inhibitory neurotransmitter GABA (gamma-aminobutyric acid) activates GABA-A receptors generating phasic and tonic inhibition in neurons and regulates neuronal networks activity. Glucagon-like peptide-1 (GLP-1) is a gut hormone that promotes insulin secretion in a glucose-dependent manner. Interestingly, GLP-1 and insulin receptors are found in many brain regions. We studied how GLP-1 and its analogs plus insulin affected inhibitory synaptic and tonic currents in hippocampal pyramidal neurons and amygdala neurons.
METHODS. Brain slices from Wistar rats and whole-cell patch-clamp were used to record GABA-A receptors mediated currents in the hippocampal and amygdala neurons. Quantitative RT-PCR was run on samples from rat brain samples. Immunohistochemistry was used to identify the receptors in the brain slices.
RESULTS. GLP-1 and its mimetics transiently enhanced amplitudes and frequency of spontaneous inhibitory postsynaptic currents (sIPSCs) and enhanced inhibitory tonic current in CA3 neurons. Insulin enhanced GABA-A mediated tonic conductance in hippocampal CA1 neurons. The GLP-1 and insulin receptors mRNAs and proteins were detected in the hippocampal and amygdala samples. In amygdala neurons, acute application of insulin increased GABA-A mediated synaptic currents and reduced the action potential firing frequency.
CONCLUSIONS. Our results show that GLP-1 and insulin enhance sIPSCs and extrasynaptic GABA-A receptors in hippocampal and amygdala neurons demonstrating that metabolic hormones influence function of these brain structures.

Title: Neonatal estradiol exposure to female rats changes $GABA_A$ receptor expression and function during adulthood

Authors: *P. PORCU[1], A. LOCCI[2], G. TALANI[1], E. SANNA[1,2], A. CONCAS[1,2];
[1]Neurosci. Inst., Natl. Res. Council of Italy (CNR), Monserrato, Italy; [2]Dept. of Life and Envrn. Sci., Univ. of Cagliari, Cagliari, Italy

Abstract: Exposure of developing female rats to estradiol during the perinatal period affects brain sexual differentiation and induces a long-lasting dysregulation of the gonadal axis with decreased progesterone secretion, and a persistent reduction in brain concentrations of its neuroactive metabolite allopregnanolone. Given that allopregnanolone is a potent modulator of $GABA_A$ receptor ($GABA_AR$) expression and function, we evaluated whether neonatal estradiol treatment, alters $GABA_AR$ expression and function in the hippocampus of adult female rats.
On the day of birth, pups received a single administration of β-estradiol 3-benzoate (EB; 10 μg in 50 μl of sesame oil, s.c.) or vehicle. Experiments were performed in 90-120 days old rats. Given that $GABA_AR$ subunit expression varies in response to steroid fluctuations that occur during the estrus cycle, vehicle-treated rats in the proestrus and diestrus 1 phases were used as controls. Neonatal EB treatment increased the abundance of extrasynaptic α4 (+47%) and δ (+30%) subunits ($p<0.05$), and decreased the abundance of synaptic α1 (-36%), α4 (-32%), and γ2 (-36%) subunits ($p<0.05$), compared to vehicle-treated rats in proestrus. Plasma allopregnanolone levels in the same rats were higher in diestrus 1 vehicle-treated rats vs. proestrus ones (+30%, $p<0.05$), and were decreased by neonatal EB treatment compared to vehicle-treated rats in proestrus (-69%, $p<0.001$) and diestrus 1 (-76%, $p<0.001$). Modulation of GABAergic tonic currents recorded in DG granule cells was increased in EB-treated rats and vehicle-treated rats in diestrus 1, compared to vehicle-treated rats in proestrus, with a THIP-induced larger shift in holding current and greater increase in the noise variance ($p<0.05$). EB treatment also altered GABAergic phasic currents with a decrease in decay time ($p<0.05$).
The changes in the expression and function of $GABA_ARs$, induced by neonatal EB treatment, may not be related to the fluctuations in allopregnanolone concentrations, given that vehicle-treated rats in diestrus, which have opposite neurosteroid levels than EB-treated rats, show the same functional changes in $GABA_ARs$ as EB-treated rats. Rather, these changes may represent a compensatory mechanism to counteract the persistent long-term reduction in allopregnanolone

concentrations, induced by neonatal estradiol treatment. These enduring changes in $GABA_AR$ plasticity may be relevant for regulation of neuronal excitability in the hippocampus and for the etiology of psychiatric disorders that originate in development and show sex differences.

Title: Novel, simplified $GABA_A$ receptor modulators based on the scaffold of Valerenic acid and derived from a ligand-based pharmacophore model

Authors: *M. J. STADLER[1], G. PARISI[2], S. MONTICELLI[2], D. LUGER[1], W. HOLZER[2], T. SEIDEL[2], C. SCHWARZER[3], V. PACE[2], T. LANGER[2], S. HERING[1];
[1]Pharmacol. and Toxicology, Univ. of Vienna, Wien, Austria; [2]Pharmaceut. Chem., Univ. of Vienna, Vienna, Austria; [3]Med. Univ. Innsbruck, Innsbruck, Austria

Abstract: Valerenic acid (VA) is a major constituent of common *Valerian, a prevalently used herbal medicinal plant* that selectively modulates $GABA_A$ receptors comprising β_2 or β_3 subunits. VA's anxiolytic and anticonvulsive properties without concomitant sedation combined with a promising pharmacokinetic profile make this compound an interesting drug candidate [1, 2]. The aims of this study were the synthesis of simplified molecules maintaining subunit-selective properties based on the VA scaffold and their *in vitro* and *in vivo* characterization.
A pharmacophore model based on the known $\beta_{2/3}$ subunit-selective $GABA_A$ modulators VA, loreclezole, etomidate, suggested a series of novel VA analogues. Their effect on GABA-induced chloride currents (I_{GABA}) through $GABA_A$ receptors composed of $\alpha_1\beta_{1\text{-}3}\gamma_{2S}$ subunits expressed in *Xenopus laevis* oocytes was analysed by means of the two-microelectrode voltage clamp technique. Pentylenetetrazole-tests (PTZ) were performed to investigate potentially anticonvulsant activity.
Efficacy of I_{GABA} enhancement by derivatives AR-013, AR-016, SM-226-1 and SM-392-1 was comparable to that of VA, while slightly reduced potency was observed. Compound SM-408-2 diplayed selectivity for $GABA_A$ receptor containing β_2 or β_3 subunits and was significantly more potent and efficient than VA. PTZ-induced seizure threshold was shifted by SM-408-2 at

concentrations of 0.1 mg/kg bodyweight indicating potent anticonvulsant activity. The other studied compounds were either less efficacious or did not display significant potentiation of I_{GABA} at concentrations ≥30 μM.
Our data suggest that pharmacophore based development of $\beta_{2/3}$-selective VA analogs may be a promising approach for development of non-sedating anxiolytics and anticonvulsants. SM-408-2 displayed higher in vitro and in vivo potency than VA and may thus serve as a scaffold for the development of novel, selective $GABA_A$ receptor modulators.

Title: Elucidating putative binding site for THIP on α4-containing receptors

Authors: ***L. Y. HARTIADI**, N. ABSALOM, H. J. LEE, P. K. AHRING, M. CHEBIB;
Fac. of Pharm., The Univ. of Sydney, Sydney, Australia

Abstract: 4,5,6,7-tetrahydroisoxazolo (5,4-c)-pyridine-3-(ol) (THIP) is a $GABA_A$ receptor agonist that displays 'superagonism' on δ-containing receptors and partial agonism on γ-containing receptors. Radioligand binding studies have shown that THIP competes with GABA, indicating that THIP binds to the same site as GABA. However, the selectivity of THIP on δ-containing receptors over γ-containing receptors remains elusive. It is believed that the δ subunit replaces the γ subunit to form a stoichiometry of β-α-β-α-δ. We hypothesize that there is an additional binding site for THIP that resides on the interface of α4-δ and that this site confers THIP sensitivity for δ-containing receptors.
In this study, THIP activation on α4β1-3δ and α4β1-3 $GABA_A$ receptors expressed in *Xenopus laevis* oocytes were compared using two-electrode voltage clamp electrophysiology. To further determine where THIP binds, mutations on α4 principal site were generated and their effects

towards GABA and THIP on α4β2δ and α4β2 receptors were studied.
THIP potency at α4β2-3δ and α4β2-3 was similar while THIP was more potent at α4β1δ compare to α4β1. THIP acted as a superagonist on all of the receptors, except for α4β1 where THIP displayed full agonism. Although there were no changes to the GABA concentration-response curves for the mutants, a significant change on the efficacy of THIP was observed for all receptors. The amino acids tested in the experiments contribute in part to the efficacy of THIP at α4-containing receptors.

Abstract: Previously, we found that a patient with intractable motor tic disorder was responsive to the ground leaf juice of a local herb, *Clerodendrum inerme* (*CI*). Her tics subsided 1 hour after

taking *CI*.[1] Using methamphetamine-induced hyperlocomotion (MIH)[2] and impairment of prepulse inhibition of acoustic startle response (PPI) in mice, we identified an active *CI* constituent, hispidulin. It is a flavonoid reported to be a positive allosteric modulator (PAM) of $GABA_A$ receptors consisting of various α subunits, including the α6 subunit ($\alpha6GABA_AR$) that mainly exists in cerebellar granule cells. In a screening assay for 92 neurotransmitter receptors/degradation enzymes/transporters, we found hispidulin displayed significant (>50% at 10 μM)) binding affinity only at $GABA_ARs$ ($IC_{50:}$ 0.73~1.78 μM) and catecholamine-o-methyl-transferase (COMT) ($IC_{50:}$ 1.32 μM). We further elucidated whether COMT and cerebellar $\alpha6GABA_ARs$ are action targets of hispidulin for its alleviation of MIH and PPI impairment. Hispidulin given by either *i.p* (10-30 mg/kg) or intra-cerebellar (*i.c.b.*, 10 nmol) injection, significantly alleviated MIH and PPI impairment. The *i.c.b.* effect of hispidulin was prevented by *i.c.b.* furosemide, a non-competitive $\alpha6GABA_AR$ antagonist, and was mimicked by *i.c.b.* Ro 15-4513, a $\alpha6GABA_AR$ PAM, but not by *i.c.b.* diazepam, an $\alpha6GABA_AR$-inactive benzodiazepine. Conversely, *i.cb.* diazepam did not affect MIH or PPI impairment, while it reduced MIH when given systemically at doses (4-10 mg/kg, *i.p.*) having significant benzodiazepine adverse effects, including sedation, anxiolysis and motor-impairment. Hispidulin at systemic doses effectively alleviated MIH did not affect apomorphine-induced hypolocomotion and stereotypy behaviors. A typical COMT inhibitor, OR-482 (10 mg/kg. *i.p.*), did not affect MIH. These results suggest that hispidulin alleviates MIH and PPI impairment in mice via acting as a PAM of cerebellar α_6GABA_ARs. This study also suggests the potential for using selective α_6GABA_AR PAMs as a novel treatment for neuropsychiatric disorders with sensorimotor gating deficit.

Abstract: Previously, we found that hispidulin, a constituent of a local herb that effectively remitted tic attacks in a patient with intractable motor tic disorders, significantly alleviates methamphetamine-induced hyperlocomotion (MIH) and impairment of prepulse inhibition of acoustic startle response (PPI), via acting as a positive allosteric modulator (PAM) of cerebellar α6 subunit-containing $GABA_A$ receptors (α6$GABA_A$Rs).[1] Since hispidulin is also a PAM of other $GABA_A$Rs, here we used Compound 6, a newly developed PAM selective for α6$GABA_A$Rs[2] as a tool to examine the role of cerebellar α6$GABA_A$Rs in animal models mimicking Tourette syndrome (TS) and other neuropsychiatric disorders with sensorimotor gating deficit. These include MIH and PPI impairment, apomorphine-induced climbing behaviors, and stereotypy behaviors induced by intra-dorsal striatal injection of the siRNA of SlitTrk. The latter a TS model we established[3] based on the findings that SliTrk is only expressed in adult striatal cholinergic interneurons that are reduced in postmortem brains of TS subjects. Compound 6 (10 mg/kg, *i.p.*) significantly alleviated MIH and PPI impairment. These effects were antagonized by intra-cerebellum microinjection of furosemide, a selective α6$GABA_A$R antagonist. Compound 6 did not affect apomorphine-induced stereotypy climbing behaviors, but significantly reduced the stereotypy behaviors in mice induced by siRNA of SlitTrk. At the same dose, Compound 6 has no motor-impairing, sedative or anxiolytic activity. These results suggest that Compound 6 successfully gets into the brain to alleviate MIH and PPI impairment possibly via enhancing cerebellar inhibitory control on the striatal dopaminergic activity through positively modulating α6GABAARs in cerebellar granule cells, but not affect dopamine receptor response directly. Cerebellar α6GABAARs may be a new target for the treatment of TS or neuropsychiatric disorders with sensorimotor gating deficit, and α6$GABA_A$R selective PAMs may be a novel therapy for these neuropsychiatric disorders.

Title: Neurosteroids selectively disinhibit the cortex and facilitate cortical spreading depression.

Authors: *A. PARGA[1,2], S. VENUGOPAL[2], T. ANDERSON[2];
[1]Univ. of Arizona, Phoenix, AZ; [2]Univ. of Arizona - Col. of Med. - Phoenix, Phoenix, AZ

Abstract: Migraine is one of the most common neurological disorders occurring in 20% of women and 6% of men. While the underlying cause of migraine remains unknown, a key finding is that the brains of migraine patients are hyperexcitable. Cortical inhibition mediated by GABAergic interneurons is thought to play an important role in regulating brain excitability and the development of cortical spreading depression (CSD). CSD is a neurological process that underlies migraine aura and can lead to activation of the migraine pain pathway. Neurosteroids are brain-derived hormones which can be directly synthesized de-novo within individual neurons and glia and are potent allosteric modulators of GABA-A receptors. Frequent triggers of migraine including stress, diet, the menstrual cycle and pregnancy are known to increase neurosteroid levels. The aim of this study was to examine the role of neurosteroids, such as allopregnanolone, on migraine using an *in-vitro* model of CSD. Using a combined intrinsic optical imaging (IOS) and patch-clamp electrophysiology approach we determined that application of endogenous and synthetic neurosteroids paradoxically increases the probability of inducing CSD by up to 40%. This was in contrast to the GABA-A delta specific agonist THIP (gaboxadol) which failed to increase the probability of inducing CSD. To investigate the underlying mechanism we performed a detailed analysis of the action of neurosteroids on inhibitory cortical synaptic neurotransmission. We found that in contrast to THIP, neurosteroids preferentially act to increase phasic and tonic inhibition onto inhibitory interneurons while

decreasing inhibition onto excitatory pyramidal neurons. These results suggest neurosteroids facilitate CSD by selectively disinhibiting the cortex which may increase the incidence of attacks of migraine with aura.

Title: Different Benzodiazepines seem to interact differently with $GABA_A$ receptors

Authors: *P. SCHOLZE[1], A. A. ELGARF[1], F. STEUDLE[1], G. LI[2], J. M. COOK[2], M. ERNST[1]; [1]Med. Univ. Vienna, Vienna, Austria; [2]Dept. of Chem. and Biochem., Univ. of Milwaukee, Milwaukee, WI

Abstract: Gamma-Aminobutyric acid (GABA) is the main inhibitory neurotransmitter in the central nervous system. $GABA_A$ receptors exist in an enormous diversity of subtypes. Six α, three β, three γ, the δ, ε, θ, π, and three ρ subunits can, and most of them actually do, assemble into a multitude of different homo- or hetero-pentameric receptors, each of them displaying unique pharmacological properties. Selective modulation of $GABA_A$ receptors containing the α5 subunit is believed to have considerable therapeutic potential in several psychiatric and neurological conditions characterized by cognitive dysfunction.
Some α5-preferring (selective) compounds have already been identified, such as the chiral imidazobenzodiazepine SH-053-2'F-R-CH3 (Gallos et al., 2015) and other structurally similar compounds.
Aim of the current study was to compare the binding affinities and electrophysiological efficacies of several different benzodiazepines; all of them structural variations of well-known compounds and predicted to be potentially α5-selective. Efficacies were tested using two-electrode voltage clamp recordings in rat recombinant $GABA_A$-R subtypes expressed in Xenopus

oocytes. Potencies were investigated by inhibiting [3H]flunitrazepam binding to human kidney 293 cells, transiently transfected with expression plasmids coding for different $GABA_A$-R subunits.
Surprisingly, results indicated that benzodiazepine-derivatives with similar chemical modifications showed dissimilar trends for their efficacies, affinities and "α5-selectivity". Specifically, comparing chiral derivatives (R-, S-methyl isomers) showed slight differences for some compounds, while for another compound one enantiomer had a greatly reduced activity and binding affinity compared to the other enantiomer. Accordingly, this suggests that some compounds interact differently with the $GABA_A$-receptor binding pocket than others and stimulates further interest for better understanding the structure binding relationship between various ligands and their binding sites on different $GABA_A$-R subtypes.

Title: Investigations into the pharmacology and physiology of gabaergic neurotransmission in planaria.

Authors: *L. RAMAKRISHNAN;
Chem., St. Cloud State Univ., Saint Cloud, MN

Abstract: Planaria (flatworms) belonging to the phylum Platyhelminthes, possess a mammalian-like bilaterally symmetric nervous system and all major neurotransmitters. Though the presence of GABA and its metabolic enzymes in the nervous system of planaria are proven, its pharmacological and physiological actions remain poorly understood due to *lack of direct evidences supporting the presence of specific GABA-binding receptor proteins*. Planarians exhibit seizure-like movements (pSLM), defined as asynchronous paroxysms (e.g. C-like movements, twitching behaviors), after being exposed to pro-convulsants such as, glutamatergic

agonists or GABAergic antagonists. We characterized pharmacological alteration of GABAergic neurotransmission in planaria using Picrotoxin (PTX), a classical convulsant that acts exclusively on GABAergic neurotransmission. We also conducted behavioral pSLM testing of four potential anticonvulsant drugs, which have been previously tested in rat and mice epilepsy models. The chosen drugs, which are structurally related in terms of having a lactam functional group, are: 2-phenylbutyramide (2-PBA), N-carbamoyl-2-phenylbutyramide (NC-2PBA), 3-ethyl-3-phenylpyrrolidin-2-one (3-EPPD) and 3-methyl-3-phenylpyrrolidine-2,5-dione (3-MPPD). The results from the screenings demonstrated potential anticonvulsant activity by 2-PBA and NC-2PBA but not by 3-EPPD and 3-MPPD. Further testing of 2-PBA up to a maximal concentration of 1 mM demonstrated 50-60% alleviation of 5 mM picrotoxin-induced pSLM activity. To investigate expression and localization of GABAergic proteins in planarian nervous system, we plan to conduct glutamate decarboxylase and GABAergic protein gene silencing using siRNAs which will be delivered using alanine-based cationic polymer nanoparticles. We have conducted proof of concept studies in HEK293 cells expressing GFP, wherein GFP gene silencing was induced by delivering siRNA targeting GFP mRNA was delivered using cationic polymer nanoparticles.

Title: Developmental characterization of intrinsic physiology and inhibitory regulation of Dentate Semilunar Granule Cells.

Authors: *A. GUPTA[1,1], B. SWIETEK[1], J. GUEVARRA[1], Y. SHAH[2], V. SANTHAKUMAR[1]; [1]Rutgers, Newark, NJ; [2]The Col. of New Jersey, Ewing, NJ

Abstract: Semilunar granule cells (SGCs) are a class of excitatory dentate projection neurons distinguished from the classical granule cells (GCs) by their somato-dendritic morphology and intrinsic physiology. In young adult 30-40 day rats, SGCs have greater synaptic and extrasynaptic (tonic) GABAergic inhibition than GCs. This study was conducted to identify

whether SGCs are anatomically and physiologically distinct from GCs regardless of animal age and to determine the developmental changes in intrinsic physiology and inhibitory regulation of SGCs during early life. Acute hippocampal slices from 11-150 postnatal day (PD) male Wistar rats particularly at two early developmental time points: late neonatal (PD11-13) and adolescent (PD28-42) were used to obtain whole cell recordings from SGCs in the inner molecular layer and GCs. Current and voltage clamp recordings were used to record intrinsic physiology and spontaneous inhibitory synaptic currents (sIPSCs). Tonic GABA currents were measured as the baseline current is blocked by Gabazine (10 μM). All recorded cells were filled with biocytin and processed to distinguish SGCs by the semilunar shape of the soma in the inner molecular layer and wide dendritic arbors compared to GCs. Morphological reconstructions revealed SGCs with greater dendritic angle than GCs in sections from PD11-150 rats. SGC firing rate (120pA-200pA) was significantly higher in late neonatal than adolescents. Although input resistance was not different between the two groups, the membrane sag in response to hyperpolarizing current injection was significantly higher in late neonatal rats compared to adolescent rats suggesting reduction in SGC H-currents during development. Analysis of synaptic currents revealed that sIPSC frequency in SGCs was consistently higher than in GCs from age-matched rats. Frequency of sIPSCs in SGCs and GCs was significantly higher in adolescent rats. Tonic GABA current amplitude in SGCs was also significantly greater than in GCs in adolescent rats. However, in keeping with developmental expression of tonic GABA currents in other cell types, tonic GABA currents amplitude was low and not different between SGCs and GCs in late neonatal rats. These data demonstrate that SGCs are distinct from GCs in morphology and inhibitory synaptic inputs from early in development. We speculate that complementary changes in H-currents and tonic GABA currents may underlie the relative stability of SGC input resistance during development.

Title: The role of neurosteroid-delta-GABAR interaction in epileptogenesis

Authors: *S. JOSHI[1], K. RAJASEKARAN[3], J. WILLIAMSON[2], J. KAPUR[2];
[1]Dept of Neurol., [2]Univ. of Virginia, Charlottesville, VA; [3]Univ. of Texas, Dallas, VA

Abstract: We determined the role of neurosteroid-δ subunit-containing GABAA receptor (δ-GABAR) interaction in epileptogenesis following statue epilepticus (SE).
SE was induced in adult rats by lithium-pilocarpine. The surface expression of δ-GABARs was determined using biotinylation assay and Western blotting. The neurosteroid modulation of tonic current was studied by whole cell patch clamp technique. The GABAR subunit mRNA expression was determined by real-time PCR. The time course of onset of spontaneous seizures following SE was studied by continuous video-EEG monitoring.
We compared the time course of changes in δ, α4 and γ2 subunit expression following SE to onset of epilepsy, marked by the 2nd spontaneous seizure, which ranged between 7-18 days. There was a specific and early down-regulation of δ-GABAR expression before the animals became epileptic. The total and surface expression of δ subunit was reduced in hippocampi of 7 days post-SE (7-SE) animals. In contrast, the expression of α4 and γ2 subunits was unchanged at this time. The expression of mRNAs of these subunits matched with the expression of their proteins. The reduction in δ-GABAR expression as accompanied by diminished neurosteroid modulation of tonic current of DGCs in 7-SE animals.
We tested the effect of inhibition of neurosteroid synthesis on the onset of epilepsy. Animals were treated with finasteride at 4 days post-SE prior to the appearance of spontaneous seizures. Finasteride-treated animals (86%) experienced seizures; however, seizures did not occur in vehicle-treated or untreated animals. Finasteride treatment also accelerated the onset of epilepsy, 2nd spontaneous seizure. The time to 2nd spontaneous seizure ranged from 5-8 days in finasteride-treated animals, which was significantly shorter than that in vehicle-treated or untreated animals (7-18 days).
Next, we prevented the down-regulation of δ-GABAR expression and determined whether it suppressed epileptogenesis. NMDAR blockade with MK801 or ketamine during SE prevented the reduction in reduction in δ subunit mRNA and protein expression, without terminating or shortening the duration of SE. The neurosteroid modulation of tonic current of DGCs was also preserved in MK801- or ketamine-treated animals. Lastly, MK801 treated animals did not develop epilepsy during 30 days post-SE monitoring, whereas only a fraction of ketamine-treated animals became epileptic.
These studies revealed that reducing neurosteroid synthesis prior to seizure onset hastened epileptogenesis and suppression of δ-GABAR downregulation inhibited epileptogenesis.

Title: Modulation of inhibitory receptors by non-psychoactive cannabinoids

Authors: J. ASSIS MANUEL[1], R. A. GRAY[2], T. D. M. HILL[2], A. J. RUIZ[1], *R. J. HARVEY[1]; [1]UCL Sch. of Pharm., London, United Kingdom; [2]GW Res. Ltd, Cambridge, United Kingdom

Abstract: Glycine and type A γ-aminobutyric acid receptors (GlyRs and $GABA_A$Rs) are ligand-gated ion channels that mediate fast inhibitory neurotransmission in the nervous system. Direct modulation of GlyRs and $GABA_A$Rs by a number of cannabinoids has been previously described. However, the direct effect of cannabidiol (CBD) and cannabidivarin (CBDV) on these receptors has not yet been studied in depth. To further interrogate the effect of CBD and CBDV on glycinergic and GABAergic systems, we examined the affinity of CBD and CBDV for $GABA_A$R ligand, benzodiazepine, Cl^- channel and GABA transporter binding sites by radioligand binding and used whole-cell patch-clamp recordings to examine the effect of CBD and CBDV on Cl^- conductance mediated by transiently expressed GlyR and $GABA_A$Rs. Radioligand binding reveals that CBD and CBDV possess no appreciable affinity for the $GABA_A$R ligand or benzodiazepine binding sites (displacement of [^{3}H]muscimol or [^{3}H]diazepam) or the GABA transporter at concentrations up to 10μM. However, both CBD (IC_{50} 2.57 μM) and CBDV (IC_{50} 2.47 μM) displaced specific binding of [^{3}H]picrotoxinin from the $GABA_A$R Cl^- channel. Electrophysiological examinations reveal a direct positive enhancing effect of CBD and CBDV on glycine and GABA mediated Cl^- currents (I_{Gly} and I_{GABA}). Furthermore, the extent of I_{Gly} and I_{GABA} potentiation is dependent on the receptor subunit composition: Cl^- currents mediated by GlyR α3S and $GABA_A$Rs containing α1 and α2 subunits show the greatest potentiation. These findings uncover subtype-specific modulation of inhibitory receptors by CBD and CBDV, offering new opportunities for therapeutic intervention in the nervous system.

Title: Electrophysiological and behavioral characterization of a genetic mouse model of diminished synaptic inhibition in the spinal dorsal horn

Authors: *L. TUDEAU[1,2], W. T. RALVENIUS[1], M. POE[3], J. M. COOK[3], H. C. JOHANNSSEN[1], H. U. ZEILHOFER[1,2];

Abstract: Diminished synaptic inhibition in the superficial dorsal horn is believed to underlie several chronic pain syndromes. Here, we describe electrophysiological and behavioral changes in a genetic mouse model of diminished spinal synaptic inhibition, i.e. in mice that lack a major $GABA_A$ receptor ($GABA_AR$) α subunit (α2) from the spinal cord and the spinal terminals of peripheral sensory neurons (hoxb8-gabra2$^{-/-}$ mice). We first characterized changes in GABAergic inhibition in the superficial dorsal horn where α2$GABA_ARs$ are abundantly expressed. These experiments were done on a vGAT::ChR2 transgenic background to allow optogenetic activation of inhibitory neurons in spinal cord slices. In hoxb8-gabra2$^{-/-}$ mice, light-evoked GABAergic IPSC amplitudes were reduced by about half ($p = 0.017$) with no significant change in decay kinetics. Despite the reduction in synaptic inhibition, hoxb8-gabra2$^{-/-}$ mice did not show behavioral sensitization to acute painful stimulation, suggesting the presence of a yet-to-be

identified homeostatic plasticity mechanism. Hoxb8-gabra2$^{-/-}$ mice did not only show unchanged sensitivity to acute pain but also developed normal pain sensitization in the CCI model of neuropathic pain, indicating that altered expression and posttranslational modification of α2GABA$_A$Rs are not essential for neuropathic hyperalgesia. However, the antihyperalgesic effects of systemic application of the GABA$_A$R modulator HZ-166 were virtually abolished in hoxb8-gabra2$^{-/-}$ mice, and, in line with this observation, modulation of GABAergic IPSCs by HZ-166 was strongly reduced. These results indicate that adaptive changes can compensate for diminished spinal inhibition to restore normal pain sensitivity and that, although α2GABA$_A$Rs are not required for the induction of neuropathic hyperalgesia, they are essential for the antihyperalgesic actions of the novel benzodiazepine site agonist HZ-166.

Title: Disinhibition of the HPA axis during the postpartum period induces deficits in maternal behaviors and postpartum depression-like behaviors

Authors: *J. L. MAGUIRE, A. HOOPER, L. C. MELÓN;
Neurosci., Tufts Univ. Sch. of Med., Boston, MA

Abstract: Dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis has been implicated in the pathophysiology of postpartum depression, largely based on endocrine changes in patients. However, investigation into the pathophysiological mechanisms underlying postpartum depression has been limited due to the lack of animal models. Our research team has characterized two independent mouse models which exhibit abnormal maternal care and depression-like behaviors during the postpartum period which share a common pathophysiological mechanism, involving the inability to suppress the stress-induced activation of the HPA axis during pregnancy and the postpartum period. The stress-induced activation of the HPA axis is normally suppressed during pregnancy and lactation, which is thought to be a

protective mechanism to prevent adverse effects of stress hormones on the fetus. Our lab recently discovered a critical role for the K^+/Cl^- co-transporter, KCC2, in the stress-induced regulation of the HPA axis at the level of corticotropin-releasing hormone (CRH) neurons in the paraventricular nucleus of the hypothalamus (PVN). To determine whether disinhibition of the HPA axis plays a role in mood disorders associated with the postpartum period, we generated mice which lack KCC2 specifically in CRH neurons (KCC2/Crh mice). KCC2/Crh mice exhibit the inability to suppress the HPA axis during pregnancy and the postpartum period, which is associated with an increase in pup mortality, abnormalities in maternal care, and depression-like behaviors during the postpartum period. Silencing CRH neurons governing the activity of the HPA axis using Gi DREADDs stereotaxically injected into the PVN of KCC2/Crh mice, decreases the abnormal maternal care and depression-like behaviors in postpartum KCC2/Crh mice. Conversely, activating CRH neurons in the PVN using Gq DREADDs increases pup mortality, induces abnormalities in maternal care, and depression-like behaviors in postpartum CRH-Cre mice. These data suggest that the inability to suppress the HPA axis during pregnancy and the postpartum period plays a role in postpartum depression-like behaviors and deficits in maternal care in mice.

Title: Conventional theory does not adequately explain benzodiazepine-$GABA_A$ receptor interactions

Authors: *O. MOODY[1], A. JENKINS[2];
[2]Anesthesiol., [1]Emory Univ., Atlanta, GA

Abstract: Classical benzodiazepine (BZD)-$GABA_A$ receptor ($GABA_AR$) pharmacology states that positive BZDs allosterically shift the GABA dose-response curve leftwards in a parallel manner. Potentiation (enhanced receptor activation) of $GABA_ARs$ depends on the BZD used and

the subunit composition of receptors, specifically the α and γ subunit isoforms that make up the high-affinity binding site for BZDs on $GABA_A$Rs. Using the clinically-relevant BZD, midazolam, we have shown that the degree of potentiation measured depends on the type of protocol used to expose receptors to midazolam, affecting the time course of action and decay of potentiation. We used whole-cell patch clamp recording of HEK293T cells expressing $\alpha_x\beta_2\gamma_2$ $GABA_A$Rs and exposed cells to submaximal GABA concentrations with and without midazolam (10nM-10μM). First, we found that the degree of potentiation depends on the α subunit isoform. At 1μM midazolam (in presence of EC_{10} GABA), α1-3 and α5-containing receptors showed between 200-350% enhancement of GABA current with α2/3 showing greater enhancement than α1/5 (n=5-12 cells per group). We tried several exposure protocols to get consistent, reversible midazolam potentiation before choosing a protocol that depended on exposing the receptors to GABA after midazolam exposure ended, producing a rapid onset to peak potentiation. Second, a GABA dose-response on $\alpha_1\beta_2\gamma_2$ receptors in the presence of 1μM midazolam showed a significantly smaller ($p<0.05$, t=2.395, df=21) half-maximal (EC_{50}) concentration (35.9 ± 8.3 μM) relative to the EC_{50} in the absence of midazolam (76.8 ± 17.1 μM) (mean ± SEM). The Hill coefficient was also significantly increased ($p<0.05$, t=2.533, df=21) from 1.00 to 1.435 in the presence of 1μM midazolam while the maximum peak current remained unchanged. We found that these findings are consistent with simple allosteric kinetic schemes where BZDs selectively alter the binding of each GABA molecule. Therefore, the assumption of a parallel leftward shift in the GABA dose-response curve in the presence of midazolam does not adequately explain the continued midazolam potentiation seen in the presence of GABA after midazolam exposure has been stopped unless we consider other factors like lipid partitioning, low-affinity BZD sites and the possibility that the Hill equation may misrepresent the types of concentration effects seen in our experimental data.

Title: Adolescent synaptic pruning in CA3 hippocampus is due to α4βδ gabar expression.

Authors: *J. PARATO, S. SMITH;
SUNY Downstate, Brooklyn, NY

Abstract: During puberty, synaptic pruning occurs in multiple regions of the brain, including the CA1 hippocampus (Yildrim et al., 2008; Afroz, Parato et al., 2016) and prefrontal cortex (Rakic et al. 2011). Dysregulation of pruning is linked to disorders such as schizophrenia (Glantz and Lewis, 2000) and autism (Hutsler and Zhang, 2010). Schizophrenia normally develops after puberty, indicating that adolescent pruning may be a factor. (Rolls et al., 2005; Paus et al., 2008). We have recently shown (Afroz, Parato, et al., 2016).that adolescent synaptic pruning in CA1 hippocampus is due to the emergence of α4βδ GABARs on dendritic spines. These receptors produce a shunting inhibition which impairs activation of NMDA receptors and reduces expression of Kalirin-7 (Kal7), a Rho-GEF (guanine nucleotide exchange factor) which is necessary for spine stability (Ma et al., 2011).
Another region of the brain which undergoes synaptic pruning is CA3, which is a hippocampal region that facilitates the encoding and retrieval of associations, particularly of spatial locations in rodents, and pattern separation in humans (Deuker et al., 2014). Studies have found that scavenging plays a role in pruning in CA3 (Shi et al., 2015), but the possible trigger for this process is not known.
Thus, we examined spine density using Golgi staining and assessed α4 and Kal7 levels across adolescence in the female mouse (puberty, ~PND 35, assessed by vaginal opening; post-puberty, PND 56) using immunohistochemical techniques. We found that GABAR α4 expression increases by 53% at puberty in the CA3 hippocampus ($p<.05$). Knock-out of α4 prevented the post-pubertal decrease in spine density observed in wild-type (pubertal WT, 1.6 ± 0.1 sp/μm; post-pubertal WT, 1.2 ± 0.1 sp/μm, post-pubertal α4-/-,1.6 ± 0.1 sp/μm; $p<.05$). Analysis of spine types, revealed a 48% decrease in mushroom spines ($p<.05$), an effect prevented by α4 knock-out. We also measured a 14% decrease in Kal7 levels from pre-puberty to puberty ($p<.05$), which would decrease spine stability, an outcome not seen in the α4 -/- CA3 hippocampus ($p<.05$), suggesting a mechanism for the high level of spine density in this group of animals. Our data suggest that pubertal expression of α4βδ GABARs triggers synaptic pruning in CA3 hippocampus via decreased expression of Kal7.

Title: The developmental decrease in neuronal chloride concentration is independent of slicing trauma in thalamo-cortical brain slices

Authors: *J. C. GLYKYS, K. STALEY;
Dept. of Neurol., Massachusetts Gen. Hosp., Boston, MA

Abstract: The intraneuronal chloride concentration ($[Cl^-]_i$) is critical for determining the polarity of signaling at $GABA_A$ synapses in the central nervous system. Sectioning hippocampal brain slices increases $[Cl^-]_i$ in the superficial layers. It is unknown if this same effect occurs in the neocortex and thalamus. Therefore, we aimed to study whether cutting trauma also increases $[Cl^-]_i$ in the neocortex and thalamus, and whether the effects of trauma change during development. Neuronal $[Cl^-]_i$ (Clomeleon expressing neurons) was imaged by multiphoton microscopy in acute thalamo-cortical brain slices at developmental ages ranging from post-natal day 5 (P5) to P20. We observed: 1) $[Cl^-]_i$ is higher in the most superficial areas in both neocortical and thalamic brain slices at all ages tested and, 2) there is a developmental decrease in $[Cl^-]_i$ that is independent of acute trauma caused by brain slicing. We conclude that $[Cl^-]_i$ has a developmental progression during P5-20 in both the neocortex and thalamus. However, in both brain regions and during development the neurons closest to the slicing trauma have an elevated $[Cl^-]_i$. We hypothesize that this is due to a disruption of the extracellular matrix in addition to the sectioning of neuronal processes.

Title: Characterization of neuronal chloride microdomains

Authors: *N. RAHMATI, K. J. STALEY;
Neurol., Harvard Med. Sch. & Massachusetts Gen. Hos, Boston, MA

Abstract: Chloride is a minor neuronal cytpolasmic anion whose concentration is maintained by secondary cation-chloride cotransporters. Electrophysiological estimates of cytoplasmic neuronal

chloride concentrations are notable for the variance between neurons and also between different compartments of the same neuron. Recently published and preliminary studies from investigators in our group utilizing multiphoton microscopy and transgenic chloride-sensitive fluorophores have confirmed the variance in chloride concentration varies in different brain regions (e.g. in cortical vs. subcortical neurons), different neurons, and different cytoplasmic milieus, including cell bodies, dendrites and even different segments of the same dendrites. If chloride concentrations differ in these microdomains, and this underlies the variance in electrophysiological measures of the reversal potential for $GABA_A$ receptor-mediated chloride currents (EGABA), then the local EGABA should be predictable from the fluorophore data. To test this idea, we are characterizing the chloride microdomains using both microscopic analysis of the high-sensitivity chloride fluorophore Super Clomeleon, and by simultaneous electrophysiological measures of the local EGABA in organotypic slice cultures of murine hippocampus. These studies will shed light on neuronal chloride homeostasis and the existence of functionally significant neuronal chloride microdomains.

Title: μ-opioid receptor-mediated catecholamine secretion in adrenal tissue

Authors: *L. DUNAWAY, L. SOMBERS;
Chem., North Carolina State Univ., Raleigh, NC

Abstract: The adrenal glands regulate physiological responses to stressors, in part by secretion of the catecholamines, epinephrine and norepinephrine. A variety of peptides, including opioid peptides, are thought to be co-stored with catecholamines in dense core vesicles in adrenal cells. The opioid system is strikingly complex, and the precise interaction between opioid peptides and

catecholamines is not well understood. We have used fast-scan cyclic voltammetry coupled to carbon-fiber microelectrodes to study the kinetic properties of the opioid/catecholamine interaction in a rat adrenal slice preparation. These experiments are complicated by the fact that many peptides, both endogenous and synthetic, foul the electrode surface and interfere with catecholamine detection. To address this issue, a sawhorse waveform was developed to clean the electrode surface, enabling reproducible measurements. This allows simultaneous monitoring of the application and clearance of exogenous opioid peptide (met-enkephalin or its synthetic analog DAMGO), and the effects of this manipulation on local catecholamine dynamics. We found that an acute application of M-ENK or DAMGO, which is specific to the mu opioid receptor, evokes catecholamine release that is sensitive to blockade by naltrexone, a non-selective opioid receptor antagonist. Further, these mu opioid receptor agonists facilitate nicotine-evoked catecholamine release. DPDPE, a delta opioid receptor agonist, does not elicit a physiological response. These results demonstrate that M-ENK evokes catecholamine secretion in the adrenal medulla by binding to mu opioid receptors, providing a chemical mechanism by which opioid peptides can regulate an organism's response to physiological and environmental demands.

Title: A structure-activity relationship study of the pan-opioid antagonist AT-076 reveals a kappa-selective antagonist with exceptionally high binding affinity

Authors: *E. TUAN, V. B. JOURNIGAN, N. T. ZAVERI;
Astraea Therapeut., Mountain View, CA

Abstract: The kappa opioid receptor is a $G_{i/o}$-coupled G-protein-coupled receptor that binds endogenously to the peptide dynorphin. A mounting body of evidence suggests that the receptor is involved in affective states such as pain, consciousness, stress, and mood. Interestingly, many of the receptor's effects appear to invoke opposing effects to those of the mu-opioid receptor, the receptor that classically mediates the various effects of morphine, heroin, and other addictive opioids. Along these lines, selective kappa-opioid antagonists such as JDTic have shown marked

effects at attenuating depression, anxiety, and drug-dependence in animal models and may have potential as drugs for treating these disorders. In 2015, we reported the discovery of AT-076, the first small-molecule opioid pan antagonist, which had nanomolar affinity at all four opioid receptors: mu-, delta-, kappa-, and nociceptin. AT-076 was discovered from a medicinal chemistry and structure-activity relationship (SAR) study of the common opioid antagonist core scaffold, *trans*-(3R,4R)-dimethyl-4-(3-hydroxyphenyl)piperidine, a pharmacophore that is also present in other opioid antagonists such as the kappa-selective antagonist JDTic, mu-selective antagonist LY246736 (Alvimopan), and the non-selective opioid antagonist LY255582. Unlike JDTic, however, AT-076 has high binding affinity for the nociceptin opioid receptor. We have continued to explore the SAR of this scaffold at the various opioid receptor subtypes and synthesized several AT-076 analogues. We report here the initial in vitro pharmacological characterization of these analogues. Of particular note are AT-496 and AT-501, which possess exceptionally high binding affinity for the kappa opioid receptor. Both compounds also display modest selectivity for the kappa opioid receptor, where they bind with picomolar K_i, over the mu- and nociceptin opioid receptors, where they bind with nanomolar K_i.

Title: A comprehensive brain mapping study of 77 orphan GPCRs in mouse and human brain reveals new drug targets for psychiatric disease

Authors: ***A. EHRLICH**[1,2], G. MAROTEAUX[1,2], M. OSIKOWICZ[1], E. DARCQ[1,2], A. ROBE[3], L. VENTEO[4], J. A. J. BECKER[3], B. KIEFFER[1,3,2];
[1]Douglas Res. Inst. and Hosp., Verdun, QC, Canada; [2]Psychiatry, McGill Univ., Montreal, QC, Canada; [3]Igbmc, Inst. Génétique Biologie Moléculaire Cellulaire, Illkirch, France; [4]Label Histologie, Riems, France

Abstract: G protein-coupled receptors (GPCRs), are seven transmembrane receptors that orchestrate cellular responses required for most physiological functions, making GPCRs obvious pharmacological targets for psychiatric disease. Around 140 GPCRs, are termed “orphan” receptors (oGPCRs), meaning that they have yet to be paired with a putative endogenous ligand

and/or paired with a physiological function and roughly 80 have enriched expression in the central nervous system. Thus, these oGPCRs represent an untapped resource for psychiatric drug discovery yet, a detailed *in vivo* characterization of brain oGPCRs has been lacking. Here, using two distinct methods of in situ hybridization (ISH), indirect DIG-labeled riboprobes and a direct method, RNAscope®, the neuroanatomical expression of 77 oGPCRs are examined in the mouse brain. oGPCR expression patterns were scored across 14 brain regions, and hierarchical clustering compiled the oGPCRs into a heatmap revealing three categories of expression: (1) widespread expressing oGPCRs suggest uniform roles across the brain, (2) moderate expressing oGPCRs suggest refined function in neuronal networks and (3) discrete expressing oGPCRs suggest tightly controlled roles in brain function. Further cross-species analysis of our data of the 77 oGPCRs was done with publicly available mouse and human data-sets, to find our analysis highly correlated. For 26 oGPCRs, the pattern of expression was remarkably found in brain regions with critical roles in reward and aversion pathways, sites of deficit in psychiatric disease. We next obtained human brain tissue from the Douglas Bell Canada Brain Bank for these 26 oGPCRs, total RNA was prepared from 8 control subjects across the 14 brain regions corresponding to those analyzed in the mouse and then submitted to a highly sensitive and direct method of digital gene expression analysis with the Nanostring nCounter system®. This robust analysis correlated highly with our mouse ISH data for the 26 oGPCRs, adding translational value to their unique expression profiles. Taken together, we provide the first cross-species comparison of the expression of 77 oGPCRs in the mouse and human brain, this collective exposes Gpr26, Gpr85, Gpr101, Gpr149 as novel candidates for development of new psychiatric drugs.

Title: Synaptic mechanisms of OPRM1 A118G (MOR N40D) gene variants in human neurons

Authors: *A. HALIKERE[1], J. C. MOORE[2], J. TISCHFIELD[2], R. P. HART[3], Z. P. PANG[4]; [1]Dept. of Neurosci. and Cell Biol., CHINJ, RWJMS, Rutgers Univ., New Brunswick, NJ; [2]Genet., RUCDR/Infinite Biologics, The Human Genet. Inst. of New Jersey, Dept. of Genetics, Rutgers Univ., New Brunswick, NJ; [3]Cell Biol. and Neurosci., The Human Genet. Inst. of New Jersey, Dept. of Cell Biol. and Neuroscience, Rutgers Univ., New Brunswick, NB; [4]Neurosci. and Cell Biol., Child Hlth. Inst. of New Jersey, Robert Wood Johnson Med. School, Rutgers Univ., New Brunswick, NJ

Abstract: Mu opioid receptor (MOR) signaling modulates synaptic transmission and thus plays a pivotal role in regulating reward behaviors relevant to addiction. However, the molecular and synaptic mechanisms of opioid signaling in the context of drug addiction are poorly understood. Interestingly, the single nucleotide polymorphism (SNP) rs1799971 (OPRM1 A118G) in the human MOR has been linked to impaired MOR trafficking and signal transduction and has been implicated in increased predisposition to drug abuse disorders and alcohol use disorders. The A118G SNP produces a non-synonymous amino acid substitution, replacing an asparagine with an aspartate at position 40 (MOR N40D). Although heterologous expression systems and animal studies suggest altered receptor trafficking, ligand binding affinities and altered intracellular signaling, these studies have provided largely inconclusive and even conflicting evidence regarding the cellular and molecular mechanisms of the MOR N40D SNP. To investigate the molecular, cellular, and synaptic consequences of this SNP in a human neuronal context, we derived human neurons, using the induced neuronal (iN) cell technology, from induced pluripotent stem (iPS) cell lines generated from multiple human subjects carrying either homozygous N40 or D40 alleles. Our compelling preliminary data reveal that D40 MOR iNs exhibit more potent inhibition of synaptic release following MOR activation by DAMGO ([D-Ala^2, NMe-Phe^4, Gly-ol^5]-enkephalin) when compared to N40 MOR expressing iNs. Furthermore, pre-exposure of these human neurons to DAMGO for 24 hours diminishes their sensitivity to DAMGO, possibly due to the desensitization and internalization of membrane MORs following prolonged activation of the receptors. Moreover, N40 MOR carrying human neurons regained partial sensitivity to DAMGO during a 7-day pre-exposure paradigm, whereas D40 failed to re-sensitize. We thus hypothesize that human N40 and D40 MORs have differential membrane recycling dynamics. We are currently testing this hypothesis. Our system using iNs carrying human MOR gene variants provides the unique opportunity to study the neurophysiology of MOR regulation on synaptic transmission in a human system and will likely provide novel information about the neurocircuitry of reward behavior.

Title: High content screening of mu-opioid receptor internalizationusing fluorescent rabbit monoclonal antibodies against its N-terminal fragment

Authors: *A. E. KALYUZHNY, J. HAGEN, N. HOPP, M. GRAHEK, J. HUMPHREY, G. DU, P. MURTHA, M. COOPER, C. AUTIN, B. AGGELER;
Bio-Techne, Minneapolis, MN

Abstract: Trafficking of mu-opioid receptors from the cell membrane into cytoplasm is one of the key mechanisms underlying desensitization of these receptors which is implicated in tolerance and dependence to narcotic opiates. Usually, endocytosis of mu-opioid receptors is analyzed qualitatively by utilizing cells transfected with mu-opioid receptor tagged with such haptens as HA and c-*myc* at their N-termini followed by immunocytochemical detection using tag-specific secondary antibodies conjugated to fluorescent dyes. We have developed a more efficient protocol to monitor receptor endocytosis by employing Alexa 594 conjugated rabbit monoclonal antibodies against the N-terminal part of OPRM1. Treatment of HEK293 cells transfected with GFP tag at its N-terminus of rat OPRM1 with agonist of mu-opioid receptors DAMGO produced strong internalization of receptors which was blocked by antagonist Naloxone. The specificity of internalization was confirmed by detecting complete overlap of green (GFP) and red (Alexa 594) fluorescence using confocal microscope. The extent of mu-opioid receptor internalization has been further analyzed using the High Content Screening (HCS) platform, allowing automated examination hundreds of cells treated with drugs. The advantage of this new technique is that it can be applied to native neuronal cells because they do not require transfecting with hapten-containing mu-opioid receptor constructs. By measuring the fluorescence intensity of mu-opioid receptors localized on the cell membrane and in the cytoplasm, it becomes possible to accurately quantify internalization of mu-opioid receptors.

Title: $P2Y_1$ receptor-mediated modulation of neuronal activity in the mouse olfactory bulb

Authors: *D. HIRNET, K. SCHULZ;
Div. of Neurophysiol., Univ. of Hamburg, Hamburg, Germany

Abstract: Purine nucleotides such as ATP and ADP modulate the communication between cells throughout the nervous system. In the mouse olfactory bulb (OB), the first olfactory relay station, ATP is released from sensory axons together with glutamate as a neurotransmitter and stimulates calcium signaling in glia cells. It has recently been shown that ATP also evokes neuronal network activity in the OB, though the origin of this effect could not be identified so far. We used spatiotemporal defined photolysis of caged ATP and caged ADP in acute mouse OB slices to investigate purinergic modulation in glomeruli, specific processing units of the OB. Therefore, we released the active molecules locally restricted to glomeruli and recorded the response in mitral cells and external tufted cells conveying to this glomerulus by whole-cell patch clamp. The release of ATP led to a $P2Y_1$ receptor-dependent increase in synaptic activity and a prominent depolarization of mitral/tufted cells (MC/TC). This depolarization was reduced in synaptic isolation (TTX, NBQX, DAP-V, CPCCOEt, ZM241385, DPCPX). However, under these conditions ATP as well as ADP still caused a $P2Y_1$-mediated inward current in MCs. Given the increase in membrane conductivity underlying the induced inward current at negative holding potentials, we conclude that purine nucleotides seem to modulate unspecific cation channels in mitral cells. Our results show, that purinergic signaling is present in one of the processing units in the OB and presumably is able to modulate the processing of odor information.

Göttingen, Göttingen, Germany; [6]Max Planck Inst. for Mol. Genet., Berlin, Germany; [7]MassGeneral Inst. for Neurodegenerative Dis., Boston, MA

Abstract: Caffeine is associated with procognitive effects in humans by counteracting overactivation of the adenosine A_{2A} receptor ($A_{2A}R$), which is upregulated in the human forebrain of aged and Alzheimer's disease (AD) patients. We have previously shown that an anti-$A_{2A}R$ therapy reverts age-like memory deficits, by reestablishment of the hypothalamic-pituitary-adrenal (HPA) axis feedback and corticosterone circadian levels. These observations suggest that $A_{2A}R$ over-activation and glucocorticoid dysfunction are key events in age-related hippocampal deficits; but their direct connection has never been explored. We now report that inducing $A_{2A}R$ overexpression in an aging-like profile is sufficient to trigger HPA-axis dysfunction, namely loss of plasmatic corticosterone circadian oscillation, and promotes reduction of GR hippocampal levels. The synaptic plasticity deficits triggered by GR in the hippocampus are amplified by $A_{2A}R$ over-activation and were rescued by anti-A_{2A} therapy; finally, we demonstrate that $A_{2A}R$ act on GR nuclear translocation and GR-dependent transcriptional regulation. We provide the first demonstration that $A_{2A}R$ is a major regulator of

GR function and that this functional interconnection may be a trigger to age-related memory deficits. This supports the idea that the procognitive effects of $A_{2A}R$ antagonists, namely caffeine, on Alzheimer's and age-related cognitive impairments may rely on its ability to modulate GR actions.

Title: Exogenous ATP modulates prostaglandin E_2 synthesis during inflammation

Authors: *R. S. AKUNDI, S. AKTER;
South Asian Univ., New Delhi, India

Abstract: Brain inflammation is a common occurrence following responses to varied insults such as bacterial infections, stroke, traumatic brain injury and neurodegenerative disorders. A common mediator for these varied inflammatory responses is prostaglandin E_2 (PGE_2), produced by the enzymatic activity of cyclooxygenases (COX) 1 and 2. Previous attempts to reduce neuronal inflammation through COX inhibition, by use of nonsteroidal anti-inflammatory drugs (NSAIDs), have met with limited success. It is well-known that inflammation and cell injury leads to the release of significant amounts of adenosine triphosphate (ATP). Here, we show that exogenous ATP modulates the inflammatory response of LPS-activated macrophage and neuronal cell-lines by 2-5 fold. We have further identified P2Y6 as one of the purinergic receptors involved in this pathway through the use of specific agonists and antagonists. We also find the involvement of p38 mitogen-activated protein kinase in this pathway. Targeting the P2 receptors, therefore, provides a therapeutic alternative to reduce inflammation in the brain. It paves the way for P2 receptor-based anti-inflammatory drugs (PBAIDs) which will retain the activities of essential COX enzymes, yet will significantly reduce inflammation by decreasing the enhanced production of PGE_2 by extracellular ATP.

Title: Trafficking of the neuropeptide galanin and its receptors in live cells

Authors: ***T. LI**[1,2], V. VUKOJEVIć[2], Y. BAI[1], Y. YANG[1], L. TERENIUS[2], T. HÖKFELT[3], P. SVENNINGSSON[2], Z.-Q. XU[1,3];

Abstract: The neuropeptide galanin was tagged at its N terminus with TAMRA or FAM to study trafficking and binding in live PC12 and HEK293 cells. We explored some of these important processes with the help of two quantitative methods: Fluorescence Correlation Spectroscopy (FCS) and its dual-color, two channel variant, Fluorescence Cross-Correlation Spectroscopy (FCCS) as well as Fluorescence recovery after photo bleaching (FRAP). Using these approaches we characterized the cellular dynamics and lateral diffusion at both the nano- and microscale levels. Our results show that in both cell lines functional GalR1-EGFP and GalR2-EGFP were expressed on the plasma membrane and internalized into cytoplasmic vesicles after stimulation with tagged galanin. Moreover, galanin receptors co-localize, co-migrate and form complexes with galanin peptide in live cells, and the complexes dissociate before being delivered to the lysosome. Inhibition of cholesterol-dependent GalR1 internalization by exposure to methyl-β-cyclodextrin or cholesterol oxidase reduced formation of the GalR1-galanin complex, and induced faster lateral diffusion of GalR1 on the membrane. In contrast, cholesterol depletion did not visibly alter lateral mobility of GalR2 and formation of the GalR2-galanin complex. Our study indicates that galanin receptor subtypes exhibit subtle differences with regard to lateral diffusion and that they are differentially dependent on cholesterol.

Title: Oxytocin alters excitatory synaptic transmission in rat insular cortex

Authors: ***J. A. VARELA**, V. KRISHNA, J. P. CHRISTIANSON;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: The neuropeptide oxytocin (OT) is a highly conserved neural modulator and is known to contribute to social and fear behaviors. OT positive axons and OT receptors (OTR) are found in the insula of rat but little is known regarding the physiological consequences of OT acting in this region. We sought to describe the effects of OT on synaptic transmission in layer 5/6 pyramidal neurons of the insular cortex. Studies were done using visualized whole cell patch clamp recordings and extracellular field potentials from 300μm slices taken from 6 to 9 week old male Sprague Dawely rats; data were included for analysis if they were found in the deep layers of Agranular or Granular insular cortex 2.8mm (+/- .5mm) caudal to bregma and appeared to have pyramidal morphology (confirmed by biocytin staining with patch-clamp experiments or by visual inspection on field potential experiments). Bath application of OT (500 nM) decreased of the mEPSC amplitude and increased the inter-event intervals (IEI), ps < 0.05. However, preliminary data shows that in 3 out 4 cells spontaneous excitatory post-synaptic currents (sEPSCs) the IEI was decreased with no clear change in amplitude and sIPSCs amplitude and IEI were unchanged. OT did not influence evoked excitatory post-synaptic potentials (fEPSPs) per se (N=8), but OT applied during low frequency stimulation (LFS, 900 stimulations at 1Hz) appeared to promote long term depression (N=3) when compared to control (N=3); data collection is ongoing. Together these data suggest that OT may alter both presynaptic glutamate release probability and postsynanptic AMPA receptor kinetics to promote LTD-like neuroplasticity.

Title: Expression of functional ox2 receptor in the human cervix cell line c33a

Authors: E. PERDONA', F. FAGGIONI, *M. A. CORSI;
Aptuit Ctr. For Drug Discovery & Develop., Verona, Italy

Abstract: Orexin-A and orexin-B, are neuropeptides produced by perifornical and lateral hypothalamic neurons that project throughout the brain and bind two different G protein-coupled receptors, orexin-1 receptor (OX1R) and orexin-2 receptor (OX2R). OX1R signals through Gq coupling whereas OX2R has been reported to be coupled to Gq or Gi/Go. The modulation of the OXRs has the potential to impact various pathophysiological conditions such as stress, anxiety, pain, disturbances of the sleep-wake cycle, addiction and feeding disorders. Biological experiments are most often performed with immortalized cell lines because they are readily available and can be expanded without limitation. However, cell lines may differ from the *in vivo* situation in important aspects such for instance the presence of accessory proteins needed for the signal transmission and the presence of the native receptor coupling machinery. It becomes essential to confirm in primary cells the pharmacology of ligands originally identified on recombinant systems. The aim of this study was to identify and characterize the functional activity of endogenously expressed OXRs in a physiological cell line. Human cervical carcinoma cells, C33A and human neuroepithelioma cells, MCIXC were studied for this scope. The gene expression was studied by RT-PCR whereas functional expression and antagonism profile were characterized by calcium mobilization measurement and D-myo-inositol-1-monophosphate (IP1) accumulation, respectively. Both cell lines expressed OX2R mRNA, whereas OX1R mRNA only in C33A cells. Increasing concentrations of orexin-A- and orexin-B-induced a calcium response only in C33A cells with a potency of 8.06±0.02 and 8.65±0.01, respectively (n=3). No calcium response was observed in MCIXC. To determine the relative effect of OX1R or OX2R in the [Ca^{2+}]$_i$ mobilization induced by orexin-A, C33A cells were pre-incubated with either the OX1R selective antagonist SB-334867 or OX2R selective antagonist JNJ-10397049 or with the dual OX1R/OX2R antagonists ACT-078573 or MK-6096. Increasing concentrations of all five compounds fully inhibited the calcium response induced by orexin-A with fpKi value of 6.06 ± 0.04 for SB-334867, 9.00 ± 0.05 for JNJ-10397049, 9.66 ± 0.06 for ACT-078573 and 9.94 ± 0.05 for MK-6096. These potency values were confirmed with the IP-1 accumulation assay. These results indicate the lack of a Gq/PLC-coupled OX2R in MCIXC cells. Moreover, the calcium mobilization induced by orexin-A in C33A cells is exclusively mediated by OX2R

indicating that C33A cell line could represent a useful tool for the pharmacological characterization of new chemical entities.

Title: Wnt-5a/Frizzled-9 regulates dendritic spine formation through Gαo and Gβγ

Authors: *V. T. RAMIREZ, E. RAMOS-FERNÁNDEZ, N. C. INESTROSA;
Pontifical Catholic Univ., Santiago, Chile

Abstract: Wnt ligands play crucial roles in the development and regulation of synapse structure and function. Specifically, Wnt-5a acts as a secreted growth factor that regulates dendritic spine formation in rodent hippocampal neurons, resulting in postsynaptic development that promotes the clustering of the postsynaptic density protein-95 (PSD-95). Here, we focused on the early events occurring after the interaction between Wnt-5a and its Frizzled receptor at the neuronal cell surface. Additionally, we studied the role of heterotrimeric G proteins in Wnt-5a- dependent synaptic development. We report that Frizzled9 (FZD9), a Wnt receptor related to Williams' syndrome, is localized in the postsynaptic region, where it interacts with Wnt- 5a. Functionally, FZD9 is required for the Wnt- 5a-mediated increase in dendritic spine density. FZD9 forms a pre-coupled complex with Gαo and Gβγ under basal conditions that dissociates after Wnt-5a stimulation. Accordingly, we found that G-protein inhibition abrogates Wnt-5a- dependent pathway in hippocampal neurons. In particular, the activation of Gαo appears to be a key factor controlling the Wnt-5a-induced dendritic spine density. In addition, we found that Gβγ is required for the Wnt-5a-mediated increase in cytosolic calcium levels and spinogenesis. Our

findings reveal that FZD9 and heterotrimeric G proteins form a crucial protein complex that regulates Wnt-5a signaling and dendritic spines in cultured hippocampal neurons.

Title: Comparison of Leu^8- and Pro^8-oxytocin potency, efficacy and functional selectivity at the human and marmoset receptors.

Authors: *M. PIERCE[1], S. MEHROTRA[1], M. L. TOEWS[2], J. A. FRENCH[3], T. F. MURRAY[1]; [1]Dept. of Pharmacol., Creighton Univ., Omaha, NE; [2]Pharmacol. and Exptl. Neurosci., Univ. of Nebraska Med. Ctr., Omaha, NE; [3]Psychology, Univ. of Nebraska Omaha, Omaha, NE

Abstract: The nonapeptide oxytocin (OT) is an important modulator of social behavior. OT binds to the oxytocin receptor (OTR) and activates multiple G proteins that exert diverse effects on cell function, including stimulation of cAMP (Gs), inhibition of adenylyl cyclase (Gi/o), stimulation of potassium channel currents (Gi), and activation of phospholipase C (Gq). In mammals, the nonapeptide OT sequence is highly conserved (Cys-Tyr-Ile-Gln-Asn-Cys-Pro-**Leu**-Gly; Leu^8-OT). Five novel OT ligand variants were recently discovered in New World Monkeys. In marmosets (*Callithrix*), an amino acid change to proline occurs in the 8^{th} position of the peptide (Pro^8-OT). Here we used stably transfected CHO cells expressing marmoset (mOTR) or human (hOTR) oxytocin receptors to assess OT-OTR signaling. To assess OTR activation of Gq, functional assays were performed using fluo-3 to measure OT-induced intracellular Ca^{2+} mobilization. To assess OTR coupling to Gi, a FLIPR Membrane Potential (FMP) assay was performed to measure OT-induced changes in membrane potential. The FMP assay reports hyperpolarization occurring as a consequence of stimulation of K^+ channel currents. OT-stimulated [^{35}S]GTPγS binding assays were used to directly assess OTR activation of Gi/o. Pro^8-OT was more efficacious than Leu^8-OT in mOTR CHO cells in Gq-mediated Ca^{2+} mobilization assays, with both peptides displaying similar subnanomolar potencies. In contrast, the potency and efficacy of Pro^8-OT and Leu^8-OT as stimulators of intracellular Ca^{2+} in hOTR cells did not differ. Membrane potential assays demonstrated Leu^8-OT to be substantially more potent and modestly more efficacious than Pro^8-OT in both mOTR- and hOTR-expressing cells. Surprisingly, in both hOTR and mOTR cells, Leu^8-OT-induced hyperpolarization was largely insensitive to treatment with PTX, suggesting a minor role for Gi/o-activation in OT-induced

membrane hyperpolarization. To explore the role of Ca^{2+}-activated potassium channels in OT-induced membrane hyperpolarization we tested the effects of pretreatment with charybdotoxin, paxilline and Tram-34. Only Tram-34, a selective blocker of the intermediate conductance (IK) channel $K_{Ca}3.1$, attenuated the hyperpolarizing response to OT ligands. A dependence of the hyperpolarization on intracellular Ca^{2+} was confirmed by its elimination with BAPTA-AM. Analysis of OT-stimulated [^{35}S]GTPγS binding to hOTR membranes revealed that Pro^8-OT may function as an inverse agonist at the hOTR. A more thorough understanding of these distinct pharmacologic signatures for Leu^8-OT and Pro^8-OT interaction with OTRs may provide insight into therapeutic targeting of OTRs.

Title: Immunohistochemical localization of a functional PAC1 antagonist antibody in the rodent trigeminovascular system

Authors: *S. MILLER[1], H. LIU[2], J. K. PRETORIUS[3], H. SUN[1], G. HILL DELLA PUPPA[1], D. W. SMITH[3], C. XU[2];

Abstract: Pituitary adenylate cyclase-activating polypeptide (PACAP) has been implicated in the pathophysiology of migraine. PACAP binds to the vasointestinal peptide receptors and PACAP receptors (PAC1 receptors). To further understand the mechanism of PAC1 mediated signaling in migraine, we generated mouse monoclonal antibodies against PAC1 receptors. We show that the antibody 1.8.1 blocks PACAP-induced cAMP production in cells overexpressing rat or human PAC1 receptors with nanomolar potency. To explore whether these functional antibodies could be used to map PAC1 receptor localization in tissues, we further tested 1.8.1 binding on fixed cells overexpressing rat, mouse or human PAC1 receptors using immunocytochemistry. Immunofluorescence was detected in cells overexpressing the rodent or human PAC1 receptors, but not in parental cells. The specificity of 1.8.1 for immunohistochemical applications was confirmed by comparing staining in fixed tissues from PAC1 knock out mice versus wild-type littermates. In trigeminal and sphenopalatine ganglion of

wild-type mice, 1.8.1 labelled a fraction of the neurons and in the spinal trigeminal nucleus, 1.8.1 labelled the neuropil. In the same tissues PAC1 knock out mice showed only faint fluorescent labeling, which was considered non-specific. Fluorescent staining of 1.8.1 in rat tissues was compared to in situ hybridization (ISH) with specific PAC1 receptor probes. Neurons in the trigeminal ganglion were less intensely stained than in the sphenopalatine ganglion. The degree of the fluorescent signal corresponded to a lower ISH signal in the trigeminal ganglion compared to the sphenopalatine ganglion. Likewise, staining of the spinal trigeminal nucleus matched the ISH signal in this area. The only discrepancy was found in the dura blood vessels, where staining was detected, but no ISH signal. Together these data contribute to our understanding of PAC1 receptor localization in the trigeminovascular system and as it may relate to migraine pathophysiology.

Title: Melanin-concentrating hormone-mediated signaling induces cilium shortening via Gi/o-dependent Akt phosphorylation

Authors: *Y. SAITO[1], A. HAMAMOTO[2], S. YAMATO[1], Y. KOBAYASHI[1];
[1]Hiroshima Univ., Hiroshima 739-8521, Japan; [2]Kurume Univ., Kurume, Japan

Abstract: Primary cilia are microtubule-based organelles present on nearly every cell in the mammalian body. The cilium has an important chemosensory function in many types of cells and ciliary dysfunction is associated with ciliopathies such as polycystic kidney disease and obesity. Although the ciliary membrane is contiguous with the plasma membrane, ciliary localization of protein is tightly regulated and only certain molecules are permitted to traffic there. Melanin-concentrating hormone (MCH) is the natural peptide ligand for two G-protein-coupled receptors (GPCR), MCHR1 and MCHR2. The MCH-MCHR1 system has been implicated in the regulation of feeding, sleep and emotional processing in rodents. Recently, MCHR1 expression was detected in primary cilia of the central nervous system. However, the underlying function and signaling pathway via MCHR1 located in primary cilia is unclear. Here we show that treatment of MCH significantly reduces cilia length in hTERT-RPE1 epithelial cells (hRPE1) transfected with MCHR1. Quantitative analysis indicated that the rate of MCH-induced cilia shorting progressed in time-dependent manner during the first 3 h with an EC50 value of 0.49 nM. MCH elicits receptor internalization, calcium mobilization, ERK activation, and inhibition of cAMP accumulation in MCHR1-expressing hRPE1 cells. However, these fundamental signaling pathways seem to be independent of the pathway that causes cilia shortening. Notably, we found that MCH causes an increase in Gi/o-dependent Akt activity, and that this pathway would be the principal step in the initial stage of MCH-induced ciliary shortening. These data suggests that MCH-MCHR1 governs the sensitivity by controlling the length of the cell's sensory organelle. Further characterization of MCHR1 as a ciliary GPCR provides a potential molecular mechanism to link defects in cilia with obesity. Further studies will be required to determine whether the MCH-MCHR1 axis is directly involved in controlling the cilia length in vivo, and in turn its physiological roles in the brain.

Title: Characterization of leptin receptor expressing neurons in the mouse NTS

Authors: J. DO[1], *T. KOWAL[2], L. FLOREANI[3], D. MCCRIMMON[1], M. MARTINA[1,3]; [1]Physiol., Northwestern University, Feinberg Sch. of Med., Chicago, IL; [2]Physiol., Northwestern Univ. Dept. of Physiol., Chicago, IL; [3]Lab. of Neurogenomics, Intl. Sch. for Advanced Studies, Trieste, Italy

Abstract: Leptin is an anorexigenic hormone acting through activation of specific leptin receptors, which belong to the G-protein-coupled receptors (GPCRs) family. Leptin causes a slow long-lasting depolarization in neurons of the nucleus of the solitary tract (NTS). However, the precise identity of the cells expressing the leptin receptor and the mechanism underlying the leptin-induced depolarization are still unknown. Our study has two main goals: 1- to uncover the expression of individual genes that identify neuronal subpopulations of cells expressing the leptin receptor; and 2- to identify the identity of the ion channel(s) mediating the action of leptin in these different cellular populations. To pursue these goals we combine genetic tagging of leptin receptor expressing neurons, electrophysiological recordings and single cell RT-PCR to test the expression of a list of channels and neuropeptides. We found that NTS leptin receptor expressing neurons appear to belong to two at least distinct populations, one expressing galanin and one expressing CCK. Additionally, in virtually all of the cells harvested we detected the transcript for the leakage channel NALCN. Together our data suggest that leptin receptor expressing NTS neurons form different subpopulations and that in all of them NALCN channels could in part mediate the depolarizing action of leptin.

Title: Oxytocin increases excitability and burst firing of CA2 pyramidal neurons and tunes their synaptic output

Authors: *N. N. TIRKO[1], M. MITRE[2], R. C. FROEMKE[2], M. V. CHAO[2], R. W. TSIEN[1]; [1]NYU Neurosci. Inst., New York Univ. Sch. of Med., New York, NY; [2]Skirball Inst., NYU Sch. of Med., New York, NY

Abstract: Oxytocin neuromodulation is important in many regions of the mammalian brain responsible for social behaviors, and acts to increase information salience and circuit plasticity. We find that CA2, a distinct hippocampal area that is critical for social memory in mice, robustly expresses oxytocin receptors (OTR) and contains a high density of oxytocinergic axons originating from the paraventricular nucleus.

Oxytocin has been shown to employ various mechanisms to alter circuit function including disinhibition, increased inhibitory tone, and potentiation of excitatory inputs. In CA2 we find that OTR activation strongly modulates both excitatory neurons and fast-spiking PV-positive interneurons, raising two lines of questions: what mechanisms underlie OTR modulation of cell behavior, and how does OTR modulation of excitation and inhibition within CA2 ultimately alter circuit output?

To study the mechanisms downstream of OTR activation, we examined CA2 pyramidal cells. Application of the oxytocin receptor agonist (TGOT) depolarizes the cells (~5 mV; 100% of cells recorded) and increases total membrane resistance and excitability. Additionally, action potential (AP) amplitude and afterhyperpolarization magnitude both decrease, leading to repetitive spiking and high frequency burst activity (~30 Hz). The mechanisms underlying these effects are downstream of G-protein coupled receptor activation of phospholipase C (PLC). We find that PLC activation leads to both reduction of M-current conductance, which depolarizes the cell and increases membrane resistance, and PKC-mediated modulation of voltage-gated Na^+ channels (VGSC), which reduces their maximal conductance and voltage-dependent availability. The effects of TGOT can be mimicked by a combination of M-current inhibition and PKC activation.

Reduction in M-current conductance and phosphorylation of VGSC both shape the firing activity of CA2 pyramidal cells, but so does inhibitory transmission. Pharmacologically blocking inhibition reduced frequency and increased duration of AP bursts. What is the relevance of the burst characteristics? Using optogenetic stimulation, we show that AP burst pattern and frequency are important for controlling the output onto CA1 pyramidal cells, the primary target of CA2 axons. High frequency bursts more efficiently transfer excitatory charge to CA1 cells. We hypothesize that OTR modulation of both excitation and inhibition in CA2 tunes its output onto CA1, potentially sculpting hippocampal information transfer during periods of oxytocin release *in vivo*.

Title: Functional consequences of the heteromerization between dopamine D1 and type-2 corticotropin releasing factor receptors

Authors: *H. E. YARUR[1], C. A. LOPEZ[2], K. GYSLING[2];
[1]Pontificia Univ. Catolica De Chile, Santiago, Chile; [2]Dept. of Cell. and Mol. Biol., Pontificia Univ. Católica de Chile, Santiago, Chile

Abstract: G-protein coupled receptors (GPCR) are capable of form homomers and heteromers providing new properties in the signaling and/or regulation of the respective GPCRs. It has been shown that D1 dopamine receptors (DAD1) are capable of form a heteromer with type-2α corticotropin releasing factor receptors (CRFR2α) when both receptors are heterologously co-expressed in HEK293t cells. The evidence suggests that their heteromerization changes the subcellular localization of both receptors and could modulate their signaling in the cell system.In order to further study the consequences of DAD1/CRFR2α heteromerization, we have determined the impact of their heteromerization in the recycling of DAD1. To this end, we have analyzed the behaving of a mutated form of DAD1 lacking its recycling domain using protein immunoprecipitation and immunofluorescence microscopy. The results showed that activation of DAD1 does not modify the level of DAD1/CRFR2α heteromerization and that the recycling of DAD1 is not necessary for DAD1/CRFR2α heteromerization. However, data showed that the endocytosis of DAD1 increases its heteromerization with CRFR2α. Interestingly, we observed an increase of CRFR2α in the early endosome compartment when is co-expressed with DAD1 and the mutated form of DAD1. We are evaluating the effect of the agonist in the signaling of DAD1, CRFR2α and the heteromer DAD1/CRFR2α by cAMP and ERK signaling.Thus, our data suggest that heteromerization of CRFR2α with DAD1 increases the availability of functional CRFR2α.

Title: Functional authentication of two isoforms of a gastropod gonadotropin-releasing hormone receptor.

Authors: *S. I. KAVANAUGH, P.-S. TSAI;
Integrative Physiol., Univ. of Colorado, Boulder, CO

Abstract: Gonadotropin-releasing hormone (GnRH) is the most upstream neuroendocrine activator of reproduction in vertebrates. A GnRH-like molecule was previously identified in the mollusk, *Aplysia californica,* interestingly, this GnRH (ap-GnRH) does not appear to have a reproductive role. In our earlier study, we cloned the full-length cDNA of a Type II putative ap-GnRH receptor (ap-GnRHR). This receptor contains two potential translation start sites, each accompanied by a Kozak sequence, suggesting the translation of both a long and a short form of the receptor is possible. The putative ap-GnRHR maintains the conserved structural features and motifs of other Type II GnRH receptors and shares high sequence identity with the octopus GnRHR. The expression of the putative ap-GnRHR short form is ubiquitous in all tissues examined, whereas the expression of the long form is confined to the central nervous system, hermaphroditic duct, ovotestis and osphradium. The goal of this study is to examine, through a series of functional characterizations, if these two receptor isoforms are authentic ap-GnRHR. The cDNA encoding the long or the short receptor was subcloned into the pAWG vector and transfected into Drosophila S2 cells, a protostomian cell line. Transfected cells were subject to a radioreceptor assay using ^{125}I-labeled ap-GnRH as a radioligand. Further, they were treated with various concentrations of ap-GnRH or a related peptide, *Aplysia* adipokinetic hormone (ap-AKH), and measured for the accumulation of cAMP and inositol phosphate (IP). Radioreceptor assay revealed that only the long form of the receptor selectively bound to the radioligand, with cold ap-GnRH displacing the bound radioligand at EC_{50} of 3.54×10^{-8} M. Cells transfected with either form of the receptor did not respond to ap-GnRH or ap-AKH treatment with cAMP accumulation. However, cells transfected with the long receptor increased intracellular IP in a dose-dependent manner when treated with ap-GnRH, leading to a 3- to 6-fold increase in IP accumulation over controls. The results from our studies show that despite the more prevalent expression of the short receptor, only the long receptor is a bona fide ap-GnRHR. Our study also cautions against the naming of a receptor based solely on sequence homology before a thorough functional characterization.

Title: Tanning the GnRH neurons-Melanocortin receptor 1 in GnRH neurons

Authors: C. HAERING, *S. S. CONSTANTIN, S. WRAY;
NIH, Bethesda, MD

Abstract: The accurate migration, precise signaling and pulsatile activity of Gonadotropin-releasing hormone-1 (GnRH) neurons are crucial for the onset of puberty and fertility in both male and female mammals. Our lab generated transcriptome data of primary GnRH neurons that showed high levels of melanocortin receptor 1 (Mc1R) mRNA. The McR subfamily, known to play a role in pigmentation, inflammation, exocrine secretion and energy homeostasis, consists of 5 members (Mc1-5R) that are G-protein coupled receptors. The broad agonist for McRs, α-Melanocyte-stimulating hormone (α-MSH), derived from proopiomelanocortin (POMC), had been shown to increase calcium oscillations in murine GnRH neurons in acute adult brain slices via Mc3R and Mc4R. We sought to determine whether Mc1R modulates GnRH neuronal activity and the signal transduction pathway utilized. Experiments performed include 1) RT-PCR of single GnRH neurons and 2) calcium imaging to pharmacologically address the function of McRs in the GnRH neuronal population. RT-PCR verified the presence of Mc1R, Mc3R and Mc5R transcript in a subset of neurons. Calcium imaging demonstrated that a subset of GnRH neurons was activated by α-MSH application. Notably, this activation occurred using a low concentration, 5 nM, implicating activation via Mc1r. After blockade of GnRH neuronal inputs using an amino acid blocker cocktail, α-MSH still activated GnRH neurons, indicating direct postsynaptic activation. Future experiments will examine whether expression and function of McRs in GnRH neurons change during development.

Title: Exercise-induced neurotransmitter switching in the adult mouse midbrain

Authors: *H. LI, K. B. JACKSON, N. C. SPITZER;
Neurobio. Section, Div. of Biol. Sciences, Kavli Inst. for Brain, UCSD, La Jolla, CA

Abstract: Neurotransmitter (NT) switching is a newly appreciated form of plasticity in the mature brain (Spitzer, 2015). However the environmental cues that trigger it, the extent to which it occurs throughout the CNS and its functions are largely unknown. We have searched for activity-dependent NT switching in motor circuitry where the mechanism underlying plasticity remains obscure.

We began by comparing the number of neurons expressing c-Fos in motor nuclei of mice with free access to running wheels to the number in sedentary control mice. We found that mice that exercised by running for 1 week showed a 5-fold increase in the number of c-Fos+ cells in the midbrain pedunculopontine nucleus (PPN) accompanied by a 33% decrease in the number of choline acetyltransferase (ChAT+) neurons and a 51% increase in the number of glutamate decarboxylase 1 (GAD1+) neurons. Stereological counts showed that the decrease in number of ChAT+ neurons in the PPN occurred exclusively in the caudal region that projects to the brain stem, STN, VTA, and the thalamus, but not in the rostral PPN or in the adjacent LDT nucleus. The number of neurons losing ChAT (n=605±19) matched the number of neurons gaining GAD1 (n=575±156). TUNEL staining revealed the absence of apoptosis and Ki67/DCX staining demonstrated the absence of neurogenesis. Moreover, the number of neurons expressing nitric oxide synthase 1 (NOS1) that is highly co-localized with ChAT in the caudal PPN did not change.

To determine functional correlates of NT switching in the caudal PPN, we performed behavioral analyses and found that runners progressively increased the running episode duration and acquired better motor control during self-training on running wheels. They also performed better than controls on the rotarod motor learning/coordination test; no significant difference was seen in the locomotor activity test or analysis of metabolism. To test for causal relationships, we are determining whether overexpressing ChAT via stereotaxic injection of ChAT-Cre mice with AAV-DIO-ChAT prevents the acquisition of motor learning by running.

To find out whether ChAT loss and GAD1 gain occur in the same cell population, we are

combining sensitive FISH with IHC to triple-stain ChAT mRNA, GAD1 mRNA and NOS1 protein to see whether levels of ChAT and GAD1 change in the same population of neurons. This study is expected to be pertinent to understanding the mechanism underlying motor learning as well as neurological disorders of the motor system.

Title: Neurotransmitter switching in the adult mammalian hippocampus

Authors: *S. ZAMBETTI, J. O. CONNORS, N. C. SPITZER;
Biol. Sci., UC San Diego, LA Jolla, CA

Abstract: Neuroplasticity is the ability of the brain to adapt in response to internal and external stimuli. Although much progress has been made in the characterization of classical forms of synaptic plasticity (Feldman et al., 2009), the mechanisms underlying changes in brain structure and function are not completely understood. The discovery of a form of plasticity called neurotransmitter (NT) respecification or switching, in which a neuron acquires a new function by losing, gaining or replacing a neurotransmitter (Spitzer, 2015), adds complexity to the nervous system but casts new light on these mechanisms. We have investigated whether NT switching contributes to the plasticity of the hippocampus, focusing our attention on adult neurogenesis. Environmental enrichment and voluntary running increase neurogenesis in the subgranular zone (SGZ) of the dentate gyrus (DG) in adult mice (Vivar et al., 2013). Here we demonstrate that running not only increases neurogenesis and improves learning performance but also changes the NTs expressed in a neuronal population in the hilus of the DG. Adult mice that have engaged in voluntary running for 1 week display a robust decrease in the number of neurons expressing neuropeptide Y (NPY) and a parallel increase in the number of neurons expressing the glutamatergic marker, VGluT1. However, the number of somatostatin (SST) neurons in the hilus and the number of NPY neurons in the CA1 (stratum oriens) remain constant. No cell death or neurogenesis is involved: experimental animals do not exhibit changes in apoptosis (TUNEL) or in the number of BrdU-DCX positive cells in the hilus after 1 week of voluntary running.

Together our data suggest that hilar NPY neurons acquire a glutamatergic phenotype when losing NPY. NPY knockout mice show reduced neurogenesis (Decressac et al., 2011) and hilar NPY neurons project to the outer molecular layer (Deller & Leranth 1990), the target zone of the input from the entorhinal cortex (EC; Förster et al., 2006). We hypothesize that the changes in the number of NPY and glutamatergic neurons act as a regulatory mechanism for neurogenesis and change the response of granule cells to the EC. Viral manipulation of the expression level of NPY and VGluT1 will allow us to understand the function of NT switching in the hilus with respect to neurogenesis. Our strategy is to prevent the loss of NPY and gain of glutamatergic phenotype during running by stereotaxically injecting Cre-dependent viruses encoding NPY and small interference (si) VGluT1 into the DG of NPY-Cre mice (Shi et al., 2013) before the onset of the running period.

Title: Neuronal activity regulates neurotransmitter switching in the adult brain

Authors: *D. MENG[1,2], S. LEUTGEB[1,2], K. DEISSEROTH[3,4], N. C. SPITZER[1,2];
[1]Div. of Biol. Sci., [2]Kavli Inst. for Brain and Mind, UC San Diego, La Jolla, CA; [3]Dept. of Bioengineering and Howard Hughes Med. Inst., [4]Dept. of Psychiatry & Behavioral Sci., Stanford Univ., Stanford, CA

Abstract: The nervous system responds to changes in endogenous activity and the external environment by modulating its function through various forms of neuroplasticity, many of which occur at the synapse. It has been believed that neurotransmitters are fixed and invariant in the brain. However, recent work has demonstrated neurotransmitter switching, a newly recognized form of neuroplasticity, both in the developing and adult nervous system. Neuronal activity has been shown to play an essential role in neurotransmitter switching in the developing nervous system, acting by a non-cell-autonomous mechanism through the release of BDNF (Guëmez-

Gamboa et al., 2014; Marek et al., 2010).
Here we have investigated the role of neuronal activity in neurotransmitter switching in the adult nervous system. Previous work from our lab demonstrated that exposing adult rats to a long-day photoperiod (19L:5D) decreases the number of dopaminergic neurons in the paraventricular nucleus of the hypothalamus (PaVN) compared to the number in a balanced-day photoperiod (12L:12D). We have now suppressed the activity of different neuronal populations in the PaVN with viral and genetic tools to determine the effects on transmitter switching in dopaminergic neurons.
To suppress overall PaVN neuronal activity, a Cre-dependent AAV virus expressing inwardly rectifying potassium channels (AAVdj-DIO-Kir) was stereotaxically injected into the PaVN along with a Cre-expressing AAV virus under the Synapsin promoter (AAV1-Syn-Cre). To suppress the activity of PaVN excitatory neurons, AAVdj-DIO-Kir was injected with a Cre-expressing AAV virus under the CaMKII promoter (AAV9-CaMKII-Cre). To suppress the activity of dopaminergic neurons, TH (tyrosine hydroxylase)-Cre transgenic rats were injected with AAVdj-DIO-Kir.
Preliminary results show that 1) Suppressing overall neuronal activity does not affect the number of dopaminergic neurons in the PaVN after 12L:12D; 2) Suppressing activity of excitatory neurons decreases the number of dopaminergic neurons in the PaVN after 12L:12D without affecting the number of neurons expressing nitric oxide synthase, suggesting that the effect is specific; 3) Specifically suppressing activity of PaVN inhibitory dopaminergic neurons blocks transmitter switching after 19L:5D without changing TH expression after 12L:12D, suggesting a cell-autonomous activity-dependent mechanism for neurotransmitter switching in the adult brain.

Title: Neurotransmitter switching in mouse prefrontal cortex

Authors: *S. K. GODAVARTHI, N. C. SPITZER;
Neurosci., Univ. of California San Diego, San Diego, CA

Abstract: Expression of appropriate neurotransmitters (NTs) is essential for development and function of neural circuits (Misgeld et al., 2002; Root et al., 2008). However, the NT expressed by a neuron is not immutable and fixed, but capable of change in response to alteration in electrical activity – both during development and in adult stages (Borodinsky et al., 2004; Demarque and Spitzer, 2010; Dulcis et al., 2013; Meng et al., SfN 2016). This NT switching is proposed to play a key role in normal development and maintenance of homeostatic plasticity (Demarque and Spitzer, 2012), but imbalances in excitation-inhibition are frequently reported in neurodevelopmental disorders. Accordingly, we are investigating if and how inadvertent and unwanted NT switching contributes to these disorders, specifically autism and autism spectrum disorders. We have focused on prefrontal cortex (PFC), a key player in the emergence of the autism phenotype both anatomically and behaviorally (Amaral et al., 2008.
Our strategy is to compare NT expression between the PFC of control mice and environmental models of autism (EMA) obtained by injecting valproate or poly inosine:cytosine in pregnant dams at E12.5 (Shi et al,. 2009; Sui et al., 2012). EMA mice at P10 showed a ~50% decrease in GAD67+ neurons (inhibitory neuron marker), specifically in the medial PFC when compared to controls. No such difference was detected in the lateral PFC. We found a parallel increase in the number of VGluT1+ cells (excitatory neuron marker) in the medial PFC of EMA mice. TUNEL staining revealed no change in apoptosis and NeuN counts were comparable between EMA and control groups. Moreover, there was no change in number of nitric oxide synthase (NOS1)+ cells, suggesting that the observed NT switching is specific. These data indicate that there may be respecification of GAD67+ neurons in the medial PFC in EMA, with VGluT1 as the switching partner.
We are currently seeking a marker for the subpopulation of neurons that loses GAD67, using antibodies to calcium-binding proteins and peptide transmitters, which will enable prevention of NT switching and determination of the consequences for behavior. In order to learn if the changes persist into adulthood, we will examine EMA mice at P90 for the expression of these NTs.
This study is expected to be pertinent to understanding the behavioural alterations resulting from unintended and unanticipated NT switching. The results will provide insight into the way multiple causative factors give rise to the common set of behavioural symptoms seen in autism spectrum disorders.

Title: Investigating mechanisms by which the WDR proteins regulate the deubiquitinating enzyme USP-46 *In vivo* to control *C. elegans* AMPA receptor GLR-1

Authors: *M. HODUL[1,2], C. L. DAHLBERG[3,2], P. JUO[1,2];
[1]Neurosci., [2]Developmental, Mol. and Chem. Biol., Tufts Univ., Boston, MA; [3]Dept. of Biol., Western Washington Univ., Bellingham, WA

Abstract: Ubiquitination is a key regulator of synapse development and function. Addition and removal of ubiquitin is an important mechanism that regulates the abundance of glutamate receptors at synapses. We previously identified Ubiquitin Specific Protease-46 (USP-46) as the first deubiquitinating enzyme (DUB) to regulate glutamate receptors. We showed that *usp-46* loss-of-function mutants have decreased levels of the AMPA-like glutamate receptor GLR-1 in the ventral nerve cord (VNC) of *C. elegans*. USP-46 deubiquitinates GLR-1 and promotes its degradation in the lysosome. USP-46 has low enzymatic activity and overexpression of the DUB by itself does not affect GLR-1 levels, suggesting that USP-46 activity is tightly controlled in neurons. We and others have shown that the WD40 repeat proteins, WDR-48 and WDR-20, interact with USP-46 and increase its catalytic activity in vitro. We previously found that co-expression of both WDR proteins increases GLR-1 abundance in the VNC in a USP-46-dependent manner. Here we show that neuronal expression of either WDR-48 or WDR-20 alone results in a small increase in USP-46 protein abundance *in vivo*, whereas co-expression of the WDR proteins results in a large 3-4 fold increase in USP-46 protein levels. These data indicate that the WDR proteins promote the abundance of USP-46 *in vivo*. We tested the hypothesis that the WDR proteins promote USP-46 protein levels by stimulating USP-46 to deubiquitinate itself *in trans* by measuring the effects of WDR protein co-expression on the abundance of a catalytically-inactive version of USP-46(C>A). We found that the WDR proteins were still able to increase the levels of USP-46(C>A) by 3-4 fold, suggesting that USP-46 does not regulate its own stability. Since USP-46 levels and activity are sensitive to the expression levels of the WDR proteins and synaptic activity can regulate GLR-1 levels, we are currently investigating whether the expression and/or localization of the WDR proteins are altered in various synaptic activity mutants.

Title: Dynamic changes in Kv7/KCNQ channel complex at the axonal initial segment of hippocampal neurons during homeostatic plasticity

Authors: *Z. HUANG, S. LEE, J. CAVARETTA, G. LEE, H. CHUNG;
Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: Homeostatic intrinsic plasticity maintains neuronal firing within an optimal operating range; its dysfunction is hypothesized to cause multiple neuronal hyperexcitability disorders including epilepsy and chronic pain. However, the molecular players mediating homeostatic intrinsic plasticity and the sites of their actions remain largely unknown. We have recently reported that chronic activity blockade by voltage-gated sodium (Na_v) channel antagonist tetrodotoxin (TTX) leads to homeostatic regulation of action potential firing rates in hippocampal culture neurons, and identified K_v7/KCNQ potassium channel genes and current as possible key players of this regulation. Kv7/KCNQ channels composed of Kv7.2/KCNQ2 and Kv7.3/KCNQ3 subunits are voltage-gated potassium channels that potently limits repetitive and burst firing of action potentials in neurons. Consistent with their ability to inhibit excitability, they are preferentially enriched at the plasma membrane of the axon with the highest concentration at the axon initial segment (AIS). Here, we investigated the extent to which chronic activity blockade alters expression of K_v7 channels, and their interacting proteins including calmodulin (CaM), Ankyrin-G, AKAP79/150, and syntaxin-1A. Immunoblot analysis showed a significant reduction in the expression of $K_v7.3$, CaM, and AKAP79/150 in hippocampal neurons after 48 h TTX treatment. In contrast, syntaxin 1A level was enhanced by TTX treatment. Immunocytochemistry revealed a noticeable decrease in $K_v7.2$ expression specifically at the axonal initial segments (AIS) of hippocampal neurons upon 48 h TTX treatment, whereas the same treatment increased the level of AIS marker Ankyrin-G and shortened the distance from soma to the start of the AIS. The investigation of chronic inactivity-induced changes of CaM, AKAP79/15, and syntaxin 1A in the axon is ongoing. These results suggest that alterations of Kv7 channel protein complex at the AIS may in part contribute to the expression of homeostatic intrinsic plasticity.

Title: Homeostatic plasticity induces rapid temperature adaptation of the life-saving C-start mediated by NMDA receptors and gap junctions at Mauthner cell level in larval zebrafish

Authors: ***A. HECKER**, W. SCHULZE, S. SCHUSTER;
Dept. of Animal Physiol., Bayreuth, Germany

Abstract: Homeostatic plasticity describes the ability of neurons to regulate their own synaptic input and excitability. These regulations usually occur after ex- or intrinsic perturbations, which affect those neuronal properties. However, the majority of studies regarding homeostatic plasticity were done using cell cultures, slices or electrophysiology. In this study we tried to link homeostatic plasticity of distinct brainstem neurons directly to its elicited behavior in larval zebrafish by making use of a combination of non-invasive imaging techniques, behavioral observations and pharmacology.
We extrinsically altered properties of the life-saving escape response (C-start) and its command neurons (Mauthner (M)-cells) by significantly decreasing the water temperature. We used simultaneous live-cell calcium imaging of both M-cells to indirectly measure their neuronal activity and monitored the linked C-start escape latency over 10 h (100 min at 28.5°C and 500 min at 19.5°C) in semi-fixed larvae. The latency of an acoustically elicited C-start shows a rapid adaptation after an initial cooling-induced slowdown. Throughout the experiments the M-cell $[Ca^{2+}]$-signal correlates significantly with the latency: it is lower in the beginning of the cold phase ($\Delta F/F$: 22 %) and is fully compensated at the end of the experiments ($\Delta F/F$: 40 %). The surprising correlation of the M-cell $[Ca^{2+}]$-signal and C-start latency suggests a common mechanism of adaptation.
To identify this mechanism, we repeated the experiments using antidromic (AD) stimulation. Hence, instead of activating the sensory input, we evoked an action potential directly in both M-cells, still causing calcium influxes in both M-cell somata. Again we found an adaptation after an initial decrease of the $[Ca^{2+}]$-signal, suggesting that the adaptation cannot solely be due to mechanisms at the input level. However, both the NMDA receptor antagonist MK-801 as well as

the gap junction blocker carbenoxolone blocked adaptation in AD-stimulated larvae. Homeostatic plasticity is linked to NMDA receptors by altering the number of NMDA receptors at synapses or changing their NR2 subunit composition. Gap junctions as part of club endings in the M-cells lateral dendrite are responsible for electrical transmission and therefore involved in regulating synaptic strength. In this study, we not only demonstrated a concurrent and remarkable rapid adaptation of a behavior and its underlying neural network to an environmental perturbation, but also suggest that this adaptation depends on homeostatic plasticity affecting NMDA receptors as well as synaptic strength through gap junctions.

Title: Homeostatic modulation of neocortical plasticity: extinction of aversive taste memory prevents the maintenance of *In vivo* insular cortex LTP

Authors: *A. RIVERA-OLVERA[1], M. L. ESCOBAR[2];
[1]Facultad De Psicologia, UNAM, Ciudad DE Mexico, Mexico; [2]Facultad De Psicologia, UNAM, Ciudad de Mexico, Mexico

Abstract: Accumulating evidence indicates that extinction process does not reflect loss of the original memory, but rather reflects the emergence of a new learning, which in turn requires consolidation in order to be stored in the long term. On the other hand, it is considered that synaptic strength is homeostatically regulated in order to maintain the circuit stability that is crucial for memory storage. Thus, homeostatic plasticity dynamically adjusts the capacity of synapses to express plastic changes depending on previous experience. In particular, training in several behavioral tasks modifies the possibility to induce long-term potentiation (LTP). Our previous studies in the insular cortex (IC) have shown that induction of LTP in the basolateral amygdaloid nucleus (BLA)-IC projection previous to conditioned taste aversion (CTA) training modifies the extinction process of this task. In this regard, we have also reported that prior training in CTA prevents the subsequent induction of LTP generated by high frequency

stimulation (HFS) in the same pathway. Here, we evaluate the effect of CTA extinction training on the ability to induce subsequent LTP in the BLA-IC projection in vivo. Thus, 48h after CTA extinction animals received HFS in BLA in order to induce IC-LTP. Our results show that extinction training allows the induction but not the maintenance of IC-LTP. These findings reveal that extinction training is able to modify the permanence of subsequent synaptic plasticity on IC, suggesting a homeostatic regulation on this pathway. Title: Pharmacological rescue of synaptic scaling.

Authors: *V. TATAVARTY, H. LIN, G. G. TURRIGIANO;
Brandeis Univ., Waltham, MA

Abstract: Multiple genes have been discovered that may contribute to Autism Spectrum Disorders (ASDs). It is unclear at this point if there is an underlying neurophysiological deficit that is common to the Autism caused by the various linked genes. Our previous results demonstrated that lack of MeCP2, an ASD associated gene leads to a deficit in Synaptic Scaling (SS) (Blackman et. al.2012.). SS is a form of synaptic plasticity that controls synaptic strength and firing rate homeostasis both *in vivo and in vitro.* To determine if aberrant SS is a common underlying feature of ASDs, we investigated if the loss of another ASD associated gene SHANK3 causes deficits in SS. SHANK3 is known to be an important regulator of synaptic plasticity and mutations in this gene have been reported in human subjects suffering from ASD. Our results show that cultured cortical neurons expressing a short hairpin directed against SHANK3 are unable to scale up synaptic strength. In addition, SS leads to accumulation of Shank3 at synapses. Interestingly, our preliminary data also shows that treatment of SHANK3-deficient neurons with a therapeutic dose of Lithium can rescue scaling *in vitro*. These results are consistent with the hypothesis that failure to regulate synaptic strength via scaling may

contribute to autism pathogenesis in different genetic backgrounds. Finally, since scaling can be measured quickly and accurately using electrophysiology and fluorescence microscopy in vitro, pharmacological rescue of scaling in general can serve as an ideal assay for high throughput screening of drugs to treat ASDs.

Title: Impaired astrocytic calcium signalling interferes with experience-dependent plasticity (EDP) in layers 2/3 of the murine barrel cortex.

Authors: *J. BUTCHER[1], R. E. SIMS[2], H. R. PARRI[2], S. GLAZEWSKI[1];
[1]Sch. of Life Sci., Keele Univ., Newcastle, United Kingdom; [2]Sch. of Life and Hlth. Sci., Aston Univ., Birmingham, United Kingdom

Abstract: In response to changes in whisker experience of adolescent mice, cortical neurons in layers 2/3 of the murine barrel cortex can exhibit two general forms of EDP: input-specific coding plasticity (CP) and homeostatic plasticity (HP). CP refers to changes in neuronal transmission and connectivity of individual synapses and is thought to enable information storage within a neuronal network. HP is most often a global phenomenon that acts as a negative feedback mechanism to keep the activity of a neuronal network within a set operating range. To determine possible astrocyte roles in both CP and HP we utilised IP3-R2 knock out (KO) mice, in which astrocytes exhibit diminished [Ca2+] responses. To evoke CP, all but one whisker (single-whisker experience - SWE) were removed unilaterally for 18 days, followed by regrowth for 5-9 days. To evoke HP, all whiskers were trimmed unilaterally for 1, 3, 7, 14, 25 and 32 days and re-attached on the day of recording. We found no significant differences in the magnitude of principal and surround responses in undeprived WT and KO mice and in the amount of plasticity

induced in SWE animals (all pairs $p>0.05$, U-test, N=20). In all-whisker-deprived WT animals the principal whisker responses showed rapid depression 1 day after deprivation (t-ratio 7.3, $p<0.0001$, N=15), started to recover at 3 days, were above control levels at 7-14 days (t-ratio 3.7, $p<0.003$, N=15), indicating HP, and back to control levels at 25-32 days. However, IP3-R2 KO mice exhibited a linear decay in magnitude of responses with deprivation time which was significant after 14 days ($p<0.05$, N=6) with an impaired HP rebound at 25 and 32 days which was not significant ($p>0.05$, N=10). In acute slice experiments, the LTD/LTP induction frequency curve was shifted towards LTP in the KO mice and mimicked in WT recordings by patch electrode filling of astrocytes with the calcium chelator BAPTA. These data implicate astrocytes as potent regulators of experience-dependent coding depression and homeostatic up-regulation of whisker-evoked responses.

Title: Evidence for homeostatic and Hebbian plasticity components in cortical layer 2/3 neurons

Authors: ***K. D. FOX**[1], S. D. GREENHILL[2], S. GLAZEWSKI[3];
[1]Cardiff Univ., Cardiff, United Kingdom; [2]Neurosci., Aston Univ., Birmingham, United Kingdom; [3]Biosci., Keele university, Keele, United Kingdom

Abstract: Previous studies have shown that cortical layer 2/3 neurones show Hebbian forms of synaptic plasticity. The layer 4 to layer 2/3 pathway shows both LTP and LTD. LTP is absent in this pathway in mutants lacking autophosphorylation of CaMKII, as is experience dependent potentiation induced by single whisker experience. LTD occurs in this pathway in the deprived whisker's barrel-column, but can be occluded by whisker deprivation. In this study, we wished to determine whether homeostatic plasticity could also be detected in layer 2/3 neurones. We deprived C57BL/6J mice of all whiskers unilaterally for 1, 3, 7 or 14 days and measured principal whisker responses to a standard whisker deflection. Responses were depressed after a single day of whisker deprivation but returned toward baseline after 3 days in a homeostatic fashion despite continued whisker input deprivation. Principal whisker responses slightly overshot baseline values after 7 and 14 days deprivation. The homeostatic response was

prevented in mice lacking synaptic scaling (C57BL/6OlaHsd, Ranson et al 2012, PNAS 109, 1311) and by administration of XPro1595 (Xencor, CA), a selective inhibitor of soluble TNF. TNF-alpha has itself been implicated in synaptic scaling (Stellwagen and Malenka 2006, Nature 440, 1054). We conclude that layer 2/3 neurones exhibit both Hebbian and homeostatic components of synaptic plasticity in the barrel cortex.

Title: Glial sources of TNF during homeostatic synaptic plasticity

Authors: *R. HEIR, H. ALTIMIMI, D. STELLWAGEN;
McGill Univ. Ctr. For Res. In Neurosci., Montreal, QC, Canada

Abstract: In order for neural circuits to function well, overall activity levels must be kept within an optimal range for neurotransmission by homeostatic plasticity mechanisms. The process of homeostatic strengthening of excitatory synapses in response to chronic activity deprivation is mediated by the glial release of tumour necrosis factor alpha (TNF), which modulates synaptic receptor trafficking. While it has become clear that glia play a critical role in some forms of homeostatic plasticity, the glial source—whether from astrocytes or microglia—has been a matter of some debate.
Here we show that both astrocytes and microglia can supply TNF depending on the context. In dissociated neuron-glial cultures we show that astrocytes are capable of supplying TNF during homeostatic plasticity, and that this occurs at least in part by the modulation of mRNA levels. We show that 48 hour activity deprivation of cultures with tetrodotoxin (TTX) results in an increase in TNF mRNA levels as well as an increase in surface GluA1 levels. Depletion of microglia from these cultures does not prevent the production of TNF in response to activity deprivation, nor does it prevent the increase in surface GluA1, suggesting that astrocytes are capable of producing TNF that results in AMPA receptor trafficking in this context. In addition, we use organotypic hippocampal slice cultures in order to investigate glial release of TNF in a

situation more closely representing *in vivo* conditions. We find that in this system, microglia are capable of supplying TNF in response to activity deprivation. Together, these experiments suggest that both microglia and astrocytes can serve as a source of TNF during homeostatic plasticity, and that the glial subtype responsible for TNF release is context-dependent. These experiments will allow a deeper understanding of the mechanisms by which different glial subtypes can contribute to the functioning of synapses.

Title: How spontaneous activity drives homeostatic synaptic plasticity

Authors: *C. J. NEFF[1], C. A. FRANK[2];
[1]Interdisciplinary Grad. Program in Neurosci., [2]Anat. and Cell Biol., Univ. of Iowa, Iowa City, IA

Abstract: Forms of homeostatic plasticity have been shown to help maintain neuronal output within a physiologically appropriate range. Failure of homeostatic regulation is thought to be a component of diseases such as migraine, ataxia, and epilepsy. Our lab uses the Drosophila neuromuscular junction (NMJ) as a model synapse. The best-characterized model of homeostatic plasticity at the fly NMJ is the potentiation of vesicle release following glutamate receptor perturbations. Perturbing the postsynaptic glutamate receptors causes a decrease in the amplitude of spontaneous release events and triggers a retrograde signal, leading to a compensatory increase in the number of vesicles released per evoked potential. The number of vesicles released per evoked potential is called quantal content, and this increase in quantal content is termed homeostatic potentiation.
From this paradigm, we assume a relationship exists between the amplitude of spontaneous release events and quantal content. If the system regulating these phenomena is truly homeostatic, we expect that the quantal content should change in response to all changes in spontaneous activity amplitude. One way we have tested this is through studying the reversibility

of homeostatic potentiation. We have found that upon removal of the glutamate receptor perturbation midway through development, quantal content decreases to control levels. We are currently studying reversibility in both sustained and acute time scales, as well as studying which molecular factors are necessary for reversibility.
A second experimental paradigm can be used to induce a homeostatic decrease in quantal content. Overexpression of the vesicular glutamate transporter, or VGlut, causes an increase in the amplitude of spontaneous release events, which is offset by the homeostatic depression of quantal content. Through an ongoing genetic screen, we have identified factors that have a deficit in evoked release only in the context of homeostatic depression, which in turn exacerbates the decrease in quantal content. We are interested in determining whether the same factors required for homeostatic depression are also required for the reversal of homeostatic potentiation. Finally, we are studying the reversibility of homeostatic depression.

Title: Presynaptic scaling of active zone size and number homeostatically tunes global synaptic strength

Authors: *P. GOEL[1,2], J. PALUCH[1], J. WONDOLOWSKI[1], L. NUNNELLY[1], D. DICKMAN[1,2];
[1]Dept. of Neurobio., [2]USC Grad. Program in Mol. and Computat. Biol., USC, Los Angeles, CA

Abstract: Synaptic structure can change in subtle and dramatic ways throughout the development, growth, maturation, and aging of the brain, yet synaptic strength is typically maintained within remarkably stable physiological ranges. We have investigated mutations and manipulations that lead to extreme changes in synaptic growth and structure at

the *Drosophila* neuromuscular junction. Although these conditions lead to enlarged synaptic vesicle size and inhibited or exuberant synaptic growth, remarkably, synaptic strength is maintained at wild type levels. These synapses have increased quantal size due to excess neurotransmitter release per synaptic vesicle, but express a compensatory, homeostatic decrease in presynaptic release, termed presynaptic homeostatic depression (PHD). Using quantitative imaging and analysis of synaptic architecture, we find that scaling of active zone size compensates for reciprocal changes in active zone number to achieve stable levels of synaptic strength. We further show that when actives zones are not tuned in this way, basal synaptic strength deviates from wild type. Finally, synapses simultaneously expressing PHD and active zone scaling can also homeostatically potentiate synaptic strength when postsynaptic receptors are acutely blocked. This demonstrates the extraordinary plasticity and stability of this synapse, where three homeostatic signaling systems can dynamically respond to diverse challenges and still maintain stable levels of synaptic strength. Together, this suggests that when this synapse is confronted with extreme changes in active zone number, homeostatic tuning of active zone size achieves stable synaptic strength.

Title: Retrograde potentiation of presynaptic release is suppressed when three homeostatic perturbations are chronically combined at an individual synapse

Authors: *X. LI[1,2,3], P. GOEL[1,4,2], J. WONDOLOWSKI[1,2], J. PALUCH[1,2], D. DICKMAN[1,2,4,3]; [2]Dept. of Neurobio., [3]Neurosci. Grad. Program, [4]Grad. Program in Mol. and Computat. Biol., [1]USC, Los Angeles, CA

Abstract: Synapses have the remarkable ability to adaptively modulate synaptic strength in response to perturbations that would otherwise destabilize neurotransmission. However, little is known about how synapses respond when confronted with conflicting homeostatic challenges.

We have interrogated the trans-cellular dialogue orchestrating the homeostatic control of synaptic strength in response to three perturbations to structure and function at the glutamatergic *Drosophila* neuromuscular junction. First, manipulations that increase synaptic vesicle size lead to excessive glutamate release, increased quantal size, but normal synaptic strength due to a homeostatic decrease in quantal content, termed presynaptic homeostatic depression (PHD). Second, acute pharmacological or chronic genetic perturbations to postsynaptic glutamate receptors leads to a decrease in quantal size but normal synaptic strength due to a retrograde homeostatic increase in presynaptic release, termed presynaptic homeostatic potentiation (PHP). Third, we have found that presynaptic active zone size inversely scales in mutants with extreme changes in active zone number, maintaining stable transmission. We have combined these three manipulations at a single synapse over acute and chronic times to elucidate the interface between these homeostatic signaling systems.
We find that synapses expressing active zone scaling and PHD can acutely express PHP to maintain stable synaptic strength, demonstrating a remarkable ability to coordinate diverse homeostatic expression mechanisms. Further, genetic mutations that lead to PHP can be expressed together with active zone scaling or PHD through development to stabilize synaptic strength. However, when a synapse confronts all three challenges over chronic time scales, active zone scaling and PHD are fully expressed, but PHP signaling is completely silenced. Indeed, we find no evidence that PHP signaling is ever permitted to advance beyond the postsynaptic cell. As a result, this silencing leads to a maladaptive, non-homeostatic reduction in neurotransmission, where the homeostat governing synaptic strength ceases to operate. Surprisingly, we find that expression of active zone scaling and PHD interferes with the Tor-dependent modulation of postsynaptic translation required for chronic forms of PHP. Thus, synapses expressing PHD and active zone scaling retain the adaptive ability to acutely potentiate synaptic strength. However, when these challenges are integrated over chronic time scales, potentiation is silenced due to an anterograde disruption of postsynaptic translational signaling.

Title: Differential expression of JAK2-STAT3 during homeostatic plasticity

Authors: *S. CHOI, G. COLLINGRIDGE;
Ctr. For Synaptic Plasticity, Bristol, United Kingdom

Abstract: Many studies have been published about Hebbian synaptic plasticity which is synapse specific. However, not enough mechanisms were found about homeostatic plasticity which is activity-dependent but not synapse-specific. In this study, we found differential expression of JAK2-STAT3 proteins after 48 hr after bicuculline (Bic) treatment, but not after tetrodotoxin (TTX) treatment NMDA receptor dependent manner. Interestingly, mRNA level of all known JAKs and STATs did not altered after Bic treatment in the same condition. Moreover, we also could find time-dependent increment of STAT3 mRNA which have long poly A tail after Bic treatment. And it is well known that STAT3 mRNA contains consensus CPE site. These data suggest that JAK2-STAT3 pathway may have important role in homeostatic plasticity. And they also suggest that regulation of CPE-mediated local translation might be crucial for regulating homeostatic plasticity.

Title: Distinct requirements for pallidin and the schizophrenia susceptibility gene dysbindin in promoting synaptic vesicle recycling and homeostatic plasticity

Authors: *X. CHEN[1,2], W. MA[1], S. ZHANG[1], J. PALUCH[1], W. GUO[1,2], D. K. DICKMAN[1];
[1]Dept. of Neurobio., [2]Neurosci. Grad. Program, USC, Los Angeles, CA

Abstract: Membrane trafficking pathways must be exquisitely coordinated at synaptic terminals to maintain proper functionality, particularly during adaptive responses to high activity and to perturbations of neurotransmission. We have generated null mutations in *Drosophila* in the central Biogenesis of Lysosome-Related Organelles Complex-1 subunit *pallidin* to test whether this complex may be a fundamental mediator of adaptive synaptic responses to stress. We find

that *pallidin* is not required for synapse morphology or structure at the neuromuscular junction. However, *pallidin* is necessary to sustain the synaptic vesicle pool under high frequency stimulation, where we observe a loss of early endosomes with a concomitant increase of tubular endosomal structures. The schizophrenia susceptibility factor *dysbindin* binds to *pallidin* and is necessary for presynaptic homeostatic potentiation, an adaptive increase in presynaptic release in response to perturbation of postsynaptic glutamate receptor function. We find that *dysbindin*, like *pallidin*, is also necessary to sustain neurotransmission during high activity. Surprisingly, *dysbindin* achieves homeostatic potentiation through a modulation of the readily releasable synaptic vesicle pool, while *pallidin* is not necessary for this process and potentiation is fully expressed in *pallidin* mutants. We provide additional evidence that the majority of *dysbindin* is localized to synaptic vesicle pools, while *pallidin* localizes primarily to the presynaptic cytoskeleton. Together, our data reveals shared and distinct functions of *pallidin* and *dysbindin* in activity- and plasticity-dependent trafficking of synaptic vesicles.

Title: Hypoperfusion-induced changes in neuronal network oscillations in the mouse forebrain

Authors: *Y. NISHIMURA, R. ABE, T. SASAKI, Y. IKEGAYA;
Lab. of Chem. Pharmacology, Grad. Sch. of Pharmaceut. Sci., The Univ. of Tokyo, Tokyo, Japan

Abstract: Neuronal activity is highly sensitive to changes in oxygen tension. Numerous studies have revealed signaling pathways and molecular mechanisms underlying the neuronal degeneration observed with hypoxia/ischemia. However, there is still a lack of information on the pathophysiological basis of ischemia. In this study, we examined the impact of hypoxic/ischemic conditions on neuronal ensemble activity patterns in the mouse brain using *in vivo* extracellular electrophysiological recordings from up to 8 sites in the thalamus, dorsal

hippocampus, and neocortex, while cerebral hypoperfusion was induced by unilateral common carotid artery occlusion (CCAO), a technique that reduces the blood supply to the forebrain. After a few minutes, the occlusion triggered a rapid change in the power of the local field oscillations. In the hippocampus, but not in the neocortex, corpus callosum and thalamus, the absolute power changes at all frequency ranges (relative to the baseline) became less pronounced with time, and no significant changes were observed 30 min after the occlusion-induced hypoperfusion. Next we focused on the hippocampal neuronal activity and tested how more severe ischemic damage alters its network activity by photothrombosis, a model of ischemia that significantly reduces blood supply, which induces neuronal degeneration in a small area of the brain. Similar to CCAO, hippocampal LFP power showed an immediate change in response to photothrombosis and kept decreasing significantly 60 min after the onset of photostimulation. These results suggest that LFP power within the hippocampus never returned to the pre-photostimulation baseline when significant ischemia related to neuronal degeneration was induced. We also tested whether continuous ischemic challenge induced by the occlusion for up to 1 week alters neuronal activity. In the hippocampus, corpus callosum and the thalamus, the chronic occlusion did not lead to a reduction in the power of the local field oscillations. However, in the neocortex, there was a tendency that its neuronal activity decreased. These results indicate that certain neuronal populations have the ability to maintain internal neurophysiological homeostasis against ischemic challenge.

Title: Homer1a mediated experience-dependent synaptic plasticity in mouse primary visual cortex

Authors: *V. B. CHOKSHI[1,2], M. GAO[4], P. WORLEY[3], H.-K. LEE[3,2];
[1]Biol., [2]The Mind Brain Inst., [3]The Solomon H. Synder Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD; [4]Dept. of Neurol., Barrow Neurolog. Inst., Phoenix, AZ

Abstract: Sensory systems are developed to be able to sense the environment around us. It is well accepted that the information of past experience is stored as changes in the strength of

synapses. Homeostatic regulation of these synapses is required to maintain stability in the neural circuits in response to prolong changes in sensory experience. Experience-dependent homeostatic synaptic plasticity (EHP) has been shown in various model systems including mouse primary visual cortex. Short dark exposure of an animal induces homeostatic scaling up of excitatory synaptic strength, measured in terms of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor (AMPAR) currents. In contrast, two hours of brief light exposure following dark exposure, scales down the synaptic strength to normal levels. We found that metabotropic glutamate receptor 5 (mGluR5) acts as an activity sensor to scale down the synapses with light exposure. These receptors are coupled to synaptic proteins by a scaffolding protein, Homer1. Constitutively Homer1 exists as dimers and can couple mGluR5 to its other synaptic targets and downstream signaling molecules. But upon high neuronal activity, neurons express its splice variant called Homer1a (H1a), which acts as monomers and competitively binds mGluR5. Hence, H1a dissociates mGluR5 from the other targets. We found using H1a knockout mice that mGluR5 and H1a interaction is required for scaling down synapses in visual cortex with visual experience. To rule out potential developmental effects of knocking out H1a as well as cell autonomous effects, we are currently using a genetic strategy to acutely knockout H1a in a subset of neurons. So far our results suggest that H1a acts as a sensor of acute increase in neural activity and switches the mode of mGluR5 signaling in order to maintain homeostasis in the visual cortex.

Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: For normal brain functions such as learning and memory to take place, the operational dynamic range of neural circuits must be maintained homeostatically, but the underlying molecular and synaptic mechanisms are largely unknown. Here we show that the activity-dependent transcription factor Npas4 plays a key role in setting the homeostatic balance of the hippocampus microcircuit and that it does so by selectively modulating the mossy fiber inputs to CA3 pyramidal neurons. Genetic manipulation of Npas4 selectively altered excitatory synapses on pyramidal neurons in CA3, but not in CA1. Both global knockout and selective deletion of Npas4 in CA3 led to a dramatic increase in the frequency of miniature excitatory synaptic currents (mEPSCs) in CA3 pyramidal neurons, while re-expression of Npas4 in CA3 in the global knockout mouse was sufficient to rapidly restore this synaptic deficit to the wild type level. Npas4 modulates excitatory inputs to CA3 pyramidal neurons through selectively altering synaptic inputs from dentate gyrus granule cells through the mossy fiber pathway, which is one of the many inputs converged onto CA3 pyramidal neurons. We found that mossy fiber synapses were homeostatically modulated to maintain the balance of the hippocampal circuit. Npas4 expressed in CA3 pyramidal neurons acutely modulates the size of thorny excrescences (TE), the distinct postsynaptic structure of mossy fiber synapses formed on CA3 pyramidal neurons. In the absence of Npas4, kainic acid-induced homeostatic down-sizing of TE is blocked. Furthermore, we have identified a previously unknown transcriptional target of Npas4 that mediates homeostatic modulation of TE. Our study therefore identified a molecular and synaptic mechanism controlled by Npas4 that is required to maintain the homeostatic balance of the hippocampus microcircuit. Consistent with this idea, Npas4 total knockout mice are significantly more susceptible to kainic acid-induced seizure. Given our previous finding that Npas4 is selectively required in CA3 for contextual memory formation (Ramamoorthi *et al.* Science, 2011), these new results indicate a critical role for circuit balance in learning and memory.

Title: A presynaptic glutamate receptor confers robustness to neurotransmission and homeostatic potentiation

Authors: *B. KIRAGASI[1,2], J. WONDOLOWSKI[2], Y. LI[3], G. W. DAVIS[4], D. K. DICKMAN[1,2];
[1]Dept. of Neurobio., [2]USC, Los Angeles, CA; [3]Eunice Kennedy Shriver Natl. Inst. of Child Hlth. and Human Develop., Bethesda, MD; [4]Univ. of California, San Francisco, San Francisco, CA

Abstract: Homeostatic signaling systems are thought to interface with other forms of plasticity to ensure flexible yet stable levels of neurotransmission. The role of neurotransmitter receptors in this process, beyond mediating neurotransmission itself, is not known. Through a forward genetic screen using electrophysiology in *Drosophila*, we have identified the non-NMDA ionotropic glutamate receptor subunit *DKaiRID* to be required presynaptically for the homeostatic potentiation of synaptic strength. We find that *DKaiRID* is necessary in motor neurons to enable both acute and long term expression of homeostatic plasticity without altering synapse morphology or ultrastructure. *DKaiRID* confers robustness to the calcium sensitivity of baseline synaptic transmission, with significantly reduced release at lowered extracellular calcium, while high extracellular calcium restores both neurotransmission and homeostatic potentiation. Importantly, acute pharmacological blockade of *DKaiRID* disrupts homeostatic plasticity, indicating that this receptor operates at or near presynaptic release sites to potentiate both baseline and homeostatic release. We also demonstrate that calcium permeability through *DKaiRID* is necessary for the calcium sensitivity of baseline transmission, but is not required for homeostatic signaling. Finally, we have identified an additional receptor and auxiliary subunit that may work with *DKaiRID* to facilitate presynaptic homeostatic potentiation. We propose that *DKaiRID* is a glutamate autoreceptor that confers robustness to promote synaptic strength with active zone specificity.

Title: Homeostatic regulation of cortical firing rates is inhibited by sleep.

Authors: *K. B. HENGEN, A. TORRADO PACHECO, G. G. TURRIGIANO;
Biol., Brandeis Univ., Waltham, MA

Abstract: By continuously recording extracellular signals from ensembles of single neurons in primary visual cortex of freely behaving rats during the critical period for ocular dominance plasticity, we recently demonstrated that 1) individual neurons in freely behaving animals have a firing rate set-point, and 2) when firing rates are perturbed by monocular deprivation (MD), the homeostatic return to the set-point is expressed during waking and not sleep. This observation raises the important question of whether sleep inhibits an otherwise ongoing homeostatic process, or whether normal sleep/wake cycles are essential for the expression of firing rate homeostasis.

To answer this question, we recorded activity from ensembles of cortical single units in juvenile rats (postnatal days 24-34) continuously for 10 days during a monocular deprivation (MD) paradigm. As expected, amongst neurons that were "online" for the entire recording, firing rates dropped during early MD. To directly assess the role of wake and sleep during 24h at the height of the homeostatic (late) phase of MD, we enhanced every other naturally occurring waking state using non-stressful techniques such as novel object introduction and tactile stimulation. Enhanced waking states did not affect firing rates of neurons in the non-deprived (control) hemisphere, while the same behavioral epochs resulted in substantial increases in homeostatic recovery of firing rates.

Our control data indicate that extended waking in a familiar environment is insufficient to drive changes in neuronal firing rates in the primary visual cortex. In contrast, data from neurons in the deprived hemisphere strongly support the conclusion that sleep inhibits homeostatic plasticity during late MD, and that enhanced waking expands the time window for the expression of homeostasis. These results raise the possibility that various plasticity mechanisms may require temporal segregation, or that brain-state related changes in chemical composition may preclude homeostatic plasticity during sleep.

Title: Homeostatic scaling of intrinsic excitability involves upstream signaling pathways that are distinct from homeostatic scaling of excitatory synapses

Authors: A. WEISS[1], S.-S. JANG[2], E. KIM[1], G. LEE[1], *H. CHUNG[1];
[1]Dept Mol. and Integrative Physiol., [2]Neurosci. Program, Univ. of Illinois At Urbana Champaign, Urbana, IL

Abstract: Homeostatic plasticity maintains neuronal firing and synaptic strength within physiologic limits. Prolonged blockade of neuronal activity for 2 days in culture and in vivo causes a compensatory increase in firing rates as well as synaptic strength. Interestingly, activity blockade for 2-4 weeks in vivo causes temporal lobe epilepsy, implicating homeostatic plasticity in epileptogenesis. However, the molecular mechanism underlying homeostatic plasticity is not fully understood. We have recently reported that prolonged activity blockade by the voltage-gated sodium channel antagonist tetrodotoxin (TTX) leads to homeostatic increases in action potential firing rates, and decreases in multiple K+ channel transcripts in cultured hippocampal neurons (Lee and Royston et al., 2015). This TTX-induced scaling of intrinsic excitability and down-regulation of K+ channel genes is mimicked by inhibition of NMDA receptors (NMDAR) but not L-type voltage-gated Ca2+ channels (VGCC) (Lee and Royston et al., 2015). Here, we show that the same prolonged activity blockade leads to homeostatic increases in miniature excitatory postsynaptic potentials, and such synaptic scaling is mimicked by inhibition of L-type VGCCs but not NMDARs. These results together indicate that homeostatic scaling of intrinsic excitability involves upstream activity sensors and their downstream signaling pathways that are distinct from those underlying homeostatic scaling of synaptic strength. We further found that prolonged inhibition of neuronal activity or NMDARs but not L-type VGCCs markedly decreased BDNF transcripts and TrkB activity. Based on these preliminary results, we are currently testing the hypothesis that down-regulation of BDNF-TrkB signaling pathways upon reduced NMDAR activity leads to transcriptional down-regulation of K+ channel genes and the expression of homeostatic scaling of intrinsic excitability.

Title: Calcium signaling mediates retrograde homeostatic compensation at the *Drosophila* neuromuscular junction

Authors: *L. GRAY[1], R. BALL[2], G. KAUWE[1], M. MORI[1], E. ISACOFF[2], P. HAGHIGHI[1]; [1]Buck Inst. For Res. On Aging, Novato, CA; [2]Mol. and Cell Biol., Univ. of California, Berkeley, Berkeley, CA

Abstract: Alterations in synaptic activity trigger homeostatic responses that modulate synaptic strength; these responses manifest as changes in postsynaptic receptor expression and retrograde regulation of transmitter release. The *Drosophila* larval NMJ provides an excellent experimental paradigm for studying synaptic homeostasis: removal of the GluRIIA glutamate receptor subunit decreases single channel mean open time, thereby reducing miniature synaptic currents; however, evoked synaptic currents remain comparable to wild type, implying a retrograde compensatory signal to enhance neurotransmitter release. We have hypothesized that a change in synaptic calcium influx, as a result of the genetic removal of GluRIIA, plays a role in retrograde signaling. To address this hypothesis, first we tested whether synaptic calcium influx is altered by genetic manipulation of GluR subunits. To achieve this, we combined two-electrode voltage clamp and calcium imaging using a synaptically targeted fluorescent calcium indicator, SynapGCamp3. Genetic removal of the GluRIIA subunit or overexpression of a GluRIIA mutant transgene ($GluRIIA^{M/R}$), in which a methionine near the opening of the pore was mutated to an arginine, both strongly reduced synaptic calcium influx. Both of these genetic manipulations strongly enhanced presynaptic release. These findings partially support our hypothesis by highlighting a link between reduced synaptic calcium influx and retrograde enhancement of presynaptic release, but raise the question of whether increasing calcium influx in these combinations would block retrograde signaling. To address this, we turned to an obligatory GluR subunit at the NMJ, GluRIIC. GluRIIC does not contain the signature pair of glutamine (Q) residues near the pore of the channel that are shared by most glutamate receptor subunits; this glutamine pair is thought to confer calcium permeability to the channel. We reasoned that engineering a pair of glutamines in this position in GluRIIC ($GluRIIC^{QQ}$) could increase synaptic calcium permeability at the NMJ. We could then test whether restoring calcium permeability to GluRIIA mutants would suppress homeostatic compensation in these animals. Our imaging and electrophysiological examination supports this prediction. Overexpression of $GluRIIC^{QQ}$ restored synaptic calcium influx and suppressed the enhancement in presynaptic release observed in GluRIIA mutant larvae. These findings provide strong evidence in support of our hypothesis that alteration in synaptic calcium influx plays a critical role in triggering the retrograde compensatory signal at the NMJ.

Title: Chronic enhancement of neuronal activity induces homeostatic down-scaling in $STEP_{61}$-dependent manners

Authors: *S.-S. JANG[1,2], H. JEONG[1], H. OH[1], S. ROYSTON[1,2], M. VEST[1], J. XU[3], P. LOMBROSO[3,4], H. CHUNG[1,2];

Abstract: Prolonged changes in network activity induce homeostatic plasticity at excitatory synapse by regulating postsynaptic α-amino-3-hydroyle-5-methyl-4isoxazolepropionic acid receptors (AMPAR) and N-methyl-D-aspartate receptors (NMDAR), both of which are primary mediators of excitatory synaptic transmission. Previously, we reported that chronic activity blockade of hippocampal neurons induces synaptic scaling by decreasing the expression and activity of Striatal-Enriched protein tyrosine Phosphatase ($STEP_{61}$), which plays a critical role in the dephosphorylation of NMDAR subunit GluN2B and AMPAR subunit GluA2. However, very little is known about the role of $STEP_{61}$ in homeostatic downscaling of excitatory synaptic strength following chronic elevation of neuronal activity, and the signaling pathway involved. In this study, we induced chronic elevation of hippocampal neuronal activity by inhibiting GABAa receptors through the treatment of bicuculine (BC) or picrotoxin (PTX) for 24-48 h. Such prolonged activity elevation enhanced $STEP_{61}$ protein expression and decreased Tyr-phosphorylation of GluA2 and GluN2B from 24-48 h. Consistent with the ability of $STEP_{61}$ to induce internalization of AMPAR and NMDAR through dephosphorylation, we found that prolonged activity elevation for 24-48 h decreases surface expression of GluA2 and GluN2B expression. We are currently investigating how chronic activity elevation increases $STEP_{61}$ expression by examining the signaling pathways downstream of NMDAR and L-type voltage-gated calcium channels. Further insights into the functional implication of $STEP_{61}$ in synaptic down-scaling would be provided by experimental results using pharmacologic and genetic inhibition of STEP.

Title: Homeostatic scaling-down of excitatory synapses during sleep driven by Homer1a

Authors: ***G. H. DIERING**[1], R. NIRUJOGI[2], R. H. ROTH[1], P. F. WORLEY[1], A. PANDEY[2], R. L. HUGANIR[1];
[1]Neurosci., [2]Inst. of Genet. Med., Johns Hopkins Univ., Baltimore, MD

Abstract: Homeostatic scaling is believed to regulate neuronal firing through global, non-Hebbian, adjustments to synaptic weights while maintaining the information stored through Hebbian plasticity mechanisms. While scaling has clearly been demonstrated in neurons in culture, true physiological functions of homeostatic scaling in vivo are not known. Sleep plays an essential role in normal cognitive functions. Evidence suggests that the benefits of sleep may occur via synaptic mechanisms, including a global weakening of synapses. Using sub-cellular fractionation, biochemistry and quantitative proteomics, we characterized the changes that occur in forebrain excitatory post-synaptic densities (PSD) through the dark/light cycle in mice. During the light phase when mice spend more time asleep we observed reduced levels of synaptic AMPA receptors and reduced AMPA receptor phosphorylation consistent with global synaptic weakening. These changes are driven by the immediate early gene Homer1a which is kept at low levels in the PSD during wake by the neuromodulator noradrenaline. During sleep, Homer1a remodels the mGluR1/5 signaling complex which is important for the consolidation of contextual memory. These findings reveal part of the molecular mechanisms at play during sleep and suggest that the physiological function of homeostatic scaling-down may be to renormalize synaptic strength during sleep.

Title: Neuregulin1 (NRG1)/ErbB4 signaling regulates visual critical period cortical plasticity

Authors: *T. IKRAR[1], Y. SUN[1], N. GONG[1], M. F. DAVIS[2], S. P. GANDHI[2], X. XU[1];
[1]Anat. & Neurobiology, Sch. of Med., [2]Dept. of Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Experience dependent critical period plasticity has been extensively studied in the visual cortex. Adjustments of excitatory and inhibitory synaptic strength are believed to be a major mechanism by which cortical networks adapt to sensory input over a range of timescales from seconds to days. During the developmental critical period, the most dramatic consequence of occluding vision through one eye (monocular deprivation) is a rapid loss of excitatory synaptic inputs to parvalbumin expressing (PV) inhibitory neurons in visual cortex. Subsequent cortical disinhibition by reduced PV cell activity allows for excitatory ocular dominance plasticity. However, the molecular mechanisms underlying critical period synaptic plasticity are unclear. Neuregulin1 (NRG1) is essential for the normal development of the nervous system, and signaling through its tyrosine kinase receptor ErbB4 has been implicated in synaptic plasticity and GABAergic circuit development. We test whether NRG1/ErbB4 signaling regulates functional circuit connections of PV interneurons and excitatory neurons during the critical period of visual development. Here we show that brief monocular deprivation during the critical period down-regulates neuregulin1(NRG1)/ErbB4 signaling in PV neurons (but not excitatory neurons), causing retraction of excitatory inputs to PV neurons. Exogenous NRG1 rapidly restores excitatory inputs onto deprived PV cells through downstream PKCdependent activation and AMPA receptor exocytosis, thus enhancing PV neuronal inhibition to excitatory neurons. NRG1 treatment prevents the loss of deprived eye visual cortical responsiveness *in vivo*. Our findings reveal molecular, cellular and circuit mechanisms of NRG1/ErbB4 in regulating the initiation of critical period visual cortical plasticity.

Title: A forward genetic screen identifies a link between the homeostatic control of sleep behavior and synaptic plasticity

Authors: *K. KIKUMA[1,2], M. AMAR[2], H. YANG[1,2], D. DICKMAN[2];
[1]Neurosci. Grad. Program, [2]Dept. of Neurobio., USC, Los Angeles, CA

Abstract: Homeostasis is a fundamental form of feedback regulation that precisely maintains the functionality of a system at set point levels of activity. Sleep is an ancient behavior under homeostatic control, yet despite intensive study, the biological function of sleep remains enigmatic. Synaptic plasticity is likely to change during sleep, but the relationship between these processes is unclear and controversial. The *Drosophila* neuromuscular junction has been established as a model system to study the homeostatic control of synaptic plasticity. At this glutamatergic synapse, acute pharmacological perturbation of postsynaptic glutamate receptors triggers a retrograde signal that results in an increase in presynaptic release, restoring proper levels of synaptic strength, a process termed presynaptic homeostatic potentiation (PHP). Using an electrophysiology-based forward genetic screen to isolate genes necessary for PHP, we have identified a sleep gene, *insomniac*. Interestingly, *insomniac* encodes an adaptor that targets substrates for protein ubiquitylation and degradation. Intriguingly, the sleep homeostat has been reported to be impaired in this mutant. Together, these findings provide amongst the first genetic and molecular links between the homeostatic control of sleep and synaptic plasticity. We find that *insomniac* is expressed in both presynaptic motor neurons and postsynaptic muscles, but is needed in the postsynaptic cell to drive the acute induction and expression of PHP. While we find no major defects in synaptic growth or architecture in *insomniac* mutants, Insomniac is localized to Golgi and ER structures, suggesting that modulation of the postsynaptic secretory pathway may be a target of the retrograde homeostatic signaling system. Finally, we have identified a putative substrate that colocalizes with Insomniac in Golgi and ER structures and implicates unconventional protein secretion in the induction of homeostatic plasticity. An

attractive hypothesis is that Insomniac controls postsynaptic secretory pathways to homeostatically modulate synaptic strength, and, perhaps, sleep behavior.

Title: Tyrosine kinase-based synaptic signals drive the long-term maintenance of homeostatic neuroplasticity

Authors: *C. FRANK[1], D. J. BRUSICH[2], A. M. SPRING[1];
[1]Anat. and Cell Biol., Univ. of Iowa, Iowa City, IA; [2]Biol., Wartburg Col., Waverly, IA

Abstract: Forms of homeostatic neuroplasticity endow neurons and circuits with an ability to maintain physiologically appropriate levels of synaptic output. Broken control of neuronal circuit function is hypothesized to contribute to conditions such as epilepsy and ataxia, as well as complex neurodevelopmental disorders like autism. Yet the molecular signals that direct the homeostatic control of synaptic outputs are poorly defined. We address this gap genetically by utilizing a model synapse, the glutamatergic Drosophila neuromuscular junction (NMJ). At the NMJ, genetic and pharmacological manipulations can decrease the sensitivity of postsynaptic receptors to single vesicles of neurotransmitter (quantal size). Decreased quantal size triggers retrograde, muscle-to-nerve signaling that drives increased transmitter release. In recent years, the NMJ has been key in characterizing conserved presynaptic processes that trigger a rapid homeostatic potentiation of neurotransmitter release. By contrast, almost nothing is known about how postsynaptic cells control the homeostatic potentiation of presynaptic neurotransmitter release or how the NMJ monitors its output over long periods of time. Through genetic screening and electrophysiological analyses, we have characterized how two classical tyrosine kinases in the postsynaptic muscle work to maintain the homeostatic signaling capacity of the NMJ throughout development. Our data demonstrate that the first one of these tyrosine kinases, C-terminal Src kinase (Csk), limits expression of the Neural Cell Adhesion Molecule (NCAM)

homolog Fasciclin II (FasII). Limiting FasII expression is necessary in order to propagate muscle-to-nerve homeostatic signaling. In the absence of Csk function, excess FasII/NCAM protein at the NMJ appears to inhibit the activity of a second tyrosine kinase in the muscle, the Drosophila Heartless (Htl) FGF Receptor. Htl and its signaling effectors are required for homeostatic potentiation and activation of the protein translation factor, Target of Rapamycin (TOR). TOR is an instructive factor previously shown to drive the long-term maintenance of synaptic homeostasis. We hypothesize that postsynaptic Htl/FGFR tunes synaptic strength throughout development by relaying multiple anterograde (nerve-to-muscle) and retrograde (muscle-to-nerve) signals.

Title: Dynamic effects of ethanol on microglia

Authors: ***T. J. WALTER**, F. CREWS;
Univ. of North Carolina - Chapel Hill, Carrboro, NC

Abstract: Alcoholism causes significant suffering, and further insight into the causes and consequences of this disease is necessary to provide more effective treatment. Recent research suggests not only that alcohol impacts microglia - the resident macrophages of the brain - but that microglia may contribute to the detrimental effects of alcoholism. Therefore, further investigation of the effects of alcohol on microglia may provide new insight into the causes of alcoholism. To more thoroughly define the effects of alcohol on microglia, BV2 microglial cells were treated with ethanol. The ethanol was allowed to evaporate away, thereby mimicking acute intoxication and withdrawal. Expression of various immune genes was examined at different time points. At early time points, while ethanol was still present, decreased expression of inflammatory genes TNF and Ccl2 was observed. However, at later time points, after the ethanol had evaporated, expression of TNF and Ccl2 was increased. These results suggest a dynamic, biphasic effect of ethanol on microglia. To further examine this dynamic effect, BV2 microglial cells were treated with lipopolysaccharide (LPS), a potent inflammogen, either during or after ethanol exposure. The presence of ethanol blunted LPS-induced expression of TNF and Ccl2.

However, treatment with LPS following ethanol treatment and evaporation increased expression of TNF and Ccl2. To determine whether alcohol induced similar effects in vivo, C57BL/6 mice were gavaged with an acute dose of ethanol. Expression of various immune genes was examined at different time points. Similar to the results obtained in vitro, TNF expression was decreased during intoxication but increased during withdrawal. Other immune genes such as Ccl2, IL-1B and IL-6 only increased during withdrawal. Microglial-specific genes such as CD68 also increased during withdrawal. Overall, these results suggest that alcohol has dynamic, biphasic effects on microglia. During acute intoxication, ethanol exhibits an anti-inflammatory effect, while withdrawal from ethanol has a pro-inflammatory effect. These results may lead to a greater understanding of the causes and consequences of alcoholism and potentially provide new insights for treatment.

Title: The role of microglial tlr-myd88 function in the cns after chronic intermittent ethanol.

Authors: *P. D. RIVERA[1], K. M. MILLER[2], H. S. SWARTZWELDER[2], S. D. BILBO[1]; [1]Dept. of Psychology and Neurosci., Duke Univ., Durham, NC; [2]Dept. of Psychiatry and Behavioral Sci., Duke Univ. Med. Ctr., Durham, NC

Abstract: It is now appreciated that drugs of abuse - including alcohol - promote a neuroimmune response from glia, primarily microglia, which may play an important role in mediating addictive-like behaviors. For example, alcohol consumption is linked to an increase in innate immune receptors, Toll-Like-Receptors [TLRs], within the CNS in humans and rodents. However, because central immune signaling pathways are pleiotropic and redundant, the elucidation of specific molecular pathways underlying excessive alcohol-induced pathophysiology, and therefore effective interventions, has been difficult. One major difficulty is that TLRs may be broadly expressed in CNS tissue. For example, TLR4 is expressed in neurons, astrocytes, and endothelial cells, in addition to microglia. Thus, the specific contribution of microglial TLR responses after excessive alcohol consumption has yet to be deciphered. Therefore, to better understand the pathogenesis of alcohol addiction, the innate immune

response specifically from microglia vs. other cell types after binge chronic intermittent ethanol (CIE) consumption was examined. To do so we used a novel transgenic mouse line in which TLR function is specifically ablated only in microglia within the CNS (CX3CR1-Cre x MyD88$^{f/f}$). Male CX3CR1-Cre$^{+/-}$ x MyD88$^{f/f}$ mice (8 weeks old) were exposed to either CIE (20% w/v) or chronic intermittent water (CIW, controls) for 16 days (10 doses). Blood was collected in a parallel group after ethanol dosing to measure blood alcohol levels (BALs). Mice were sacrificed 24 hrs after the last ethanol dose and the brain was extracted and flash frozen. Brains were sectioned, punches of the central amygdala and prefrontal cortex were taken, and a Toll-like receptor-signaling pathway PCR array was examined. Both CIE and CIW groups showed normal weight gain and reached BALs of ~100 mg/dL. Any changes in the gene expression profiles between the CIE and CIW groups would prove beneficial to understanding the role of microglial TLR-MyD88 signaling. Future directions include examining the gene expression profiles of CIE adolescent mice versus adult mice.

Title: Chronic ethanol exposure provokes diverse microglial activation patterns in region-specific manner in the mouse brain.

Authors: *S. MONTGOMERY[1], M. BAJO[1], S. HUITRON-RESENDIZ[2], T. NADAV[2], L. N. CATES[2], E. F. CRAWFORD[1], K. CHENG[3], H. YIN[3], A. J. ROBERTS[2], M. ROBERTO[1]; [1]Committee on the Neurobio. of Addictive Disorders, The Scripps Res. Inst., LA Jolla, CA; [2]Mol. and Cell. Neurosci., The Scripps Res. Inst., La Jolla, CA; [3]Chem. and Biochemistry, BioFrontiers Inst., Univ. of Colorado Boulder, Boulder, CO

Abstract: Neuroinflammation and aberrant neuroimmune responses are common characteristics of a variety of neurodegenerative diseases and psychiatric disorders, including alcohol use disorder (AUD). Alcohol exposure has been shown to induce diverse neuroimmune responses between brain regions in both animal models and humans. In this study, we focused on microglia, the resident immune cells of the brain and critical regulators of the brain's innate immune response. We used a 2BC-CIE (two-bottle choice - chronic ethanol intermittent vapor exposure) paradigm to induce ethanol dependence in C57BL/6J mice and examined expression of microglial markers (Iba-1 and CD11b) via immunohistochemistry in the central amygdala (CeA) and prefrontal cortex (PFC) - brain regions that play an integral role in the development of alcohol dependence. During early ethanol withdrawal (4-8 h), we found an increase in Iba-1 expression and total optical density (OD) in the PFC but not in the CeA. However, chronic ethanol increased ramification of CD11b+ microglia in the CeA. Further morphological analyses of CD11b+ microglia in the PFC are currently under investigation. In a separate study, we systemically administered a TLR4-inhibitor, T5342126 (57 mg/kg, injected i.p for 14 days) and found that it reduced the OD of Iba-1 in the CeA of both ethanol-dependent and non-dependent mice. Overall, our data indicate that the development of alcohol dependence involves brain region-specific dysregulation of microglial responses, which may contribute to ethanol-induced neuroadaptive changes in the neural networks of those regions. Thus, understanding brain-region specific mechanisms behind chronic ethanol-induced neuroimmune responses and how these responses change throughout different stages of addiction is critical for further development of novel immune-based therapies, specifically for the treatment of AUD.

Abstract: Binge drinking, the most common pattern of alcohol intake in the United States, is characterized by discrete episodes of high blood alcohol content. Binge drinking damages brain structures such as the hippocampus and medial prefrontal cortex (mPFC), causing cognitive impairments. Using a rodent model of binge alcohol damage, we have found decreased granule neurons in the dentate gyrus (DG) and altered microglia morphology in the mPFC. In contrast to binge drinking, exercise benefits neural health; we have shown voluntary exercise restores the binge-damaged DG. The beneficial actions of exercise appear to be due in part to its profound effect on glia. Thus, investigating the interactive effects of binge alcohol and exercise allows us to explore how glia respond to neural damage and recovery. This area of research is also clinically relevant due to the positive association between alcohol and exercise, such that drinkers tend to be more physically active than abstainers.
We are investigating the interactive effects of binge and exercise on the number and morphology of microglia in the mPFC. Adult female Long-Evans rats were gavaged with ethanol (25% w/v) in nutritionally complete diet every 8 hours for 4 days. Control animals received isocaloric control diet. After 7 days of abstinence, rats remained sedentary or exercised for 10 days. We found increased microglia in the mPFC of exercised control animals, and binged animals independent of exercise. Morphological analysis revealed a subpopulation of larger, thicker microglia consistent with descriptions of primed microglia. These primed microglia were found in all animals regardless of experimental condition, however, the binge exercise group had the most. In a separate cohort of animals that exercised for 4 weeks post binge, we found that binge exercise animals had a significant decrease in microglia compared to binge sedentary and control exercise animals. Thus, longer periods of post-binge exercise are associated with a decrease in microglia. Furthermore, computational arbor analytics of remaining microglia revealed that the binged animals (regardless of exercise) had microglia with thicker arbors and significantly less branching. It appears that despite a binge-induced increase in microglia, prolonged post-binge exercise significantly reduces microglia numbers. Furthermore, the remaining microglia display a phenotype indicative of partial activation, suggesting that it is the primed microglia that survive prolonged post-binge exercise. We are continuing to investigate how binge alcohol coupled with exercise alters microglia and the implications of this for overall neural health and functioning.

Title: Hyperthermia activates microglia to engulf inhibitory synapses in early-life seizures

Authors: *R. KOYAMA[1], Y. KASAHARA[1], K. SHIBATA[1], S. UJITA[1], S. SUGIO[2], K. F. TANAKA[3], K. SHIBASAKI[2], Y. IKEGAYA[1];
[1]Grad. Sch. of Pharmaceut. Sciences, The Univ. of Tokyo, Tokyo, Japan; [2]Dept. of Mol. and Cell. Neurobio., Gunma Univ. Grad. Sch. of Med., Gunma, Japan; [3]Dept. of Neuropsychiatry, Keio Univ. Sch. of Med., Tokyo, Japan

Abstract: Hyperthermia (typically greater than 38°C)-induced febrile seizures are the most common type of seizures in early childhood. Prolonged febrile seizures could afterwards initiate the development of acute encephalopathy consisting of a cluster of seizures and postictal coma, which is often followed by the development of epilepsy. The induction of delayed seizures after febrile seizures indicates the prolonged impairment in the excitatory versus inhibitory balance (E/I balance) of synapses; however the cellular and molecular link between hyperthermia and E/I imbalance is missing. Here we report that microglia, the brain-resident immune cells, disrupt the synapse E/I balance in dentate circuits with the phagocytic capacity. Microglia detected the increase in brain temperature during experimental febrile seizures by the $Ca2^{+}$-influx through activation of transient receptor potential vanilloid 4 (TRPV4), which is a thermosensor activated by >34°C. The TRPV4-mediated $Ca2^{+}$-influx led microglia to preferentially engulf inhibitory synapses, resulting in a decrease of the density of inhibitory synapses in the dentate gyrus. Finally, minocycline, an inhibitor of microglial activation, decreased the delayed seizure severity after febrile seizures. Thus, our study provides a novel mechanism by which the brain hyperthermia impairs the synapse E/I balance via activation of microglia.

Title: Synaptic excitation and ltp are altered in juvenile trem2-deficient mice

Authors: *P. W. HICKMOTT[1], A. MADANY[2], M. CARSON[2];
[1]Psychology & Interdepartmental Neurosci. Pgm., Univ. California, Riverside, Riverside, CA;
[2]Div. of Biomed. Sci. and Interdepartmental Neurosci. Pgm., Univ. of California, Riverside, Riverside, CA

Abstract: Microglia are the resident tissue macrophage of the central nervous system. Within the brain, microglia are the only cells expressing the Triggering Receptor Expressed on Myeloid cells-2 (TREM2). Humans completely lacking a functional TREM2 pathway develop early onset dementia, while mutations in the ligand-binding pocket of TREM2 are associated with increased risk of Alzheimer's disease. Until recently, microglia were characterized primarily for their tissue defense and tissue repair functions but now microglia are realized to play key roles in modulating synaptic maturation. Here we examined the synaptic maturation within the CA1 region of the hippocampus. Histologically, we find that TREM2 deficient mice have reduced numbers of vGlut1+ puncta indicative of fewer excitatory synapses, without any apparent deficiencies in GAD65+ puncta indicative of unchanged numbers of inhibitory synapses. To determine whether these histologic measures were associated with physiologic changes, we recorded excitatory and inhibitory synaptic currents (EPSCs and IPSCs) from the CA1 region of hippocampus. In brief, we found alterations in EPSC amplitudes but not IPSC amplitudes. Long-term dynamics, measured by comparing the ability to induce long-term potentiation (LTP), were also affected. These data illustrate that primary defects in microglia are sufficient to cause alterations in synaptic development.

Title: TREM2 and CCR2 mediated regulation of hippocampal synapse development

Authors: *A. MADANY, Y. OTANI, D. DAVIS, S. SLONIOWSKI, I. ETHELL, M. J. CARSON;
Univ. of California Riverside, Riverside, CA

Abstract: Microglia are the resident brain macrophage, long recognized to support brain function in both health and disease. Recently, microglia are recognized to contribute to synaptic editing and/or maturation in a C1q dependent fashion. Triggering Receptor Expressed on

Myeloid cells-2 (TREM2) is an immunomodulatory receptor expressed on microglia within the brain. Individuals lacking a TREM2 pathway develop early onset cognitive dementia (Nasu-Hakola disease), whereas individuals with mutations in the ligand binding pocket of TREM2 have increased risk of Alzheimer's disease. Therefore, we hypothesized that synaptic maturation in TREM2 deficient mice or might be altered either inherently or as a consequence of potentially aberrant responses to systemic inflammation. Therefore, we quantified vGlut1+ and GAD65+ puncta in the hippocampus of TREM2KO and wild-type (WT) mice at postnatal day 15 +/- systemic immune challenge. While systemic inflammation causes a sustained decrease in vGlut1+ puncta in WT mice, we found that in untreated TREM2KO mice the numbers of vGlut1+ puncta were decreased to the levels similar to immune challenged WT mice brain. We found that both homeostatic (developmental) and immune challenge induced editing of vGlut1+ puncta was dependent on C1q in WT mice, while immune challenge induced editing was also dependent on CCR2 and an apparent influx of blood derived macrophages. By contrast, the numbers of vGlut1+ puncta in untreated TREM2KO mice were already reduced to levels similar to immune challenged WT mice. Furthermore, the decreased numbers of vGlut1+ in TREM2KO mice was not dependent on C1q nor CCR2. Taken together these data reveal that (1) both microglia and brain infiltrating macrophages can regulate excitatory synapse maturation during systemic inflammation; (2) TREM2 prevents non-C1q and macrophage mediated synaptic editing during normal development; (3) defects in microglia can alter developmental maturation of brain function in the absence of induced injury or infection.

Title: Noradrenergic modulation of microglial dynamics and synaptic plasticity

Authors: *R. STOWELL, G. SIPE, A. MAJEWSKA;
Univ. of Rochester, Rochester, NY

Abstract: Microglia, the innate immune cells of the central nervous system (CNS), respond rapidly and dynamically to homeostatic perturbations of the CNS milieu. In the healthy unperturbed brain, microglial processes make frequent contracts with neurons at synapses, impacting synaptic remodeling and turnover of dendritic spines. However, it remains unclear what receptors and signaling pathways govern microglial surveillance and synapse monitoring. Noradrenaline is a powerful signal that can affect many aspects of synaptic function and plasticity. Because microglia express high levels of **β**2 adrenergic receptors (AR) compared to other cell types in the brain, we asked whether noradrenergic tone could alter microglial behavior with respect to synapses through **β**2 AR signaling. To begin to test this hypothesis we have manipulated **β**2 AR signaling pharmacologically using the following agents: Nadolol (BBB impermeant **β**AR antagonist), Clenbuterol (BBB permeant **β**2 AR agonist), and ICI 118-51 (BBB permeant **β**2AR antagonist). We paired nadolol with clenbuterol to stimulate **β**2 AR centrally without concomitant peripheral stimulation. We then evaluated changes in basic microglial physiology through a combination of *in vivo* two-photon microscopy and immunohistochemistry staining for Iba-1 and CD68. We have found that stimulation of **β**2 AR signaling *in vivo* reduces microglial motility and pseudopodia formation and causes microglia to assume a less ramified morphology. Thus our next question was if these changes in basic microglial function could impact microglial interactions with neurons and ocular dominance plasticity. Using intrinsic optical signal imaging we have shown that pharmacological manipulation of **β**2 AR signaling impairs ocular dominance plasticity during the visual critical period in mice. We are now testing the direct involvement of microglia in this impairment through cre-mediated excision **β**2 AR specifically in microglia. Based on our results we believe that **β**2 AR signaling serves important roles in modulating microglial physiology and our future experiments will begin to address how the endogenous ligand, norepinephrine, is involved in mediating the effects observed. These results and future findings will improve our understanding of the signaling mechanisms that govern microglial interactions with synapses and impact activity-dependent synaptic modification.

Title: Deficient autophagy in microglia results in impaired synapse pruning and social behavior

Authors: *H.-J. KIM[1,2], M.-H. CHO[2], W.-H. SHIM[3], J.-K. KIM[3], S.-Y. YOON[2];

Abstract: Autism spectrum disorders (ASDs) are neurodevelopmental disorders caused by various genetic and environmental factors resulting in the abnormalities of synapses. Microglia are suggested to be related with ASDs and play a role in refining synapses during development. Autophagy and related pathways are also suggested to be related with ASDs. However, the precise roles of autophagy in microglia on synapses and ASDs are unknown. Here we show that microglial autophagy refines synapses and regulates neurobehaviors. We found that atg7 deletion in the myeloid cell specific lysozyme-M cre mice showed social behavioral defects and repetitive behaviors, characteristic features of ASDs. These mice also showed increased dendritic spines, synaptic markers and altered connectivity between brain regions indicating defects in synapse refinement. Degradation of synaptosomes was impaired in atg7-deficient microglia and immature dendritic filopodia were increased in neuron cultures with atg7-deficient microglia. Our results first demonstrate the role of microglial autophagy in synapse regulation and neurobehaviors. We anticipate our results to be a starting point for more comprehensive understanding of microglial autophagy in ASDs and putative therapeutics development.

Title: The inflammatory response following a laser-induced cortical microhemorrhage in a rodent model is dominated by migration of brain-resident microglia

Authors: *S. AHN[1], J. ANRATHER[2], N. NISHIMURA[1], C. B. SCHAFFER[1];
[1]Meinig Sch. of Biomed. Engin., Cornell Univ., Ithaca, NY; [2]Feil Family Brain and Mind Res. Inst., Weill Cornell Med. Col., New York City, NY

Abstract: Clinical studies have linked microhemorrhages with cognitive decline, although how these small bleeds impact cognition is not understood at the cellular level. We used optical approaches to create microhemorrhages and image the cellular responses in the brain of mice. Irradiation with tightly-focused femtosecond laser pulses ruptured targeted penetrating arterioles, producing a hematoma of ~150-μm diameter in the cortex. Such lesions did not cause neural death, but did drive an increase in the number of nearby activated inflammatory cells. Such inflammation could have a profound impact on neural health and function. Here, we aim to understand the relative role of brain-resident and blood-derived inflammatory cells. We used chimeric transgenic animals with different inflammatory cell populations labeled with fluorescent proteins, and mapped the spatial and temporal profile of the cellular response after a microhemorrhage. We observed brain-resident microglia activate soon after the microhemorrhage and the doubling of their density adjacent to the lesion is the dominant aspect of the inflammatory response. A small number of blood-derived inflammatory cells were also found, with ~3 proinflammatory monocytes (CCR2+) entering the brain during the first two days after the lesion, and ~3 patrolling monocytes (CX3CR1+) entering after two days. The doubling of microglia density one day after the lesion could be due to migration and/or proliferation of microglia. Using time-lapse imaging, we observed microglia immediately send processes to, and then migrate over one day toward, the ruptured arteriole. For microglia within 150 μm of the targeted vessel, the migration speed was 0.9 μm/hr over the first 16 hours and then slowed. We used EDU staining to look for signs of microglia proliferation and found just one EDU positive microglia out of 163 (5 hemorrhages across 2 mice). Together these data suggest that the microglia density increase after a microhemorrhage is almost exclusively due to migration. Over two weeks the microglia density returned to baseline. To determine if apoptosis played a role in this decrease, we used TUNEL staining at four days after the lesion and found no TUNEL-positive microglia (0 out of 93 microglia; 6 hemorrhages across 2 mice). In summary, small brain bleeds trigger migration of nearby microglia toward the lesion, doubling the microglia density, and drive the infiltration of a very small number of inflammatory and patrolling monocytes. In ongoing work, we are exploring how this inflammation could affect the health and function of nearby brain cells and thus drive cognitive decline.

Title: The role of APOE in MS-associated neuroinflammation

Authors: *E. CUDABACK;
Dept. of Hlth. Sci., Depaul Univ., Chicago, IL

Abstract: Multiple sclerosis (MS) is an autoimmune demyelinating disease of the central nervous system (CNS) that causes debilitating symptoms due to a loss of neuron conductivity. Encephalitogenic CD4+ T helper (Th) cells inappropriately respond to myelin antigens and invade the CNS, producing a variety of pro-inflammatory cytokines that activate resident innate immune cells, namely microglia and astrocytes, resulting in exacerbated or protracted neuroinflammatory responses that are thought to contribute to MS pathology. Autoreactive Th17 cells in particular are pathogenic in many inflammatory disorders, including MS, and make up a substantial portion of the inflammatory infiltrate in active lesions presenting in MS patients. While the molecular determinants influencing sensitivity and responsiveness of the affected brain to these inflammatory insults remain poorly understood, genetic studies have identified many potential disease risk alleles. Indeed, evidence suggests that *APOE* may act as an MS modifier, specifically influencing disease progression, severity, and cognitive outcomes, although observations in humans have been inconsistent. Because *APOE* genotype is known to differentially influence glial inflammatory responses to a broad range of insults, we decided to examine how *APOE* genotype modulates microglial and astrocyte activation in response to Th17 cell signaling cues. Our results support a role for *APOE* in MS neuroinflammation and expand our understanding of CNS inflammatory mechanisms, allowing for additional characterization of novel cellular and molecular therapeutic targets for MS.

Title: Microglia rapidly adopt a filopodia-rich phenotype during hypoxia by sensing tissue acidosis.

Authors: *L.-P. BERNIER, L. DISSING-OLESEN, J. K. HEFENDEHL, J. M. LEDUE, B. A. MACVICAR;
Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Microglia are highly motile cells that play a pivotal role in monitoring brain homeostasis by constantly probing the environment and responding to extracellular cues. They are involved in stroke-related pathologies by undergoing complex long-lasting transcriptional and functional changes. However the acute response of microglia to the metabolic stress of ischemia remains unclear. Here, we used two-photon imaging *in vivo* and in acute brain slices to monitor the initial effect of hypoxia on the morphological phenotype and dynamic properties of microglia. The highly ramified morphology of resting microglia is rapidly transformed during oxygen depletion with extension of fine actin-dependent filopodia followed by retraction of microtubule-dependent ramifications. This rapidly reversible switch in morphology drives significant changes in microglial sensing, affecting the capacity of microglial cells to respond to tissue damage. During short hypoxic insults, we show that this initial phenotypic switch is induced by microglia sensing the accompanying acidic shift in the extracellular environment. Concurrent observations indicate that rapid extension and retraction of actin filament-rich filopodia at the tip of major ramifications is an integral part of the microglial sensing behavior. This finely tuned random-searching dynamic process depends on compartmentalized cAMP signals, and overproduction of intracellular cAMP triggers dysregulated filopodia extension and retraction of ramifications, thereby leading to a phenotype similar to that observed during hypoxia. Characterizing the highly specialized sensing structures of microglia and defining the molecular cues responsible for the functional switch of microglial behaviour observed upon oxygen depletion will likely provide promising targets for stroke treatment.

Title: Transducing acidosis to panic: role of microglial and renin angiotensin system (RAS) mechanisms

Authors: ***A. WINTER**[1], R. SAH[2], L. VOLLMER[2], R. AHLBRAND[2], E. KRAUSE[3]; [1]Psychiatry, [2]Univ. of Cincinnati, Cincinnati, OH; [3]Univ. of Florida, Gainesville, FL

Abstract: Panic disorder (PD) is a complex anxiety disorder characterized by spontaneous, recurrent panic attacks consisting of intense fear, cardiovascular, and respiratory symptoms. Altered acid-base homeostasis has been observed in PD patients. CO_2 inhalation, an inducer of acidosis, evokes panic attacks in PD patients. Recent studies from our lab reported a role of microglial acid sensing and pro-inflammatory cytokine IL-1β in CO2-evoked fear (Vollmer et al Biological Psychiatry 2016). CO2 evoked microglial activation occurs within the subfornical organ (SFO), an area lacking the blood-brain-barrier and relevant to homeostasis. However, mechanisms transducing microglial acid sensing and inflammation to panic-relevant behavior are currently unknown. The current study investigated a potential role of renin angiotensin system (RAS) as an effector transducing microglial acid sensing to CO2-evoked fear. Microglial-RAS interactions have been recently reported, and importantly, RAS polymorphisms have been reported in PD patients . Angiotensin expressing neurons are abundant in the SFO and our recent studies show expression of IL-1b receptors on these neurons suggesting potential link between RAS and inflammatory mechanisms. Angiotensin II-type I receptor antagonist, losartan, was delivered intracerebroventricularly (ICV) in the vicinity of the SFO. Losartan or vehicle injected mice were exposed to CO_2 inhalation for 10 min. Fear (freezing) was measured during the 10 min CO_2 exposure and 24 hr post-CO_2 during exposure to context alone. A significant attenuation of freezing was observed in losartan treated mice during CO_2 (46%; $p<0.05$) and during conditioned contextual fear (47%; $p<0.05$). cFos immunohistochemistry revealed a significant decrease in cFos+ cells within the lateral hypothalamus (LH: 40%, $p<0.05$) and periaqueductal gray (PAG: 20%, $p<0.05$), brain regions connected to the SFO that regulate panic-relevant fear, cardiovascular and respiratory responses. Tracing studies are currently being

performed to validate this circuitry. Collectively, our data suggest SFO microglial inflammation-RAS interactions in transducing CO_2-evoked fear, providing a novel mechanistic basis for understating panic pathophysiology.

Title: Cytosolic immature cathepsin D controls F-actin-mediated lamellipodia extension in microglia

Authors: ***Y. LIU**[1], T. ZHANG[1], L. QIN[1], Y. ZHANG[2], X. LI[1], J. YANG[1], Y. HU[1], Z. GUO[1], H. LOU[1], M. HO[3], S. DUAN[1];
[1]Dept. of Neurosci., Zhejiang Univ., Zhejiang, China; [2]Affiliated Hosp. of Nantong Univ., Nantong, China; [3]Tongji Univ. Sch. of Med., Shanghai, China

Abstract: Rapid moving cells such as microglia evolve complex mechanisms that dynamically shape cytoskeleton to provide structural cues for injury-induced migration. During structural reorganization, endosome/lysosome-related enzymes, with their degradative function, have been implicated in signaling migration, debris uptake, and injury repair. However, to date, how these enzymes modulate cytoskeletal dynamics remain mysterious. Here we present evidence that the immature 48kDa lysosomal enzyme cathepsin D (cathD) translocates to the microglial cytosol via a mechanism that depends on Hsp70-mediated membrane permeability. Upon ATPγS stimulation, cytosolic cathD localizes to the F-actin lamellipodia at the leading edge, where directional migration begins to occur. Down regulation of cathD expression using siRNA, drug inhibitor, or in cathD-deficient microglia leads to the maintenance failure of lamellipodia protusions, albeit initial extensions remain unaffected. Intriguingly, cathD interacts with the actin-severing protein cofilin and controls the availability of G-actin monomers via cofilin phosphorylation. On the other hand, treatment with cytochalasin D rescues the cathD-mediated

lamellipodia maintenance defects, pinpointing a role for cathD in controlling the amount of available raw materials, rather than the functional extension for actin filament assembly. Taken together, our results identify a key lysosomal factor that exhibits an unconventional cytosolic localization during ATP-evoked responses in microglia. Cytosolic cathD contributes to actin filament assembly and cytoskeleton reorganization via regulating cofilin activity. These findings underlie the mechanism of microglial migration and significantly advance our understanding in how microglia respond to pathological injury.

Abstract: Microglia, the brain resident macrophages, play important roles in life-long brain maintenance and in pathological conditions. In addition, these cells are crucial players during central nervous system development. Yet, the mechanisms that regulate the dynamics during this maturation process has not been fully elucidated. Using genome-wide single-cell transcriptomic analysis and chromatin profiling we revealed that microglia undergo three temporal developmental stages in synchrony with the brain: early, pre-, and adult microglia, which are under the control of distinct regulatory circuits. Environmental perturbations, such as disrupted microbiome or prenatal immune activation, led to dysregulation of the developmental program, particularly in terms of inflammation. Knockout of MafB, a transcription factor which is predominantly expressed in the adult microglia, resulted in disturbance of homeostasis and increased expression of inflammatory genes. Together, our work identifies the circuits of a

microglia developmental programs that maybe associated with susceptibility to neurodevelopmental disorders.

Title: Nuclear GAPDH cascade and cellular autofluorescence: microglia-mediated novel mechanisms involved in cognitive deficits in schizophrenia

Authors: *A. RAMOS[1], N. ELKINS[1], T. TSUJIMURA[1], T. SAITO[2], F. EMILIANI[1], N. GAMO[1], C.-Y. LI[1], T. SEDLAK[1], C. KORTH[3], K. ISHIZUKA[1], A. SAWA[1];
[1]Psychiatry and Behavioral Sci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [2]Aomori Univ., Aomori, Japan; [3]Univ. of Duesseldorf Med. Sch., Duesseldorf, Germany

Abstract: Behavioral flexibility is one of the most important behavioral constructs that is required for adaptability. This behavior is affected under stress conditions, and its disturbance is involved in many neuropsychiatric disorders, in particular schizophrenia. Nonetheless, molecular and cellular mediators for this behavior are unclear.
To address this question, we used LPS-treated mice (a model frequently used to represent brain pathology upon stressors such as immune inflammatory or oxidative stress). We found that the mice displayed behavioral inflexibility in a paradigm using rule shifting. Interestingly, the behavioral deficits were ameliorated by a compound (1R,3R)-1,3-dymethyl-2-propargyl-1,2,3,4tetrahidrosiquinoline (called RR). RR is a potent blocker of the nuclear GAPDH cascade (Hara *et al*. Nat Cell Biol. 2005). Therefore, we next validated whether the nuclear GAPDH cascade was indeed activated after LPS treatment. We found that the cascade was activated selectively in microglia. Several studies in behavioral neuroscience have indicated the involvement of the prefrontal cortex for behavioral flexibility. Consistent with this notion, we observed selective activation of the nuclear GAPDH cascade in cortical, but not striatal, microglia. Together, we now propose that a nuclear pool of GAPDH that is known to modulate epigenetic and transcriptional machinery specific to microglia may be a key molecular and cellular mediator for behavioral flexibility.

To extend this preclinical observation into clinical settings, we have looked for molecular and cellular markers that correlate with behavioral inflexibility (e.g., deficits in Wisconsin Card Sorting Test) in patients with schizophrenia (SZ). We found that autofluorescence in lymphoblasts is significantly higher in SZ, compared with matched controls, which is independent of medication. In particular, the extent of the behavioral inflexibility was correlated with the levels of impairment in the cellular autofluorescence. As far as we have tested multiple independent behavioral constructs in humans, behavioral flexibility is the only one that shows correlation with autofluorescence. Importantly, the aberrant autofluorescence has been normalized by RR, the blocker of the nuclear GAPDH cascade.
Together, we propose that: 1) The activation of the nuclear GAPDH cascade in cortical microglia is involved in a mechanism responsible for behavioral flexibility. 2) Autofluorescence that may reflect the activation of the nuclear GAPDH cascade pathway is a possible high throughput biomarker for behavioral inflexibility in schizophrenia.

Title: THIK-1 regulates cytokine release by microglia

Authors: V. KYRARGYRI[1], C. MADRY[1], R. JOLIVET[1,2,3], *D. ATTWELL[1];
[1]Univ. Col. London, London, United Kingdom; [2]Univ. of Geneva, Geneva, Switzerland; [3]CERN, Geneva, Switzerland

Abstract: Microglia are the resident macrophages of the central nervous system (CNS), which continually survey the brain for infectious agents, amyloid plaques and unnecessary neurons and synapses. Upon activation, microglia generate an inflammatory response, which can lead to neuronal cell death in a number of neurodegenerative diseases. This involves activation of the NLRP3 inflammasome and subsequent release of proinflammatory cytokines (Guo et al., Nat. Med., 2015). We recently found that microglial surveillance is regulated by the resting membrane potential, which is set by the tonic activity of THIK-1, an anaesthetic-sensitive two-pore domain K^+ channel highly expressed by microglia in the brain (Madry et al., submitted). In addition to their tonic activity, THIK-1 channels are activated by brain damage or ATP, causing

a strong hyperpolarisation via K^+ efflux, which may be an important trigger for inflammasome activation. Indeed, we now report that THIK-1 also plays an important role in regulating the microglial inflammatory response. Acute hippocampal slices from P12 rats were exposed for 3 h to lipopolysaccharide (LPS) followed by 3 h incubation with LPS and ATP. The supernatants were collected and the amounts of released interleukin (IL)-1β and TNFα were quantified by ELISA. LPS alone (but not ATP) induced a release of IL-1β and TNFα, however the production of IL-1β (but not of TNFα) was greatly increased after application of LPS and ATP together. Blocking THIK-1 with tetrapentylammonium (TPA) abolished the release of IL-1β and TNFα in response to LPS alone, or to LPS with ATP, whereas 4-AP and charybdotoxin had no effect, excluding a role for voltage- and Ca^{2+}-activated K^+ channels. Pharmacological inhibition of THIK-1 channels by TPA also abolished the cell death induced by LPS and ATP, as measured by assaying LDH released into the supernatant. Our results show that, in addition to controlling microglial surveillance, THIK-1 is also necessary for microglia to generate an inflammatory response, and raise the possibility of therapeutic targeting of THIK-1 in neuroinflammation-driven diseases.

Title: Neuroprotective effect of nicotine by inhibition of microglial proton currents via alpha7 nAChR

Authors: ***M. NODA**[1], A. KOBAYASHI, 812-8582[2];
[2]Pharmaceut. Sci., [1]Kyushu Univ., Fukuoka, Japan

Abstract: Alpha 7 subunits of nicotinic acetylcholine receptors (nAChRs) are expressed in microglia and are involved in the suppression of neuroinflammation. Over the past decade, many reports show beneficial effects of nicotine, though little is known about the mechanism. Here we show that nicotine inhibits lipopolysaccharide (LPS)-induced proton (H^+) currents by using primary cultured microglia. (Methods) The H^+ channel currents were measured by whole-cell

patch clamp method under voltage-clamp condition. The morphological change was observed by immunocytochemical method. The expression level of H^+ channels was measured by western blotting. Neurotoxicity was tested by using primary cultured neurons from mouse hippocampus and cortex and LPS-treated microglial conditioned medium. The number of live neuronal cells with or without LPS application was checked by using Cell Counting Kit-8. (Results) H^+ currents in cultured newborn mouse brain microglia recorded at physiological temperature were specifically activated at positive potentials by 24-h LPS pretreatment. Increased H^+ current in activated microglia was attenuated by blocking NADPH oxidase, confirming its physiological role of electrical charge compensation following negatively charged superoxide generation in the extracellular compartment. Nicotine produced a dose-dependent inhibition of LPS-activated H^+ current, with an apparent IC_{50} of 112.1 nM. Morphological changes associated with LPS-induced microglial activation were almost completely reverted by nicotine. Nicotine reverted only H^+ current levels but not increased HVCN1 protein expression upon LPS exposure of cultured microglia. The inhibitory effect of nicotine was exerted via nAChRs, being completely counterbalanced by pretreatment with specific alpha7 nAChRs inhibitors such as alpha-bungarotoxin or methyllicaconitine. Nicotine pretreatment of LPS-stimulated microglia was able to inhibit neurotoxic effects of microglial-conditioned cell culture medium. (Discussion) These results suggest that alpha7 nAChRs in microglia may be a therapeutic target in neuroinflammatory diseases.

Title: Elimination of microglia in adult mouse forebrain does not alter kynurenine 3-monooxygenase activity

Authors: *K. V. SATHYASAIKUMAR[1], P. SEVERSON[2], B. L. WEST[2], R. SCHWARCZ[1]; [1]Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Plexxikon Inc., Berkeley, CA

Abstract: Kynurenine 3-monooxygenase (KMO) plays a key regulatory role in the kynurenine pathway (KP) of tryptophan degradation, which contains several neuroactive metabolites. Impairment of KMO has been implicated in several major brain diseases including Huntington's disease and schizophrenia. In the mammalian brain, KMO has been suggested to be predominantly localized in microglial cells (Alberati-Giani et al., 1996; Heyes et al., 1996;

Guillemin et al., 2001), but verification *in vivo* has not been provided so far. The present study was designed to examine possible impairments in KP metabolism in the mouse brain after depleting microglial cells in the central nervous system through pharmacological inhibition of the colony stimulating factor 1 receptor (CSF1R). The CSF1R inhibitor PLX5622 depletes microglia in normal mice by 80% after 1 week of treatment, as determined by anti-IBA-1 immunohistochemistry (Dagher et al., 2015). In the current tests, separate male C57BL/6J mice (~2-month-old) were fed PLX5622 (1200 ppm in chow) for 21 days, while controls received normal chow. Animals were euthanized either on day 22 (control: n=6; treated: n=6) or, after receiving normal chow for an additional 21 days, on day 43 (n=3). To verify the depletion of microglia in the forebrain, the expression of several marker genes was assessed in one hemisphere using real-time PCR. *KMO* expression, KMO activity, KYNA and 3-hydroxykynurenine (3-HK) levels were determined in parallel using the second hemisphere. As expected, expression of the marker genes *Aif1* (-89%), *Csf1r* (-97%), *Cx3cr1* (-97%), *Siglech* (-97%) and *Tmem119* (-90%) was dramatically reduced on day 22 but had recovered by day 43. In contrast, PLX5622 did not cause any significant changes in either *KMO* expression or KMO activity at any timepoint. The brain levels of KYNA and 3-HK were also unchanged. Taken together, our data suggest that microglial cells do not harbor the majority of KMO in normal adult mouse brain. Possible compensatory events following PLX5622 treatment, as well as alternative scenarios in dysfunctional states, are currently under investigation.

Title: Sex-specific vulnerability to maternal immune activation - Are microglia involved?

Authors: *S. M. SCHAAFSMA, K. E. LAUPMAN, E. M. HOL, M. JOËLS;
Brain Ctr. Rudolf Magnus / Translational Neurosci., Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

Abstract: Prenatal stress, including maternal immune activation (MIA), has long term effects on brain and behavior. It is becoming increasingly clear that environmental factors such as prenatal

stress, in addition to genetic factors, play an important role in the etiology of neurodevelopmental and neuropsychiatric disorders. Prenatal stress has sex-specific effects, with males showing the most pronounced deficits in behaviors when exposed to early prenatal stress. Many neurodevelopmental and neuropsychiatric disorders show a sex bias in incidence. E.g. for every girl diagnosed with an autism spectrum disorder, there are 4 males. Microglia are the main innate immune cells of the brain and respond quickly to injury and inflammation. Chronic activation of microglia can have detrimental effects and is observed in patients diagnosed with a neurodevelopmental disorder. Prenatal stress can activate microglia which can last well into adulthood. Besides microglia´s immune function, these cells are also involved in the masculinization process. Blocking male-specific neonatal microglia activation prevents masculinization of brain and behavior in male rodents (Lenz *et al.* J. Neurosci. 2013). We hypothesize that males that are exposed to MIA experience two hits on their neonatal microglia (due to MIA and due to masculinization) - versus one hit in females - which may explain the male-specific effects of prenatal stress on behavior later in life. Time pregnant C57BL/6J mice were sc injected with 0.30 mg/kg LPS in saline, or vehicle only at gestational day 7. Neonatally, 6 experimental groups were created within each litter. To induce masculinization in females 0.625µg PGE2 in 1µl saline (or vehicle only for controls) was injected icv in each hemisphere at postnatal day (PD)0 and PD1. To block masculinization in males 25µg indomethacin in DMSO in saline (or vehicle only for controls) was injected sc at PD0 and PD1. One additional male and female were left in the nest to serve as full controls. At PD4 the pups were sacrificed and their brains, fixed in PFA, used for immunohistochemistry. Data will be presented on quantitative (# microglia) and qualitative measures of microglia activation (cell morphology and excretion profile indicating M1 or M2 activation) in brain areas relevant to neurodevelopmental disorders (amygdala, hippocampus, mPFC). Additionally, preliminary behavioral data, focusing on anxiety, cognition, repetitive, and social behaviors will be presented. Our data may help elucidate the underlying mechanism of the sex-specific effects of prenatal stress and contribute to the understanding of the male-biased incidence of neurodevelopmental disorders.

Title: Alterations in glial iron homeostasis in hypoxic conditions and effects of induced hypothermia on iron regulatory proteins in cell culture

Authors: *A. L. ARAL[1], M. A. ERGUN[2], B. ENGIN[5], A. Ö. BÖRCEK[3], L. PINAR[4], M. K. BAYKANER[3], H. BOLAY[6];

Abstract: Fetal and neonatal inflammatory responses may contribute towards neonatal brain injury and developmentally related disabilities such as cerebral palsy as well as cognitive deficits later in life. Pathogenesis of the brain white matter lesions in newborns involves damage related to hypoxia with inflammation-induced brain injury. Microglia and astrocytes do not only initiate, but also contribute to the growth of lesions within the white matter as well as representing a potential strategic target for treatment in hypoxic disorders. The proper homeostasis of cellular iron transporters and proteins involved in iron storage, are important to prevent excess iron overload or iron starvation in cells. In this study we aimed to show the effects of hypoxia on iron related proteins and cytokine production in glial cells, and assess if hypothermic preconditioning has any effect on iron levels and molecules involved in regulating iron homeostasis.Microglia and astrocyte cell cultures were prepared from the cerebral cortex of neonatal C57BL/6 mice (n=3). Both cell types were incubated in hypoxic conditions for 12 hours. Effects of hypoxia with glucose deprivation on iron transport protein expression were evaluated at the mRNA level by quantitative real-time PCR. Cellular iron accumulation was evaluated using Perl's histochemistry. Cytokine levels have been studied using commercial ELISA kits. Hypoxia stimulated the expression of the ferritin in both cell types. Histochemical staining of accumulated iron in the cells correlated with ferritin expression. In addition to proinflammatory cytokine levels, iron-influx proteins TfR1 and DMT-1 increased after hypoxia especially in microglia. Iron-efflux protein ferroportin increased after hypoxic conditions in both cells. Hypothermic preconditioning prior to hypoxia decreased the cellular iron significantly in microglia. Hypothermia increases the expression of transport protein levels differently. In conclusion, in our study, hypoxic conditions accompanying glucose deprivation stimulated iron accumulation in microglia and astrocytes and triggered the expression of iron homeostasis proteins differently. Increased cellular iron and its efflux from glial cells might create a signal to trigger inflammatory responses which play role in hypoxic ischemic injury. Hypothermic preconditioning decreased the ferritin expression especially in microglia, which might suggest that the hypothermic control of cellular iron transporters and iron levels has a regulatory effect especially on the inflammatory pathways stimulated with hypoxic injury.

Title: Role of spinal microglia in DCP-induced contact dermatitis.

Authors: *B. CHOI, H. MIN, S. LEE;
Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Studies indicate an important role of spinal cord glial cells in central sensitization of not only pain but also itch sensation. In diphenylcyclopropenone (DCP)-induced contact dermatitis leading to chronic itch state, astrocyte activation caused by scratching stimulus triggers activation of STAT3/LCN2 signaling cascade and contributes to enhancement of itch signal sensation at the spinal cord level. Meanwhile, it was also reported that spinal microglia are activated through CX3CL1/CX3CR1 signaling in 2,4-dinitrofluorobenzene (DNFB)-induced contact dermatitis model. In this regard, we tested if spinal cord microglia activation is involved in chronic itch in DCP-induced contact dermatitis model. After 5 consecutive days of DCP challenge, a significant activation of spinal cord microglia was detected in the spinal dorsal horn. Inhibition of the DCP-induced microglia activation by intrathecal injection of minocycline attenuated scratching behavior, suggesting putative involvement of spinal cord microglia activation in itch sensitization. The mechanisms of spinal cord microglia activation after chronic DCP treatment have been further explored. Our data suggest that, similar to spinal cord astrocytes, spinal cord microglia activation affects chronic itch sensation.

Title: Transforming growth factor - beta1 attenuates pro-inflammatory activation in microglia through ALK5-dependent signaling

Authors: *Q. CHEN[1], B. V. CHEUNG[2], T. SHIMADA[1], M. MATSUMOTO[3], H. ITO[1], K. TAJINDA[1];
[1]Astellas Res. Inst. of America LLC, Skokie, IL; [2]Master of Biotech. program, Northwestern Univ., Evanston, IL; [3]Neurosci. Res. Unit, Drug Discovery Research, Astellas Pharma Inc., Tsukuba, Japan

Abstract: Microglia are the residential immune cells in the brain and play important roles in the maintenance of tissue homeostasis under physiological conditions. The abnormally activated microglial cells have been found in a variety of neuropsychiatric disorders and neurodegenerative diseases. During the neuroinflammation, over-activated microglia undergo a morphological change, synthesize and release various cytotoxic mediators such as pro-inflammatory cytokines and reactive oxygen species. Overproduction of these cytotoxic mediators could disrupt the normal brain development and neuronal function which are considered to be pathophysiological mechanisms in psychiatric disorders. Transforming growth factor - beta 1 (TGFβ1) is a pleiotropic cytokine and a potent regulator of neuroinflammation and cytotoxicity. TGFβ1 plays a critical role in supporting microglial development and maintaining functional microglial signature in the brain. Here, we investigated the anti-inflammatory mechanism of TGFβ1in LPS- stimulated primary microglial cells. We examined both the canonical and non-canonical pathways in TGFβ1-treated microglial cells. Western blot and immunocytochemistry results showed that Smad2/3 signaling was selectively activated in primary microglia. TGFβ1 treatment could effectively reduce proinflammatory cytokines and iNOS expression in LPS-activated microglial cells. The further mechanism studies found that TGFβ1 induced TGFβ receptor ALK5 expression in microglia cells. In addition, pharmacological inhibition of ALK5 signaling partially diminished the anti-inflammatory effects of TGFβ1 in LPS stimulated microglia. Further experiments are ongoing to investigate the role of TGFβ1 in regulation of inflammatory signaling in microglial cells. Our data suggested that activation of TGFβ/ALK5 signaling in microglia could effectively alleviate microglia mediated neuroinflammation.

Title: Piwi-like 4 regulates neuroinflammation via the nf-κb and p38 mapk pathways

Authors: *Q. HU[1], C. SUBHRAMANYAM[2], C. WANG[2], Q. CAO[2];
[1]Anat., [2]Natl. Univ. of Singapore, Singapore, Singapore

Abstract: In neurodegenerative diseases, chronic inflammation hampers regeneration and exacerbates the pathology. It is mainly caused by excess activation of microglia, the immune cells in the central nervous system (CNS). Recently, small RNAs have been shown to regulate gene expression at multiple levels. In particular, the Piwi subclass of the Argonaut family binds to a cohort of small RNAs called piwi-interacting RNAs (piRNAs). Though pilot studies have established that piRNA/Piwi mainly function to silence transposons in germline cells, it is found that mouse hippocampal neurons express piRNAs and that numerous piRNAs were differentially regulated in a rat stroke model. Hence, we investigated the role of Piwi in regulating the activation of microglia. Our data showed that inflammatory signals could strongly induce the expression of Piwil4 in murine BV-2 cells, a microglial cell model. The induced Piwil4 protein was mainly localized in the cell nucleus. In the loss-of-function assays, we detected a significant decrease in the LPS-induced expression of pro-inflammatory genes. On the other other hand, some anti-inflammatory and wound healing factors were upregulated by Piwil4 knockdown. In addition, we also observed that in LPS-treated microglia, the depletion of Piwil4 led to decreased production of reactive oxygen species and nitric oxide, both of which not only eliminate pathogens but also damage healthy nerve tissue if not contained properly. Accordingly, when dopaminergic neuronal cells were exposed to conditioned medium collected from Piwil4-depleted LPS-activated microglia, less cell toxicity and death were observed. We further found that Piwil4 could regulate the nuclear accumulation of NF-κB and its chromatin binding to target genes. In addition, the activation of p38 MAPK, as well as JNK, was also affected by Piwil4 knockdown. As a result, the AP-1-regulated gene expression could be attenuated. Hence, our study reveals that Piwil4 can modulate microglial activation at the transcriptional level, providing a novel strategy to fight against chronic inflammation in neurodegenerative diseases.

Title: Brain-derived neurotrophic factor promotes a neuroprotective phenotype in microglia during stress or inflammation

Authors: *A. M. DUGAN[1], J. M. PARROTT[1], L. REDUS[1], J. G. HENSLER[1], J. C. O'CONNOR[1,2];
[1]Pharmacol., Univ. of Texas Hlth. Sci. Ctr. at San Antonio, San Antonio, TX; [2]Audie L. Murphy VA Hosp., San Antonio, TX

Abstract: Both chronic stress and peripheral inflammation reduce expression of brain-derived neurotrophic factor (BDNF) in the brain and may contribute to depression. We have previously observed that BDNF deficient ($BDNF^{+/-}$) mice are more susceptible to both inflammation- and stress-induced depressive-like behaviors. In both cases, $BDNF^{+/-}$ mice exhibited a significantly greater shift in kynurenine metabolism toward overproduction of neurotoxic metabolites when compared to wild type (WT) controls. $BDNF^{+/-}$ mice also failed to up-regulate the anti-inflammatory cytokine interleukin-10 (IL-10) after stress when compared to WT controls. We aimed to investigate whether BDNF is directly involved in the cellular regulation of these neuroinflammatory factors in the context of stress or immunological challenge. Because microglia are the principle cells responsible for neurotoxic metabolism of kynurenine within the brain, we first sought to determine whether BDNF directly regulates microglial expression of kynurenine pathway enzymes. BV-2 mouse microglial cells were treated with vehicle or corticosterone (CORT, the major hormone involved in stress responses) in the presence or absence of BDNF in order to model the effects of stress in BDNF competent or deficient conditions. After 6h, CORT increased microglial kynurenine monooxygenase (KMO) expression with and without BDNF. However, after 24h, BDNF treatment reduced indoleamine-2,3-dioxygenase (IDO) expression in CORT-treated microglia. This pattern of expression in response to CORT and BDNF suggests that BDNF reduces the activity of the KP in microglia. In similar experiments aimed to address the role of BDNF regulation of microglia under inflammatory conditions, BV-2 microglia were treated with vehicle or lipopolysaccharide (LPS, an inflammatory stimulus) in the presence or absence of BDNF. BDNF treatment reduced LPS-

induced expression of microglial pro-inflammatory cytokines tumor necrosis factor-α (TNFα), interleukin-1β (IL-1β), and the activation marker ionized calcium-binding adapter molecule-1 (IBA1). Importantly, BDNF treatment increased microglial IL-10 expression after exposure to LPS. These data suggest that BDNF modulates the metabolic and inflammatory responses of microglia, which may be involved in conferring vulnerability/resilience to stress- or inflammation-induced psychiatric disorders.

Title: Maternal immune activation and later-life behavioral deficits: is there a link with embryonic microglia migration?

Authors: C. LACABANNE[1,2], A. BENMAMAR--BADEL[3], S. LAYE[2], *G. N. LUHESHI[1]; [1]Douglas Mental Hlth. Univ. Inst., McGill Univ., Verdun, QC, Canada; [2]INRA-Université de Bordeaux, Bordeaux, France; [3]Ecole Normale Supérieure de Lyon, Univ. de Lyon, Lyon, France

Abstract: Microglia, the resident immune cells of the central nervous system (CNS), have recently been demonstrated to have a central role in a number of aspects of neural development, including cell proliferation, neurogenesis, synaptogenesis and programmed cell death. Microglial function in the foetal brain has been shown to be sensitive to environmental insults with some suggesting a link with neurodevelopmental defects. Of the environmental insults, maternal immune activation (MIA) has been repeatedly associated with the pathogenesis of several neurodevelopmental conditions in the offspring. We thus hypothesized that microglia could be involved in neuronal and behavioural defects in the offspring that have been exposed to MIA. In addition to the type and severity of infection, the stage of embryonic development is a significant factor in this hypothesis and to test the signfiicance of this we decided to target a very early stage of gestation, namely the time when microglia first migrates to the fetal brain. Microglial precursors originate from the yolk sac and invade the brain very early (Embryonic day (E) 9.5) in the developmental process. In the present study, we tested the effect of an immune challenge (lipopolysaccharide, LPS) at E9.5 on the microglial migration process conducting a combination of molecular (gene expression), imaging (two-photon, confocal imaging and 3D reconstruction) and a battery of behavioural approaches. The disruption of early microglia migration by maternal

inflammation resulted in dysfunctional microglia and subsequent neuronal and behavioural defects in offspring. Our results will contribute to our understanding of the role of microglia in early prenatal infection on later-life behavioral deficits.

Title: Measurements of hydrogen peroxide in line and their change by hypoxia and microglia modulation

Authors: *K. PARDO-PEÑA[1,2], F. PEÑA-ORTEGA[2], A. MORALES-VILLAGRÁN[3], N. CAMACHO-HERNÁNDEZ[2], J. LOREA-HERNÁNDEZ[2];
[2]Developmental Neurobio. and Neurophysiol., [1]UNAM, Queretaro, Mexico; [3]Mol. and Cell Biol., CUCBA, Univ. de Guadalajara, Guadalajara, Mexico

Abstract: Hydrogen peroxide (H_2O_2) is a prominent member of the Reactive Oxigen Species (ROS) family, which can be produced and or release by different cell-types. Episodes of hypoxia, and the subsequent reoxygenation, result in the accumulation of ROS and the induction of oxidative stress. These hypoxic conditions can promote the increase of extracellular H_2O_2 concentrations. On the other hand, microglia can modulate circuit activity and the response to hypoxic events. Thus, dynamic measurements of H_2O_2 concentrations are a valuable tool for the

understanding of microglia function during hypoxia. In this study, we developed a new technique for measuring H_2O_2 concentration in brainstem slices with one second resolution. This method consists of mixing the extracellular fluid obtained from the brainstem slices with an enzymatic reactor composed by horseradish peroxidase and Amplex UltraRed, which generates a derivate (resorufin) that fluoresces at 590 nm when excited at 560 nm. Resorufin excitation was induced with a laser beam whereas the fluorescence intensity was determined with a photomultiplier. By this procedure the fluorescent signal intensity was proportional to H_2O_2 concentration. Our data show that both hypoxia and microglial-activation with lipopolysaccharide (LPS) increase extracellular H_2O_2 concentration. When microglia is activated by LPS (500 ng/ml), the H_2O_2 concentration increased dramatically to 18.3±0.5 μM, compared to baseline levels which were 1.6±0.4 μM. This increase lasted as long as LPS was present in the bath and did not return to normal levels upon the application of Minocycline (30 μM; a microglial inhibitor; 17.8±0.6 μM). However, when Minocycline was administered as pretreatment, LPS-induced microglia activation produced a reduced release of H_2O_2, only reaching a concentration of 4.7±1.7 μM. On the other hand, hypoxic conditions sustained for 15 consecutive minutes produced an increased in H_2O_2 concentration of 5.0±0.3 μM, whereas during reoxygenation the H_2O_2 concentration remained elevated at 5.6±1.0 μM. Interestingly, this increase produced by transient hypoxia lasted for at least 90 minutes.Pretreatment with Minocycline, 60 minutes before hypoxia, reduces by 64% the increase in H_2O_2 concentration during hypoxia (1.8±0.6 μM) but only by 17% during reoxygenation (4.65±0.2 μM). Interestingly, Minocycline reduced H_2O_2 concentration by itself. These data support the use of this technique for the determination of H_2O_2 release from microglia with high temporal resolution, *in vitro*. Furthermore it would allow to correlate changes in neural function with the release of this ROS, both under normal and pathological conditions.

Title: Effects of early life infection and iron deficiency upon neurodevelopment in the neonatal piglet

Authors: *B. J. LEYSHON[1], R. W. JOHNSON[1,2];
[1]Div. of Nutritional Sci., [2]Dept. of Animal Sci., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: During the postnatal period the developing brain is vulnerable to insults including nutrient insufficiency and infection that may lead to disrupted development and cognitive dysfunction. Iron deficiency (ID) is the most common micronutrient deficiency worldwide. Pregnant women and young children are most vulnerable to ID. Iron is a necessary cofactor for a variety of biological processes in both the immune and neurodevelopmental domains, including synthesis of lipids for myelination and meeting the metabolic demands of the growing brain. Since ID and the associated anemia often presents with immunodeficiency, the objective of this study was to investigate negative impacts on neurodevelopment, microglial phenotype and immune function manifested by early life ID coupled with respiratory infection using a neonatal piglet model. On postnatal day 2 (PD 2) piglets were divided into four groups, and fed either control or ID milk replacer. Piglets were inoculated with either vehicle or porcine reproductive and respiratory syndrome virus (PRRSV; P-129) on PD 8. Baseline blood samples were collected prior to inoculation (PD 7) and repeated once weekly. Rectal temperatures, feeding score and sickness behaviors were measured daily until piglets were sacrificed on PD 28 for tissue collection. Hematocrit and hemoglobin were reduced by ID but not PRRSV infection. Both groups of PRRSV infected piglets displayed increased serum viremia on PD 14. However, PRRSV piglets fed control diet displayed decreased viremia on PD 21 and PD 28, while those fed an ID diet displayed similar viremia throughout, suggesting that ID impaired immune function necessary for viral clearance. Similarly, ID piglets infected with PRRSV initially displayed reduced sickness behavior score compared to those fed control diet, which progressively worsened while PRRSV piglets fed control diet displayed improved sickness score after PD 20. Brain weight was reduced by PRRSV infection but not ID. Primary microglia isolated from brain displayed increased MHCII expression and phagocytic activity in PRRSV infected piglets compared to uninfected piglets. However, ID did not impair microglial MHCII expression or phagocytosis. Taken together, these data suggest that ID decreases peripheral immune function leading to decreased viral clearance, but immune activity in the brain is protected from acute ID. Future areas of inquiry for this project include evaluating microglial cytokine production and gene expression in the context of ID and PRRSV infection, especially genes pertaining to glycolytic and oxidative metabolism, a key difference between pro-inflammatory (M1) and pro-resolving (M2) phagocytes.

Title: Activation of the PGE2 EP1 receptor promotes microglial phagocytosis through CD36 receptor recycling

Authors: *B. MA[1], B. SLOOTSKY[2], H. PHILLIPS[3], K. KOLAROVA[3], S. DORÉ[3];
[1]Dept. of Anesthesiol., Univ. of Florida Col. of Med., Gainesville, FL; [2]Dept. of Anesthesiology, Ctr. for Translational Res. in Neurodegenerative Disease, Univ. of Florida, Col. of Medicine;, GAINESVILLE, FL; [3]Dept. of Anesthesiology, Ctr. for Translational Res. in Neurodegenerative Disease, Univ. of Florida, Col. of Medicine;, Gainesville, FL

Abstract: We have previously documented that the deletion of the prostaglandin E2 (PGE2) EP1 receptor undermined microglial phagocytosis in vivo. However, the related mechanism still remains unknown. CD36 is a type II scavenger receptor that mediates microglial phagocytosis. Moreover, it was reported that microglial CD36 contributes to hematoma clearance after intracerebral hemorrhage (ICH). In this study, we sought to identify the effects of two EP1 receptor agonists on phagocytosis and CD36 receptor recycling in microglial cultures.
The EP1 agonists 17-phenyl trinor-PGE2 (17-pt-PGE2) and ONO-DI-004 were used in our study to treat mouse primary microglial cultures. Fluorescent latex beads or CFSE-labeled red blood cells (CFSE-RBCs) were added to microglial cells at a concentration of 10 beads/RBCs per cell for live-cell imaging. Immunocytochemistry was also performed with antibodies against ionized calcium-binding adapter molecule 1 (Iba1, a microglial marker). Furthermore, we analyzed CD36 receptor recycling in primary microglial cells by using an established receptor recycling assay.
The primary microglial cells were incubated with fluorescent latex beads and treated with the EP1 agonist 17-pt-PGE2 for 120min. We found that 10uM of 17-pt-PGE2 significantly increased the number of attached beads to microglial cells from 40 to 120min of incubation. Furthermore, we analyzed CD36 receptor recycling using an established receptor recycling assay and the quantitative results showed that 10uM of 17-pt-PGE2 treatment markedly increased the positive-staining area of recycled CD36 receptor in microglial cells. We then treated primary microglial cells with another EP1 agonist, ONO-DI-004, for 120min at the concentration of 5 and 10uM, respectively. The fluorescent area of CFSE-RBCs after ice-cold PBS washing was markedly increased with 10uM ONO-DI-004 treatment. In the live-cell imaging experiment, 10uM of

ONO-DI-004 treatment also significantly increased the number of attached CFSE-RBCs to microglial cells from 25 to 60min of incubation.
Together, this study demonstrates that the PGE2 EP1 agonists 17-pt-PGE2 and ONO-DI-004 can promote microglial phagocytosis in vitro and that enhanced CD36 receptor recycling could mediate these effects.

Title: A putative interaction of tspo with nadph oxidase in primary microglia

Authors: ***M. K. LOTH**[1,2], S. R. GUARIGLIA[2], J. CHOI[2], D. B. RE[2], T. R. GUILARTE[1,2]; [1]Envrn. & Occup. Hlth., FIU, Miami, FL; [2]Envrn. Hlth. Sci., Columbia Univ., New York, NY

Abstract: Translocator protein 18 kDa (TSPO) is a glial protein that is extensively used as a biomarker of neuroinflammation. We have previously shown that TSPO ligands (TSPO-L) induce cellular functions in microglia consistent with an activated state, suggesting an important role of TSPO in the inflammatory response to brain injury. In particular, exposing microglia to TSPO-L (1-100 nM) induces ROS production that can be abrogated by NADPH oxidase (NOX) inhibitors, suggesting an association between TSPO and NOX, a multi-subunit enzyme that is highly enriched in microglia and is a major source of ROS in the CNS. To further elucidate the relationship between TSPO and NOX, we determined the source of ROS production resulting from microglia exposure to TSPO-L. Intracellular and extracellular ROS production was inhibited by NOX inhibitors, but not by a mitochondria permeability transition pore inhibitor, indicating that the source of ROS production is from NOX and not from mitochondria. These findings were confirmed using the mitochondria specific ROS probe MitoSOX. To assess if TSPO and NOX are interacting, we performed co-immunoprecipitation experiments. The results indicate that gp91phox and p22phox co-immunoprecipitated with TSPO supporting a functional protein-protein interaction. Our findings provide novel insight on the potential function and subcellular localization of TSPO in microglia. To further explore the subcellular localization of TSPO, we performed triple-label immunofluorescent confocal imaging of TSPO with the

mitochondrial protein VDAC and the principal NOX subunit gp91phox, both of which revealed significant colocalization. We are currently confirming our results using immuno-EM labeling. Together our findings suggest a novel interaction of TSPO with NOX in primary microglia with significant implications for a new understanding of TSPO glial cell biology and for the development of therapeutic strategies [supported by NIEHS grant ES007062 to TRG].

Title: Mitochondrial fragmentation induced ROS triggers p62 mediated autophagy in microglia

Authors: *U. CHAE[1], H. LEE[2], D.-S. LEE[1];
[1]Kyungpook Natl. Univ., Taegu-City, Korea, Republic of; [2]Biomed. Res. Institute, Chung-Ang Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Autophagy have a critical role in many process, including elimination of dysfunctional organelles, repair mechanism and programmed cell death. Reactive Oxygen Species (ROS) which is one of the autophagy inducer is not clearly elucidated in microglia. In this study, we demonstrated that mitochondrial ROS which was induced by mitochondrial fission can promote autophagy in microglia. Moreover, inhibition of mitochondrial fission or mitochondrial ROS could downregulates the formation of autophagosome. Notably, regulatory effect between mitochondrial ROS and autophagy is mediated by only p62 not LC3B. Taken together, these results suggest that the increased autophagy induced by LPS can be decreased by inhibition of mitochondrial ROS through downregulation of p62. Our results indicate that concrete regulatory effect between mitochondrial ROS and autophagy in microglia.

Title: Role of adult neurogenesis in increased sensitivity of ArcticAbeta mice to kainic acid

Authors: ***M. ZAICHUK**, T. GSCHWIND, I. KNUESEL, J.-M. FRITSCHY;
Univ. of Zürich, Zürich, Switzerland

Abstract: Overlap between Alzeimer's disease (AD) and epilepsy is becoming widely accepted. Going in line with the evidence of co-occurrence of both conditions in human patients, a number of transgenic AD mouse models were shown to have spontaneous epileptiform discharges, disturbed rhythmic activity or higher sensitivity to seizure inducing drugs. We used unilateral intrahipocampal injection of kainic acid to mimic temporal lobe epilepsy in a familial AD mouse model. In the hippocampus, kainic acid-mediated induction of an epileptic focus causes progressive neurodegeneration of CA1 pyramidal cells, granule cell dispersion and non-convulsive recurrent seizures that persist for months. Adult ArcticAbeta mice, that overexpress human APP with Arctic and double Swedish mutations showed increased sensitivity to kainic acid in comparison to the wild-type controls. Increased mortality of the transgenic mice was observed in the first few weeks after the injection. Adult neurogenesis was previously implicated in the epileptogenesis and was separately shown to be affected in familial AD mouse models. We studied adult neurogenesis in ArcticAbeta mice to understand their sensitivity to kainic acid. Adult transgenic mice had increased rate of cell proliferation and reduced cell survival in the subgranular zone of the dentate gyrus. Adult born neurons in ArcticAbeta mice were shown to have decreased number of dendritic spines and reduced dendritic branching during maturation. Those findings are another set of evidence showing that adult neurogenesis can be affected by the overexpression of mutated forms of APP. In addition to other factors (see Tilo Gschwind´s poster) those changes in adult neurogenesis could contribute to the epileptogenesis in AD-mice.

Title: The contribution of Alzheimer's disease-like pathology to epileptogenesis in a mouse model for temporal lobe epilepsy

Authors: *T. GSCHWIND[1], T. GFELLER[1], C. LAFOURCADE[1,2], M. ZAICHUK[1], I. KNUESEL[1], J.-M. FRITSCHY[1];
[1]Univ. of Zurich, Zürich, Switzerland; [2]Univ. de los Andes, Santiago, Chile

Abstract: The most prevalent age-related dementia, Alzheimer's disease (AD), causes synaptic dysfunction and neuronal reorganization, along with a chronic neuroinflammation. These features are similar to those seen in temporal lobe epilepsy (TLE). As observed in AD patients, marked variations in cognitive performance can occur due to undetected epileptic seizures of limbic origin.
The aim of this study is to investigate how a genetic predisposition for AD affects epileptogenesis in an animal model for TLE. For this purpose, transgenic mice overexpressing human $APP_{swe,arc}$ (arctic Aβ mice; a model of familial AD) were injected with kainic acid (KA) into the dorsal hippocampus to induce an epileptic focus, which leads to local inflammation and non-convulsive spontaneous recurrent seizures. Intrahippocampal electrodes were implanted to characterize seizure activity after KA injection. Neurodegeneration, loss of interneurons, axonal sprouting, endothelial inflammation as well as activation of innate and adaptive immune cells were assessed immunohistochemically to determine the contribution of inflammation and immune responses on the histopathological alterations caused by KA-injection. The acute effect of KA on hippocampal circuitry was analyzed using a combination of local field potential and whole cell patch clamp recordings in acute hippocampal slice.
Compared to wildtype littermates, AD transgenic mice exhibit a much higher vulnerability towards KA, in vivo and in slices. The causal investigation for this phenotype unraveled a possible link between AD-like pathology and epilepsy.

Title: Beta1 adrenergic receptors modulate neurocognitive function, neuroinflammation and pathology in a mouse model of Alzheimer's Disease

Authors: *A. K. EVANS, B. YI, M. SHAMLOO;
Neurosurg., Stanford, Stanford, CA

Abstract: Severe degeneration of Locus Coeruleus noradrenergic (NA) neurons has been reported in Alzheimer's Disease (AD), and loss of noradrenergic tone may contribute to progression of pathology, neuroinflammation and cognitive dysfunction. Beta adrenergic receptors (ADRB1 and ADRB2) on neurons, microglia and astrocytes modulate learning and memory, regulate neuroinflammation and govern compensatory and protective mechanisms for neuronal function and survival. Pharmacological and genetic disruption of noradrenergic tone has been shown to exacerbate amyloid beta deposition, markers of neuroinflammation, and behavioral deficits in mouse models of AD. We have previously implicated acute activation of ADRB1 in restoration of cognitive deficits in mouse models of AD. In a series of studies we aimed to determine effects of chronic low level activation or antagonism of the ADRB1 receptor on behavioral, pathological, and neuroimmune endpoints in mouse models of AD. Using selective beta-adrenergic pharmacology in a transgenic model in which mice express a mutated form of human amyloid precursor protein, transgenic and wildtype male mice were chronically dosed with vehicle or with either a selective ADRB1 partial agonist, xamoterol (0.3-1.0 mg/kg daily s.c. injection) or a selective ADRB1 antagonist, metoprolol (5 mg/kg daily s.c. injection). Mice were dosed for approximately 3 months and run through a series of behavioral tests during the last 6 weeks of dosing (Activity Chamber, Y-maze, Morris Water Maze, and Fear Conditioning). At conclusion, plasma was collected and brains were perfused with saline and hemi-brains were flash-frozen or paraformaldehyde-fixed for neurobiological analyses. Chronic dosing with a selective ADRB1 partial agonist, xamoterol, improved and metoprolol impaired contextual fear conditioning. Chronic dosing with metoprolol exacerbated deficits in spatial learning in transgenic mice. Modulation of ADRB1 altered amyloid beta pathology and modulated indices of neuroimmune activation (microglia/macrophage immunoreactivity, and immune-related mRNA and protein expression). These data support the hypothesis that ADRB1 activation regulates pathology and cognitive function in mouse models of AD and may do so by modulating neuroimmune function.

Title: Microvessel occlusions alter amyloid-beta plaque morphology in mouse models of Alzheimer’s disease

Authors: ***N. NISHIMURA**, E. D. BANDER, Y. LEE, C. MUOSER, C. B. SCHAFFER; Biomed. Engin., Cornell Univ., Ithaca, NY

Abstract: Vascular health is correlated to the incidence and severity of Alzheimer’s disease (AD). In mouse models of AD (APP/PS1) we tested the hypothesis that occlusions of the microvasculature could alter amyloid-beta (Aβ) accumulation using in vivo time-lapse multiphoton microscopy of amyloid plaques and vasculature. We found that femtosecond laser-induced occlusions in single capillaries or small arterioles beneath the brain surface generated a shift in the type of Aβ deposits observed over the period of one week. For larger pre-existing plaques, occlusions caused an increase in the intensity of Aβ labeling with methoxy-X04 (labels fibrillar Aβ, Fig. a). We then varied the types of microvascular lesions to confirm that these results were not artifacts of our laser-induced lesion model. We used photothrombosis with intravenously-injected rose bengal to occlude several arterioles and capillaries in a region (Fig. b). This larger injury demonstrated a similar increase in labeling intensity in pre-existing plaques after injuries. Some plaques also disappeared after the lesion. This suggests that “diffuse” plaques can turn into to dense plaques, potentially explaining the observation of both types of plaque in humans and animals. These results suggest that microvascular lesions can alter the deposition and clearance of Aβ and confirm that Aβ plaques are not static, but can change in response to vascular lesions.

Title: Investigating the effects of hypertension on a transgenic model of Alzheimer disease

Authors: *A. LEVIT[1], V. HACHINSKI[2], S. WHITEHEAD[1];
[1]Dept. of Anat. & Cell Biol., Univ. of Western Ontario, London, ON, Canada; [2]Clin. Neurolog. Sci., London Hlth. Sci. Ctr., London, ON, Canada

Abstract: Characterizing the role of hypertension in neurodegeneration could have important clinical implications and may be crucial for the study of Alzheimer disease (AD) etiology. Neurovascular pathology, which can result from systemic vascular disease, disrupts CNS proteostasis and can lead to AD. Inflammation, BBB dysfunction, and neurovascular uncoupling have all been proposed as mechanisms by which neurovascular pathology can disrupt CNS glia and neurons, but it remains to be resolved whether hypertension can cause these pathogenic processes. We hypothesize that hypertension can increase inflammation, astrogliosis, and BBB breakdown in a transgenic rat model of Alzheimer disease, and initiate cognitive impairment. This transgenic strain of Fischer 344 rats (TgF344) overexpresses mutant amyloid precursor protein with Swedish and Indiana mutations but does not develop overt pathology; this presents a model that can be used to test whether hypertension can induce early stages of AD-related changes. The TgF344 rats received 8 weeks of continuous angiotensin II (Ang-II) infusion by subcutaneous osmotic minipump to induce hypertension. Control groups for strain and Ang-II were also studied (n=13-15). Elevated blood pressure impaired both wildtype and transgenic rats in delayed match-sample testing in the Morris Water Maze, with a trend of greater impairment in the transgenic strain. Brain tissue cross-sections were analyzed for activation of microglia, astrogliosis, and vascular associated pathology. Tissue analysis indicates that the transgenic strain has increased activation of microglia in white matter which is further exacerbated by hypertension. Spontaneous neuropathology has not been previously reported in the transgenic strain, but increased microglia activation suggests the presence of abnormal white matter inflammation. White matter pathology may account for the greater cognitive effect that hypertension had on the transgenic group. These findings prompt further investigation of the pathological interaction between elevated blood pressure and overexpression of the mutant human amyloid precursor protein.

Title: Comparison of brain vasculature network characteristics between wild type and Alzheimer's disease mice using topological metrics

Authors: *M. HAFT JAVAHERIAN[1], V. MUSE[1], J. C. CRUZ HERNÁNDEZ[1], C. KERSBERGEN[1], I. IVASYK[1], Y. KANG[1], G. OTTE[1], S. LORTHOIS[2], C. B. SCHAFFER[1], N. NISHIMURA[1];
[1]Biomed. Engin., Cornell Univ., Ithaca, NY; [2]Inst. de Mécanique des Fluides de Toulouse, Toulouse, France

Abstract: There is a strong clinical correlation between Alzheimer's disease (AD) and microvascular disorders. In mouse models of AD, our lab has found blood flow dysfunction in brain capillaries, suggesting the need to study the function of vascular networks at the capillary level. However, the ability to deliver blood flow continuously to all neurons also depends on connections between vessels, requiring that we also characterize the topology of brain vascular networks. Here, we use graph theory and topological metrics to characterize the connectivity of brain capillary networks in AD and control mice.
We imaged cortical vascular networks using *in vivo* two-photon excited fluorescence microscopy in APP/PS1 (AD) and littermate, wild type (WT) mice (3 mice per group; ~1,100 vessels per mouse; Fig. a). Then, we represented the vascular network using graphs in which individual vessels are defined by the path they take through the tissue and their connections to other vessels (Fig. b).
Two metrics suggested interesting differences between WT and AD mice. The average shortest path length is the mean of the smallest number of vessel segments that joins all pairs of vessel junctions. In AD animals this metric was 10.5 ± 0.6 vessels (mean ± standard deviation), which was just 8% lower ($p = 0.07$, t-Test) than in WT animals (11.4 ± 0.7 vessels). The average clustering measures the tendency of vessels in the network to group together; higher numbers imply that vessels and their neighbors have more connections to each other. In AD animals this metric was 37% ($p=0.09$) lower than WT animals. This metric is related to the redundancy of networks connections, which enables the vascular system to maintain blood supply even with occluded vessels, suggesting that capillary networks in AD mice are less connected and redundant than in WT animals.
In order to study how the brain blood flow is affected during the progression of AD, we developed a novel formalism to compare and describe the differences in the brain capillary vascular networks.

Title: Genetic evidence for the substantial contribution of the trail/trail-receptor system to amyloid-beta neurotoxicity in the mouse

Authors: G. DI BENEDETTO[1], L. LEMPEREUR[2], F. SERAPIDE[1], O. VALERIO[1], H. WALCZAK[3], *R. BERNARDINI[1,4], G. CANTARELLA[1,4];

Abstract: We have shown that TRAIL, a proapoptotic cytokine belonging to the TNF superfamily, is a potent inducer of neuronal death in animal models of Alzheimer's disease (AD). TRAIL effects appear mediated by its death receptor, mouse TRAIL-receptor (TRAIL-R), also known as mouse death receptor 5 (DR5). In fact, immunoneutralization of TRAIL results in restored cognitive behavior, as well as in silencing of an array of inflammatory molecules in the AD 3x transgenic mouse brain. To further dissect the role of the TRAIL system in the AD

neuroinflammatory setting, we employed Trail-r-deficient mice. In initial in-vitro experiments, we analysed the impact of treatment with amyloid-beta (AB) as compared to TRAIL on survival of dispersed Trail-r-deficient embryonal hippocampal cells. Subsequently, we evaluated the expression of TRAIL, TRAIL-R and markers for microglia and astrocytes in hippocampi of animals following stereotactical treatment with fragment 1-42 of AB. Hippocampal cells from Trail-r-deficient mice showed significant resistance to death induction by both AB 1-42 or TRAIL as compared to cells Trail-r-proficient mice. Immunofluorescence experiments performed on brains indicated that activation of microglia (Iba-1) and astrocytes (GFAP) was blunted following stereotactical treatment of Trail-r-deficient mice with AB 1-42. Consistently, TRAIL immunoreactivity was absent in the same animals. Moreover, western blot analysis of hippocampal homogenates from Trail-r-deficient mice treated with AB, showed decreased expression of IL-1, as well as of the phosphorylated form of tau protein, along with reduced activation of caspase-3. Together, these results show that the lack of TRAIL-R is associated with a dramatic reduction of detrimental effects of AB, providing genetic evidence that TRAIL released during neuroinflammatory processes plays a major role in AB-induced neurotoxicity in the mouse. On the basis of these results the TRAIL system may be envisioned as a potential candidate for therapeutic intervention in AD.

Abstract: Alzheimer’s disease (AD) is a neurodegenerative process involving amyloid-β (Aβ) peptide deposition and progressive memory loss. Bexarotene, a retinoid X receptor (RXR)

agonist, has been proposed as a promising therapy for AD, resolving both the amyloid pathology and memory loss. Despite the first compelling report (Cramer et al., Science 335:1503-1506, 2012), however, multiple failures have been documented (Landreth et al., Science 340:924-g, 2013), raising concern about whether RXR agonist could in fact become a novel disease-modifying strategy for AD. To help clarify this, we first investigated the effect of specific RXR pan agonist HX630 in APP23 transgenic mice. Oral administration of HX630 to the 8.5-month-old APP23 mice (5 mg/kg/day, for 17 days) did not achieve any significant memory improvement, or brain Aβ reduction. In contrast, oral co-administration of HX630 (5 mg/kg) with retinoic acid receptor (RAR)α,β agonist Am80 (tamibarotene, 0.5 mg/kg) for 17 days significantly improved memory deficits (Morris water maze) in APP23 mice and reduced the level of insoluble Aβ peptide in the brains. Am80 alone produced no effect. These results thus indicate that effective memory improvement via reduction of insoluble Aβ peptide in 8.5-month-old APP23 mice requires co-activation of RARα,β and RXRs. It is suggested by our group that higher dose of bexarotene binds to RXR in RAR-RXR heterodimer and enhances RAR signaling. The effect of bexarotene by combinational administration with Am80 in APP23 mice, is under investigation.

Abstract: Introduction: Dementia is a term that encompasses various types of neurodegenerative diseases of the brain that cause a gradual decline in mental abilities. Loss of cholinergic neurons in the brain cholinergic system including the hippocampus is a hallmark of many dementia cases. In this study, we report the therapeutic effects of administration of human placenta-derived mesenchymal stem cells (pMSCs) in dementia model Sprague-Dawley (SD) rats using two different cell injection methods: intracerebroventricular (ICV) and intravenous (IV) injections.
Methods: Dementia modeling was carried out by intraventricular injection of 192 IgG saporin, which causes lesion of cholinergic neurons. Fifty male SD rats were divided into four groups: normal (n=9), lesion (n=9), ICV (n=12) and IV (n=12). All rats were then subject to Morris water maze test and subsequent immunostaining analyses using markers for human cytoplasm, acetylcholinesterase (AChE), choline acetyltransferase (ChAT) and microglial cells at the hippocampus.
Results: Lesioned rats showed poor performance in the Morris water maze test compared to the normal rats. Both ICV and IV pMSC administration allowed significant cognitive recovery compared to the lesioned rats. AChE was also significantly recovered back to normal levels at the hippocampus in rats injected with pMSCs post-lesion. ChAT did not co-localize with pMSCs, showing that pMSCs did not directly differentiate into cholinergic cells. Stem cell count showed a significantly greater number of pMSCs at the hippocampal dentate gyrus in IV group rats compared to ICV group rats. Number of microglial cells increased in lesioned rats, and was significantly reduced back to normal levels after pMSC injection.
Discussion: Our results demonstrate that injection of pMSCs facilitates recovery of cholinergic neuronal population and function, as well as cognitive behavior. The mechanism through which such recovery happens does not seem to be direct differentiation of injected pMSCs into cholinergic neurons, but rather seems to be through paracrine effects that resemble microglial function. Further research will be necessary for elucidation of the exact mechanisms involved and establishment of optimal parameters for successful cell homing.

Title: Microglial kca3.1 channels as a potential therapeutic target for alzheimer's disease

Authors: *I. MAEZAWA[1], H. M. NGUYEN[2], J. DI LUCENTE[3], V. SINGH[2], L. SINGH[2], M. CHAVEZ[3], H. WULFF[2], L.-W. JIN[1];
[1]M.I.N.D. Inst, UC Davis, Sacramento, CA; [2]Pharmacol., [3]Pathology, UC Davis, Davis, CA

Abstract: Microglia play a pivotal role in the initiation and progression of Alzheimer's disease (AD) by either clearing amyloid-β (Aβ) deposits or releasing cytotoxic substances in response to activation by various stimuli including Aβ aggregates such as oligomer (AβO). We here propose microglial KCa3.1 channels as a novel pharmacological target for curbing the harmful effects of Aβ-activated microglia. In the forebrain, KCa3.1 is predominantly expressed in microglia, where its activation by cytoplasmic Ca^{2+} provides the driving force for further Ca^{2+} entry, thus modulating Ca^{2+} signaling and microglial activation. KCa3.1 has been shown to be involved in oxidative burst, nitric oxide (NO) production, and microglia-mediated neuronal killing. We previously reported that AβO-induced microglial activation and microglial neurotoxicity *in vitro* required KCa3.1 activity and could be inhibited by the specific KCa3.1 blocker TRAM-34 (*J Biol Chem* 286:3693, 2011). To further investigate the potential of KCa3.1 inhibition for AD therapy, we generated the following lines of evidence: (1) A seven-day course of intraperitoneal TRAM-34 (40mg/kg/day) inhibited microglial activation induced by intrahippocampal injection of AβO in rats. (2) A three-week course of TRAM-34 administration to mice with induced Aβ accumulation improved their performance in a hippocampus-dependent novel objection recognition task to the control level. (3) TRAM-34 prevented AβO-induced reduction of hippocampal long-term potentiation (LTP), an effect related to the ability of TRAM-34 to reduce microglial production of NO and IL-1β. (4) TRAM-34 did not affect the ability of microglia to phagocytose AβO. (5) Microglial KCa3.1 expression was upregulated in the brains of 5xFAD mice and patients with AD. For future clinical development, we resynthesized senicapoc, which is orally available, structurally similar to TRAM-34, and was shown to be safe and well tolerated

in Phase-2 and Phase-3 clinical trials for sickle cell anemia. We found that senicapoc had excellent brain permeability with a C_{brain}/C_{plasma} value about 6 in mice and rats. Senicapoc inhibited AβO-induced microglial activation and microglial neurotoxicity similar to TRAM-34, and mitigated microglial activation *in vivo* in 5xFAD mice when it was administered by medicated diet for six months. Senicapoc-treated 5xFAD mice also showed hippocampal LTP indistinguishable from that of wild-type mice. Taken together, these observations support that KCa3.1 is a potential therapeutic target for AD.

Title: A 3D Alzheimer’s disease brain model recapitulates microglial activation, recruitment and neuronal loss

Authors: *J. PARK[1,2], D. KIM[3], R. E. TANZI[3], H. CHO[1,2];
[1]Mechanical Engin. and Engin. Sci., UNC Charlotte, Charlotte, NC; [2]Ctr. for Biomed. Engin. and Sci. (CBES), Charlotte, NC; [3]MassGeneral Inst. for Neurodegenerative Dis., Massachusetts Gen. Hospital, Harvard Med. Sch., Charlestown, MA

Abstract: Microglia are a type of resident brain immune cells, which are neuroprotective by phagocytosing beta-amyloids (Abeta), secreting growth factors and anti-inflammatory cytokines in Alzheimer’s disease (AD), whereas their chronic activation leads to the secretion of proinflammatory mediators that cause neurodegeneration. However, it has been challenging to study the impact of microglia contribution on AD pathogenesis due to lack of relevant human cellular models. Here, we propose a 3D human AD brain model based on a novel microfluidic device that makes it possible to co-culture human AD neuron cells and human microglia in a 3D microenvironment. Human neural stem cells, which were genetically engineered to overexpress FAD-related genes, were grown in a Matrigel-filled central chamber up to 9 weeks and generated an AD pathogenic signature, including excessive accumulation of pathogenic Abeta species.

Immortalized adult human microglia cells were co-cultured for a week in an angular chamber connected to the neuronal central chamber and their interaction were monitored in a real-time and at a single cellular resolution. Using this unique 3D oranotropic culture system, we found that microglial recruitments toward 3D AD cultures are robustly elevated (~10 fold) as compared to control wild-type 3D cultures. The elevated migratory activity was proportional to the levels of pathogenic Abeta species. Notably, AD neuron signaling impacted broadly on microglial immune responses by inducing more chemokines: CCL2 (2.1-fold), CCL5 (26-fold), CXCL10 (2.6-fold), CXCL12 (1.2-fold) compared to normal neurons, and leukocyte growth factors: GM-CSF, G-CSF, which were not induced by normal neurons. Furthermore, we observed increases in neuronal loss in 3D AD cells with microglial cells as compared to the control cells or to AD cells without microglial cells. Finally, we also found increases in cytokine levels including IL-1beta (2.1-fold increase) and caspase-3 activation on AD neurons only in the case of co-culturing with 9-week differentiated AD neurons. Taking together, these clearly demonstrate that our AD brain model is a valid AD cellular model particularly in recapitulating microglia-neuron interaction.

Title: Reducing the incidence of stalled blood flow in brain capillaries leads to improved cognitive function in a mouse model of Alzheimers disease

Authors: *O. BRACKO, J. C. CRUZ HERNÁNDEZ, L. VINARCSIK, N. NISHIMURA, C. B. SCHAFFER;
Biomed. Engin., Cornell Univ., Ithaca, NY

Abstract: Alzheimer’s disease (AD) is the leading cause of dementia. AD is accompanied by a ~30% reduction in cerebral blood flow in both patients and mouse models, which likely contributes to the cognitive decline and pathology. No physiological explanation for the blood flow deficit has emerged.
We have shown that there is a five-fold elevation of the number of stalled capillaries with no

blood flow (to 1.6%) in a mouse model of AD (APP/PS1) as compared to age-matched controls. The majority of these capillary stalls were caused by neutrophils adhered to the endothelium. Administration of antibodies that reduce neutrophil adhesion (anti-Ly6G) led to a ~60% reduction in the number of stalled capillaries and a ~40% increase in blood flow in penetrating arterioles within minutes, while isotype control antibodies had no impact.

To determine the cognitive impact of improving blood flow, we performed behavioral assays that assess cognitive and motor function after acute (3h and 24h after one dose) and chronic (after 4 weeks of injection) treatment with anti-Ly6G or isotype control antibodies (IP, 2mg/kg mouse weight) in ~11-month old AD and wildtype mice (n = 10 per group). To measure short-term memory we used object replacement (OR), Y-maze, and novel object recognition tests. In the OR task, we found that after a single treatment memory function was significantly improved in AD mice to near wildtype levels (see Fig; 2-way ANOVA and Wilcoxon post-hoc test; 3h AD_{Tx} vs. 3h AD_{Ctr} p= 0.02). These results were even more pronounced after chronic treatment for 4 weeks (see Fig; 4 weeks AD_{Tx} vs. 4 weeks AD_{Ctr} p= 0.01). We found similar improvement in the Y-maze and novel object tasks. In contrast, motor function/coordination deficits in AD mice were not improved by anti-Ly6G therapy (as assessed by open field and balance beam walk).

In conclusion, treatment with anti-Ly-6G antibodies significantly improved impaired cognitive function in AD mice, thus strengthening the hypothesis that stalled blood flow in capillaries contributes to cognitive decline in AD.

Title: Are parvalbumin interneurons selectively targeted by ineffective autophagy and mitophagy in aging brain?

Authors: *Q. TANG, B. KRAEMER, M. DIXIT, J. B. RUDEN, P. J. SPITZLER, L. L. DUGAN;
Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: PV neurons are critically involved in information processing, memory and cognition, and dysfunction of these interneurons is observed in both aging and AD. We previously reported that aging produces a decrease in the number of PV neurons throughout hippocampus and frontal cortex, and demonstrated this was mediated by inflammatory induction of the innate immune enzyme, NADPH oxidase. However, the mechanism whereby Nox activation led to PV neuron is unclear. Nox has been shown to inhibit autophagy, and we recently observed ineffective autophagy in aging brain. Here we asked whether age-related PV neuron loss might reflect vulnerability to impaired autophagy. We in fact found a significant loss of PV-immunoreactive fibers in areas where autophagy protein aggregates were observed. These aggregates included p62 and lamp1, and often contained PV. We also noted loss of GAD67 immunoreactivity associated with the same autophagy aggregates. GAD67 is the inducible GAD found in PV interneurons, further support the idea that ineffective autophagy may be damaging PV interneurons. Other inhibitory and excitatory neuronal types appeared to be spared. We then asked why PV interneurons might be selectively targeted. PV interneurons are arguably the most metabolically active neurons in brain, are enriched in mitochondria to support their high metabolic demand, and are vulnerable to hypoxia and other metabolic stressors. Thus, PV interneurons likely recycle mitochondria at an enhanced rate, relying on mitophagy for this. We found that the mitophagy proteins parkin and pink1 colocalized with PV process, and further observed structures which contained partially degraded mitochondria, which were PV immunoreactive on the exterior. Based on our published data and the above results, we propose that inflammatory stress and Nox induction works in concert with the high metabolic load (metabolic stress) that PV interneurons experience, to impair mitophagic clearance of damaged mitochondria. Ineffective mitophagy then further impairs metabolism in these neurons, making them more susceptible to local autophagic injury, possibly from their own mitophagic cargo. This could provide a link between inflammation, impaired autophagy-mitophagy, and vulnerability of PV neurons to aging.

Title: Stalled blood flow in brain capillaries is responsible for reduced cortical perfusion in mouse models of Alzheimer's disease

Authors: ***J. CRUZ**[1], O. BRACKO[1], C. KERSBERGEN[1], V. MUSE[1], I. IVASYK[1], M. HAFT-JAVAHERIAN[1], J. ZHOU[1], J. D. BEVERLY[1], E. SLACK[1], G. OTTE[1], T. P. SANTISAKULTARM[1], C. IADECOLA[2], N. NISHIMURA[1], C. B. SCHAFFER[1]; [1]Cornell Univ., Ithaca, NY; [2]Weill Cornell Med. Col., New York, NY

Abstract: A ~30% reduction in cerebral blood flow is observed in patients and animal models of Alzheimer's disease (AD). Although this hypoperfusion likely contributes to cognitive impairment and disease progression, no physiological explanation for this phenomenon has emerged. We observed that leukocytes often plug capillaries in the brains of AD mouse models, effectively stopping blood flow in the smallest brain blood vessels. Here, we tested the hypothesis that these leukocytes plugs are the cause of the overall blood flow reduction. Using *in vivo* two-photon excited fluorescence imaging in transgenic AD mice (APP/PS1), we found that 1.6% of brain capillaries had stalled blood flow compared to 0.3% in age-matched, littermate controls (AD n=28 and wild-type n=12; $p<0.0001$, Mann-Whitney). This capillary stalling occurred early in disease progression, before deposition of amyloid plaques. Using in vivo labeling approaches, we determined that ~60% of the capillary stalls were caused by leukocytes. We found that administration of antibodies against the neutrophil receptor Ly-6G (1A8 clone) reduced the fraction of capillaries with stalled flow by 63%, while isotype control antibodies did not impact the stalls (AD_{Tx} n = 9, AD_{Ctr} n= 6; $p = 0.0004$, Mann-Whitney; **Fig 1A)**. Blood flow in penetrating arterioles increased by 40% after anti-Ly-6G treatment in both 3-4 month old ($p < 0.001$, Kruskal-Wallis test with Dunns multiple comparisons correction) and

11-14 month old AD mice ($p < 0.001$), while isotype antibodies led to no change in flow speed (**Fig 1B**). Anti-Ly-6G treatment had no impact on blood flow speed in 3-4 month old wildtype mice.

Brain hypoperfusion likely contributes to cognitive deficits in AD patients and, by impairing vessel-mediated clearance of amyloid-beta, may accelerate disease development. We have shown that neutrophils plug blood flow in a small fraction of brain capillaries and that blocking this adhesion substantially increases brain blood flow in mouse models of AD. Therapies that interfered with this capillary plugging could complement those aimed at reducing amyloid deposits.

Title: Gamma oscillations attenuate amyloid pathology and trigger a distinct microglia response in mouse models of Alzheimer’s disease

Authors: *H. F. IACCARINO, A. C. SINGER, A. J. MARTORELL, A. RUDENKO, F. GAO, T. Z. GILLINGHAM, R. G. CANTER, R. RUEDA, E. N. BROWN, E. S. BOYDEN, L.-H. TSAI;
MIT, Cambridge, MA

Abstract: Gamma oscillations (20-50 Hz), a common local field potential signature in many brain regions, are generated by a resonant circuit between fast-spiking (FS)-parvalbumin (PV)-interneurons and pyramidal cells. Changes in gamma have been observed in several neurological disorders. However, the relationship between gamma oscillations and cellular pathologies of these disorders is unclear. Here, we investigated this relationship using the 5XFAD mouse model of Alzheimer’s disease (AD) and found reduced behaviorally driven gamma activity before the onset of plaque formation or evidence of cognitive decline. Because of the early onset, we aimed to determine if exogenous gamma manipulations could influence the progression of disease pathology. We discovered that optogenetically driving FS-PV-interneurons at gamma frequency (40 Hz) reduced levels of amyloid-β $(Aβ)_{1-40}$ and $Aβ_{1-42}$ isoforms in the hippocampus of 5XFAD mice. Neither driving FS-PV-interneurons at other frequencies, nor driving excitatory neurons,

reduced Aβ levels. Furthermore, driving FS-PV-interneurons at 40 Hz reduced enlarged endosomes and amyloid precursor protein (APP) cleavage intermediates in hippocampus. Gene expression profiling revealed an induction of microglia specific genes associated with morphological transformation of and increased Aβ phagocytosis by microglia. Finally, we showed that 40 Hz activity alleviated tau pathology in the TauP301S mouse model. Overall, our findings uncover a previously unappreciated function of the brain's gamma rhythms in neuroprotection by recruiting both neuronal and glial responses to mitigate AD-associated pathology.

Title: Diminished mitochondrial activity in myeloid cells in response to $A\beta_{42}$ oligomer stimulation is associated with altered kynurenine pathway activity

Authors: *P. S. MINHAS, S. D. MHATRE, P. K. MOON, Q. WANG, C. A. TSAI, A. J. RUBIN, J. WANG, K. I. ANDREASSON;
Dept. of Neurol. & Neurolog. Sci., Stanford Univ., Stanford, CA

Abstract: Alzheimer's Disease (AD) is a debilitating condition affecting over 5 million Americans that is characterized by mitochondrial dysfunction and neuroinflammation. Some studies suggest that supplementation with nicotinamide adenine dinucleotide (NAD+) may ameliorate AD phenotypes. Interestingly, the kynurenine pathway (KP), which arises as a result of tryptophan metabolism to kynurenine (KYN), is the only *de novo* biosynthetic source of NAD+. Moreover, the KP has been implicated in models of Huntington's and AD, leading to the hypothesis that dysregulation of the KP may disrupt endogenous NAD+ synthesis and contribute to AD-associated mitochondrial dysfunction. We tested whether $A\beta_{42}$ oligomers, which are necessary for development of AD phenotypes and result in a vigorous innate immune response, affect endogenous NAD+ production in myeloid cells. Stimulating primary murine macrophages with $A\beta_{42}$ oligomers (1μM), we measured KP enzyme expression (qRT-PCR), mitochondrial

activity (XTT and seahorse analysis), NAD+/NADH, and ATP in the absence and presence of KYN supplementation. $A\beta_{42}$ stimulation resulted in significant decreases in XTT activity, NAD+, and ATP levels ($p < 0.0001$) after 20 hours and decreases mRNA levels of quinolinate phosphoribosyltransferase (QPRT) ($p < 0.04$), which encodes the enzyme that produces *de novo* NAD+ from the KP. Analysis of SIRT3, a sirtuin responsible for resolving mitochondrial stress, revealed a significant decrease in SIRT3 enzymatic activity ($p<0.001$) within mitochondria corresponding to decreases in *de novo* NAD+. No changes in cell death, as measured by propidium iodide staining, were observed between conditions. KYN supplementation rescued $A\beta_{42}$-mediated loss of XTT activity, NAD+, and ATP levels, suggesting that the KP contributes to *de novo* NAD+ production in the setting of immunogenic $A\beta_{42}$ stimulation. Our findings suggest a novel role for the KP as a potential therapeutic target for generating NAD+ and healthy mitochondrial activity in models of AD.

Title: Role of RAGE in Alzheimer's Disease

Authors: *M. S. KINDY, J. YU, H. ZHU, S. TAHERI;
Pharmaceut. Sci., Univ. of South Florida, Tampa, FL

Abstract: Alzheimer's disease (AD) is a common neurodegenerative disorder of mostly unknown etiology, with the exception of some genetically inherited cases. AD is an age-related chronic neurodegenerative disease and is the most common form of senile dementia, associated with memory loss and failure of executive function to the point of becoming highly dependent on expensive and intensive care. AD is characterized by the aggregation of amyloid-β (Aβ) peptide into neuritic plaques and hyperphosphorylated tau protein accumulating into neurofibrillary tangles (NFTs). Oxidative stress, microglial activation and inflammatory responses seem to contribute to the pathogenesis. The receptor for advanced glycation endproducts (RAGE) is a

multi-ligand receptor of the immunoglobulin superfamily of cell surface molecules. The formation of advanced glycation end products (AGEs), the first ligand of RAGE identified, requires a complex series of reactions including non-enzymatic glycation and free radical reactions involving superoxide-radicals and hydrogen peroxide. Binding of RAGE ligands results in activation of nuclear factor-kappaB (NF-κB). Previous studies have implicated RAGE in the pathogenesis of AD, but to date, the specific role has not been elucidated. We hypothesize that the detrimental actions of RAGE are triggered upon binding to its ligands, such as AGEs (advanced glycation end products), S100/calgranulin family members, and High Mobility Group Box-1 (HMGB1) proteins. We have determine the role of RAGE in the pathogenesis of AD in animal models of AD; determined the mechanism of action of RAGE engagement and activation in AD; and determined the potential role of RAGE in the pathogenesis of AD in patients and autopsy samples. From these studies, we have a better understanding of the role RAGE plays in AD and to design therapeutic strategies to treat the disease.

Title: Region- and age-specific effects of apoe4 on expression of trem2 mRNA and microglial phenotype in young adult targeted replacement mice

Authors: ***T. JONES**, J. VALLEJO, B. CHAVIRA, C. DE VERA, M. CASTRO, G. JENTARRA;
Midwestern Univ., Glendale, AZ

Abstract: Background: The APOE4 genotype is a risk factor for late-onset Alzheimer disease (AD). Altered neuroinflammatory signaling is consistently observed in the AD brain. Communication between neuronal and microglial cells occurs in part through triggering receptor expressed on myeloid cells 2 (TREM2). TREM2 regulates the balance between phagocytic and pro-inflammatory activity in microglia, and loss-of-function of this receptor is consistent with an enhanced inflammatory state, characteristic of AD brain. Mutations in TREM2 confer increased risk for AD, suggesting that this receptor is protective in the CNS. We evaluated the effects of APOE4 expression on microglial functional profile in APOE3 (E3) and APOE4 (E4) targeted

replacement (TR) mice. *We hypothesized that the cortex and hippocampus of E4 mice would exhibit a pro-inflammatory bias that would increase as the mice age consistent with progression of inflammation in AD brain.*
Methods: E4 and E3 mice (4 and 6 months old) were transcardially perfused with sterile PBS. The brain was removed and the cortex and hippocampus dissected and snap frozen for qRT-PCR analyses.
Results: At 4 months of age, cortical TREM2 mRNA was decreased in E4 mice compared E3 mice. Arginase 1 (Arg1) mRNA, associated with anti-inflammatory (M2) microglia, was significantly decreased in the cortex of APOE4-TR mice at 4 months, while NOS2 mRNA was not altered. In contrast, hippocampal TREM2 mRNA was increased in E4 mice, while Arg1 and NOS2 were unaltered, indicating regional heterogeneity to the inflammatory changes that may be relevant to AD. Interestingly, by 6 months of age, hippocampal TREM2 mRNA was decreased, while Arg1 and NOS2 mRNAs were increased in E4 mice. With respect to age, cortical TREM2 mRNA significantly decreased over time in both groups of mice, whereas hippocampal TREM2 mRNA significantly decreased in E4 but not E3 mice. Cortical Arg1 expression increased over time in both E3 and E4 mice while in the hippocampus only E4 mice had increased Arg1 mRNA. NOS2 mRNA was decreased in the cortex of both E3 and E4 mice, while in the hippocampus, there was a significant increase specific to E4 expression.
Conclusion: The purpose of this study was to determine whether two known risk alleles, APOE4 and TREM2, may be acting synergistically to enhance risk for developing late-onset AD. We show that the APOE4 genotype modifies inflammatory signaling in a distinct manner in the cortex vs the hippocampus and that the effects of APOE4 on microglial phenotype are more pronounced in the hippocampus as the mice age. The differing inflammatory profiles in these two regions could underlie the distinct temporal progression of symptoms known to occur in AD.

Abstract: Microglia (MG), the brain resident immune cells, can be activated to produce pro-inflammatory responses towards various stimuli. Classically activated M1 MG may exacerbate neuronal death in ischemic stroke and Alzheimer's disease. Here, we investigated the suppression of the M1 MG using dimethyl fumarate (DMF), a fumaric acid ester approved as a multiple sclerosis therapy. DMF may confer neuroprotective effects via activation of the nuclear-erythroid factor 2 (Nrf2) pathway to regulate oxidative stress induced by M1 MG. We showed that DMF suppresses molecular and functional characteristics of M1 MG induced by lipopolysaccharide (LPS). DMF inhibited the expression of pro-inflammatory cytokines TNF-α, IL-1β, and iNOS and reduced the level of co-stimulatory surface molecules CD86, CD80, and CD40 in primary cultured MG activated by LPS. In vivo, C57BL/6 mice administered DMF for 3 days prior to a systemic LPS challenge decreased frontal cortex mRNA expression of TNF-α, IL-1β, iNOS, and IL-6. To see whether these observations were mediated through Nrf2, we examined the induction of Nrf2 target genes HO-1, NQO1, Gclc, and Gclm. We found that Nrf2 gene targets were upregulated in both cultured MG and the mouse frontal cortex, suggesting that DMF activates Nrf2. Interestingly, in MG cultured from Nrf2 knockout mice, we found that Nrf2 differentially mediated the effects of DMF regarding the expression of co-stimulatory surface molecules. Regulation of CD40 by DMF was Nrf2 independent, while modulation of CD86 and CD80 by DMF was Nrf2 dependent. To address whether DMF impacts neurotoxicity associated with M1 MG, we examined cell viability of hippocampal neurons exposed to conditioned media collected from LPS or LPS/DMF treated MG. We observed that neurons receiving the conditioned media from DMF treated MG had a significantly higher viability when compared to neurons receiving conditioned media without DMF, suggesting a potential neuroprotective effect of DMF. In summary, our findings demonstrate that DMF inhibits neuroinflammation through modulating M1 MG activation by Nrf2-independent and -dependent pathways.

Title: Educational attainment confers protection against amyloid deposition during early but not later old age on higher order cognition

Authors: M. E. FARRELL[1], G. N. BISCHOF[2], *D. C. PARK[1];
[1]Ctr. For Vital Longevity, Univ. of Texas At Dallas, Dallas, TX; [2]Dept. of Nuclear Med., Inst. of Neurosci. & Med. (INM-3) Res. Ctr., Juelich, Germany

Abstract: Background. Both normal aging and amyloid deposition, a biomarker for preclinical Alzheimer's disease, are associated with declines in cognition. Education has long been established as a protective factor against dementia onset, a phenomenon referred to as cognitive reserve. The present study sought to determine whether educational attainment mitigates the impact of amyloid burden on cognitive performance across multiple domains, and whether this relationship was modified by increasing age. Methods. 224 participants (age 55-89) from the Dallas Lifespan Brain Study were included. All had completed extensive cognitive testing and an F-18 Florbetapir PET scan. ANOVAs were conducted of the effect of Age, Amyloid Status (positive or negative) and Education Level (<bachelor's, bachelor's +) on reasoning, spatial working memory, verbal working memory, episodic memory and processing speed, while controlling for sex. Results. The analyses yielded a significant three-way interaction of age, education, and amyloid status for reasoning and spatial working memory, but not verbal working memory, episodic memory or processing speed. The High Education/Amyloid Positive Group experienced a protective effect of high educational attainment for reasoning and spatial working memory, performing similarly to High Education/Amyloid Negative at younger ages (55-69), but that benefit dissipated with increasing age. In contrast, Low education/ Amyloid Positive adults performed at a consistently poor level across age. Conclusion. These findings indicate that a high level of educational attainment confers resilience and protects individuals carrying amyloid from the negative effects of amyloid on reasoning and spatial working memory, though this protective effect is mitigated by increasing age. The benefits of education were differentially beneficial to reasoning and spatial working memory, suggesting that educational attainment is most protective for measures of higher order, abstract processing where experience and world knowledge offers little support for task performance.

Title: Electrophysiological markersof top-down control in younger and older participants.

Authors: *N. NAPIORKOWSKI[1], H. MÜLLER[1], T. TÖLLNER[1], A. PETERSEN[2], I. WIEGAND[2], K. FINKE[1];
[1]Ludwig Maximilian Univ. of Munich, Muenchen, Germany; [2]Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Mild Cognitive Impairment (MCI) and more so, Alzheimer’s disease (AD) leads to reduced visual top-down control. Thus, decreasing efficiency in prioritizing relevant over irrelevant information might be a potential early cognitive marker of AD (Redel et al., 2012). It is less clear, however, whether such a gradual decline in top-down control also occurs in healthy aging. Furthermore, neural correlates, such as, e.g., neurophysiological markers, of individual

top-down control efficiency are not defined. In the current study, two groups of younger (n = 30; mean age = 27) and older participants (n = 33; mean age = 69)were assessed with partial report based on Bundesen's theory of visual attention (TVA; Bundesen, 1990). Report accuracy was used for computationally modelling and quantifying the individual efficiency of top-down control. Furthermore, EEG was assessed simultaneously in order to measure electrophysiological correlates on individual top-down control. In a second session, individual visual processing speed and visual short-term memory storage capacity were assessed based on a TVA-based whole report in order to control for effects of these variables. ERP analyses focused on ERP components that might be related to top-down control (Luck & Hillyard, 1994; Wiegand et al., 2015): the Posterior positive contralateral (Ppc) and the Posterior-Contralateral Negativity (PCN or N2pc). We asked whether top-down control efficiency changes with age and tested whether Ppc and PCN are related to individual top-down control in both age groups. Groups did not differ significantly in top-down control. When participants within both groups were split into efficient and inefficient ones with respect to top-down control, significant differences were found in the amplitude of the Ppc and the PCN in both age groups. These differences remained significant when controlling for visual processing speed and visual short-term storage capacity. Our findings suggest that the efficiency of top-down control is robust and reliably reflected in individual amplitudes of the Ppc and PCN in normally aging individuals. With respect to pathological neurodegeneration, we suggest that top-down control and its neurophysiological correlates might be early neuro-cognitive indicators of AD.

Title: Memory for lifelike events in older adults with memory impairment

Authors: ***C. OEDEKOVEN**[1], J. L. KEIDEL[1], G. RACZEK[2], C. M. BIRD[1];
[1]Sch. of Psychology, [2]BSMS, Univ. of Sussex, Brighton, United Kingdom

Abstract: Memory for events is severely affected early on in the course of Alzheimer's disease (AD). This parallels neuroimaging investigations which show hypometabolism and atrophy in brain areas involved in memory retrieval. In this study we examined the memory retrieval network in older adults at risk of AD using a naturalistic memory task involving memory for short videos. Previous research in young adults has shown that retrieval practice of memories for events stabilizes them and thus improves later recall (Bird, Keidel et al. 2015). These study highlighted posterior cingulate as a key region involved in retrieval-mediated consolidation. This region is one of the areas affected earliest in AD. The aim of our fMRI study was to investigate the cognitive and neural processes underpinning memory for lifelike events in older adults and how they are impaired in the very early stages of AD.
As part of an ongoing study, we scanned a group of 54 older adults (aged 72.6 years, range 43-88, 21 female) recruited from Memory Assessment Service clinics. In the MRI scanner, participants watched and then silently retrieved 8 short video clips. Afterwards they described the videos to the experimenter. Univariate analyses were conducted using SPM8 and whole-brain searchlight representational similarity analyses (RSA) using the CosmoMVPA toolbox.
On average participants recalled 6.7 details for each video, but there was large variability in individuals' performance (range 1.2 - 14.8 details). In a regression analysis of memory retrieval taking into account the amount of details remembered, better performance was correlated with increased activity in bilateral posterior medial frontal lobe and bilateral inferior frontal gyrus (IFG). An RSA identified a network of regions where patterns of activity during encoding correlated with immediate recall of the same video, which included striatal as well as hippocampal regions.
The correlation of bilateral IFG activity with the amount of detail recalled is consistent with the proposal that these regions integrate episodic information with prior semantic knowledge (Binder et al., 2009) and might be an indicator of compensatory activity in accordance with the Posterior-Anterior Shift with Aging (Cabeza and Dennis 2012; Davis et al., 2008). In comparison to the earlier study in young adults, we did not see reinstatement effects in the posterior cingulate. This may reflect breakdown in neuronal function in this region and partially explain the generally low group performance on the memory task.

Title: Visual episodic memory does not depend on precuneus disease: evidence from posterior cortical atrophy

Authors: *K. WIN[1,2], P. YUSHKEVICH[3], D. WOLK[2], M. GROSSMAN[1,2];
[1]Neurol. Dept, Penn Frontotemporal Degeneration Ctr., Philadelphia, PA; [2]Neurosci. Grad. Group, Univ. of Pennsylvania, Philadelphia, PA; [3]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Motivation: Posterior cortical atrophy (PCA) is characterized by a progressive decline in visuoperceptual processing. Predominant sites of atrophy are occipitotemporal and parietal cortices (OTPC), including precuneus, which has been shown to be involved in memory. However, it is unclear whether visual episodic memory (VsEM) deficits in PCA are directly due to precuneus atrophy. The underlying pathology of most PCA cases is Alzheimer's disease (AD), but episodic memory (EM) has rarely been assessed. Here, we comparatively examined VsEM and visuoperceptual function in PCA and AD patients, and related these measures to precuneus atrophy. Because hippocampus, besides precuneus, mediates EM, we also examined the contribution of hippocampus (HC) to the VsEM.
Method: 17 elderly controls (Ctl), 13 PCA and 26 AD were matched in age, sex, and education. PCA and AD were matched in disease severity. We used Rey Complex Figure (RCF) copy to assess visuoperceptual function, RCF recall to assess VsEM, and d-prime to assess recognition memory. All subjects underwent T1 and high-res T2 MRI. A multi atlas algorithm was applied to label HC subfields: Cornu Ammonis (CA1), dentate gyrus (DG), and subiculum.
Results: Compared to Ctl, PCA patients were significantly impaired on RCF copy and RCF recall but had intact d-prime; AD patients were impaired on RCF copy, recall, and d-prime. Compared to PCA, AD patients were more impaired on Rey Copy, and d-prime. Equivalent deficit on RCF recall was observed between PCA and AD. Multiple regression analysis showed that only RCF copy, not d-prime, significantly predicted RCF recall in PCA; in AD, both RCF copy and d-prime predicted RCF recall. Whole brain imaging showed that PCA had a significant atrophy in OTPC, including bilateral precuneus and right HC; AD had a widespread atrophy in OTPC, including bilateral precuneus and HC. Regression analyses showed that in PCA, RCF copy was related to left superior occipital gyri, left superior and inferior parietal gyri, including precuneus and angular gyrus (AG); in AD, to right precuneus and those same areas involved in PCA. RCF recall in PCA was related to left AG; in AD, to right HC, right superior and inferior parietal gyri, including AG and precuneus. Examination of HC subfields showed that right CA1 was differentially atrophied in PCA but this atrophy did not modulate VsEM. In AD, RCF recall was related to bilateral CA1 and left DG.
Conclusion: Despite precuneus atrophy in PCA, impaired VsEM function is more directly related to visuoperceptual impairments. In AD, VsEM is modulated in part by HC and precuneus. We conclude that precuneus disease in PCA does not necessarily compromise VsEM function.

Title: Chronic HDACi therapy to long term neurological disease

Authors: M. ALAM, M. GETZ, B. COMBS, *K. HALDAR;
Biol. Sci., Univ. of Notre Dame, NOTRE DAME, IN

Abstract: Crossing the blood-brain barrier and safely harnessing molecular dysregulation through drugs like histone deacetylase inhibitors (HDACi) has been a major challenge in the treatment of neurological disorders. We earlier reported the development of a triple combination formulation (TCF) comprising the pan-HDACi vorinostat, the caging agent 2-hydroxypropyl-b-cyclodextrin (HPBCD), and polyethylene glycol (PEG) to treat Niemann-Pick type C (NPC) disease, a difficult- to- treat the cerebellar disorder. While vorinostat alone showed no benefit in a mouse model, TCF boost HDACi across the blood-brain barrier, to preserve neurites and Purkinje cells, delay symptoms of neurodegeneration, extend mouse lifespan from weaning well into adulthood without toxicity even when used long term. Ongoing mechanistic analyses of TCF action in the brain suggests chronic, low levels of transcriptional dysregulation can be tolerated by reduction of the inflammatory response to rescue function of NPC1 and as well as broad range of cellular targets (deficiencies in some of which also cause neurological disease). Together, the data suggest that the TCF application may provide therapeutic and mechanistic insight into a broad range of neurological diseases caused by both monogenetic and polygenetic defects. Preclinical studies currently in progress suggest an approved optimized formulation will enter Phase Ib trials for the first monogenetic neurological indication (NPC) within 12 months.

Title: Translational validity of the psychomotor vigilance paradigm in an acute pharmacological model of neurocognitive decline in primates

Authors: *I. HERNADI, V. OLAH, A. TRUNK;
Grastyan Translational Res. Ctr., Univ. of Pecs, Pecs, Hungary

Abstract: Age-associated pathological decline in cognitive function have become a major demographic health threat worldwide. Until now there are no effective pharmacological interventions against neurocognitive disorders, such as Alzheimer's disease (AD). In order to develop a new pre-clinical disease model in non-human primates (NHP) we implemented the so called 'reverse translational' approach where we developed a unified version of the psychomotor vigilance task (PVT) in humans and NHPs. We collected reaction time (RT) data to target stimuli as task performance indices. Fixation times (FT) before target stimuli were distributed randomly from 1 to 10 sec (expectancy effect). Then we investigated the effects of pharmacologically induced cognitive impairment in NHPs. The main endpoints were to detect similarities of target expectancy between healthy humans and NHPs, then we tested the transient adverse effects of pharmacological amnestic agent, scopolamine (15 ug/kg b.w.) on task performance in NHPs. Finally we measured the reversing effects of cholinesterase inhibitor donepezil (100 and 200 ug/kg b.w.) on scopolamine induced impairments of target expectancy in NHPs. Results suggested that both humans and NHPs showed similar task performance with comparable RT distribution (expectancy effect). In NHP subjects the prior scopolamine treatment further increased the RT and abolished the previously observed target expectancy effects, and donepezil pre-treatment significantly reversed impairments of task performance. Based on the present results we conclude that the common primate PVT paradigm has high translational validity and it may be suitable for preclinical testing of novel therapeutic interventions against cognitive impairment.

Title: Relative frontal and temporal contributions to social knowledge in bvFTD

Authors: *A. HALPIN, R. LANGEY, N. MIN, C. YORK, O. KOFMAN, K. RASCOVSKY, D. IRWIN, C. JESTER, C. MCMILLAN, M. GROSSMAN;
Frontotemporal Degeneration Ctr., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Behavioral variant frontotemporal dementia (bvFTD) is a form of frontotemporal degeneration (FTD) characterized by a progressive deterioration of social comportment and cognition. These social limitations may be due to a loss of social knowledge or faulty implementation of known social rules. Given that fMRI studies have associated social knowledge with right anterior temporal activation in healthy adults, we sought converging evidence for the neural underpinnings of social knowledge in bvFTD with predominant temporal or frontal disease. Social knowledge was assessed using the Social Norms Questionnaire (SNQ), which measures whether an individual can appreciate widely accepted social boundaries. We administered the SNQ to 49 bvFTD patients, 21 Alzheimer's disease patients (AD) and 22 healthy controls (HC). 16 temporal-bvFTD patients were identified based on the co-occurrence of semantic variant primary progressive aphasia (svPPA) and 33 patients were classified as frontal-bvFTD given their predominant frontal disease and associated executive deficits. Groups were matched for age, education, and disease duration. We report SNQ Total Scores (SNQ-T; overall measure of social norm interpretation) as well as SNQ Overadherence Scores (SNQ-O; rigid interpretation of social norms), and SNQ Break Scores (SNQ-B; difficulty identifying socially unacceptable behavior). We found that temporal-bvFTD have impaired SNQ-T scores relative to frontal-bvFTD ($U=91$; $p<0.01$), AD ($U=65$; $p<.01$) and HC ($U=16$; $p<.01$). Temporal-

bvFTD also had impaired SNQ-B scores relative to frontal-bvFTD (U=53; p<0.01), AD (U=50; p<.01) and HC (U=41; p<.01). In addition, temporal-bvFTD patients had impaired SNQ-O scores relative to HC (U=64; p.001). Frontal-bvFTD had impaired SNQ-T and SNQ-O scores relative to HC (U=235; p=.025) and (U=224; p=0.015) respectively. AD also had impaired SNQ-T scores and SNQ-O scores relative to HC (U=111, p=.003) and (U=114; p=.004) respectively. Frontal-bvFTD and AD did not differ from HC on the SNQ-B (all p>0.1). It is unlikely that social limitations are related to disease severity since AD had lower average MMSE scores and fewer social deficits than temporal-bvFTD. Together, we observed more overall social norm impairments in temporal-bvFTD than any other group, and only temporal-bvFTD had impaired break scores. These finding emphasize the role of temporal cortex in supporting social knowledge.

Title: Cumulative effect of systemic chemotherapy on cognitive function

Authors: ***S. JUNG**[1,2], J. MIN[3];
[1]Seoul Natl. Univ. Boramae Med. Ctr., Seoul, Korea, Republic of; [2]Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of; [3]Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of

Abstract: Introduction: Although more than a third of cancer survivors treated with chemotherapy suffer from chemotherapy-induced cognitive impairment, the underlying mechanism has been poorly understood. Moreover, most systemic chemotherapy is performed as a cyclic manner with multiple doses. There have been several studies which suggested that the mechanism of chronological effect of multiple doses of chemotherapy differ from the mechanism of the effect of single-dose chemotherapy. We aimed to demonstrate the cumulative effect on

cognitive function of systemically administered Adriamycin (DXR) in the rat models. Methods: Nine-to-ten-week-old male Sprague-Dawley rats were injected intravenously with a weekly dose of 2.5mg/kg DXR for 6 weeks (total 15mg/kg) or the same volume of saline as control. Rats were assessed with a battery of behavioral tests to assess global motor performance (rotarod test), cognitive function (object recognition test and radial arm maze test) and mood-related responses (tail suspension test and elevated plus maze test). Changes in the protein expression in the prefrontal cortex, the hippocampus and the cerebellar cortex in the DXR-treated and control group were analyzed by Western blotting. Results: The DXR-treated rats displayed persistent deterioration in the attention since day 7 and in the spatial working memory since day 1 following DXR injection as compared to controls. They showed depressive behavior since day 7 following DXR injection without anxious behavior. β-amyloid expression was increased in the prefrontal cortex and in the hippocampus since day 7. Conclusions: Taken together, these results indicate that cyclic chemotherapy can impair attention and working memory and may increase the risk of depression which is accompanied by alteration of β-amyloid expression in the brain.

Title: Reversal learning deficits in behavioral variant frontotemporal degeneration

Authors: *K. TERNES[1], J. KABLE[2], J. MCGUIRE[3], K. RASCOVSKY[1], C. MCMILLAN[1], M. GROSSMAN[1];
[1]Univ. of Pennsylvania Dept. of Neurol., Philadelphia, PA; [2]Univ. of Pennsylvania Dept. of Psychology, Philadelphia, PA; [3]Boston Univ. Dept. of Psychological & Brain Sci., Boston, MA

Abstract: Behavioral variant frontotemporal degeneration (bvFTD) is clinically characterized by deficits in executive function and social behavior. One source of executive dysfunction involves a lack of cognitive flexibility, however the neuroanatomic source of this deficit is poorly understood. Reversal learning tasks evaluate simple strategy learning and whether an individual can flexibly adapt these strategies. We examined the neural basis of reversal learning in bvFTD (N=25), mild Alzheimer's disease (AD; N=12), and healthy controls (HC; N=17) who also had structural MRI. All patients and controls were matched for demographic factors including age, education and gender (all $p>0.1$). All patients and controls completed a computerized task in which subjects chose between two multicolored fractal stimuli containing different shape and color features. We used a probabilistic reinforcement paradigm to reinforce selection of one of the two fractals in the first "learning" block and implicitly reinforced the novel fractal in the second "reversal" block. We categorized subjects as "learners" if they endorsed the target stimulus in >50% of first block trials. Of the "learners", we categorized "reversers" as those that endorsed the novel stimulus in >50% of second block trials. Chi-square analyses evaluated the proportion of "learners" and "reversers" in patient groups. We observed an equal distribution of learners between each group: 76% HC, 76% bvFTD, 58% AD ($X2=1.51$; $p=0.68$). However, within-group analysis showed the rate of reversers was less in bvFTD (42%; $X2=5.23$, $p=0.02$) unlike AD (57%; $X2=0.003$; $p=0.96$) and HC (77%; $X2=0.001$; $p=0.98$) who were equally likely to reverse. The rate of reversal in bvFTD also differed from HC and AD ($X2=3.80$; $p=0.05$). Neuroimaging analyses using voxel-based morphometry showed gray matter atrophy in orbitofrontal cortex (BA 10, 47) and dorsolateral prefrontal cortex (BA 9) in bvFTD non-reversers relative to HC ($q<0.005$ TFCE FWE-corrected). Together, the behavioral and imaging findings suggest disease in DLPFC and OFC contribute to selective reversal learning deficits in bvFTD by limiting cognitive flexibility and decision-making especially when contingencies and rewards change.

Title: Cerebral metabolic correlates of disorientation in alzheimer's disease.

Authors: *G. WEISSBERGER[1], R. MELROSE[2], T. NARVAEZ[2], D. HARWOOD[2], M. MANDELKERN[2], D. SULTZER[1];
[1]GRECC, [2]West Los Angeles Veteran's Admin., Los Angeles, CA

Abstract: Orientation to time, date, and place is commonly used clinically to stage and monitor progression of Alzheimer's disease (AD) but few studies have examined its neural substrates. The present study aimed to compare the neural substrates underlying performance on DRS and MMSE orientation items to the remaining items of the DRS Memory subtest and MMSE in patients with mild to moderate AD in order to identify neural structures unique to orientation. 90 patients (*M* age = 78.4, *SD* = 7.9; 80% male; *M* education = 13.9, *SD* = 3.5) with mild to moderate AD were recruited from the Los Angeles (LA) community and the Greater LA Veteran's Administration Healthcare System. Participants underwent Fluorodeoxyglucose Positron Emission Tomography (FDG-PET) and a comprehensive neuropsychological battery in which they were administered the DRS (*N*=87; *M* = 103.5, *SD* = 20.6) and MMSE (*M* = 19.4, *SD* = 5.6). Scores on DRS orientation, MMSE orientation, remaining items from DRS Memory (DRS Memory "other" items), and remaining items from the MMSE (MMSE "other" items) were separately summed and correlated with cerebral glucose metabolism (CGM). PET analyses were conducted in SPM8. Results maps were thresholded at the voxel level at $p<.001$. Findings were considered significant at the cluster level $p<.05$, corrected using the Family Wise Error procedure (FWE). The SPM analysis revealed multiple areas of significant positive association between cortical metabolism and total orientation score of the DRS. Specifically, hypometabolism related to worse performance on DRS orientation in 4 clusters spanning many regions associated with AD pathology including the posterior and middle cingulate gyri, bilateral inferior temporal lobe, left middle temporal lobe, and left middle occipital lobe ($ps\leq.05$). In contrast, no significant clusters arose in correlating DRS Memory "other" items to CGM. With regards to the MMSE, a positive association between CGM and orientation items arose across 3 significant clusters spanning the bilateral inferior temporal lobe and middle cingulate gyrus ($ps\leq.02$). MMSE "other" items were positively associated with CGM in the left middle and inferior temporal lobe and left inferior parietal lobe ($ps\leq.02$). Findings suggest that disorientation in AD is related to cerebral hypometabolism in a widespread network of structures commonly associated with AD pathology. Although orientation is commonly considered a proxy for memory, findings reveal distinct neurobiological correlates between orientation and measures of memory on the DRS, as well as other cognitive items on the MMSE.

Abstract: Primary progressive aphasia (PPA) is a clinical syndrome characterized by progressive loss of language abilities with three phenotypic clinical presentations, including logopenic variant (lvPPA), nonfluent variant (nfvPPA), and semantic variant (svPPA). Structural and functional neuroimaging studies have implicated unique anatomic involvements within the language network in each variant. Resting state brain oscillations represent coordinated activity in large groups of neurons and hence provide a tool to quantify spontaneous neuronal activity and functional network integrity of neural circuits. We hypothesized that resting state brain oscillations will show unique deficits within the language network in each variant of PPA and these regional deficits will provide anatomical correlates for distinct alterations in speech-motor control. We examined lvPPA, nfvPPA and svPPA patients using magnetoencephalogrpahy, compared to an age-matched control group. Each patient underwent a complete clinical

evaluation including a comprehensive battery of language tests. We examined the spectral power and whole brain resting state functional connectivity patterns of alpha frequency oscillations (8-12Hz), and responses to auditory feedback perturbations of pitch, in each patient group, compared to age-matched controls. We found that lvPPA patients have significantly reduced alpha power over the posterior superior temporal, posterior parietal and occipital cortices, with a left predominant distribution. In contrast, nfvPPA patients had significantly reduced alpha power over inferior frontal cortex bilaterally. The two subgroups also showed unique deficits of functional connectivity patterns, where lvPPA patients showed reduced functional connectivity over the left posterior superior temporal and occipital regions while nfvPPA patients showed reduced functional connectivity of bilateral inferior frontal regions, compared to age-matched controls. svPPA patients showed minimal spectral differences compared to age-matched controls. We also found significantly altered auditory feedback responses in lvPPA and nfvPPA. These results demonstrate neural correlates of region specific abnormalities and unique spatiotemporal patterns of network dysfunction in distinct phenotypes of PPA, and provide evidence for neural substrates of speech motor behavioral deficits in PPA .

Abstract: Mutations in the progranulin gene (*GRN*) cause autosomal dominant frontotemporal lobar degeneration (FTLD), a common cause of early-onset dementia. Symptomatic *GRN* carriers develop heterogeneous clinical syndromes even within the same family. These syndromes include behavioral variant frontotemporal dementia (bvFTD), primary progressive aphasia (PPA), corticobasal syndrome (CBS) and Alzheimer's disease (AD). Previous studies have suggested that presymptomatic *GRN* carriers show similar gray matter volume compared to healthy controls, but reduced task-free fMRI connectivity in the salience network, known to be disrupted in bvFTD. To date, no studies have systematically explored whether presymptomatic *GRN* carriers show alterations in four intrinsic connectivity networks (ICNs) known to be disrupted in the four major *GRN* clinical syndromes. *GRN* carriers were deemed presymptomatic during a clinical consensus conference and underwent an extensive neuropsychological battery. We compared 17 presymptomatic *GRN* carriers (age 53.1 ± 11.6 years, 10 females) to demographically-matched healthy controls using voxel-based morphometry to delineate gray matter differences. Using seed-based task-free fMRI, we probed: (1) the salience network, which is atrophied in bvFTD, (2) the PPA network, (3) the CBS network, and (4) the default mode network, atrophied in AD. Although presymptomatic *GRN* carriers and controls showed similar performance on cognitive testing, carriers showed reduced gray matter in the posterior midcingulate cortex, dorsal midinsula, and small clusters throughout lateral frontotemporoparietal cortices ($p < 0.001$ uncorrected). ICN mapping showed robust regions of enhanced connectivity in key ICN hubs for all four networks. Interestingly, increased thalamic connectivity was a unifying feature across all ICNs studied. Only the PPA network revealed connectivity reductions emerging in the pons and cerebellum. While presymptomatic carriers showed areas of reduced gray matter in scattered foci, extensive regions of increased connectivity emerged in the four ICNs that degenerate during the symptomatic phase. Longitudinal studies will determine if such hyperconnectivity represents a compensatory response as carriers approach symptom onset, or whether it manifests throughout the presymptomatic phase.

Title: Similarity-based cortical thickness analysis of mild cognitive impairment (MCI)

Authors: *C. E. HAN[1], H. KAM[2], J.-K. SEONG[3,4];
[1]Electronics and Information Engin., Korea Univ., Sejong, Korea, Republic of; [2]Dept. of Visual Information Processing, [3]Sch. of Biomed. Engin., [4]Dept. of Bio-convergence Engin., Korea Univ., Seoul, Korea, Republic of

Abstract: Mild Cognitive Impairment (MCI) patients may convert into Alzheimer's disease (AD), the most common cause of dementia; however does not all of them. The former is called 'MCI converters' while the latter is called 'MCI non-converters'. Comparing those two MCI types has a great value to understand disease progression and may help to design early interventions. The 'region-specific' differences of brain atrophy between them were previously reported. However, difference in *overall* atrophy patterns was less studied. Thus, we here provide a statistical framework of similarity-based analyses using a MRI dataset from the Alzheimer's Disease Neuroimaging Initiative (ADNI). The dataset consists of T1-weighted structural images of 101 MCI converters, 104 MCI non-converters, and 114 matched healthy subjects where each patient has 3 volumes at the baseline, 1 year and 2 year follow-ups. First, we constructed a similarity matrix between any pair of subjects in their cortical thickness of whole brain which is a surrogate of brain atrophy. We obtain the cortical thickness from T1-weighted MR images using FreeSurfer with visual validation. Due to inter-subject variability of the brain shape, we resample the brain surfaces and its corresponding cortical thickness with 81,924 vertices using our in-house software. The pairwise similarity between any pair of subjects is computed with both a correlation coefficient and the mutual information. Then, we performed following statistical analyses. If the mean inter-group similarity is lower than the mean intra-group similarity, there exists a group difference. To estimate the significance level, we used permutation testing. We observed the significant difference between MCI groups ($p<0.001$). For the correlation with non-imaging measures including the Mini Mental State Examination (MMSE), for each patient we average similarities with the healthy subjects. Since similarity is defined between a pair of subjects, it only captures relative locations of subjects to the others. The averaging anchors each subject to the healthy subjects and thus enables a correlation study. We observed a weak but significant positive correlation with MMSE ($r\sim 0.2$), and a moderate but significant negative correlation with age ($r\sim -0.37$). As a longitudinal analysis, we collected

similarity at 1 year and 2 year with respect to the baseline. We compared slopes of similarity decrease over time between groups expecting larger slopes in the MCI converters; however, it was insignificant. Our approach may provide a complementary view of disease progression in terms of cortical thickness. Further analyses are needed including investigation of shape manifolds.

Title: A new biomarker of pericyte injury and blood-brain barrier dysfunction

Authors: ***A. P. SAGARE**[1], M. D. SWEENEY[1], A. MONTAGNE[1], J. MAKSHANOFF[1], D. LAZIC[1], M. G. HARRINGTON[2], B. V. ZLOKOVIC[1];
[1]Dept. of Physiol. and Biophysics, USC, Los Angeles, CA; [2]Huntington Med. Res. Inst., Pasadena, CA

Abstract: Increasing evidence supports that neurovascular dysfunction contributes to several neurodegerative disorders. Our recent study shows that blood-brain barrier (BBB) disruption and increased permeability, especially in the hippocampus, positively correlates with elevated levels of soluble platelet-derived growth factor receptor-β (sPDGFRβ) in cerebrospinal fluid (CSF) in patients with mild dementia. PDGFRβ is expressed in the brain by vascular mural cells - brain capillary pericytes and arterial vascular smooth muscle cells (VSMCs). To determine which vascular cell type(s) contributes to increased sPDGFRβ in CSF, we compared PDGFRβ expression and sPDGFRβ shedding in response to injury in early passage primary cultures of

human brain pericytes, brain arterial VSMCs, and brain endothelial cells. We developed quantitative Western blot and meso-scale discovery (MSD) assays to analyze the levels of sPDGFRβ. PDGFRβ protein was undetectable in endothelial cells, but was found both in pericytes and VSMCs. PDGFRβ relative protein abundance was higher by 4.2-fold ($p < 0.05$) in pericytes compared to VSMCs. Compared to the basal sPDGFRβ levels in the culture medium (1.43 ± 0.15 ng/ml), both hypoxia (1% O_2) or amyloid-β peptide (25 μM) increased shedding of sPDGFRβ into the culture media compared to normoxia (21% O_2) over 48 h. This was associated with the corresponding loss of cell-associated PDGFRβ from pericytes without any change in cellular levels of PDGFRβ in VSMCs. We further validated sPDGFRβ as a CSF marker of pericyte injury *in vivo* in 16-month-old pericyte deficient *Pdgfrβ*$^{+/-}$ mice and Alzheimer's Tg2576 mice which develop significant age-dependent pericyte loss. We found significant 289% and 58% increase in CSF levels of sPDGFRβ in *Pdgfrβ*$^{+/-}$ and Tg2576 mice, respectively. Thus, sPDGFRβ is a biomarker of pericyte injury, and elevated sPDGFRβ levels in cerebrospinal fluid in patients with dementia and/or other neurodegenerative disorders likely reflects pericyte injury. These results together support the potential for sPDGFRβ to be developed and validated as a biomarker of brain pericyte injury and BBB dysfunction.

Title: Vascular risk factors, education and physical fitness are associated with differences in brain volumes

Authors: *C. PINTZKA[1], T. HANSEN[1], A. K. HÅBERG[1,2];
[1]St. Olavs Hosp., Trondheim, Norway; [2]Neurosci., Norwegian Univ. of Sci. and Technol., Trondheim, Norway

Abstract: Vascular risk factors are associated with brain atrophy and are recognized as important risk factors for developing dementia, including Alzheimer's disease (AD). Education and physical fitness have been shown to reduce dementia risk and have been associated with larger brain volumes. The aim of the present study was to investigate the effects of different factors on brain volumes in a large general population sample. We included participants from the HUNT MRI study (n=1006, age 50-66 years), which is a representative sample from the Nord-

Trøndelag Health Study (The HUNT Study), a large multiphase, health study on the inhabitants in the county of Nord-Trøndelag. All participants were scanned with the same 1.5T MRI scanner. A T1 weighted MPRAGE ADNI volume was used to estimate brain volumes (cortical, white matter, hippocampal and ventricular) using FreeSurfer 5.3. Intracranial volume (ICV) was derived using SPM. Each volume was first standardized and corrected for differences in sex, age and ICV using separate ANCOVAs. A multivariate regression analysis was run using the following factors from the HUNT clinical databank: education, physical fitness (VO2-max), smoking, blood pressure (SBP), waist-to-hip-ratio (WHR), non-fasting glucose, resting heart rate, alcohol consumption, presence of diabetes, and serum levels of total and HDL-cholesterol, and triglycerides. 87 subjects were excluded due to processing failure and 20 were due to brain pathologies. Clinical information were lacking in 196 subjects, leaving a total of 703 available for analysis. Using the brain parenchymal fraction (volume of gray and white matter divided by ICV) as a measure of brain health, education (p=.015), SBP (p=.007), smoking history (p=.029), VO2-max (p<.001) and WHR (p=.011) were found to be significant predictors. Education and VO2-max were positively associated with brain parenchymal fraction whereas SBP, smoking history and WHR were negatively associated. These five factors predicted 11.2% of the variance in total cortical volume, 2.4% of the variance in white matter volume, 4.0% of the variance in hippocampal volume, and 3.4% of the variance in total ventricular volume. Education (4.3%) and VO2-max (2.3%) were the most influential factors for total cortical volume. The variance in total hippocampal volume was best explained by WHR (1.3%), education (1.1%) and VO2-max (1.1%). Education and VO2-max have a significant positive effect primarily on gray matter volumes (cortical and subcortical). In our sample, these effects outweigh the negative effects of known vascular risk factors and might provide a cheap and non-pharmacological way to improve the overall brain health.

Title: Hippocampal and ventricular volumes of idiopathic normal-pressure hydrocephalus and the cerebrospinal fluid tap test

Authors: *K. KANG[1,2], J.-M. KIM[2], M.-G. LEE[3];
[1]Dept. of Neurol., Daegu, Korea, Republic of; [2]Dept. of Neurology, Kyungpook Natl. Univ. Sch.

of Med., Daegu, Korea, Republic of; [3]Dept. of Pharmacology, Kyungpook Natl. Univ. Sch. of Med., Daegu, Korea, Republic of

Abstract: We investigated differences in ventricular and hippocampal volumes between CSF tap test (CSFTT) responders and non-responders in idiopathic normal-pressure hydrocephalus (INPH) patients and compared these parameters in INPH patients with that of age- and gender-matched healthy controls. We also evaluated relationships between ventricular and hippocampal volumes and clinical profiles in INPH patients.
We enrolled 48 patients with INPH and 29 healthy controls. Ventricular and hippocampal volumes were measured on MRI, including 3-dimensional volumetric images.
INPH patients, when compared to healthy controls, had significantly larger ventricular and smaller hippocampal volumes ($p<0.01$). No difference in ventricular and hippocampal volumes was found between CSFTT responders and non-responders in INPH patients. And hippocampal volumes showed significant negative correlations with Clinical Dementia Rating Scale scores ($r=-0.443$, $p<0.01$) and Unified Parkinson's Disease Rating Scale motor scores ($r=-0.499$, $p<0.01$) in INPH patients.
Volumetric assessment of ventricular and hippocampal regions may have no predictive value in differentiating between CSFTT responders and non-responders in INPH patients. Our findings may help us understand the potential pathophysiology of unique symptoms associated with INPH.

Abstract: Two pathological hallmarks of Alzheimer's disease (AD) are Tau-containing neurofibrillary tangles and Aβ-containing neuritic plaques. Currently, a combination of measurements of the 42-residue of Aβ peptide (Aβ42), total Tau, and phosphorylated Tau (pTau) protein in human cerebrospinal fluid (CSF) is the best fluid predictor of AD progression and therapeutic efficacy. Due to the heterogeneity and multifactorial nature of AD, multiple biomarkers from peripheral and central nervous system need to be explored for their relevancy to disease onset, progression, and therapeutic prognosis. In this study, we have collected peripheral blood mononuclear cells (PBMC) and plasma from AD patients hospitalized in our Geriatric Research Education Clinical Center (GRECC)-managed hospice Dementia Special Care Unit. We have converted PBMC to induced pluripotent stem cell (iPSC) lines, and we have further differentiated iPSC into human three-dimensional (3D) neurons. At autopsy, postmortem brain tissue specimens from the same subjects were collected and processed for biochemical and Mass Spectrometry-based analysis. AD pathology was confirmed in patients from whom we derived blood, iPSC and 3D neurons. Quantitation of Aβ and Tau by ELISA illustrated much higher levels of Aβ40, Aβ42, and phosphorylated Tau at residues Thr 181 and Thr 231 in brain tissue from superior and inferior frontal cortex area, compared to those from cerebellum region. Liquid chromatography/mass spectrometry was used to analyze plasma, iPSC, 3D neurons and post-mortem brain tissue labelled with isobaric mass tags for relative protein quantification. Our study revealed compartmental segregation as well as association of differentially expressed proteins for biomarker exploration. Among them, several calcium binding proteins exhibited clear link to two AD pathological proteins, Aβ and Tau. We present a unique platform to discover and validate novel AD biomarkers that can be studied in a much large population.

Title: Relations between cognitive decline, regional specificity of brain atrophy and cerebrospinal fluid biomarkers in elderly patients with Alzheimer's disease

Authors: *Y. OIWA[1], T. KITAGAWA[1], I. NAKANISHI[1], H. TANAKA[1], M. ARITA[2]; [1]Wakayama Med. Univ., Katsuragi-Cho, Ito, Wakayama, Japan; [2]Wakayama Med. Univ. Sch. of Hlth. and Nursing Sci., Wakayama, Japan

Abstract: Background and Objective. Biochemical changes in the cerebrum are responsible for pathophysiological changes in Alzheimer's disease (AD). However, it is possible that cognitive decline in elderly AD patients is attributable to both AD-related and additional age-related changes. Contributing factors specific for cognitive decline and brain atrophy in elderly AD are still unclear. To distinguish AD-specific changes from normal aging in the elderly AD, we examined correlations between cognitive functions, MRI morphometry and cerebrospinal fluid (CSF) biomarkers. Study design and subjects. A total of 115 subjects, 64-84 years old: 76 with AD, 24 with mild cognitive impairment, and 15 cognitively normal elderly, were included in this cross-sectional study. Severity of atrophy in the target volume of interest registered in the medial temporal structures and the whole brain were measured by using MRI with voxel-based specific regional analysis system for AD (VSRAD) program. Fifty-seven of them underwent lumbar puncture to measure CSF amyloid-β1-42 (Aβ42), total tau protein (T-tau) and phosphorylated tau (P-tau).Results. Cognitive decline was correlated with aging, severity of atrophy in the entorhinal cortex, extent of gray matter atrophy in the whole brain, increase in CSF T-tau and P-tau, and decrease in CSF Aβ42. These changes in the CSF biomarkers showed good correlation with cognitive decline, but not with aging. Severity of the entorhinal cortical atrophy was correlated with increase in ratios of T-tau/ Aβ42 and P-tau/ Aβ42. In multivariate analyses, elevation of P-tau/ Aβ42 ratio carried independent prognostic significance for the severity of AD.Conclusion. This study suggests that atrophy of the entorhinal cortex associated with higher CSF P-tau and lower CSF Aβ42 is a pathogenetic mechanism for cognitive decline in elderly patients with AD.

Title: The Hippocampal Network Model - A neuroimaging approach for identifying dementia biomarkers in metabolic syndrome

Authors: *E. KOTKOWSKI, P. T. FOX;
Radiology, Univ. of Texas Hlth. Sci. Ctr. At San A, San Antonio, TX

Abstract: Metabolic syndrome or systemic metabolic dysfunction (SMD) is one of the most common disease states disproportionately afflicting the Hispanic population in the United States. Evidence suggests that effects of SMD and neurocognitive dysfunction are bidirectional and complex, with genetic, environmental, and behavioral causes (Biessels et al., 2014). It has been recently shown that the underlying pathology does not resemble that of AD (Abner et al., 2016). Studies using contrast-enhanced MRI show age-dependent blood-brain barrier (BBB) breakdown in the hippocampus, worsening with mild cognitive impairment and correlating with injuries to the BBB pericytes (Montagne et al., 2015). Rodent models have also implicated the hippocampus in cognitive deficits resulting from T2DM (Stranahan et al., 2008). Consequently, we propose to create a hippocampal network model (HNM), using meta-analytic co-activation modeling (MACM) and structural equation modeling (SEM), to detect and quantify network abnormalities associated with neurocognitive decline in SMD. Our immediate research goal is to create a functional MACM of the hippocampi in order to develop the HNM that can be used to assess cognitive impairments in individuals with SMD. Our preliminary data has found 20 key nodes of functional connectivity with both hippocampi all of which address highly significant behavioral paradigms known to be affected in individuals with dementia (i.e. working and explicit memory, cognition, etc.).

Title: MR imaging of blood perfusion at the nucleus basalis of Meynert in modulation of attention and visual processing

Authors: *A. WOJNA PELCZAR[1], N. SZABO[2], P. FARAGO[1,2], A. KIRALY[1,2], T. Z. KINCES[2,3], I. REKTOR[1,3], B. TOMANEK[1];
[1]CEITEC - Central European Inst. of Technol., Bohunice, Czech Republic; [2]Dept. of Neurol., Albert Szent-Györgyi Clin. Centre, Univ. of Szeged, Szeged, Hungary; [3]Intl. Clin. Res. Ctr., St. Anne′s Univ. Hosp., Brno, Czech Republic

Abstract: Intoduction: Many pathological brain conditions are associated with abnormal cerebral blood flow (CBF). As nucleus basalis of Meynert (NMB) plays a major role in modulation of attention and visual processing, the aim of the study was to image CBF before and after a visual task to find changes in blood perfusion at the NMB level. **Methods:** 20 healthy individuals (age: 22-35) were enrolled to the study. MR experiments were performed using a clinical 3T scanner (Prisma). Arterial spin labelling (ASL) sequence was applied before and after visual stimuli (random dot kinematogram). The 2D EPI sequence was used: TE/TR = 15/2500 ms, flip 90°, matrix 256 × 256, 4 slices, 3 mm thick. For CBF evaluation the pulsed ASL (PASL) with 700 ms bolus duration and 1800 ms inversion time was applied. A single PASL measurement consisted of 45 volumes of the tag and 45 controlled images, allowing calculation of a perfusion map. Data processing was performed using the Bayesian Inference for ASL toolset. **Results:** The data showed difference between CBF before and after visual stimuli (Fig 1). It is possible to measure activity dependent CBF in NMB in healthy individuals. Potentially, this method could be used to detect abnormalities in dementing disorders such as Alzheimer's Disease (AD) as it is suggested, that NMB plays a role in the pathomechanism of AD. Although ASL provides low signal-to-noise ratio, it requires no intravenous contrast, is available on most clinical MRI scanners and it is fast (~2 min). This makes ASL particularly appealing for diagnostic purposes. **Figure 1:** Examples of the ASL images at the NMB level before (a) and after (b) visual stimulation for one subject. The difference between images is shown in (c). Changes in CBF within the NBM are visible in (c).

Title: Quantitative neuroimaging and biomarkers in Alzheimer's disease and Lewy body spectrum diseases

Authors: *K. TRINGALE[1], P. OOMEN[2], J. BREWER[1,3];
[1]Sch. of Med., UC San Diego, San Diego, CA; [2]Vrije Univ. Amsterdam, Amsterdam, Netherlands; [3]Dept. of Neurosciences, Univ. of California at San Diego, San Diego, CA

Abstract: Dementia with Lewy bodies (DLB) is the second most common form of dementia after Alzheimer's disease (AD) and is characterized pathologically by alpha synuclein inclusions forming Lewy bodies. Dementia often presents when Lewy bodies reach the cortical and limbic areas of the brain as patients may experience cognitive decline, neuropsychiatric symptoms, and Parkinsonisms. Since DLB frequently occurs with concurrent AD-type pathology, characterized by neuritic plaques and neurofibrillary tangles, misdiagnoses are frequent. Patterns of cerebral atrophy in DLB have not been as well established as in AD. Accurate differentiation between the two types of dementia is important given the different etiologies, prognoses, and treatments. This work seeks to identify patterns of atrophy in patients with DLB compared to AD and cognitively normal controls (NC) to ultimately combine MRI with early structural biomarkers to improve diagnostic accuracy and early treatment. 101 patients aged 55 to 100 years old characterized as either NC, DLB, or AD underwent structural MRI scans with fully automated volumetric segmentation performed with the NeuroQuant software package. A subset of qualified patients also had CSF sample acquisition, analysis of B-amyloid 1-42 levels and APOE4 status, and brain autopsy. Analysis was completed via SPSS Statistics with gender, age, level of education, and intracranial volume as covariates. Groups did not significantly differ in age but did significantly differ in gender, level of education, MMSE score (29.2±1.0 for NC, 21.6±3.6 for DLB, 21.7±4.6 for AD), and level of AB42 (350.3±107.5 for NC, 437.7±50.3 for DLB, 174.2±70.7 for AD). Brain parenchymal fraction (BPF) indicated whole brain atrophy, which was most severe for AD (0.58) and intermediate for DLB (0.61), both which were significantly atrophied compared to NC (0.64). Regionally-specific volumetric imaging showed significant differences in NC and DLB, particularly the volumes of the hippocampus, amygdala, medial temporal cortex, fusiform cortex, parahippocampal gyrus, lateral ventricles, and total ventricles. Significantly different between NC and AD were the volumes of the hippocampus, amygdala, thalamus, entorhinal cortex, medial temporal cortex, fusiform cortex, inferior parietal cortex, inferior temporal cortex,

parahippocampal gyrus and the lateral ventricle and total ventricle. Significantly different between DLB and AD were the volumes of the amygdala, entorhinal cortex, medial temporal cortex, fusiform cortex, inferior parietal cortex, inferior temporal cortex. All mentioned brain regions were more severely affected in AD compared to DLB.

Disorders, Shizuoka, Japan; [4]Dept. of Biofunctional Imaging, Preeminent Med. Photonics Educ. & Res. Center, Hamamatsu Univ. Sch. of Med., Hamamatsu, Japan; [5]Central Res. Lab., Hamamatsu Photonics K.K., Hamakita, Japan

Abstract: Introduction Alzheimer disease (AD) is characterized by the deposits of amyloid-beta plaques and neurofibrillary tangles consisting of pathological tau. Several studies implicated pathological tau in mechanisms of neurodegeneration. Although it has been reported that the presence of amyloid-beta activates microglia, it remains unclear whether tau deposition and microglial activation are associated with each other. [^{11}C]PBB3 has been recently developed as a tau imaging positron emission tomography (PET) ligand. Here, we examined the degree and the relevance of these pathological markers by measuring the densities of tau and activated microglia in AD patients at an early stage using positron emission tomography (PET) with [^{11}C]PBB3 a newly-developed tracer of tau deposition and [^{11}C]DPA713 a second generation translocator protein (TSPO) tracer for activated microglia. **Methods** Seventeen AD patients (mean age 69.9±9.6) at the clinical dementia rating (CDR) being 0.5 or 1 underwent [^{11}C]PBB and [^{11}C]DPA PET measurements. The binding potential (BP_{ND}) was estimated on the simplified reference tissue model (SRTM) using PMOD 3.4 software. Statistical Parametric Mapping

(SPM) and region of interest (ROI) analysis were used to compare regional BP_{ND} levels between the AD and age matched control groups. **Results** Significant elevations of [^{11}C]PBB3 BP_{ND} were found focally in the temporal cortex in AD patients at the CDR0.5 level and broadly over the temporal, frontal, and occipital cortices in the patients with CDR1. TSPO imaging showed a significant increase of [^{11}C]-DPA713 BP_{ND} over the extensive brain regions especially in the temporal, frontal and occipital regions, which were found to be significantly overlapped to the region with tau deposition. **Discussion** The present in vivo findings were consistent with the pathological view of the spreading of tau pathology with AD progression. These results suggest that microglial activation seems to coexist with the progression of tau deposition, and that these two pathophysiological events contribute to the continuum of neuronal degeneration in AD.

Title: Estimation of age of onset in presymptomatic frontotemporal degeneration

Authors: *P. VADDI, E. MCCARTY WOOD, V. VAN DEERLIN, D. IRWIN, M. GROSSMAN, C. MCMILLAN;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Roughly 20% of frontotemporal degeneration (FTD) patients have a known genetic mutation with high penetrance. Presymptomatic mutation carriers are optimal candidates for neuroprotective clinical trials of disease-modifying agents. One challenge for trials is estimating when an individual is likely to become symptomatic. The current literature suggests that correlations between an individual's age of onset and their family members' age of onsets may help with this issue; however, the predictive accuracy of these studies have not been assessed. In this study, we investigate the predictive utility of the family's mean onset in *progranulin (GRN)* mutation carriers, an autosomal dominant mutation with very high penetrance (>95%) that results in FTD. Analyses were conducted on 25 pedigrees comprised of a total of 65 individuals. Among these, 32 have confirmed *GRN* mutations while 33 cases have clinical diagnoses compatible with an FTD phenotype (e.g., behavioral-variant or primary progressive aphasia) or related early-onset disorder. The latter 33 cases are also assumed to have GRN mutations because they are affected family members of the 32 cases confirmed to have GRN mutations. An

average of 3.79 individuals and an average of 2.49 generations are reported per family pedigree. Linear regression analyses reveal an association between an individual's onset and the family's mean onset (β=1.2015, $p<0.05$). However, a leave-one out cross-validation model suggests an individual's predicted onset was not associated with the family's mean onset (p=0.16). Together, these findings suggest that while individual and family onsets are correlated with one another, the predictive value of these associations should be interpreted cautiously. Future cross-validation studies are necessary in larger cohorts and other FTD mutations (*MAPT*, *C9orf72*) to evaluate the validity of age of onset estimates in presymptomatic FTD.

Title: Disease-specific relationship between longitudinal neuroimaging and cerebrospinal fluid

Authors: *C. A. JESTER, III[1], K. FIRN[1], K. TERNES[1], L. M. SHAW[2], D. IRWIN[1], D. WEINTRAUB[3], M. GROSSMAN[1], C. T. MCMILLAN[1];
[1]Neurol., [2]Ctr. for Neurodegenerative Dis. Res., Univerisity of Pennsylvania, Philadelphia, PA; [3]Psychiatry, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Progressive supranuclear palsy (PSP) and Parkinson disease (PD) are both characterized by parkinsonism. However, PSP is associated with elevated cerebrospinal fluid

(CSF) phosphorylated tau (ptau) and tau pathology while PD has alpha-synuclein (asyn) pathology. Neuropathological studies suggest that tau inclusions are abundant in white matter (WM), while asyn inclusions are relatively restricted to grey matter (GM) in PD. Thus multimodal neuroimaging provides a potential marker of pathology-specific longitudinal change. Here we investigate whether CSF markers of tau phosphorylated in the threonine 181 position (ptau) and total tau (ttau) can differentiate neuroimaging change in PSP (N=15) and PD (N=15). All patients had a baseline and follow-up T1 MRI of GM and DTI of WM a minimum of 6 months apart (mean difference=1.05 years ±0.45) and a lumbar puncture within 9 months (±14.6) of baseline scan. We used Advanced Normalization Tools (ANTs) to evaluate annualized GM atrophy in 112 cortical and subcortical ROIs and annualized WM change with fractional anisotropy (FA), in 48 WM ROIs. CSF was analyzed using ADNI standard operating procedures. Regression related baseline ptau and ttau to annualized change in PSP and PD (all $p<0.01$). Reduced ptau was uniquely associated with PSP WM change in cerebellar peduncle, bilateral cerebral peduncle, and fornix. Increased ttau, which is more broadly related to neuronal degeneration, was uniquely associated with PD GM atrophy in right pallidum, putamen, frontal pole, planum temporale and left thalamus. Thus, we report a double dissociation for baseline CSF and longitudinal neuroanatomic change, with WM decline in PSP related to ptau and GM decline in PD related to ttau. CSF may be a useful prognostic marker to stratify patients in protein-specific disease-modifying treatment trials.

Title: Using event related potentials to investigate aging and Alzheimer's disease in adults with Down's Syndrome

Authors: *S. JENNINGS[1], S. CHENNU[2], T. BEKINSCHTEIN[3], V. NOREIKA[4], A. HOLLANAD[1], H. RING[1];
[1]Dept. of Psychiatry, [2]Dept. of Clin. Neurosciences, [3]Dept. of Psychology, Univ. of Cambridge, Cambridge, United Kingdom; [4]Med. Res. Council Cognition and Brain Sci. Unit, Cambridge, United Kingdom

Abstract: Down's Syndrome (DS) is a genetic disorder attributed to the triplication of chromosome 21, and is associated with premature aging and an increased risk of developing Alzheimer's disease (AD). AD typically presents with memory decline however some of the earliest clinical indicators of AD in DS are compromised frontal lobe functions, such as inhibitory control. This research project aims to test the potential value of event related potentials (ERPs), for identifying age-related changes to cognitive functions underpinned by the frontal lobes. ERPs are averaged responses generated from electroencephalographic (EEG) recordings of bio-electrical activity generated by cortical neurons. The method is non-invasive and inexpensive so could present a viable, widespread screening tool. The ERPs investigated in this project are MMN and P3a, which are maximal over fronto-central sites and thus reflect activity in a brain region of interest for DS-AD; and P3b which has been repeatedly suggested in the literature to be perturbed in AD. In this study, the 36 participants with DS had significantly smaller MMN and P3b waveforms than the 39 age- and gender- matched controls. However, participants with DS had significantly larger P3a waveforms. The ERPs will be correlated with age and cognitive decline measures, with a view to identifying potential markers of AD. There is great interest in developing markers for preclinical stages of AD, so that therapeutic interventions, when they become available, can be administered when there is still functionality to be preserved rather than the more challenging task of restoring lost functions.

Title: Developing neuroimaging biomarkers for classification of Alzheimer's disease: A correlative study between brain network centrality, cognitive functions and biochemical measurements in clinical settings

Authors: *C.-P. LIN[1], S.-Y. LIN[1], T.-J. HSIEH[2], C.-C. HSU[2], L.-W. KUO[1];

Abstract: Patients suffering from Alzheimer's disease (AD) are often diagnosed after progressively altered behavior or life style, which are difficult to distinguish from the symptoms of mild cognitive impairment (MCI). The lack of early diagnosis and prognostic markers may delay patients from seeking medical care. This study aimed to characterize the brain network topology and develop neuroimaging biomarkers by employing graphical network analysis on functional MRI connectivity data. Additionally, a correlative study between neuroimaging biomarkers, cognitive functions and biochemical measurements was performed. A total of 47 subjects, including 13 AD patients, 13 MCI patients and 21 healthy controls (HC) were recruited in this study. MR protocols included resting-state functional MRI (rs-fMRI) and anatomical T1 scans. The cognitive function was assessed by mini-mental state examination (MMSE) and the biochemical measurements included albumin (ALB) and blood urea nitrogen (BUN). Region-wise group comparisons were performed using one-way ANOVA and 2-sample t-test. The correlation analysis was also performed on network centrality measures, MMSE scores and biochemical measures. Multiple comparisons were corrected with false discovery rate controlling procedure. Our preliminary results show significant differences of network centrality in left anterior cingulate, paracingulate gyri and heschl gyrus among three groups. Compared with HC group, the nodal centrality of those regions is decreased in AD group. Specifically, the nodal centrality in left anterior cingulate is positively correlated with MMSE score. The biochemical measurements, ALB and BUN, are generally correlated with network centrality. Our findings suggest that the network centrality in specific cortical regions may potentially reflect the altered cognitive functions or biochemical measures in AD patients. By increasing the subject numbers, a classification model based on brain network centrality could be established by utilizing novel machine learning algorithm and may improve the diagnostic power to identify AD in future clinical routine.

Title: *In vivo* assessment of synaptic properties in rTg4510 tauopathy transgenic mouse model by positron emission tomography

Authors: *M. SHIMOJO, M. TOKUNAGA, T. MINAMIHISAMATSU, S. UCHIDA, H. TAKUWA, Y. TAKADO, I. MATSUMOTO, M.-R. ZHANG, T. SUHARA, M. HIGUCHI, N. SAHARA;

Abstract: Progressive synaptic degeneration with intracellular tau protein inclusion represented as neurofibrillary tangles (NFTs) and neuronal loss is a common feature of tauopathy including Alzheimer's disease (AD). Cumulative evidence has indicated that synaptic loss is well correlated with cognitive decline and memory impairment of AD patients. In fact, synaptic dysfunction and disrupted neuronal activity caused by toxic tau aggregates have been hypothesized as a central component of disease-related abnormalities in animal models. It is therefore crucial to assess in vivo alteration of synaptic properties in living subject for understanding complicated pathophysiological cascade. Especially, establishment of biomarkers and/or methodologies which are non-invasively applicable to clinical diagnosis is greatly appreciated. [^{11}C]ABP688, a highly selective radioactive ligand binding to allosteric site of the metabotropic glutamate receptor subtype 5 (mGluR5), is a useful probe to monitor glutamatergic excitatory synaptic status by positron emission tomography (PET) imaging. In the present study, we investigated age-dependent change of [^{11}C]ABP688 PET image using rTg4510 tauopathy mouse model which typically develops NFTs and forebrain atrophy by 6 months of age. Intravenous bolus administration of [^{11}C]ABP688 followed by PET scan demonstrated that region specific and age dependent decline of [^{11}C]ABP688 binding potential (BPnd) in rTg4510 mouse model. [^{11}C]ABP688 BPnd began to reduce in striatum at 2-3 month of age before obvious pathological findings. Subsequently, more drastic reduction was observed in broader regions of forebrain including both cortex and hippocampus at 5-6 months of age. Interestingly, reduction level of [^{11}C]ABP688 BPnd reached to plateau range by 5-6 months of age, though MRI volumetric analysis revealed progressive atrophy in forebrain until 8-9 months of age. Our findings suggest that [^{11}C]ABP688 PET imaging is a potent biomarker to assess excitatory synaptic abnormality in animal model, and further investigation in combination with pharmacology will potentially dissect more complicated synaptic status during neurodegenerative process.

Title: Components and neural correlates of apathy and impulsivity in frontotemporal lobar degeneration syndromes.

Authors: *C. LANSDALL[1], I. COYLE-GILCHRIST[1], P. VÁZQUEZ RODRÍGUEZ[1], E. WEHMANN[2], A. WILCOX[1], K. DICK[3], P. JONES[1], K. PATTERSON[1], J. ROWE[1]; [1]Univ. of Cambridge, Cambridge, United Kingdom; [2]Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg-Eppendorf, Germany; [3]Univ. Col. London, London, United Kingdom

Abstract: Apathy and impulsivity are common and disabling consequences of frontotemporal lobar degeneration (FTLD) associated disorders. They are recognized as multifaceted constructs that often coexist, although their neural mechanisms are unclear. Treating apathy and impulsivity will become increasingly important as disease modifying treatments are developed to slow progression. We aimed to determine the link between apathy and impulsivity and identify their underlying dimensions and neural correlates in FTLD. The PiPPIN study recruited 204 patients and 50 controls. The assessment battery combined patient, carer and physician questionnaires and behavioural tasks. We derived dimensions of apathy and impulsivity using principal component analysis (PCA) on a subset of 199 patients and controls. Voxel based morphometry (VBM) analysis of T1-weighted MRI images was conducted on a subset of 100 FTLD patients and controls to identify the neural correlates of the extracted components. Eight principal components were identified, separating patient-rated questionnaires, carer-rated questionnaires and behavioural tasks. Apathy and impulsivity measures frequently loaded onto the same components, suggesting they overlap in their underlying mechanisms. Behavioural tasks and questionnaires correlated poorly, with direct implications for translational studies. Furthermore, carer and patient ratings loaded onto separate components and revealed distinct neural correlates, highlighting differences in recognition of behavioural change. VBM found corticospinal tract changes in proportion to the patient rated apathy/impulsivity component, likely reflecting preserved patient awareness of disease-related motor deficits, while insight into cognitive decline is limited. In contrast, carer ratings were associated with changes in frontostriatal circuits and brain stem systems. We propose that these associations reflect underlying changes in social, affective and motivational functions. This dimensional approach provides new insights into the neural basis of apathy and impulsivity in FTLD. Our data indicate common overlapping components related to corticospinal, thalamic and frontostriatal systems, which are differentially

sensitive to objective tests, patient and carer ratings. We propose that evaluating dimensions observed across neurodegenerative disorders may identify novel treatment targets, synergistic with the National Institute of Mental Health's Research Domain Criteria ('RDoC') approach to psychiatric symptomatology. Therapies will offer a broader impact if they are relevant for several different diagnoses.

Title: Local atrophy of entorhinal and trans-entorhinal cortex in mild cognitive impairment measured via diffeomorphometry

Authors: D. J. TWARD[1], C. C. SICAT[8], T. BROWN[8], E. A. MILLER[8], *J. T. RATNANATHER[2], L. YOUNES[3], A. BAKKER[4], M. ALBERT[5], M. GALLAGHER[6], S. MORI[7], M. I. MILLER[1];
[1]Biomed. Engin., [3]Applied Math and Statistics, [4]Psychiatry and Behavioral Sci., [5]Dept. of Neurol., [6]Psychology and Neurosci., [7]Radiology, [2]Johns Hopkins Univ., Baltimore, MD; [8]Ctr. for Imaging Sci., Baltimore, MD

Abstract: Objective:
The entorhinal cortex (EC) is the site of the earliest pathological changes in Alzheimer's disease (AD). This study aimed to quantify the spatial distribution of tissue loss over time in the EC and

the immediately lateral trans-EC (TEC) in participants with mild cognitive impairment.
Methods:
Structural MRI scans from 40 subjects who completed at least 3 scans over 2 years and have a continuous left collateral sulcus were selected from the AD Neuroimaging Initiative database. For these subjects the EC and TEC were manually segmented on T1 structural scans.
After rigid alignment a template triangulated surface was estimated characterizing the population average of the structure. The template was then mapped to each scan in the time-series, minimizing a sum of square error between segmentations, using two geodesic trajectories through diffeomorphism space: 1) template to baseline, and 2) baseline to follow ups. Mapping to each segmentation in the time-series simultaneously reduces within subject variability due to inconsistencies in anatomical definitions.
Local measures of tissue loss were chosen based on the Jacobian of each mapping including a determinant for volume, a determinant of the 2x2 Jacobian tangent to the template for surface area, and a 1x1 Jacobian normal to the template for thickness. Their logarithm was fitted by least squares to a linear model at each template vertex, with a subject specific mean and a population average atrophy rate.
Results:
Participants were 50% female, with a mean age of 71.1 and a mean education of 16.8 years. Results are summarized in the figure showing the estimated population average atrophy rate in an inferior view expressed as percent per year for volume (left), surface area (center), and thickness (right).
Conclusions:
The pattern of tissue loss detected is consistent with early stage pathology identified in autopsied brains by Braak and Braak, with most loss in the sulcal EC. More tissue loss is seen laterally (TEC) than medially (EC proper), suggesting that this region may be a neuroimaging biomarker sensitive to early changes in AD.

Title: Relationship between performance on a famous faces test and AD biomarkers in a group of normal older adults

Authors: ***R. K. BELL**, T. J. MELLINGER, K. N. SWINNERTON, W. J. JAGUST;
Univ. of California, Berkeley, Berkeley, CA

Abstract: Difficulty recalling names is a frustrating phenomenon that becomes more common as we age (Cohen & Faulkner, 1986; Finley & Sharp, 1989). This study aimed to examine the relationship between the Northwestern University Famous Faces test (NUFFACE), standard neuropsychological tests, and Alzheimer's Disease biomarkers in a group of healthy older adults. Forty cognitively normal adults (mean age 77.3 ±6.4, MMSE 28.3 ±1.5, years of education 16.2 ±2.8) participated in a neuropsychological testing session. Twenty-one also had a 1.5T structural MRI, PIB PET scan, and APOE4 genotyping. NUFFACE scores included the percent of faces the participant could name within 5 seconds (ID score) and the percent they correctly recognized (REC score). Partial correlations controlling for age, years of education, and sex assessed the relationship between NUFFACE scores, standard neuropsychological test scores, and hippocampal volume. A voxel-based morphometry analyses was performed with SPM8 using the same covariates. PIB and APOE4 status were explored as grouping variables. The ID score (r=.47, p=0.003) and REC score (r=.46, p=0.003) were significantly correlated with the California Verbal Learning Test and ID score had a trend to correlation with Category Fluency (r = .39 p = .07). Increasing age was significantly associated with lower ID and REC score (r = -.33

p = .04). PIB status (positive/negative), APOE4 carrier status, and hippocampal volume were not significant predictors of NUFFACE scores. The VBM analyses (p = .01 k = 250) revealed the left superior frontal gyrus, bilateral (left predominant) inferior precentral gyrus, and right superior parietal lobe as regions positively correlated with ID and REC score. Although face naming scores decline with age in cognitively normal adults, they are unrelated to typical AD biomarkers. The pattern in the VBM analysis suggests the association between diminished face-naming ability with age could be a reflection of age-related grey matter loss in frontal and parietal regions (Kalpouzos et al., 2007; Giussani et al. 2009) and not a pathological process. Longitudinal data will help determine if the rate of change in test performance is more likely to be associated with pathological decline.

Title: *In vivo* wide-field imaging and quantitative analysis reveals decrease of perivascular drainage in Alzheimer's disease

Authors: *S. KIM[1], P. LEE[2], J. KIM[2], Y. JEONG[1,2];
[1]Brain and Cognitive Engin. program, [2]Dept. of Bio and Brain engineering, Korea Advanced Inst. of Sci. and Technol., Daejeon, Korea, Republic of

Abstract: Alzheimer’s disease (AD) is the most common type of dementia and the hall marker of disease is the excessive accumulation of amyloid beta plaque and hyperphosphorylated tau protein. Recently researchers have doubted that excessive amyloid plaque could be a result of an imbalance between production and clearance, not just overproduction of amyloid beta. Growing evidences also support that only the clearance rate of an amyloid beta was impaired in the sporadic form of AD. Although the interest about brain clearance system is increased, the clearance happening within the cortex is not fully understood. Perivascular drainage (PVD) is one of the clearance mechanisms in the cortex referring drainage of solutes along the basement membrane of capillaries and arterial walls into subarachnoid space. Small molecules such as amyloid beta are cleared through this pathway while the contribution of PVD on AD is not well investigated.
In this study, we hypothesized that small molecules movement in the cortex is mainly dependent

both on PVD and diffusion. The PVD would give additional force macromolecules to move further toward vessels having the driving power. Unlike diffusion, this power induces unbalanced movement and distribution of small molecules in the cortex. We used *in vivo* two-photon microscopy and wide-field CCD camera to observe the PVD through fluorescent tagged dextran injected into brain parenchyma, and quantify asymmetry movement and decay rate of this substance in the brain. To assess the amount of the PVD, centering on the injection site, the analyzed area was divided into artery or vein-dominant, and the difference between those areas was used as the indices, the uniformity index (UI) and delta area above curve (ΔAAC). Injected FITC-dextran moves more and faster into artery-dominant area. The UI index illustrating the amount of unbalanced fluorescent distribution was higher than simple diffusion. The ΔAAC index that describes the difference of clearance rate between those area types was statistically different from diffusion. In aged and AD mice, the UI index were relatively steady and the ΔAAC was significantly decreased compared with normal mouse. These results demonstrates that the PVD is impaired in AD and suggest this decreased drainage causes the accumulation of amyloid beta around arteries like cerebral amyloid angiopathy. In addition, we can examine the possibility of these indices as the biomarker of brain clearance functioning.

Title: Characterization of the tau radioligand [^{3}H]THK-5351 binding in Alzheimer brain tissue

Authors: C. WINTMOLDERS, A. BOTTELBERGS, J. MARÏEN, D. MOECHARS, *X. LANGLOIS;
Janssen Res. and Develop., Beerse, Belgium

Abstract: Abnormal tau aggregation and beta-amyloid plaque deposition are essential pathological hallmarks of Alzheimer’s disease (AD). Whereas initial drug discovery efforts have focused on the beta-amyloid cascade, targeting tau is now a predominant strategy for halting AD progression since it has been shown that the density of aggregated tau correlates more closely with neuronal dysfunction and cell death, unlike beta-amyloid. Recent efforts to develop PET radioligands binding selectively to aggregated tau have allowed the visualization of tau aggregates *in vivo*. Several Tau PET ligands, including [^{18}F]AV1451(T807), [^{11}C]PBB3 and [^{18}F]THK5351, are currently evaluated in AD patients. Not only will these radioligands help to

determine the pathophysiology of tau aggregation in AD but they will also allow monitoring the therapeutic effect of new treatments in development. Therefore, characterizing the tau selectivity of these radioligands is of prime importance. The present study was initiated to look at tau selectivity of THK5351 in AD brain tissue. In competition binding experiments using the tau radioligand [^{3}H]T808 in paired helical filament (PHF) extracts from AD brain and the beta-amyloid radioligand [^{3}H]AV-45 in human beta-amyloid extracts, THK5351 was showing a moderate predicted affinity (Ki=182 nM) for PHF tau and a poor selectivity versus beta-amyloid (Ki = 348 nM). Tested in parallel, T807 displayed a much higher affinity for PHF tau (Ki = 1 nM) and selectivity versus beta-amyloid (Ki = 246 nM). When testing [^{3}H]THK5351 directly in beta- amyloid extracts, its Kd derived from saturation experiments was equal to 443 nM. When tested on PHF tau, [^{3}H]THK5351 bound to a similar site as [^{3}H]T808 (Kd = 7 nM) but with a lower affinity (Kd = 600 nM) and also to another site. In autoradiography experiments, [^{3}H]THK5351(10 and 30 nM) was compared to [^{3}H]AV-45 (3 nM) and [^{3}H]T808 (10 nM) on AD brain sections. For comparison, immunohistochemistry with the anti-tau antibody AT8 and the anti-amyloid antibody 4G8 was performed on adjacent sections. Whereas [^{3}H]T808 showed a typical tau laminar pattern and [^{3}H]AV-45 a typical amyloid granular pattern, [^{3}H]THK5351 displayed a combination of both. When a high concentration of cold T807 was co-incubated with [^{3}H]THK5351, only the granular pattern remained. Moreover, cold THK5351 could fully inhibit [^{3}H]AV-45 binding whereas cold T807 was ineffective. Altogether, our data indicate that TH5351 binds to both tau and beta-amyloid in the AD brain tissue available to us. These results should be taken in consideration when interpreting recently available human PET data with [^{18}F]THK5351.

Title: Electroencephalogram-based functional connectivity changes in patients with prion diseases

Authors: *E. FRANKO[1], O. JOLY[2], T. WEHNER[3], S. MEAD[4];
[1]Nuffield Dept. of Clin. Neurosciences, Univ. of Oxford, Oxford, United Kingdom; [2]MRC Cognition and Brain Sci. Unit,, Cambridge, United Kingdom; [3]Natl. Hosp. for Neurol. and Neurosurg., London, United Kingdom; [4]NHS Natl. Prion Clinic, Natl. Hosp. for Neurol. and Neurosurgery, UCL, London, United Kingdom

Abstract: Prion diseases are universally fatal and often rapidly progressive neurodegenerative diseases. Electroencephalography (EEG) has long been used in the diagnosis of sporadic Creutzfeldt-Jakob disease, however, not much is known about the changes in connectivity. Here, we characterise the EEG-based connectivity in different types of human prion disease.
In the National Prion Monitoring Cohort study we recorded encephalography on 301 occasions in 29 healthy controls and 67 patients with prion disease. The patients had either inherited prion disease or sporadic Creutzfeldt-Jakob disease. In the sensor space, we computed the de-biased squared weighted Phase Lag Index (Vinck et al., 2011) as a measure of connectivity in three frequency bands (theta, alpha, beta) for patients with asymptomatic, symptomatic inherited prion disease, sporadic Creutzfeldt-Jakob disease and for healthy controls.
We found reduced connectivity in the alpha and beta bands in symptomatic patients compared to healthy controls. In contrast, in the theta band the connectivity was stronger in the symptomatic patient group than in controls (Figure 1). Moreover, similar differences were found between patients with asymptomatic and symptomatic inherited prion disease.
To the best of our knowledge, this is the first study that reports changes in EEG-based connectivity in different types of prion diseases. Our results suggest that this quantitative EEG-based functional connectivity separates the symptomatic patients from controls and from asymptomatic PRNP gene mutation carrier.

Title: Inhibitory control in alzheimer's disease, mild cognitive impairment and healthy aging: an fmri study

Authors: *A. C. LUEDKE[1], J. FERNANDEZ-RUIZ[2], A. GARCIA[1], D. P. MUNOZ[1];
[1]Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada; [2]Physiol., Natl. Autonomous Univ. of Mexico, Mexico City, Mexico

Abstract: Alzheimer's disease (AD) and amnestic mild cognitive impairment (aMCI) are associated with cognitive changes including response inhibition; a capacity commonly measured using the Stroop task. Although compensatory increases in neural activity during the Stroop task have been reported across aging, it is still uncertain whether AD and aMCI lead to a further increase in activity changes. The goal of this work is to elucidate the neural correlates of inhibitory control, as measured by Stroop interference, using fMRI, in AD, aMCI, and healthy older adults. 16 mild AD participants (mean age 74.6 ± 7.6, 8 female), 16 age-matched controls (mean age 74.5 ± 7.6, 8 female), and 12 participants with aMCI (mean age 64.4 ± 9.3, 6 female) completed a rapid event-related version of the Stroop task. We contrasted incongruent minus congruent conditions at stimulus onset to investigate neural activity related to Stroop interference within each group, i.e. conflict between stimulus word and colour (e.g. green written in yellow). Verbal responses were recorded, and Stroop interference (incongruent reaction time - congruent reaction time), and number of errors were calculated. There were significant group differences on Stroop interference and number of incongruent errors. The AD group had a significantly greater Stroop effect, and made more incongruent errors, compared to the aMCI and control groups. The imaging analyses showed that controls had more activity in brain areas relating to the incongruent condition (during inhibition) compared to AD, including the inferior frontal gyrus, precuneus, anterior cingulate, and dorsolateral prefrontal (DLPF), and orbitofrontal cortices. aMCI participants showed similar activity to the control group, with the exception of less activity in the DLPF and orbitofrontal cortices. In conclusion, when compared to healthy older adults the AD group showed hypoactivations in brain areas involved in inhibitory control, suggesting the ability to compensate when faced with interference is altered in AD. This is in line with the behavioural data, which revealed a significantly greater Stroop interference and more errors in AD. Despite having similar behavioural performance on the Stroop task as controls, the aMCI group showed neural changes related to inhibitory control, less activity in the DLPF and orbitofrontal cortices, which may suggest early changes not yet detectable behaviourally in the Stroop task.

Title: Longitudinal alteration of intrinsic neural activity in the striatum in mild cognitive impairment

Authors: *P. REN[1], R. LO[3], B. CHAPMAN[1], M. MAPSTONE[4], A. PORSTEINSSON, 14623[2], F. LIN[1];
[1]Univ. of Rochester, Rochester, NY; [2]Univ. of Rochester, ROCHESTER, NY; [3]Tzu Chi Univ., Hualien, China; [4]Univ. of California-Irvine, Irvine, CA

Abstract: Objective: To identify neural targets for early detection and prevention of Alzheimer's disease (AD) associated neurodegeneration, the current study investigated the longitudinal change of the striatum, and the relationship between striatal dysfunction and AD pathology in mild cognitive impairment (MCI). **Methods:** Two-year longitudinal resting-state fMRI data from 15 healthy control (HC) and 20 MCI participants in the Alzheimer's Disease Neuroimaging Initiative (ADNI) database were obtained. We analyzed the amplitude of low-frequency fluctuations (ALFF) (0.01-0.08 Hz) and further decomposed two frequency bands (slow-4: 0.027-0.073 Hz; and slow-5: 0.01-0.027 Hz) in the caudate and putamen, two main components of the striatum. Measures of cerebrospinal fluid pTau and beta-amyloid$_{1-42}$ from baseline were used to calculate Aβ/pTau ratio. **Results:** Compared to the HC group, the MCI group showed significantly greater decline in putaminal ALFF, including the slow-4 band. Controlling for age and group (MCI vs. HC), lower baseline Aβ/pTau ratio was significantly associated with greater decline of ALFF in the right putamen in the overall sample. The slow-4 band, relative to slow-5 band, showed a stronger correlation between Aβ/pTau ratio and decline of ALFF in the right putamen. **Conclusions:** The function of the putamen declines early in the AD-associated neurodegenerative process. The abnormality of ALFF in the putamen, particularly the slow-4 frequency band, may be a sensitive measure of evolving AD pathology regardless of the current clinical MCI diagnosis.

Title: Structural MRI shows accelerated reduction in gray matter density and white matter integrity in asymptomatic progranulin mutation carriers

Authors: *C. A. OLM[1], C. T. MCMILLAN[1], D. J. IRWIN[2], V. VAN DEERLIN[3], P. A. COOK[4], J. C. GEE[4], M. GROSSMAN[1];
[1]Dept. of Neurol., [2]Dept. of Neurology, Dept. of Pathology and Lab. Med., [3]Dept. of Pathology and Lab. Med., [4]Dept. of Radiology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Objective: Mutations in the progranulin (*GRN*) gene are associated with frontotemporal degeneration (FTD) spectrum disorders due to TDP-43 inclusions. Potential treatments are likely to halt or slow disease progression, but not reverse degeneration. Therefore, it is essential to identify biomarkers preferably before the onset of symptoms, if possible. We use longitudinal structural and diffusion MRI to identify regions displaying early degeneration in asymptomatic *GRN* mutation carriers (aGRN+), relative to family members who are non-carriers (aGRN-). Methods: Cognitively normal relatives of clinically diagnosed GRN+ FTD patients were identified as either aGRN+ (N=11, mean age=46.5) or aGRN- (N=6, mean age=39.7). For inclusion in this study, each participant completed two MRI sessions (mean intervals: aGRN+=3.2 years, aGRN-=4.0 years) with T1-weighted and diffusion tensor imaging (DTI) sequences. Voxel-wise difference images were created for each participant by subtracting the follow-up cortical gray matter probability (GMP) image from the baseline GMP image. Similarly, difference images were created using radial diffusivity (RD) to examine white matter (WM). We expect small differences to represent normal aging related changes in both groups, with larger values representing degeneration in the aGRN+ participants. We performed voxel-wise whole-brain comparisons of the difference images to identify regions of greater change in

aGRN+ participants relative to aGRN- participants ($p<0.05$, cluster extent>600mm^3). Finally, we used DTI tractography to find WM tracts connected to any affected GM region. Results: aGRN+ participants had greater decrease in GMP than aGRN- in left inferior temporal and supramarginal cortices. In white matter, aGRN+ participants had greater increase in RD in bilateral superior longitudinal fasciculi (SLF) and corona radiata. These results indicate accelerated declines in both GM density and white matter integrity in aGRN+ participants. The WM tracts connected to the identified GM regions overlapped the clusters of worsening WM in the left SLF. Conclusions: Longitudinal MRI provides evidence of accelerated GM and WM structural changes in aGRN+ participants relative to aGRN- family members. The affected regions have previously been shown to exhibit disease in clinically diagnosed GRN+ FTD patients. Thus, a potential biomarker for treatment trials may be structural changes in these regions in aGRN+ participants.

Title: The olfactory system and its relevance for behavioral screening and diagnostic imaging in neurological disorders.

Authors: *A. VAN DER JEUGD[1], D. SHAH[2], I. BLOEMEN[1], L. VAN DEN BROECK[1], P. HANSQUINE[1], A. VAN DER LINDEN[2], R. D'HOOGE[1];
[1]Kuleuven, Leuven, Belgium; [2]Biomed. Sci., Univ. of Antwerp, Antwerp, Belgium

Abstract: There is considerable variation in the prevalence and magnitude of olfactory dysfunction among neurodegenerative diseases. For example, the average olfactory dysfunction of Alzheimer's, Parkinson's, Huntington's and Down syndrome is severe (clinical Smell Identification Test scores ~20). Such findings have led to the suggestion that olfactory testing may aid in the diagnosis of several neurodegenerative diseases. Moreover, the Down syndrome-related dysfunction is unlikely secondary to the Alzheimer's-like neuropathology (amyloid beta

plaques and tau tangles) associated with this disorder because it occurs at an age before this pathology is manifest.
These deficits in odor identification, detection, discrimination, and memory manifest themselves before the time the classic phenotypic elements of the disorders appear, although it is unknown how far in advance the olfactory loss precedes the phenotypic expression. It is noteworthy that patients with multiple sclerosis exhibit olfactory dysfunction proportional to plaque burden in subfrontal lobes. It is also of interest that some patients with Creutzfeldt-Jacob disease present with olfactory dysfunction associated olfactory tract involvement of the prion protein, lending some credence to the concept that the olfactory pathway may represent a route of infection and possible means of spreading the infection.
We are using transgenic Alzheimer's mice as a preclinical model platform for developing ethological behavioral screening tests and imaging biomarkers for pathology, and for evaluating treatments of relevant symptoms. Resting-state fMRI has emerged as a way to probe the brain network in disorders. Furthermore, with the establishment of functional connectivity fingerprints in Alzheimer's brain, and correlating this to behavioral phenotypes related to olfactory dysfunction, we try to improve our understanding of the etiology and progression of Alzheimer's disease and use these tools to track disease progression and treatment response in preclinical trials.

Title: Confirming the network degeneration hypothesis for intrinsic brain networks and for distinct neurodegenerative syndromes

Authors: ***J. NEITZEL**[1,2], J. DIEHL-SCHMID[3], M. ORTNER[3], T. GRIMMER[3], I. YAKUSHEV[4], P. BUBLAK[5], C. PREUL[5], K. FINKE[1], C. SORG[2];

[1]Ludwig-Maximilians-Universität, Muenchen, Germany; [2]Neuroradiology, [3]Psychiatry and Psychotherapy, [4]Nuclear Med., Klinikum rechts der Isar, Technische Univ. München, Munich, Germany; [5]Hans-Berger Dept. of Neurol., Univ. Hosp. Jena, Jena, Germany

Abstract: The network degeneration hypothesis suggests that for a given neurodegenerative syndrome, onset and spread of neurodegeneration is associated with a specific brain network and its dysfunction. Here, we tested this assumption for intrinsic brain networks (IBN) in different syndromes of frontotemporal lobar degeneration (FTLD) and two variants of Alzheimer's disease (AD). We expected that each syndrome is associated with reduced intrinsic functional connectivity (iFC) in one core network and potentially in additional networks.
37 biomarker-confirmed FTLD subjects, of which 19 presented with behavioral variant frontotemporal dementia (bvFTD) and 18 with primary progressive aphasia (PPA), and 36 biomarker-confirmed AD subjects, of which 23 presented with the amnestic variant (aAD) and 13 with posterior cortical atrophy (PCA) were assessed by resting-state functional MRI. The following network connectivity measures were determined for canonical IBNs such as the default mode network: (i) network iFC derived from independent component analysis and (ii) degree centrality (DC iFC) derived from graph theory analysis within IBN boundaries. Compared to 18 healthy controls, all four patient groups showed changed network iFC in syndrome-associated core networks. Specifically, in aAD patients we found reduced iFC in the default-mode network and additionally in the right and left attention networks. In PCA patients, iFC was reduced in the dorsal attention network and additionally in the default-mode network. For bvFTD patients, changed iFC was found in the saliency network as well as in the default-mode, right and left attention networks. PPA patients showed changed iFC in the left attention network and additionally in the saliency network. Furthermore, areas of reduced DC iFC overlapped with standard IBN templates taken from the literature.
The present findings suggest that the assumptions made by the network degeneration hypothesis applies to large-scale IBN. It seems that changes of iFC are tied to the brain's functional network architecture.

Title: Memory and hippocampal volume in behavioural variant Frontotemporal Dementia.

Authors: *C. PENNINGTON[1,3], D. TSIVOS[3], B. WOOD[2], M. KNIGHT[2], S. DILLON[3], R. KAUPPINEN[2], E. COULTHARD[1,3];
[1]ReMemBr Group, [2]Exptl. Psychology, Univ. of Bristol, Bristol, United Kingdom; [3]North Bristol NHS Trust, Bristol, United Kingdom

Abstract: Background: Behavioural variant frontotemporal dementia (bvFTD) is typified by profound alterations to personality and behaviour. Historically, memory was considered to be relatively preserved, but there is now increasing recognition of the impact bvFTD has upon memory, even in the early stages of the disease. The underlying neural substrates for amnesia are thought to differ between bvFTD and Alzheimer's disease (AD): hippocampal atrophy is primarily implicated in AD, whilst frontal network dysfunction is hypothesised to contribute to deficits in bvFTD. We used cutting-edge MRI techniques to investigate hippocampal sub-region atrophy in bvFTD and AD cohorts and healthy older adults, alongside ratings of anterograde visual and verbal memory. We hypothesise that AD and bvFTD affect distinct hippocampal subfields.
Methods: Patients with a clinical diagnosis of bvFTD or AD and age matched cognitively healthy control subjects underwent MR brain imaging, and completed the Montreal Cognitive Assessment (MoCA), the Hopkin's Verbal Learning Test Revised (HVLT-R) and Brief Visual Memory Task (BVMT).The hippocampus was segmented into 6 regions: Cornu ammonis 1, 2 and 3, Dentate Gyrus, Strata radiatum/lacunosum/moleculare and Subiculum, with separate volumes measured for the right and left hemispheres. Ethical approval for this study was obtained from the Frenchay NHS Research Ethics Committee.
Results: Preliminary data in 12 AD, 7 bvFTD and 49 healthy older people demonstrates significant impairment in HVLT-R and BVMT total recall scores in both patient groups. AD and bvFTD patients showed significant impairment on the total recall score of the BVMT and HVLT-R ($p<0.0001$, unpaired t test). No differences could be detected between the AD and bvFTD groups. Not all patients were able to undergo MR scanning: preliminary analysis showed equivalent degrees of atrophy of all hippocampal sub-regions in the bvFTD (N=5) and AD groups (N=6).
Discussion: This study found significant memory impairment in bvFTD, with affected individuals performing at a level equivalent to AD on tests of both visual and verbal memory. Intriguingly, we found no differences in the degree of hippocampal sub-region atrophy present in bvFTD and AD. Although sample sizes are currently small, this raises the possibility that episodic memory deficits seen in AD and bvFTD could both be due to hippocampal atrophy, rather than having separate neural substrates. Further testing aims to increase sample size and seek correlations between cognitive performance and specific hippocampal sub-regions.

Title: Novel extracellular vesicle-based approach for alzheimer's disease diagnosis and monitoring effects of the treatment

Authors: *T. V. BILOUSOVA, J. CAMPAGNA, M. ALAM, P. HEINZELMAN, D. BAI, P. SPILMAN, V. JOHN;
UCLA, Los Angeles, CA

Abstract: Alzheimer's disease (AD) is the most prevalent age-related form of dementia and currently no cure exists. Many potential therapeutics have been tested in the clinic and have failed. Two main reasons why clinical trials of potential new AD therapeutics have not been successful include: the late stage of intervention and the absence of sensitive, noninvasive methods to follow the effect of treatment on pathology-related biomarkers to enable optimization of the drug dose. We are attempting to address this problem by using an extracellular vesicle-based approach. The ability to detect brain-derived extracellular vesicles (EVs) in blood opens a window into the brain and creates the possibility of development of brain-specific liquid biopsy for AD and other neurological conditions. Our new method comprises immunopanning-magnetic isolation of brain-derived EVs from plasma with consecutive analysis of EV surface markers using a recently developed "ExoScreen" method (Yoshioka et al., 2014) based on Perkin-Elmer's AlphaLISA (a bead-based luminescent oxygen channeling immunoassay) technology, and downstream analysis of the disease stage and treatment-specific biochemical changes in EV compositions. We are currently testing the method using AD animal models being treated with selective BACE inhibitors and SIRT1 enhancers. We are also performing longitudinal analysis of human plasma samples from patients with known brain imaging and mini-mental state examination (MMSE) status to correlate brain biochemical and functional changes with the brain-derived EV composition in blood. The method is aimed to overcome heterogeneity in brain-derived EV quantity within plasma samples and detect small scale changes in the disease-specific and treatment-related biomarkers. When fully developed, our method may create a non-invasive blood-based early diagnostic test for AD, a way to monitor drug treatment effects, and to identify novel biomarkers and targets for new AD therapeutic development.

Title: Severity score a predictive tool for Alzheimer's disease

Authors: *F. V. CHIRILA[1], D. L. ALKON[2];
[1]Blanchette Rockefeller Neurosciences Inst., Morgantown, WV; [2]Blanchette Rockefeller Neurosciences Inst., Rockville, MD

Abstract: The value of diagnostic biomarkers derives from their ability to monitor disease progression and remission, as well as their predictive accuracy before the onset of the disease. Detection of the disease even before its onset, could provide important opportunities for prevention and/or planning therapeutic strategies. In the early stages of Alzheimer's disease (AD), within four years from the dementia onset, clinical diagnosis has a limited rate of success. Furthermore, clinical diagnostic accuracy before dementia onset has not been previously validated. Here, we present evidence for the potential predictive value of three peripheral human biomarkers for Alzheimer's disease (AD): Morphometric Imaging, PKCε and AD Index. The Biomarker Severity Score as described herein may be a continuous logistic fit function on the normalized values, between 0 and 100% of the output signal of the biomarkers for the Age-matched control (AC) and Alzheimer's disease (AD) patients. The gap in the severity score between the AD patients and AC patients is greater than 40% ($P<0.0023$, two tailed t-test, two samples, unequal variance) for each biomarker and indicates that each of these three biomarkers have the potential to detect the signature of Alzheimer's disease several years before the dementia onset($P<0.012$, two tailed t-test, two samples, unequal variance). Strategies for detecting AD before dementia onset with these biomarkers are presented here.

Title: High burden of vascular risk factors is associated with greater longitudinal increase in CSF total Tau.

Authors: *L. GLODZIK[1], T. BUTLER[2], C. RANDALL[2], E. TANZI[2], R. OSORIO[2], H. RUSINEK[2], A. DESHPANDE[2], Y. LI[2], M. DE LEON[2];
[1]NYU Sch. of Med., New York, NY; [2]NYUSM, New York, NY

Abstract: Background: Although the contribution of vascular risk to Alzheimer's diseases (AD) widely acknowledged, little is known how vascular conditions affect cerebrospinal fluid (CSF) biomarkers of AD. We investigated both cross-sectional levels and longitudinal trajectories of phosphorylated tau (p-tau), total tau (t-tau) and amyloid beta 42 in cognitively healthy subject with high and low vascular risk burden. Methods: Data was collected from 307 (mean age 64.1 ± 9.8 years, 63% female) subjects enrolled in NIH funded studies of aging and cognitive decline at the Center for Brain Health. All subjects underwent medical, neuropsychological, neurological and MRI examinations, and a lumbar puncture. CSF p-tau, t-tau and amyloid beta 42 were assayed. Baseline vascular risk burden was defined based on the Framingham Cardiovascular Risk Profile: as high ≥ 10% (n=91) or low <10% (n=216). Longitudinal data was available for 143 subjects; mean follow-up time was 3.9 ± 2.8 years. Results: At baseline high and low burden groups did not differ in any CSF biomarker. However, subjects with high vascular burden had greater increase in total tau longitudinally: Random effects mixed model: group*time interaction at p=.04, with age and baseline tau levels as covariates (Figure 1). These effects were not found for p-tau or amyloid beta 42. Conclusion: Our findings support the notion that vascular risk factors are related to increases in CSF marker of neuronal damage. We did not find evidence that more specific AD markers: ptau or amyloid beta 42 were affected.

Title: Avoiding virtual obstacles during treadmill gait in Parkinson's disease

Authors: ***C. LU**[1,2], M. MCCABE[1,2], E. TWEDELL[1,2], S. E. COOPER[1,2];
[1]Dept. of Neurol., [2]Motor Neurophysiol. Lab., Univ. of Minnesota, Minneapolis, MN

Abstract: Gait disorders are one of the most disabling symptoms of Parkinson's disease (PD) and one of the most refractory to treatment. We evaluated people with PD and healthy controls using a virtual obstacle avoidance task during visually cued treadmill walking.
We compared healthy controls to PD patients in the off-medication state. Participants were instructed to step on virtual "stepping stones" (blue squares projected onto the treadmill) during treadmill walking. Unpredictably, a stepping stone would change to an obstacle (red striped square). The participants were coached to step short to avoid the obstacles. Treadmill speed and the spacing of the stepping stones were set to match the walking speed and step length determined from self-paced overground walking. We measured the time of obstacle appearance relative to ipsilateral toe-off, and classified the following step as successful if the participant avoided stepping on the obstacle, failed otherwise. Probability of success was strongly associated with the time of obstacle appearance, with earlier-appearing obstacles more easily avoided. Logistic regression analysis demonstrated more obstacles were successfully avoided when appearing earlier. An independent *t* test showed systematic differences between groups, with PD patients requiring more time than controls to achieve equivalent obstacle-avoidance success rates.
The results demonstrate that in order for PD patients to successfully avoid an obstacle, they require a longer time to respond compared to healthy individuals. This could contribute to high fall risk in PD in daily activities. Further studies are warranted to investigate the mechanisms underlying the need for more response time. Possible mechanisms may include, but not be limited to, disturbances in motor planning (i.e., deficits in sensory and time perception), movement execution (i.e., unable to properly generate forces due to bradykinesia or delayed movement due to freezing of gait) or disordered response inhibition.

Title: Towards responsive deep brain stimulation for medically refractory freezing of gait in parkinson's disease.

Authors: *R. MOLINA[1], J. SHUTE[1], E. OPRI[1], D. MARTINEZ-RAMIREZ[2], K. FOOTE[2], A. GUNDUZ[1], M. OKUN[2];

[1]J. Crayton Pruitt Family Dept. of Biomed. Engin., [2]Ctr. for Movement Disorders and Neuroregeneration, Univ. of Florida, Gainesville, FL

Abstract: Freezing of gait (FoG) is a poorly understood symptom of Parkinson's Disease (PD) affecting ~53% of patients regardless of disease progression or medical therapy. Common PD treatments, such as medication or deep brain stimulation (DBS), do not consistently provide adequate management of FoG. There is an unmet and pressing need to develop novel therapeutic strategies to treat medically refractory FoG. Therefore, we seek to describe the role of the pedunculopontine nucleus (PPN), a brain stem structure found to excite spinal central pattern generators, in walking to outline the underlying neural mechanisms and pathogenesis of FoG. We will identify electrophysiological features of FoG for real-time detection of freezing. DBS paradigms will be designed using the extracted features and its effectiveness will be assessed using clinical scoring standards. Algorithms will be used concurrently to a neurologist's assessment of onset and cessation of FoG episodes.

All participants must meet preset criterion on the FoG-Q and a minimum of 5 freezing episodes incited by provocation protocols. Five patients will receive bilateral globus pallidus interna (GPi) and PPN DBS electrode implantation with two Activa PC+S Neurostimulation system, (Medtronic, Minneapolis, MN), one for each region. These novel devices allow simultaneous stimulation and recording from the depth electrodes using the Medtronic Nexus-D system, an external device enabling real-time control and data. Neural data is concurrently collected from multiple EMG+acceleration sensors (Delsys, Inc., Natick, MA), an 8-camera motion capture system (Vicon Peak, Oxford, UK), and ground reaction forces (Bertec, Newton, MA) over two-day monthly visits.

We have observed mu-low beta activity in GPi suppressed with medication and with increased task intensity. Similarly, low frequency activity (<10Hz) in the PPN increases with medication and with the intensity of the task. Using the clinical labels of FoG, low frequency activity has been identified to correlate to FoG episodes, a threshold detector was implemented and compared to a neurologist's time-aligned labeling of onset and cessation of FoG episodes during a continuous walking task. The subjects were asked to preform different tasks including freezing inducing tasks. Our initial results are promising and consistent across 3 patients who have come back for post-surgical recordings. There is current work in determining optimal detection and stimulation parameters.

Title: Biomechanical and electromyographic events preceding and accompanying freezing episodes during gait initiation in people with Parkinson's disease

Authors: *C. D. MACKINNON[1,2], M. N. PETRUCCI[4,5], S. L. AMUNDSEN HUFFMASTER[3,2], E. T. HSIAO-WECKSLER[4], P. J. TUITE[3], C. LU[3,2];

Abstract: Approximately one half of people with Parkinson's disease (PD) will develop a debilitating symptom termed freezing of gait (FOG). FOG is characterized by sudden episodes of inability to produce effective stepping during which the individual feels that their feet are "glued to the floor". These episodes are usually accompanied by a characteristic festination ("trembling of the knees") and are often triggered during gait initiation, turning, navigating through narrow doorways or during obstacle avoidance. Currently, the mechanisms causing FOG are poorly understood. Studying the pathophysiology and biomechanics of FOG is greatly hampered by the difficulty with capturing FOG episodes in the laboratory environment. Here we report data from rare incidents in which multiple FOG episodes were captured with quantitative methods. Specifically, we examined if FOG episodes were preceded by a common sequence of events (e.g. reduced or absent anticipatory postural adjustments) that precipitate the failure to achieve toe-off and trigger festination. The data were captured during studies examining the effects of external cueing and/or mechanical assistance on gait initiation compared to self-initiated gait (Lu et.al., 2015; Petrucci et al., 2015). Whole-body 3D kinematics, ground reaction forces (GRFs) and center of pressure (CoP) from two force platforms, surface EMG bilaterally from 5 lower limb muscles, and accelerometry (3-axes) of the lower leg and thigh were collected. Freezing episodes were defined based on: failure to achieve toe-off, and the presence of repetitive oscillations of the lower limb (festination) and accompanying EMG bursts. There were two main findings from

the analyses of these trials. First, reduced or absent anticipatory postural adjustments were not a prerequisite for the triggering of an FOG episode. Second, FOG episodes were preceded by a failed unloading (no swing phase) followed by rapid loading of the intended step leg and an unloading of the intended stance leg (reciprocal APAs). This unexpected reloading of the intended step leg was accompanied by a paradoxical rise of the heel (sometimes simultaneously on both sides) and flexion of the knee and hip, akin to the kinematic pattern of another push-off phase. Rise of the heel(s) appeared to trigger reciprocal right-left oscillations (approx. 10 Hz) in forces and EMG that characterize festination. These findings suggest that FOG is triggered by failed execution of stepping leg unloading and an inappropriately-timed second push-off phase of the intended stepping leg.

Title: Proprioceptive training improves reaching movement accuracy and postural stability limits in Parkinson’s disease

Authors: *S. BERGERON[1,2], P. BLANCHET[1,3], D. MONGEON[1], M. BLANCHET[1], M. JEAN-DÉSILETS[1], J. TREMBLAY[1], F. PRINCE[1], J. MESSIER[1,2];

Abstract: Evidence suggests impaired proprioceptive processing in Parkinson’s disease (PD). The aim of this study was to examine the impact of a proprioceptive-based exercise program on the performance of PD patients in two complex motor tasks that critically depend on proprioceptive processing. We assessed the performance of PD patients and aged-matched healthy controls (HC) in a three-dimensional (3D) reaching movements (n=10 PD, n=20 HC) and a postural stability limits tasks (n=11 PD, n=15 HC). In the reaching task, subjects

performed arm movements aimed at 3D targets defined by either vision or proprioception. The positions of the tip of the index finger and arm segments were recorded using an Optotrak motion analysis system (NDI inc.). In the postural task, subjects stood on a force platform (AMTI, inc.) with bare feet at comfortable stance width and arms crossed on the chest. They were instructed to lean as far as possible in four directions (forward, backward, rightward and leftward) without lifting their feet or flexing their hips and to maintain this maximal leaning position for 10 sec. Subjects were tested with and without vision. Accuracy and variability of reaching movements and center of pressure displacements during the stabilization phase of leaning movements were analyzed. PD patients were tested twice, before (pre-test) and after a 12 week proprioceptive training program (post-test). In the pre-test, PD patients displayed both a greater level of 3D absolute and variable reaching errors as well as smaller limits of stability relative to HC in the visual and proprioceptive conditions ($p<0.05$). Also, the between group difference in the magnitude of stability limits was larger along the medial-lateral axis than along the anterior-posterior axis ($p<0.05$). The proprioceptive training program significantly increased the spatial accuracy and decreased the variability of reaching movements ($p<0.05$). Furthermore, the program significantly increased the postural stability limits of PD patients, especially along the medial-lateral axis ($p<0.05$). Notably, the exercise program normalized the reaching accuracy and the stability limits in both the visual and proprioceptive conditions ($p>0.05$). These findings suggest that a proprioception-based training program improves the proprioceptive control of reaching and postural stability limits in PD.

Title: A sensorimotor training that improves proprioception and transfers to untrained movements in Parkinson's disease

Authors: *N. ELANGOVAN[1], P. TUITE[2], J. KONCZAK[1];
[1]Sch. of Kinesiology, [2]Dept. of Nuerology, Univ. of Minnesota, Minneapolis, MN

Abstract: BACKGROUND AND PURPOSE: Recent research shows that sensorimotor training that challenges the proprioceptive system improves proprioceptive acuity and translates to improved motor function. It is well established that people with Parkinson’s disease (PD)

experience proprioceptive impairments along with motor deficits. It is unknown whether proprioceptive function can be enhanced in PD and to what extent improved proprioceptive function translates to improved motor performance. Here, we evaluate whether proprioceptive function in PD can be enhanced by specialized visuomotor training that emphasizes precise movements and determine if such proprioceptive improvements lead to improved motor performance. We administered a sensorimotor training to PD patients using a wrist robotic device coupled with a real-time virtual visual environment. **METHOD**: 12 participants (Mean age = 61.8 yrs; mean disease duration = 2.5 yrs) diagnosed with PD were tested in their ON medication state. Training involved tilting a virtual table to position a virtual ball on a target by making precise small amplitude wrist flexion/extension movements. With increasing proficiency, task difficulty increased by adjusting the responsiveness of the virtual ball. Wrist position sense acuity and the spatial precision of an untrained goal-directed wrist reaching movements were assessed without vision before and after training. Wrist position sense discrimination thresholds were obtained using controlled robotic motion to passively rotate the wrist joint. Mean movement precision error was determined using the absolute difference between passively presented target of 15° wrist flexion and subsequent active movement to the target by the participant. **RESULTS**: All 12 participants showed improvements in wrist proprioceptive thresholds (mean: pre/post = 1.6° / 1.1°). Wrist movement precision in the untrained reaching improved in 9/12 participants (mean: pre/post = 2.6° / 1.9°). **CONCLUSION**: Wrist proprioceptive function improves after brief specialized visuomotor training in PD patients. Movement precision in an untrained motor task also improved on average by 27% in most participants, indicating that such sensory-based training directly benefits motor function. These initial findings are promising and suggest that somatosensory-based training may enhance sensorimotor function in PD.

Title: Subthalamic neural and kinematic features of freezing of gait on and off DBS in freely moving Parkinson's subjects

Authors: *J. SYRKIN-NIKOLAU, Z. BLUMENFELD, T. PRIETO, A. VELISAR, M. TRAGER, T. MARTIN, A. SRIVATSAN, E. QUINN, H. BRONTE-STEWART;
Neurol. and Neurolog. Sci., Stanford Univ., Palo Alto, CA

Abstract: Objective: Freezing of gait (FOG) is a common and debilitating symptom of Parkinson's disease (PD). Previous literature suggests that subthalamic nucleus (STN) resting state high beta band power is greater in self-reported PD freezers versus non-freezers. We report synchronized STN and kinematic data at rest and during movement including freezing episodes (FEs) in PD subjects on and off high frequency (HF) STN deep brain stimulation (DBS). Methods: 13 PD subjects (26 STNs), off-medication, performed a forward walking (FW) task, a stepping in place (SIP) task on dual force plates, and a novel FW turning and barrier course (TBC). STN LFPs were recorded from electrodes 0 - 2 or 1 - 3 of the DBS lead (model 3389, Medtronic, Inc.) via telemetry from an investigational sensing neurostimulator (Activa® PC+S, Medtronic Inc., FDA-, IDE-, IRB-, and CA Medicare-approved) before and while DBS was administered through electrode 1 or 2, respectively. Kinematic data was recorded using wireless Opal® inertial measurement unit (IMU) sensors (APDM, Inc.). Angular velocity signals from IMUs on the lower legs were used to determine gait cycle duration, swing phase duration, and swing angular range. Angular velocity signals from the lumbar IMU were used to determine forward direction and delineate periods of straight walking and turning. Kinematic analysis was performed in LabVIEW (National Instruments, Inc.) and MATLAB (The MathWorks, Inc.). Results: 13 subjects completed FW, SIP, and TBC, 6 of whom had FEs in at least one of the tasks. Preliminary results demonstrated that low beta band power was attenuated during walking when compared to the resting state (standing), which was more prominent in patients who had FEs. In some patients, there was also an attenuation of high beta power during periods of walking with FEs, in comparison to walking without freezing. STN DBS improved FOG in all freezers and attenuated beta band power. Conclusions: In some patients with FOG, neural signals during periods of walking with FEs show a decrease in high beta band power when compared to periods of walking without FEs. Analysis of the synchronized neural and kinematic signals during different walking tasks allows for a more nuanced understanding of the neural features associated with FOG.

Title: Kinematic and neural triggered adaptive deep brain stimulation for tremor dominant Parkinson's disease

Authors: *A. VELISAR[1], J. A. HERRON[2], J. SYRKIN-NIKOLAU[1], Z. BLUMENFELD[1], M. TRAGER[1], T. MARTIN[1], H. J. CHIZECK[2], H. BRONTE-STEWART[1];
[1]Neurol., Stanford Univ., Stanford, CA; [2]Dept. of Electrical Engin., Univ. of Washington, Seattle, WA

Abstract: Objective: determine safety and tolerability of adaptive or closed loop Deep Brain Stimulation (aDBS) in the subthalamic nucleus (STN) in Parkinson's disease (PD), using a neural control variable to drive aDBS and to investigate the effect on resting tremor of aDBS using either a neural or kinematic variable.Methods: Safety and tolerability of neural triggered aDBS (NaDBS) was evaluated in13 PD subjects (16 STNs) implanted with an investigational sensing neurostimulator plus a firmware upgrade (Activa® PC+S-NexusD3 system, Medtronic Inc., FDA-, IDE-, IRB-, and CA Medicare-approved) to enable aDBS using neural or kinematic control variable. The Nexus-D system is a conduit that allows bi-directional communication between the Activa® PC+S and a portable computing device (PC). The PC is an external platform that informs the Activa® PC+S to adjust stimulation using preset safe parameters. STN LFPs were recorded from electrodes 0 - 2 or 1 - 3 of the DBS lead (model 3389, Medtronic, Inc.) and 140 Hz DBS was administered through electrode 1 or 2, respectively. The percentage of stimulation time with tremor less than 0.15 rad/s and the total electrical energy delivered during aDBS as a percentage of TEED during continuous DBS ($TEED_{cDBS}$), was investigated using NaDBS or kinematic triggered aDBS (KaDBS) for > 20 minutes, in a subset of tremor dominant (TD) PD subjects. KaDBS used limb tremor power, recorded from a Bluetooth enabled smart watch, as the control variable.Results: Stimulation changes (ramps and voltage limits) were safe and tolerated in all 13 subjects. The stimulation delivered was in the safe limits imposed. In one TD PD subject during NaDBS, resting tremor was <0.15 rad/s for 33% of stimulated time and

$TEED_{NaDBS}$ = 15% of $TEED_{cDBS}$. During KaDBS, resting tremor was <0.15 rad/s for 62% of stimulated time and $TEED_{KaDBS}$ = 13% of $TEED_{cDBS}$. In another PD subject, NaDBS resulted in no tremor for 95% of stimulated time and $TEED_{NaDBS}$ = 57% of $TEED_{cDBS}$, while KaDBS resulted in no tremor for 53% of stimulated time and $TEED_{KaDBS}$ = 11% of $TEED_{cDBS}$.Conclusions: 1) NaDBS was safe and tolerable in all patients tested; 2) Two TD PD subjects tested to date responded differently to the two aDBS strategies. This suggests that aDBS strategies need to be customized to each PD subject in the TD phenotype.

Title: How tremor propagates throughout the upper limb

Authors: *S. K. CHARLES[1], A. D. DAVIDSON[2];
[1]Mech. Eng. and Neurosci., [2]Mech. Eng., Brigham Young Univ., Provo, UT

Abstract: Tremor in all of its forms (Essential Tremor, Parkinsonian Tremor, Dystonia, etc.) is arguably the most common movement disorder, estimated to affect approximately 10 million people in the US. Medication and surgical interventions have significantly reduced patient suffering, but medication is generally only partially effective, and surgical procedures are highly invasive and reserved for severe drug-resistant tremor, leaving many tremor patients without satisfactory treatment options. Surprisingly, tremor-suppressing devices are underexplored despite great potential promise. However, we do not know where in the upper limb the tremor originates (mechanically), how it propagates, and where manifests most severely, greatly limiting our ability to create effective tremor-suppressing systems. The purpose of this study is to use simulation to understand how tremor propagates through the upper limb, and to determine the feasibility of determining the mechanical origin of tremor from measurements of tremor throughout the upper limb. We have developed a mathematical model of the dynamics of the upper limb suitable for studying tremor propagation. This model focuses on the 7 major degrees

of freedom (DOF) from the shoulder to the wrist. It takes as input the muscle activity in the 14 major muscles acting on these DOF and simulates the resulting force in each muscle, torque in each DOF, and displacement (tremor) in each DOF. This model includes realistic parameter values taken from the literature, including values for muscle time constants and moment arms as well as joint inertia, damping, and stiffness. Because the displacements in each DOF are relatively small, our linear model can capture the dynamics of this non-linear system and allow us to take advantage of existing tools for analyzing the frequency response of linear systems. We have begun to simulate the propagation of tremor by "injecting" tremor in various muscles or DOF and observing patterns in the resulting tremor in each DOF. We will inject oscillatory torque in a single DOF and then move on to combinations of multiple DOF to understand propagation patterns and determine if it is possible to identify from the tremor in each DOF where the tremor originated. Finally, we will determine the effect of changes in model parameters on the propagation pattern and the ability to determine the origin of the tremor. Establishing principles of propagation will help us move closer to our end goal, which is to measure a patient's tremor, determine the origin and propagation of their tremor, and design a system to suppress their tremor in an optimal manner.

Title: Postural control and freezing of gait in Parkinson's disease

Authors: *C. SCHLENSTEDT[1], M. MUTHURAMAN[1], K. WITT[1], B. WEISSER[2], A. FASANO[3], G. DEUSCHL[1];
[1]Neurol., Univ. Hosp. Schleswig-Holstein Kiel, Kiel, Germany; [2]Sport Sci., Christian-Albrechts-University Kiel, Kiel, Germany; [3]Neurol., Morton and Gloria Shulman Movement Disorders Clin. and the Edmond J. Safra Program in Parkinson's Disease, Toronto Western Hosp., Toronto, ON, Canada

Abstract: BACKGROUND: The relationship between freezing of gait (FOG) and postural instability in Parkinson's disease (PD) is not clear. We analyzed the impact of FOG on postural control.
METHODS: 31 PD patients with FOG (PD+FOG), 27 PD patients without FOG (PD-FOG) and 22 healthy control (HC) were included and assessed in the ON state of medication. Postural control was measured with the Fullerton Advanced Balance (FAB) scale and with center of pressure (COP) analysis during quiet stance and maximal voluntary forward and backward leaning.
RESULTS: The groups were well matched concerning age, disease duration and disease severity. PD+FOG had significantly worse scores at the FAB scale (21.8 points, SD ± 5.8) in comparison to PD-FOG (25.6 points, SD ± 5.0) and HC (34.9 points, ± SD 2.4) (p<0.01). During quiet stance the average anterior-posterior COP position was significantly displaced towards posterior in PD+FOG in comparison to PD-FOG and HC (p<0.05). The COP position in the anterior-posterior orientation correlated with the severity of FOG (p<0.01). PD+FOG and PD-FOG did not differ in average COP sway excursion, sway velocity, sway regularity and postural control asymmetry.
CONCLUSIONS: Our results show that PD+FOG have reduced postural control in comparison to PD-FOG and HC. The COP shift towards posterior during quiet stance in PD+FOG leads to a restricted precondition to generate forward progression during gait initiation. The difference in COP position in PD+FOG patients may contribute to the occurrence of FOG or might be an altered stance position as a compensatory strategy to avoid forward falls.

Title: The effects of anodal tDCS over the supplementary motor area on anticipatory postural adjustments during gait initiation in people with Parkinson's disease with freezing of gait

Authors: *S. L. AMUNDSEN HUFFMASTER[1,2], C. LU[1,2], P. J. TUITE[1], C. D. MACKINNON[1,2];
[1]Neurol., [2]Movement Disorders Lab., Univ. of Minnesota Syst., Minneapolis, MN

Abstract: People with Parkinson's disease (PD) who experience freezing of gait (FOG) often show reduced or absent anticipatory postural adjustments (APAs) that are required for balance and forward propulsion during self-initiated gait. Impaired self-initiated movements in PD may result from reduced activity in the supplementary motor area (SMA). Anodal transcranial direct current stimulation (A-tDCS) can be used to facilitate activity in cortical regions underlying the stimulating electrode. We investigated if A-tDCS over the SMA can transiently improve APA magnitudes and timings in people with PD and FOG.

In our double-blinded, cross-over study, 9 PD subjects with FOG (3 females, 68 ± 9 years, off medication) underwent 2 sessions of testing (sham or A-tDCS at 1 mA for 10 min, separated by >1 week). Structural MRI scans and Brainsight software were used to target stimulation to the scalp surface over the SMA. Eight gait initiation blocks (5-6 trials/block) were collected: (1) pre-tDCS, externally cued; (2) pre-tDCS, baseline, self-initiated; and (blocks 3-8) post-tDCS, every 12 min., self-initiated. For self-initiated trials, subjects stood for 3-5 seconds before walking forward. For cued trials, subjects were given acoustic "warning" and "go" tones. Ground reaction forces were collected from force platforms beneath the feet. APA magnitudes and timing were quantified using Matlab (Mathworks, MA). Outcome measures included the magnitudes and times from APA onset to: step foot peak loading force, stance foot peak unloading and loading, peak lateral shift of the center of pressure (COP), and two peak posterior COP shifts, as well as the time to first and second toe-off. Two-way repeated measures ANOVAs (factors: stimulation type and trial block) were performed.

External cueing significantly increased nearly all of the APA measures magnitudes relative to baseline self-initiated trials ($p<0.001$) and decreased most of the time measures ($p<0.01$). There was no effect of stimulation type on APA magnitudes or timings ($p > 0.13$). With A-tDCS, some APA times significantly improved for 1 person, but worsened in 2 subjects. APA magnitudes significantly improved for 2 subjects and worsened in 2 subjects. There was no effect of visit order.

A-tDCS applied over the SMA did not have a consistent effect on people with PD with FOG. Results appear to be subject dependent, although this is confounded by symptom fluctuations and trial-to-trial variability. The lack of significance could be related to A-tDCS dosing and location. Alternatively, our results may suggest that the SMA has a limited role in self-initiated gait impairment in people with FOG.

Title: Impact of the α4β2 partial agonists on gait and motor coordination alterations in a rat model of Parkinson's disease

Authors: *W. M. HOWE[1], K. DLUGOLENSKI[2], A. ROSSI[2], D. VOLFSON[2], P. TIERNEY[2], R. KOZAK[2];
[1]Pfizer Inc, Cambridge, MA; [2]Pfizer, Inc, Cambridge, MA

Abstract: Disruptions in limb coordination, gait, and increased fall propensity are hallmarks of neurodegenerative disorders such as Parkinson's disease that are not ameliorated by standard dopamine replacement therapies. Alterations of gait and fall propensity are hypothesized to arise as top-down, cognitive control of motor output declines as a result of dual dysfunction of striatal dopaminergic and forebrain cholinergic systems. α4β2 nAChR selective nicotinic receptor (nAChR) agonists may mimic increased cholinergic modulation of top-down control, and therefore could represent a promising option for correcting the specific symptoms due to loss of such modulation. In the present set of experiments, we sought to test the capacity of α4β2 nAChR agonists to ameliorate gait disruptions associated with striatal dopaminergic depletion in rats. As a first step, two cohorts of animals (sham lesion; n=6, and unilateral 6-OHDA striatal lesion; n=5) were trained to run on a treadmill. Parametric variations of treadmill speed and angle were employed to provide a dynamic estimate of limb coordination and potentiate the delineation of specific alterations following loss of dopaminergic innervation of the striatum. Results, so far, indicate that there are no gross group differences in the capacity of animals to learn to run on the treadmill or achieve sustained bouts (>6 s) of running at different velocities and angles. Regarding gait symmetry and forepaw/hind paw coordination during running, dopaminergic depletion was associated with alterations in stride length, duration, paw angle, and unilateral inter-leg coordination. On-going experiments directly compare the capacity of α4β2 nAChR agonists to normalize these alterations in lesioned animals relative to l-dopa. The combined results of the present studies seek to extend our knowledge of the neural mechanisms contributing to the alterations in gait that accompany neurodegenerative diseases like Parkinson's, and illustrate the potential benefit of novel, non-dopaminergic treatment strategies such as α4β2 nAChR agonists.

Title: Normal and parkinsonian gait signatures in mice and human: a translational approach

Authors: A. WORLEY, C. ASHTON, L. BROOM, C. TOCCI, L. C. SHIH, *V. G. VANDERHORST;
Dept of Neurol., BIDMC, Boston, MA

Abstract: Impairment of gait can manifest itself in various ways and due to pathology at any CNS level. This implicates independent involvement of multiple CNS pathways, but these circuitries remain poorly understood. Powerful functional-anatomical approaches are available to unravel these circuitries in mouse models. However, a major hurdle that stands in the way of translation involves differences between quadruped gait in mice and biped gait in humans. We present an approach that facilitates the comparison of spatial and temporal gait parameters between these models. We will use this approach to study parkinsonian gait.
To capture mouse data we used 9 cohorts of 8-18 C57Bl6J, VGaT-ires-cre, VGluT2-ires-cre, VGluT3-ires-cre, SERT-cre, $VGaT^{fl/fl}$ or $VGluT2^{fl/fl}$ mice. In each group, we manipulated a distinct CNS target. This included 6OHDA microinjections into the substantia nigra or systemic MPTP to induce parkinsonism, and selective modulation or loss of function of forebrain or pontomedullary cell groups using chemogenetic approaches or deletions. Gait data was captured on a runway using high speed video analysis (MATlab). Each cohort served as its own control. For human data, we recruited subjects with Parkinson's Disease (PD) and controls, which walked across a walkway (Protokinetics) at varying speeds. Step by step gait measures were plotted as a function of velocity, and best fit regression models were determined prior to comparing data sets.

In mice, each gait parameter behaves differently as a function of velocity. At walking speeds this can be captured using a simple linear or non-linear regression model. Human data shows remarkably similar relationships. Regression curves of gait parameters in the experimental mouse cohorts shifted differentially, indicating region and cell-type specific control of individual gait parameters. In PD subjects compared to control, curves for stride length and cadence shifted significantly, resembling the MPTP mouse model and two pontomedullary models. This raises the question of whether the pontomedullary reticular formation mediates part of the gait abnormalities seen in PD.
This approach provides a powerful tool to analyze gait in both mouse models and human gait disorders. It opens up translational opportunities to close the gap between mouse and human gait models.

Title: Gait analysis of unilateral 6-OHDA Parkinson’s rat model

Authors: *B. K. HARVEY[1], H. A. BALDWIN[2], P. P. KOIVULA[2], J. C. NECARSULMER[2], K. W. WHITAKER[3,2];

Abstract: Gait analysis is a method for determining locomotor defects related to movement or neurological disorders. It is a particularly valuable method for assessing the progression and severity of a disease phenotype in humans and animal models of conditions associated with movement disorder. Parkinson’s disease (PD) is a progressive neurological disorder, marked by the loss of dopaminergic neurons in the nigrostriatal pathway, that is involved in the production of voluntary movement. Some of the major clinical manifestations of PD are abnormal gait, rigidity, slowness of movement, and shaking. The ability to recapitulate and measure such the

neurological sequelae in rodent models of PD are important for studying and evaluating potential therapeutics. Here we describe the use of a gait analysis system, the CatWalk, to identify objective metrics altered by lesioning of the nigrostriatal pathway in the rat brain. Previously, studies have used CatWalk to analyze gait abnormalities in the 6-hydroxydopamine (6-OHDA) model of PD, but these studies did not account for the effects of speed on reported gait parameters. Here, we account for the effects of speed on CatWalk gait analysis parameters in a unilateral 6-OHDA model of Parkinson's Disease and show that hind paw step cycle parameters, hind paw print area, and step sequence are significantly altered, when compared to non-lesioned animals.

Title: Sensorimotor integration in Parkinson's disease: optimal or not?

Authors: *S. SENGUPTA[1,2], L. P. J. SELEN[3], W. P. MEDENDORP[3], P. PRAAMSTRA[3]; [1]Donders Ctr. for Neurosci., Donders Inst., Nijmegen, Netherlands; [3]Donders Inst. for Brain, Cognition and Behaviour, [2]Radboud Univ., Nijmegen, Netherlands

Abstract: While slowness of movement is an obligatory characteristic of Parkinson's disease (PD), there are conditions where patients move uncharacteristically fast, attributed to deficient motor inhibition or impulsivity. Here we investigate deficient inhibition in the optimal sensorimotor integration framework, using a virtual ball catching paradigm (Faisal and Wolpert, 2008). In this time restricted task, in which time spend for perception is at the expense of time available for execution, healthy young subjects have been reported to optimally trade-off time for perception and time for action. An adapted version of this virtual ball catching paradigm affords an opportunity to investigate deficient inhibition by requiring participants (PD and controls) to withhold movement till the combined minimum uncertainty has been reached. Participants (7 PD patients and 7 age matched healthy controls) were instructed to catch a ball falling in a parabolic trajectory from the top of the screen. The ball disappeared as soon as movement was initiated to catch the ball, separating the task into distinct perception and action phases. The time at which

the participant initiates movement, switching from perception phase to action phase, is called the "switching time''. In order to compute the optimal switching time we also collected data to quantify sensory uncertainty and motor uncertainty independently. We determined sensory uncertainty as a function of viewing duration and horizontal velocity of the ball and motor uncertainty as a function of movement amplitude and movement time.
The mean switching time (+/- 1SD) for the elderly healthy controls was 620ms +/- 66 ms and that of the Parkinson's disease patients 592ms+/- 56ms. However, in comparison to the age matched healthy controls, PD patients initiated movements qualitatively closer to their statistical optimal switching time, although the performance of PD patients (47% correct) was poorer than the elderly healthy controls' performance (62% correct). Therefore, optimal integration of sensory and motor uncertainty and quantitative switching times suggest contradicting results on impulsivity in Parkinson's disease.

Title: Altered modulation of long-latency afferent inhibition by rubber hand illusion in patients with parkinson's disease

Authors: *R. ISAYAMA[1,3,2], G. JEGATHEESWARAN[3,2], M. VESIA[2], K. UDUPA[2], B. ELAHI[3], C. A. GUNRAJ[2], L. CARDINALI[4,5], A. FARNE[5], R. CHEN[3,2];
[1]Div. of Brain, Imaging and Behavior - Systems Neurosci., [2]Toronto Western Hosp., Toronto, ON, Canada; [3]Inst. of Med. Sci., Univ. of Toronto, Toronto, ON, Canada; [4]The Brain and Mind Inst., Univ. of Western Ontario, London, ON, Canada; [5]Lyon Neurosci. Res. Ctr., Lyon, France

Abstract: Objective: To examine multi-modal sensory integration in patients with Parkinson's disease (PD) using Rubber Hand Illusion (RHI) and its influence on sensorimotor integration. **Background:** To perform goal-directed actions, the brain must integrate sensory information about the limb position from multiple sources and transform this information to appropriate motor commands. This process is altered in PD patients as shown in reduced long-latency afferent inhibition (LAI), a neurophysiological parameter for sensorimotor integration that

presumably involves cortical association areas. However, the underlying mechanisms of impaired sensorimotor integration in PD remain unclear. We hypothesized that LAI is altered during the integration of multi-modal sensory inputs. **Methods:** Eleven patients with PD and twelve age-matched healthy controls (HC) were tested. In order to manipulate visuo-tactile-proprioceptive integration, we used RHI paradigm, in which subjects viewed a rubber hand being stroked by a brush during the application of synchronous (test condition) or asynchronous (control condition) brush strokes on their own unseen hand. LAI was elicited by an electrical digital nerve stimulation (DNS) to the participants' index finger followed by transcranial magnetic stimulation (TMS) to the primary motor cortex. The amplitudes of the conditioned (with DNS) motor evoked potentials (MEPs) to the unconditioned (without DNS) MEPs were measured before and immediately after the synchronous or asynchronous condition. PD patients were evaluated either on (PD-ON) or off (PD-OFF) dopaminergic medications on two separate days. **Results:** Behavioral data indicated that both PD and HC groups showed a greater degree of the RHI in the synchronous than the asynchronous condition. Overall, LAI was significantly reduced in PD-OFF compared to PD-ON and HC. Comparison between PD-ON and HC showed significant interaction between condition and group. In the synchronous condition compared to baseline, LAI decreased in HC but increased in PD-ON, suggesting altered LAI response to RHI in PD-ON. **Conclusions:** In PD-OFF, LAI was reduced and was not modulated by RHI indicating the deficit of sensorimotor integration. In the on medication condition, reduced LAI at baseline was improved during RHI by strengthening the inhibitory effect of DNS to M1 suggesting that dopaminergic medications modulate the interaction between visuo-tactile-proprioceptive integration and LAI.

Title: Impact of enhancing expectations on self-efficacy and motor learning in individuals with Parkinson's disease

Authors: *Y.-C. CHUNG[1], R. LEWTHWAITE[2], C. J. WINSTEIN[1], B. E. FISHER[1];
[1]Div. of Biokinesiology and Physical Therapy, USC, Los Angeles, CA; [2]Rancho Los Amigos Natl. Rehabil. Ctr., Downey, CA

Abstract: Reduced self-efficacy has been demonstrated as an independent predictor of postural instability and gait deficits for individuals with Parkinson's disease (PD), leading to the possibility that self-efficacy may be a potential target to improve motor performance in PD. Studies in non-disabled adults have shown that boosting self-efficacy via increasing an individual's expectations for future success can enhance motor performance and learning. However, this positive effect remains to be determined in PD. This study aims to investigate the impact of enhancing expectation on self-efficacy and motor learning when individuals with PD practice a novel balance task. Twenty participants with PD practiced balancing on a stability platform by keeping the platform level for as long as possible. Participants were assigned to an enhanced expectancy (EE) group or a control group. At early practice, the EE group received a statement designed to enhance expectation of future task success while the control group received no statement. Feedback was provided to both groups after each 30-s trial in the form of time in balance, calculated as accumulated time when the platform position was within +/-5 degrees from horizontal. Task performance, as measured by time in balance and the number of bouts when the platform was within +/-5 degrees, was assessed during practice and at a retention test conducted 24 hours later. Self-efficacy for 3 levels of task performance (balancing for 10, 15 and 20 seconds) was assessed at 4 time points, while a motivational questionnaire was completed by each participant following practice and retention. Self-efficacy of the EE group significantly increased after the statement for the medium performance level only (i.e. balancing for 15s) (p= .04). Enhanced self-efficacy did not appear to affect time in balance. No group difference was observed in time in balance during practice (p= .88) and at retention (p= .08). However, there was a trend that the EE group achieved similar time in balance with fewer bouts than the control group at retention (p= .09). In addition, the questionnaire showed that the EE group reported greater nervousness than the control group during practice (p= .03) and at retention (p= .02), an unexpected finding that may have counteracted the effect of enhanced self-efficacy. The preliminary results suggest that enhancing expectation appears to boost self-efficacy and result in a modification of motor control that may reflect longer durations of balance stability in PD. Further analysis will explore the impact of nervousness, which may reveal to clinicians the potential importance of improving self-efficacy without inducing nervousness.

Miami Project to Cure Paralysis

Title: MRI guided targeting and stimulation of the mesencephalic locomotor region in the Yucatan minipig

Authors: F. D. BENAVIDES[1], I. OPRIS[1], A. J. SANTAMARIA[1], F. J. SANCHEZ[1], L. M. VILLAMIL[1], Y. NUNEZ-GOMEZ[2], J. P. SOLANO[2], J. D. GUEST[1], *B. R. NOGA[1];
[1]Miami Project To Cure Paralysis, [2]Pediatric Critical Care, Univ. of Miami Sch. of Med., Miami, FL

Abstract: **Objective:** The mesencephalic locomotor region (MLR) is a target of interest to generate locomotion with deep brain stimulation (DBS) after spinal cord injury (SCI). Testing efficacy of DBS in a large animal model is an important translational step. We developed stereotaxic techniques to target the pedunculopontine (PPN) and cuneiform nuclei (CnF) in the MLR of Yucatan minipigs based on magnetic resonance imaging (MRI). A targeting protocol was tested using an MRI compatible frame and accuracy assessed in a gelatin phantom model. Subsequently, the refined protocol was assessed in animals. **Methods:** An MRI compatible frame was designed around the pig's dimensions. Contrast-filled markers permitted 3-dimensional trajectory planning. Gelatin filled porcine skull phantoms were used to test equipment, calculation procedures, and accuracy before animal experiments. The phantoms contained 24 MRI visible cylindrical plastic (PEEK) targets (1mm OD, 2mm length). The software used for trajectory and distance calculations to enter targets inside the gel phantom included Amide and ImageJ. We used a porcine neuro atlas (Felix et al, 1999) to estimate the position of PPN/CnF (medial to the lateral lemniscus below the inferior colliculus 4-6 mm lateral to the aqueduct). At surgery, a second MRI confirmed the trajectory after advancing a MRI compatible cannula. Physiological targeting was initiated under chloralose anesthesia by stimulating the electrode and assessing patterns of locomotor activation in agonist/antagonist muscles using 4 limb electromyography. This activity was assessed in response to variation of the intensity and frequency of the stimulation parameters. **Results:** Locomotor-like patterns were elicited in all animals by stimulation and changes in blood pressure and heart rate were recorded. Phantom testing proved essential to refine the stereotactic methods, resulting in an accuracy

close to 99%. The apparatus and methods allowed successful placement of an MRI-visible cannula and DBS electrode at the intended target. Physiologic testing confirmed activation of patterned locomotor activity. **Conclusion:** We developed accurate, practical methods to target the MLR in minipigs using high resolution MRI and confirmatory neurophysiology. This methodology will support further studies of the impact of graded SCI MLR-evoked locomotor stimulation.

Title: Deep brain stimulation of the mesencephalic locomotor region improves emg correlation with kinematics in the yucatan minipig

Authors: *I. OPRIS, F. D. BENAVIDES, F. J. SANCHEZ, L. M. VILLAMIL, J. D. GUEST, B. R. NOGA;
Miami Project, Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: Objective: Deep brain stimulation (DBS) of the pedunculopontine (PPN) and cuneiform nuclei (Cnf) in the mescencephalic locomotor region or MLR (mlrDBS) of the Yucatan minipig is a promising model for assessing therapies aimed at improving locomotion after spinal cord injury (SCI) or Parkinson Disease (PD). However, a detailed quantitative assessment of the electromyographic (EMG) activity with respect to the locomotion kinematics, heart rate (HR), and respiratory rate (RR), in Yucatan minipig is lacking. **Methods**: DBS was applied to PPN and Cnf of the Yucatan minipig assisted with magnetic resonance image based targeting. Locomotion patterns were obtained from EMG activity recorded in agonist/antagonist muscles in all 4 limbs. The EMG activity was tuned by changing stimulation parameters (intensity and frequency) of the targeted region. Physiological and behavioral parameters were collected during stimulation. The coupling of EMG patterns with locomotor kinematic variables

(limbs position, speed and acceleration) and HR/ RR, was characterized using a multi-variate regression model. The coefficient of determination (R^2), defined as the proportion of variance accounted for by the EMG activity-to-behavior multi-variate regression model, allowed us to assess efficacy of stimulation by comparing the effect of DBS of Cnf and PPN nuclei with the control values observed during voluntary locomotion (without DBS). To characterize the phase change during locomotion (stance and swing phases of each limb) we evaluated the phase difference in EMG activity corresponding to locomotion limb phases before and after stimulation. **Results**: DBS elicited locomotor patterns in animals and changes in RR and HR. The regression analysis demonstrated a significant increase in the coefficient of determination with DBS stimulation. Also, the locomotion phase difference decreased following DBS. When the stimulation current increased from 20uA to 40uA and up to 200uA there was a significant change in the speed of locomotion. **Conclusion**: mlrDBS modulation of locomotion may play a key role in the therapeutic improvement of gait disorders associated with SCI and PD. This approach may also be instrumental in the design of brain machine interface (BMI) and neuroprosthetics for SCI or PD patients.

Title: Posture-gait control by the lateral part of the mesopontine tegmentum

Authors: *K. TAKAKUSAKI[1], M. TAKAHASHI[2], R. CHIBA[2];
[1]Asahikawa Med. Univ., Asahikawa/Hokkaido, Japan; [2]Asahikawa Med. Univ., Asahikawa, Japan

Abstract: Recently the lateral part of the mesopontine tegmentum is one of targets of the deep brain stimulation (DBS) as a therapeutic strategy for treating posture-gait deficiency in Parkinsonian patients. The lateral part of the mesopontine tegmentum contains functionally important structures involved in the control of posture and gait. Specifically, the mesencephalic locomotor region (MLR), which may consist of the cuneiform nucleus (CNF) and pedunculopontine tegmental nucleus (PPN), occupies the interest with respect to the pathophysiology of posture-gait disorders. The purpose of this study is to understand the mechanisms involved in the control of postural muscle tone and locomotion by the mesopontine tegmentum. For this purpose, experiments were performed in decerebrate cat preparations. Our investigations revealed the presence of functional topographical organizations with respect the regulation of postural muscle tone and locomotion in the mesopontine tegmentum, i.e., MLR, are mostly located in the ventral part of the CNF and the vicinity in the dorsal part of the PPN. Moreover, the dorsal part of the CNF and the ventral of the PPN may contribute to the increase and decrease in the level of postural muscle tone, respectively. Therefore, the MLR is, functionally, surrounded by the areas involved in the augmentation and suppression of postural muscle tone. The atonia induction zone well corresponds to PPN pars compacta where abundant cholinergic neurons are located. The organization was modified by neurotransmitter systems, particularly the cholinergic PPN projection to the pontine reticular formation, corresponding to the nucleus reticularis pontis oralis. Bilateral pontine atropine injections reduced the number of atonia-evoking sites while that of the locomotor-evoking region was increased. Because efferents from the forebrain structures as well as the cerebellum converge to mesencephalic and pontomedullary reticular formation, changes in the functional organizations may be involved in the appropriate regulation of posture-gait synergy depending on the behavioral context. On the other hand, abnormal signals from the higher motor centers may produce dysfunction of the mesencephalic-reticulospinal system. Particularly, efferents from the basal ganglia output to the CNF/PPN area may strongly alter the activity of this system in Parkinson's disease. Here we highlight the significance of elucidating the mechanisms of the mesencephalic control of posture and locomotion so that thorough understanding of the pathophysiological mechanisms of posture-gait disorders can be made.

Title: A physiological role for monomeric α-synuclein.

Authors: *M. LUDTMANN[1], P. ANGELOVA[1], N. NINKINA[2], S. GANDHI[1], V. BUCHMAN[2], A. ABRAMOV[1];

Abstract: Despite the wealth of publications about misfolded alpha-synuclein in Parkinson's disease, very little has been reported about this protein's physiological function in health. This current study established an important function for unfolded monomeric alpha-synuclein in the regulation of ATP synthase activity. Using mice lacking alpha, beta and gamma-synuclein, we report that extracellular monomeric alpha-synuclein enters the cell and localises to mitochondria, interacts with the ATP synthase and modulates its function. Using a combination of biochemical assays, live cell imaging and mitochondrial respiration analysis we found that mitochondria of alpha, beta, gamma-synuclein knock-out mice are uncoupled as characterized by increased mitochondrial respiration and reduced mitochondrial membrane potential. Furthermore, synuclein deficiency results in reduced ATP synthase efficiency and lower ATP levels. Exogenous application of monomeric alpha-synuclein is able to increase the ATP synthase activity and rescue the mitochondrial phenotypes observed in synuclein-deficiency. Overall, the data suggest that monomeric alpha-synuclein is a previously unrecognised physiological regulator of mitochondrial bioenergetics through its ability to interact with the ATP synthase and increase its efficiency.

Title: Extracellular and exosomal alpha-synuclein modulate innate immunity and possibly contribute to inflammation in Parkinson's disease

Authors: *V. GROZDANOV[1], N. VERHAGEN[1], C. MEIER[1], L. BOUSSET[2], A. C. LUDOLPH[1], R. MELKI[2], J. H. WEISHAUPT[1], K. M. DANZER[1];
[1]Univ. of Ulm, Ulm, Germany; [2]Paris-Saclay Inst. of Neurosci., Gif-sur-Yvette, France

Abstract: Immune dysregulation and inflammation have been previously linked to Parkinson's disease (PD), but it remains unclear whether inflammation is a result of the disease or if it is an important factor contributing to neurodegeneration. Genes involved in familial inheritance of PD (SNCA, LRRK2) are widely expressed in the innate immune system and polymorphisms in genes involved in the immune response are associated with increased risk for PD. Furthermore, PD is characterized by pathological aggregation and accumulation of alpha-synuclein. We have previously shown that the inflammatory response by peripheral blood monocytes is dysregulated in PD patients and that extracellular alpha-synuclein oligomers induce a robust cytokine response in blood monocytes. However, the relevance of these findings for the disease remained unclear. Here, we studied the immune response of monocyte-derived macrophages from PD patients and healthy controls, as well as murine microglia to extracellular alpha-synuclein oligomers and higher molecular aggregates, which are possibly involved in different stages of synucleinopathy. We demonstrate that different alpha-synuclein species exhibit a different potency for immune activation and likely induce inflammation during early processes of the disease. We show that exosomes, which have been previously implicated in spreading of alpha-synuclein pathology, also contribute to the immune response by monocytes, macrophages and microglia. Furthermore, we characterized exosomes from PD patients and healthy controls as well as from a transgenic α-syn oligomer mouse model and assessed their ability to induce the innate immune response, paralleling our findings with exosomes from cell lines with induced alpha-synuclein pathology. We show that extracellular alpha-synuclein skews innate immune cells to a pro-inflammatory phenotype, while increased levels of alpha-synuclein expression in immune cells do not directly induce inflammatory hyperactivity. Our findings strengthen the evidence that extracellular alpha-synuclein-induced inflammation may be an important disease mechanism contributing to the death of dopaminergic neurons and suggest inflammatory response and alpha-synuclein clearance as important targets for therapies in PD.

Title: Uptake and sequestration of prion-like alpha-synuclein in a cellular model

Authors: ***M. MARANO**[1], S. SRI RENGANATHAN[1], P. E. FRASER[2], A. TANDON[1]; [1]Inst. of Med. Sci., [2]Med. Biophysics, Univ. of Toronto, Toronto, ON, Canada

Abstract: This study aims to investigate the mechanisms underlying the intercellular propagation of alpha-synuclein (a-syn) involved in Parkinson's disease (PD). In PD, patients develop neuronal protein inclusions, composed primarily of a-syn, called Lewy bodies (LB). These LBs are considered an intrinsic component of the PD neuropathology and a post-mortem diagnostic criterion. LBs are thought to originate in olfactory and enteric nerves prior to their entrance in the central nervous system; this distinctive progression of LBs from the periphery to the brain, first described by Braak and colleagues, is indicative of disease stage. Additionally, the presence of LBs in otherwise healthy neuronal grafts implanted in PD patients suggests a-syn propagates in a prion-like manner where misfolded a-syn migrates and recruits healthy a-syn within neighbouring cells.

Our goal is to develop a two-stage fluorescent assay assessing the propagation of a-syn pathology. In the first step recombinant a-syn, in a predominantly oligomeric state, was used to treat immortalized human embryonic kidney cells (HEK 293) stably expressing the A53T a-syn mutant conjugated to YFP, resulting in the formation of punctate structures. My work will characterize these punctate structures by looking for markers of aggregation and determining their subcellular location. For the second stage, we intend to treat a "donor" population of HEK 293 cells, transiently transfected with a-syn, with recombinant a-syn and subsequently co-seed these cells with a "recipient" A53T-YFP cell population to assess cell-to-cell a-syn transmission.

This project will allow us to expand our understanding of how toxic a-syn is transmitted between cells and to investigate how the cell processes aggregated a-syn. This information is important to understanding the molecular basis for the initiation and progression of synucleinopathies such as PD or Dementia with Lewy bodies. My work will solidify our understanding of the intercellular exchange of a-syn. In addition, by characterizing the systems at work under disease conditions, therapies can be directed towards augmenting cellular pathways to cope with pathological protein accumulation.

Title: 27 hydroxycholesterol induces alpha-synuclein expression in dopaminergic neurons-implications in synucleinopathies.

Authors: *J. SCHOMMER, M. KLEINJAN, G. MARWARHA, O. GHRIBI;
Univ. of North Dakota, Grand Forks, ND

Abstract: Accumulation of α-synuclein protein is a common hallmark of a group of brain disorders collectively known as synucleinopathies. These disorders include Parkinson’s disease, dementia with Lewy bodies, multiple system atrophy and Alzheimer’s disease. The role of α-synuclein in the pathogenesis of synucleinopathies is not understood, but experimental studies point to a potential neurotoxic role of high levels of this protein in its soluble or aggregated forms. The causes of synucleinopathies are likely multi-factorial with several factors including genetic susceptibility and environmental agents (dietary and chemicals) potentially participating in the pathogenesis of these diseases. The objective of our study was to test the hypothesis that the cholesterol oxidation product 27-Hydroxycholesterol (27-OHC) increases α-synuclein transcription through over-activation of its cognate receptor, liver X receptor (LXR). Reducing over-activation of LXR can potentially prevent α-synuclein overproduction and slow or reverse synucleinopathy progression. 27-OHC is the most abundant endogenous oxysterol and increased levels of this oxysterol may cause deleterious effects. We incubated human neuroblastoma (SHSY5Y) cells, mouse dopaminergic neurons differentiated from embryonic stem cells, and

human dopaminergic neurons differentiated from human normal dopaminergic neuronal precursor cells with 27-OHC and examined the effects of increased 27-OHC on the expression levels of α-synuclein. Our results show that 27-OHC dose-dependently regulates the transcription of α-synuclein through modulation of LXR in the three different cell types. Despite extensive research, no disease-modifying therapy is currently available for synucleinopathies and the search for diagnostic tests and biomarkers are still under development. The search for disease-modifying therapies or diagnostic markers would benefit from identification of factors that promote over-production of α-synuclein protein as well as the elucidation of new cellular mechanisms that regulate the transcription of α-synuclein. Identification of the oxysterol 27-OHC and the LXR as the underlying cellular mechanisms by which 27-OHC increases α-synuclein levels may help in designing therapeutic agents that can prevent, reverse, or stop the over-production of α-synuclein and ultimately may protect against synucleinopathies.

Title: Modulation of brain mitochondrial function by aggregated proteoforms of human α-synuclein

Authors: *J. B. WATSON[1], A. KUNZ[1], G. SEROBYAN[1], A. YACOUB[1], J. WHITELLEGE[1], M. CILLUFFO[2], T. SARAFIAN[1];

Abstract: The α-synuclein protein exists in a variety of aggregated forms associated with Parkinson’s disease (PD) pathology, but the specific proteoform structures that cause PD toxicity are not clearly defined. Our previous studies showed that the membrane potential was decreased while reactive oxygen species (ROS) were elevated in brain mitochondria from a pre-manifest mouse model for PD over-expressing the full-length, monomeric form of NH_2-terminally acetylated human α-synuclein (ASOTg)[Sarafian TA et al, 2013, PLoS One 8(5):e63557]. Since α-synuclein oligomers or fibrils were not detected with amyloid conformational antibodies in mitochondrial fractions from ASOTg mice, presumably excess amounts of the monomeric form were sufficient to disrupt brain mitochondria function. Preliminary studies in synapse-enriched

synaptoneurosomes (SNs) from the same overexpressing mice also detected lower mitochondrial membrane potential, but ROS and glutathione (reduced form, GSH) were diminished as well. Overall ASOTg studies suggested that there may be paradoxical effects of excess α-synuclein on non-synaptic and synaptic mitochondria. Additional immuno-gold/transmission electron microscopy detected gold labelling within numerous SN membranous structures, including mitochondria, incubated with exogenous fibrillated forms of α-synuclein. Experiments are now in progress to examine further the functions of both brain and SN mitochondria reconstituted with aggregated recombinant proteoforms (oligomers, fibrils) relative to monomeric and COOH-truncated forms of human α-synuclein.

Title: A gene-environment interaction study to examine the role of human wild-type alpha-synuclein in cadmium-induced neurotoxicity

Authors: ***J. A. JIMENEZ**[1], W. CHONG[1], G. KWAKYE[1], M. SAITO[2];
[1]Oberlin Col., Oberlin, OH; [2]Woods Hole Oceanographic Inst., Woods Hole, MA

Abstract: Alpha-synuclein (α-syn) is a ubiquitous protein whose native function is unknown. α-syn comprises 60% of Lewy bodies that are aggregates present in the brains of postmortem Parkinson’s disease (PD) patients and implicated in the pathogenesis of dopaminergic neurons. 5-10% of PD cases are familial with the remaining being idiopathic. Long-term exposure to

pesticides or metals such as cadmium (Cd) has been proposed to represent a risk factor for PD. Cd is an industrial and environmental pollutant that causes severe damage to a variety of organs, including the brain, and impairs cellular mechanisms implicated in PD. Here we investigated the role of wild-type α-syn in Cd-induced neurotoxicity in an established α-syn dopaminergic cell model of PD that overexpresses human wild-type α-syn (N27-syn) or empty vector (N27-vec). We demonstrate that N27-syn expressing cells exhibit a significant dose-dependent susceptibility to Cd neurotoxicity compared to N27-vec following a 24h exposure. Furthermore, we show that N27-syn cells exhibit reduced levels of the antioxidants glutathione and superoxide dismutase, and increased production of reactive species compared to N27-vec, suggesting the contribution of oxidative stress pathways in the cell death mechanism. We further hypothesized that wild-type α-syn may modulate Cd homeostasis. Thus, we quantified intracellular Cd levels in N27 cells following a 6h and 24h Cd exposure with inductively-coupled plasma mass spectrometry (ICP-MS) and report that N27-syn cells accumulate significantly more Cd in a time-dependent manner compared to N27-vec cells. Together these findings suggest that wild-type α-syn enhances Cd-induced neurotoxicity resulting in oxidative stress mediated cell death.

Title: The SUMO conjugase Ubc9 regulates the stability of alpha-synuclein and Dopamine Transporter in Parkinson’s disease models.

Authors: E. CARTIER[1], J. GARCIA-OLIVARES[2], E. JANEZIC[1], M. L. LIN[3], *Y.-H. KIM[1]; [1]Biol. Sci., Delaware State Univ., Dover, DE; [2]Natl. Inst. of Mental Hlth., Bethesda, MD; [3]Univ. of Florida, Gainsville, FL

Abstract: Post-translational modification (PTM) has been addressed as a key regulatory mechanism for modulating protein aggregation/degradation in neurodegeneration. However, a form of PTM, Small Ubiquitin Modifier (SUMO) has not been well studied in Parkinson’s disease (PD) pathology. Although SUMOylation may increase the solubility of alpha-synuclein, SUMOylated proteins including alpha-synuclein have been detected in the halo of Lewy bodies. Thus it is still unclear in understanding the role of SUMOylation in dopaminergic neurons. Here,

we assess the role of SUMO conjugase, Ubc9 as a critical post-translational modifier to regulate the solubility, stability, and function of dopamine transporter (DAT) and alpha-synuclein in dopaminergic neurons *in vitro* and *in vivo*. The objective of this work is to assess SUMOylation as a novel regulatory target for preventing alpha-synuclein mediated protein aggregation and regulating dopamine uptake via DAT in dopaminergic neurons. This implies that pathological changes in the SUMOylation of DAT and/or alpha-synuclein may lead to alteration in dopamine reuptake and acute regulation of protein (mis)folding or aggregation, which is related to the neuropathology of PD. We identified that both DAT and alpha-synuclein are constitutively SUMOylated in mouse striatum and midbrain. Our *in vitro* preliminary results demonstrated that Ubc9 over-expression protects rat N27 dopaminergic cells against MPP+ induced oxidative stress and prevents DAT and alpha-synuclein degradation via inhibition of proteasome and lysosome. Moreover, Ubc9-mediated SUMOylation increases the surface level of DAT in the plasma membrane and further its action enhances DAT functional expression in the plasma membrane, triggering an increase in dopamine uptake capacity. In the MPTP-lesioned mice, the chronic treatment substantially reduces the level of SUMO1 conjugated to alpha-synuclein in the mouse striatum. This implies that pathological changes in the SUMOylation of DAT and alpha-synuclein may lead to alteration in acute regulation of dopamine clearance/recycling and protein (mis)folding or aggregation, respectively. Therefore, SUMOylation of DAT and alpha-synuclein can be a potential therapeutic target for neurological disorders such as ADHD, depression, and PD.

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder with clinical symptoms of tremor, rigidity, cognitive impairment and depression. It is characterized by the loss of dopaminergic neurons that develop Lewi bodies (LB), depositions of α-synuclein and other protein aggregates that cause downstream cellular toxicity and death. Impaired lysosomal and mitochondrial function has been shown to be critical for the cellular proteolytic capacity. Recently, a variation in human transmembrane protein 175 (TMEM175), a K^+ channel localizing to lysosome was identified by GWAS as a candidate risk factor for PD. Mediating potassium conductance on lysosomal and endosomal membrane, TMEM175 was shown to regulate lysosomal membrane potential, pH stability, and organelle fusion, suggesting the possibility that it may play a causal role in the development of PD. We have shownthat deficiency of TMEM175 in rat primary neurons leads to an increase in hyperphosphorylated and detergent insoluble a-synuclein aggregates in the preformed fibril seeding model of α-synuclein aggregation, supporting the genetics data linking TMEM175, α-synuclein aggregation, and PD. We also confirmed that absence of TMEM175 results in unstable lysosomal pH in SH-SY5Y neuroblastoma cell leading to altered fusion of autophagosome to lysosome. Moreover, maturation of lysosomal proteins, lysosomal enzyme activity, and mitochondrial oxygen consumption capacity were compromised in cells lacking TMEM175, suggesting the importance of TMEM175 in lysosomal function. Together, our data suggest that TMEM175 might be a key therapeutic target of Parkinson's disease as a critical player that modulates proteolytic capacity of lysosome.

Abstract: Parkinson's disease (PD) affects ~1% of people over the age of 65 and is the second most common neurodegenerative brain disorder after Alzheimer's. The physiological decline

associated with PD is generally thought to be caused by a marked pathological deterioration of dopaminergic neurons located in the *substantia nigra*. Mutations in several different genes have been clearly linked to PD, including *SNCA* that encodes the alpha-synuclein (⟨-syn) protein, which is predominantly expressed in the brain at presynaptic terminals. The mutation in alpha-syn at A53T renders the protein more susceptible to aggregation and accumulation, which are hallmark indicators of PD pathology. Despite its low occurrence, A53T is also one of the highly penetrant and widely studied alpha-syn mutations.
Combining cutting-edge genome-editing and induced pluripotent stem cell (iPSC) technologies offers the opportunity to study patient-specific risk factors or disease-specific mutations (such as the A53T mutation in alpha-syn) in a physiologically-relevant cell type (dopaminergic neurons) and compare the function and phenotype in a series of assays to cells derived from healthy control iPS cell lines. This is revolutionary for disease modeling and drug discovery.
In this poster, we show data comparing healthy (WT) and A53T dopaminergic neurons that demonstrate alterations at the synapse, both functionally (electrophysiological MEA readout) and anatomically (neurite outgrowth and branching). The observed differences between healthy and A53T suggest early physiological changes tilted towards producing a more connected and highly-active neuronal network. In correlation with the known disease pathology, these “aging” cultures show synaptic deterioration and dendritic atrophy.
Current studies are underway to further determine if additional hallmarks of PD patho-physiology, including alpha-syn aggregation or mitochondrial dysfunction, can be measured in these human cell models.

Abstract: Loss of function mutations in the PTEN induced putative kinase 1 (PINK1) gene cause autosomal recessive early-onset Parkinson's disease (PD). PINK1 is a mitochondrial kinase and acts as a key player in the initiation of Parkin-mediated mitophagy. Recent findings draw a more complex picture and indicate important Parkin-independent functions of PINK1. The revolution of gene-editing technologies enabled the generation of unique human neuronal models to investigate the pathological mechanism underlying PD. We have generated a PINK1 knockout in healthy human induced pluripotent stem cells (iPSCs) using TALEN-technology and are currently generating PINK1-mutated lines and patient iPSCs. The PINK1 knockout iPSCs and their isogenic control were differentiated into neurons and used for several established readouts to assess mitochondrial function under different stress conditions. We were able to identify distinct mitochondrial phenotypes, which support a role for PINK1 in mitochondrial quality control. Ionophores induce loss of mitochondria in isogenic control cells but this effect is significantly hampered in PINK1 knockout lines. In PINK1 knockout neurons no ubiquitinylation or phosphorylation of several outer mitochondrial membrane (OMM) proteins was observed. Thus this neurons exhibit a severe defect in the initiation of mitophagy. As a compensatory mechanism, mitochondrial biogenesis is upregulated. As a result neurons lacking PINK1 have a significantly reduced mitochondrial membrane potential and were less sensitive to mitochondrial toxins. These findings hint towards deficits in the respiratory chain. Therefore, we performed a mitochondrial stress test of the respiratory chain, which revealed changes in OXPHOS under uncoupled conditions. To investigate whether PINK1 knockout neurons are more susceptible to apoptosis, we analysed several apoptotic markers and measured LDH release. Apoptotic markers are dysregulated and the PINK1 knockout neurons display an increased vulnerability to Rotenone as compared to isogenic control. This shows that PINK1 is not only involved in the regulation of Parkin-dependent mitophagy, but also regulates the metabolic state of the mitochondria and the cellular fate after mitochondrial damage has occurred. Using this model on a high content screening platform, we will next investigate genetic and pharmacological modifiers to apply novel neuroprotective strategies.

Abstract: We initially identified the mitochondrial chaperone Trap1 (mitochondrial Hsp90) as an interactor of Parkinson's disease (PD)-associated mitochondrial protease HtrA2 via an unbiased mass spectrometry approach. The PD kinase PINK1 is required for the phosphorylation of HtrA2 (Plun-Favreau et al., 2007) and Trap1 (Pridgeon et al., 2007) following cellular stress but the downstream signaling involving Trap1 is not fully understood. In our model, Trap1 is protective against cell death and can rescue PD loss of function phenotypes. Loss of function of Omi and PINK1 cause Parkinsonism in humans and animal and cell models. Here we also report for the first time a mutation in TRAP1 leading to a premature stop codon in the transit sequence of TRAP1 in a patient suffering from late onset idiopathic PD and report TRAP1 variants in a PD cohort. Functional analysis in patient-derived cells suggests that loss of TRAP1 results in significant loss of mitochondrial membrane potential and sensitivity to late stage quality control such as organellar removal and apoptosis. Our data also suggests that the protective mechanism of Trap1 involves regulation of energy metabolism and we propose TRAP1 as a novel susceptibility gene for Parkinson's disease acting in a signaling pathway downstream of PINK1 and HtrA2 but likely independent of Parkin.

Title: Characterization of alpha synuclein oligomers from Parkinson's patient tissue

Authors: *C. SILKY, C. REHAK, K. MOZZONI, R. YURKO, N. IZZO, G. RISHTON, G. LOOK, H. SAFFERSTEIN, S. M. CATALANO;
Cognition Therapeut. Inc, Pittsburgh, PA

Abstract: Parkinson’s disease (PD) is characterized by motor dysfunction as well as non-motor symptoms including cognitive deficits. It is pathologically differentiated from other neurodegenerative diseases by the presence of Lewy bodies (LBs), predominantly composed of alpha-synuclein (Asyn). Native Asyn is an intrinsically-disordered pre-synaptic protein involved in vesicular trafficking and neurotransmitter release. Although fibrillar aggregates of Asyn accumulate in LBs, evidence suggests that soluble, oligomeric assemblies of Asyn are the primary neurotoxic species. Oligomeric Asyn inhibits SNARE mediated vesicle fusion (Choi ’15), disrupts synaptic plasticity and impairs long-term potentiation (Diogenes ’12; Martin ‘12) which could underlie cognitive deficits in PD.
We characterized human Asyn oligomers by immunoprecipitating PBS-soluble proteins from post-mortem Parkinson’s patient brain samples with a211 antibody directed against Asyn residues 121-125 on the C-terminus. Elution with 6M Guanidine HCL released the maximum amount of Asyn oligomer from IP columns of all the conditions examined, while preserving the oligomers’ neuroactive properties in an assay measuring membrane trafficking in cultured neurons. To characterize these samples, patient-derived oligomers were run side-by-side on

native and SDS page gels. Analysis of non-denaturing Western blots revealed low molecular weight bands at 20, 35 and 50 kDa, corresponding to monomer, dimer and trimer respectively, as well as higher molecular weight species >100 kDa. Analysis of this material on denaturing Western blots revealed high molecular weight species >80 kDa with no lower species below 50 kDa. Changes in molecular weights of oligomer species under denaturing conditions has been previously documented for other oligomeric proteins like Abeta1-42.
In order to identify a method to produce oligomers from recombinant Asyn protein that most closely match those isolated from human patient brain, we compared several methods for oligomerizing full length Asyn recombinant protein (Brenner ‘08; Danzer ‘07; Choi ‘15; Tsigelny ‘08). Only Asyn protein seeded with nanomolar concentrations of synthetic Abeta 1-42 yielded neuroactive oligomers with similar molecular weights to human patient derived oligomers on non-denaturing Western blots. Lower amounts of >100kDa species and higher amount of dimer are seen in the recombinant oligomers vs. patient-derived. Additionally, both human PD patient-derived and recombinant seeded Asyn oligomers cause deficits in membrane trafficking rate in primary neuronal cultures.

Title: Functional characterization of dual-specificity tyrosine-phosphorylation-regulated kinase 1A to modulate parkin ubiquitin E3 ligase activity and the formation of toxic protein aggregates

Authors: S. JUNG[1], E. IM[1], *H. RHIM[2], K. CHUNG[1];
[1]Dept Systems Biol., Yonsei Univ., Seoul, Korea, Republic of; [2]Korea Inst. Sci. Tech. (KIST), Seoul-City, Korea, Republic of

Abstract: Mutations of parkin are linked to autosomal recessive forms of familial Parkinson's disease (PD). According to its functional relevance in abnormal protein aggregation and neuronal cell death, a number of post-translational modifications regulate the ubiquitin E3 ligase activity of parkin. Here we propose a novel inhibitory mechanism of parkin E3 ubiquitin ligase through dual-specificity tyrosine-phosphorylation-regulated kinase 1A (Dyrk1A)-mediated phosphorylation as well as its neuroprotective action against 6-hydroxydopamine (6-OHDA)-induced cell death. The present work suggests that parkin phosphorylation by Dyrk1A may affect the pathogenesis of PD under PD-inducing pathological conditions.

Abstract: Leucine-rich repeat kinase 2 (LRRK2) is a Ser/Thr kinase having mixed lineage kinase-like and GTPase domains, controlling neurite outgrowth and neuronal cell death. Mutations of LRRK2 gene cause autosomal dominant late-onset Parkinsonism. Parkinson and Alzheimer disease-associated p21 protein is reported to modulate calcium-dependent protein dephosphorylation, consequently affecting many cellular responses, including lymphocyte activation and inflammatory signaling. Based on evidence suggesting a putative role of LRRK2 during inflammatory signaling, we investigated biochemical and functional interactions between LRRK2 and p25, and its potentially regulatory role for in IL-1β inflammatory signaling. At the meeting, recent data will be presented showing that p25 is a novel substrate of LRRK2 and acts as a positive regulator of inflammatory signaling. In conclusion, LRRK2 positively regulates inflammatory responses through p25 phosphorylation in Parkinson disease.

Title: LRRK2-mediated cellular and synaptic alterations in the striatum

Authors: *L. PARISIADOU[1], C. MAKARIOU-PIKIS[1], F. KOURI[1], H. CAI[2];
[1]Feinberg Sch. of Medicine, Northwestern Universi, Chicago, IL; [2]Trangenics Section, Lab. of Neurogenetics, Natl. Inst. on Aging, Bethesda, MD

Abstract: Mutations in LRRK2 represent a strong genetic risk for both hereditary and sporadic forms of Parkinson’s disease (PD). However, there are still several fundamental aspects of LRRK2 function that remain unresolved at this time. LRRK2 is significantly enriched in spiny projection neurons (SPNs) in the dorsal striatum. This cellular expression pattern suggests that LRRK2 mutations may contribute to striatal pathophysiology in PD. The function of LRRK2 in the striatum has remained relatively under-investigated; however, we recently showed that LRRK2 directs PKA signaling in SPNs. The pathogenic $LRRK2^{R1441C}$ mutation impairs the binding of PKA with LRRK2, leading to increased levels of PKA in the dendritic spines that, in turn, result in aberrant synaptic PKA signaling. The components of PKA enzyme in neurons are confined to sub-cellular compartments, ensuring for spatial and temporal regulations of PKA signaling which lead to specificity in fundamental striatal functions. Our data suggest that

LRRK2 is strategically located in the dendritic shaft to organize signaling events in a spatiotemporal way. Therefore, we propose that increased synaptic PKA activity of *LRRK2*^{R1441C} SPNs stems from altered subcellular compartmentalization of PKA. Furthermore, since PKA is a critical effector of dopamine receptors, our central hypothesis is that LRRK2-mediated deregulation of PKA activity results in aberrant dopaminergic signaling in SPNs, which in turn contributes to PD symptomatology. In support of this idea, we provide evidence that *LRRK2*^{R1441C} mutations impact dopaminergic signaling in SPNs. Specifically, SPNs harboring *LRRK2*^{R1441C} mutations show an abnormal elevation in PKA activity in response to dopamine receptor, Drd1, activation. In addition, *LRRK2*^{R1441C} mice show altered behavioral responses under several dopamine manipulations, suggesting a novel role of LRRK2 in dopaminergic signaling which, in turn, may direct the striatal related motor functions. Taken together, our findings emphasize that LRRK2 contributes to glutamatergic synaptic functions by directing postsynaptic signaling events in the SPNs and demonstrate a novel LRRK2-based pathogenic mechanism of striatal dysfunction in PD.

Title: In silico simulation of Lrrk2 interactions in Parkinson’s Disease using SEED

Authors: *J. W. RYAN, A. WIDENER, I. C. IKEDA, T. J. SWEENEY, A. D. LEE, B. BEHROUZ;
Neuroinitiative, Jacksonville, FL

Abstract: Mutations in Leucine-rich repeat kinase 2 (LRRK2) cause autosomal dominant Parkinson’s Disease (PD). LRRK2 encodes for a large protein of the same name which interacts with over 60 other proteins and can alter several molecular pathways. Lrrk2’s role in multiple different pathways makes it difficult to successfully identify therapeutics with low off-target effects. It is therefore important to understand the molecular changes involving Lrrk2 as well as the relationship of these changes with PD pathology and normal cellular function. To aid in the research and identification of PD therapeutics, we have developed a computer simulation program, Simulation Environment for Experimental Design (SEED). We created an *in silico* pathway model around Lrrk2 interactions based on information derived from peer-reviewed manuscripts and public databases. We simulated these interactions using SEED running on

Nvidia graphics processing units (GPU) with the CUDA parallel programming platform. We visualized and quantified the simulation data from Lrrk2 overexpression and knockout models and compared it with a baseline model. Furthermore, we manipulated downstream targets of Lrrk2 in order to reverse the abnormalities observed by Lrrk2 overexpression. Elucidation of these druggable targets downstream of Lrrk2 and upstream of PD pathology may help to identify therapeutic targets for both Lrrk2-mediated and idiopathic PD.

Abstract: Parkinson's disease (PD)-linked mutations in *PARK2* and *PINK1* disrupt selective autophagic elimination of damaged mitochondria (mitophagy). Mutations in *LRRK2* are a much more prevalent cause of PD than *PARK2* or *PINK1* mutations. *LRRK2* encodes an enzyme with a kinase domain, a GTPase domain and multiple protein-protein interaction domains. Here, we investigated whether PD-linked *LRRK2* mutations affect mitophagy. Using a variety of mitophagy assays we demonstrate that mitophagy is consistently impaired in primary fibroblasts obtained from PD patients with the two most common *LRRK2* mutations (G2019S and R1441C). We observed a similar mitophagy defect in fibroblasts from non-manifesting carriers of the G2019S mutation. *LRRK2* mutant fibroblasts had a decreased mitochondrial membrane potential and enhanced mitochondrial production of reactive oxygen species. Endogenous parkin-mediated ubiquitination of mitofusin-2 on depolarized mitochondria was intact in *LRRK2* mutant fibroblasts, indicating that the mitophagy defect was downstream of parkin activation and mitochondrial ubiquitination. The mitophagy defect was rescued by pharmacological inhibition

of LRRK2 kinase activity and by overexpression of Rab10, a recently identified LRRK2 kinase substrate involved in membrane trafficking and fusion. In conclusion, we identified a mitophagy defect in human cells expressing endogenous levels of mutant LRRK2, suggesting that the pathogenic effects of *LRRK2*, *PARK2* and *PINK1* mutations may converge on a common pathway.

Title: The relationship between LRRK2 and Rab GTPase family

Authors: ***T. FUJIMOTO**, T. KUWAHARA, T. KOMORI, T. IWATSUBO;
The Univ. of Tokyo, Tokyo, Japan

Abstract: *Leucine-rich repeat kinase 2 (LRRK2)* has been identified as the most common causative gene for autosomal dominant Parkinson's disease (PD). LRRK2 regulates neurite outgrowth, lysosome integrity and intracellular trafficking in coordination with *RAB7-like variant 1 (RAB7L1)*, a putative responsible gene for another PD risk locus *PARK16*. However, the physiological and functional relationship between LRRK2 and RAB7L1 still remains unclear. We first investigated the possibility of RAB7L1 as a substrate of LRRK2 kinase activity. In vitro, we confirmed that recombinant LRRK2 efficiently phosphorylated recombinant RAB7L1. We also revealed that LRRK2 phosphorylates RAB7L1 in HEK293 cells, but our preliminary results for phosphorylation site analyses suggested that the phosphorylation sites in vitro and in vivo were different. Recently, it has been reported that a subset of other Rab GTPases are in-cell substrates of LRRK2. In our study, some Rab GTPases, but not all, were phosphorylated by LRRK2 in cell as well as in vitro, consistent with the results of prior studies. We further examined the physical interaction between LRRK2 and a set of Rab GTPases by immunoprecipitation assays. As a result, another set of Rab GTPases including RAB7L1 interacted with LRRK2 to varying degrees, regardless of their ability as a substrate. These results suggest that LRRK2 regulates intracellular trafficking by simultaneously regulating various Rab GTPases in kinase activity-dependent or interaction-dependent manners.

Title: The dynamic changes in the localization of LRRK2 in macrophage cells

Authors: *T. EGUCHI, T. KUWAHARA, G. ITO, T. IWATSUBO;
Med., The Univ. of Tokyo, Tokyo, Japan

Abstract: Background
Leucine-rich repeat kinase 2 (LRRK2) is one of the causative genes for autosomal dominant familial Parkinson's disease. LRRK2 is composed of 2527 amino acids and has multiple domains, including GTP-binding and kinase domains. The physiological and pathological functions of LRRK2 remain to be clarified.
Recent studies have revealed that LRRK2 is highly expressed in immune cells including macrophages and that its expression is induced by IFN-γ stimulation. Furthermore, genome-wide association studies have identified LRRK2 as a risk gene for inflammatory and infectious disorders, e.g., Crohn's disease and leprosy. These results suggest that LRRK2 has a role in the immune system. To reveal the role of LRRK2 in the immune system, we analyzed the intracellular localization of LRRK2 upon phagocytosis in RAW264.7 cells, a mouse macrophage cell line, as well as in bone marrow derived macrophages (BMDM).
Method
RAW264.7 cells and BMDM were activated with IFN-γ and then fed with zymosan, a yeast cell wall. The localization of LRRK2 was analyzed by immunocytochemistry. Diacylglycerol-PKC/PKD pathway, one of the major signaling pathways on phagosomes, was pharmacologically inhibited, and LRRK2 localization was analyzed.
Result
LRRK2 was localized in the cytosol in macrophages without zymosan treatment. Upon exposure with zymosan, it was up taken by cells and LRRK2 was relocalized to zymosan-containing phagosomes, in a manner to line their outer surface. PKC/PKD inhibitors suppressed LRRK2 relocalizaiton to phagosomes. PKC/PKD agonist, phorbol 12-myristate 13-acetate, relocalized LRRK2 from the cytosol to the lysosomal compartments.
Discussion
This study suggests that LRRK2 has a role in phagocytosis, and that the PKC/PKD pathway is involved in this phenomenon. PKC/PKD pathway is implicated in the regulation of anti-bacterial responses, e.g., reactive oxygen species production, bacteria killing, and induction of inflammation. The mechanism whereby LRRK2 plays a role in immune responses and

neuroinflammation, including the effects of Parkinson-linked LRRK2 mutations, should further be examined.

Abstract: Mutations in leucine-rich repeat kinase 2 (LRRK2) are implicated in both familial and sporadic Parkinson's disease (PD) as the most common causative factor. However, LRRK2's pathophysiological role remains unknown. It was recently discovered that LRRK2 is highly expressed in immune cells relating to the innate immune system and has a genetic association the immune-related disorders: Crohn's disease and leprosy. Thus, determining LRRK2's function in the central immune system and subsequent effect in dopaminergic neuronal cell death could provide insight into the pathogenesis of PD. Here we show both in vitro and in vivo that myeloid-lineage cells such as primary microglia and bone marrow-derived macrophages (BMDMs) from LRRK2 G2019S knock-in mice display increased phagocytic activity that correlates with an increase in the protein level of the ARP2/3 complex activator, WASF2. Conversely, myeloid cells from LRRK2 null mice show impaired engulfment that correlates with a decrease in WASF2 protein. We show that LRRK2-mediated phagocytic activity is kinase dependent and that LRRK2 influences the stability of WASF2 via direct phosphorylation. Lastly, survival of TH-positive neurons is reduced in mixed, wildtype-midbrain, G2019S-BMDM culture. Taken together, these results suggest that the LRRK2-G2019S mutation may contribute to the pathogenesis of PD by increasing the microglial phagocytic response via enhanced WASF2 stability and actin polymerization.

Title: Regulation of Wnt and Ca^{2+} signalling by the Parkinson's disease protein LRRK2

Authors: *A. WETZEL[1], M. HUGHES[1], T. MCKAY[2], S. WADDINGTON[3], A. RAHIM[1], K. HARVEY[1];

Abstract: The evolutionary highly conserved Wingless/Int (Wnt) signalling pathways have shown to be important regulators for neuronal development and maintenance. Moreover, Wnt signalling has been linked to several cell biological functions in midbrain dopaminergic neurons that are known to be affected in Parkinson's diseases (PD). Deregulation of Wnt signalling cause amongst others impaired synaptic stability in the striatum, a brain region where high levels of *leucin-rich repeat kinase 2* (*LRRK2*) expression have been found. Mutations in *LRRK2* are a common cause of inherited and sporadic PD. Interestingly, we showed previously that LRRK2 is a key component of three Wnt signalling protein complexes. It interacts with the LRP6 Wnt co-receptor at membranes (i), binds to all three cytoplasmatic dishevelled proteins, which play a central role in all branches of Wnt signalling (ii), and it has an important role as scaffolding protein in canonical Wnt signalling via an interaction with the β-catenin destruction complex (iii). The importance of Wnt signalling for midbrain dopaminergic neurons during neuroinflammatory responses in PD animal models has also recently been reported. In addition, LRRK2 was shown to inhibit immune responses via Ca^{2+} signalling and was further linked to other Ca^{2+}-dependent functions in autophagy and mitochondrial function. Here, we present the analysis of Wnt and Ca^{2+} signalling activity using the exciting new technology of tissue-targeted delivery of lentiviruses containing a transcription factor activated luciferase reporter to new born mice. This allows quantification of transcription factor activity over the lifetime of an animal. We compare wildtype mice with *LRRK2* knockout mice and with mice harbouring the most prevalent familial *LRRK2 G2019S* mutation. Our data collectively support the idea of LRRK2 as a modulator of Wnt and Ca^{2+} signalling. Increasing our understanding about the role of LRRK2

in these pathways during neuronal development and aging might contribute to the generation of novel PD treatments targeting early events in the pathogenesis of PD.

Title: Leucine-rich repeat kinase 2 (LRRK2) inhibitors exhibit greater pharmacological potency to reduce the Ser1292 autophosphorylation compared to Ser935 *In vitro* and *In vivo*

Authors: *H. SAMAROO[1], Y. CHEN[1], E. NEEDLE[1,2], K. WELCH[1], P. GALATSIS[3], S. STEYN[4], Z. BERGER[1], W. D. HIRST[1,5];

Abstract: Mutations in the GTPase and kinase domains of Leucine-rich Repeat Kinase 2 (LRRK2) increase the risk for PD. Previous studies suggest these mutations result in a more active state of LRRK2 which presents an opportunity for therapeutic intervention using small-molecule kinase inhibitors. Here, we validate LRRK2 auto-phosphorylation at Ser1292 (pSer1292) *in vivo* as a robust and sensitive measure of LRRK2 kinase activity, and conferring greater pharmacological potency for diverse LRRK2 inhibitors relative to pSer935 (a conventional measure of LRRK2 inhibition). We transiently transfected HEK-293T cells with LRRK2 mutant constructs containing several familial PD mutations and measured phosphorylation at Ser1292 and Ser935. We observed pSer1292 to be elevated with familial PD activating mutations (G2019S, R1441C and Y1699C) and reduced upon pharmacological inhibition. We used non-transgenic C57BL6 (NTg) and BAC-Tg mouse brain and primary mouse astrocytes overexpressing LRRK2-WT and LRRK2-G2019S to determine dose response curves for selective LRRK2 inhibitors (PF-06447475, GNE-7915, MLi-2). Specifically, all three LRRK2 inhibitors consistently showed a 2-3 fold leftward shift in IC_{50} against pSer1292 vs pSer935. Using the same G2019S-Tg model systems, we further validated the difference in pharmacological potency by determining time-course profiles of pSer1292 and pSer935 after treatment with PF-06447475. The results illustrate higher rates of de-phosphorylation at Ser1292

relative to Ser935 in both G2019S-Tg mouse brain and primary astrocytes. These data suggest that pSer1292 is a sensitive pharmacodynamic marker which consistently predicts potency in multiple PD-relevant model systems. Furthermore, we propose that pSer1292 can be utilized to determine whether disease relevant factors such as pathologic α-synuclein and other cell stressors can activate LRRK2.

Abstract: Genetic variability in and around the gene encoding for LRRK2 is associated with inherited and sporadic Parkinson’s disease (PD). LRRK2 has been linked to signalling events of autophagy and trans-golgi dynamics, but the regulation of this protein and role in neuropathology remain elusive. LRRK2 is a phosphoprotein and its phosphorylation is altered by PD-linked mutations in ways that are not well understood. For example, mutations in the GTPase domain of LRRK2 have been shown to diminish phosphorylation at sites that are not the result of autophosphorylation, although the mechanism(s) by which phosphorylation of LRRK2 is controlled by mutations are not resolved. Mitochondrial abnormalities are a common feature in PD pathogenesis, so we investigated whether mitochondrial impairment can alter LRRK2 function. We show, in striatal slices and a variety of cell types, that depletion of ATP via mitochondrial stress causes changes in phosphorylation and 14-3-3 binding of LRRK2. We set out to identify downstream effects of LRRK2 dephophorylation under mitochondrial

impairment, specifically on phosphorylation of small Rab family GTPases that may have implications in endosomal trafficking and autophagy. Our data place LRRK2 in pathways related to mitochondrial dysfunction, suggesting links to multiple forms of inherited PD and may have implications for development of LRRK2 kinase inhibitors as therapies for this disease.

Title: Calcium-dependent calpain cleavage of Parkin: relevance to Parkinson's disease

Authors: A. STOLL[1], H. WANG[1], P. ROCKWELL[1], *M. E. FIGUEIREDO-PEREIRA[2]; [1]Biol. Sci., [2]Hunter Col., New York, NY

Abstract: Parkin dysfunction during mitochondrial stress contributes to Parkinson's disease (PD) via mechanisms which are poorly delineated. In addition, mitochondrial impairment is linked to PD although the underlying mechanisms are not clearly understood. It is postulated that in neurons even a modest restriction of ATP production by mitochondria far outweighs the negligible effects of ROS. We investigated the effects of a mitochondrial inhibitor (oligomycin, Oligo) on Parkin integrity in rat midbrain and cerebral cortical cultures. Treatment with Oligo led to calpain-cleavage of Parkin. As far as we know, Parkin cleavage by calpain has not been reported. Upon calpain cleavage, Parkin migrates as a doublet. Based on computational analysis we predict two calpain cleavage sites (P1 position) in human/rat full-length Parkin: (1) Gln71 with a predicted molecular weight of 43.6, and located within the UbL domain, and (2) Ala134 with a predicted molecular weight of 36.9, and located within the linker region between the UbL and RING0 domains. Both cleavages free the partial or complete UbL domain, which could bind to proteasomes and inhibit their activity. Calpain-activation is linked to ATP-depletion and necrosis, a cell death pathway characterized by a bioenergetic catastrophe. In fact, calpain-activation was shown to be induced by electron transport chain inhibitors, such as oligomycin,

the one used in our studies. Calpain activation is calcium (Ca^{++})-dependent. While extracellular Ca^{++} is in the millimolar range, cytosolic Ca^{++} is usually less than one micromolar, except during a Ca^{++} signaling event. Ca^{++}-ATPase pumps in the plasma and ER membranes maintain this low concentration by transporting Ca^{++} away from the cytoplasm, either out of the cell or into the ER. When intracellular ATP levels are lowered, such as in the case of oligomycin treatment, Ca^{++}-ATPase pumps are impaired causing cytoplasmic Ca^{++} to be elevated leading to calpain activation. To determine whether calpain-cleavage of Parkin is Ca^{++} dependent, we treated the cells with the Ca^{++} ionophore A23187, which facilitates the transport of Ca^{++} across the plasma membrane. Treatment with A23187 mimicked the effect of Oligo by inducing calpain-cleavage of Parkin to fragments of the same size. We are addressing whether calpain cleavage of Parkin diminishes its E3 ubiquitin ligase activity. In conclusion, based on our findings we propose that stabilizing FL-Parkin could provide a novel therapeutic strategy for treating PD.

Title: The involvement of the calcium binding protein in aberrant calcium release from IP_3 receptor by alpha-synuclein oligomers

Authors: *K. YAMAMOTO, H. SAWADA;
Dept. of Neurol. and Clin. Res. Ctr., Utano Natl. Hosp., Kyoto, Japan

Abstract: There is emerging evidence implicating α-synuclein (α-SN) oligomers as potential culprits in the pathogenesis of Parkinson's disease and dementia with Lewy bodies (PD/DLB). Soluble oligomeric α-SN accumulated in the cytoplasm, can modify neuronal activities and intraneural Ca^{2+} dynamics, which may augment the metabolic burden in central neurons vulnerable for PD/DLB, but this hypothesis still remained to be fully tested. We evaluated how intracellular α-SN oligomers act on neuronal excitabilities and cytoplasmic Ca^{2+} dynamics by using whole-cell recording from pyramidal neurons in mouse neocortical slice. Intracellular application of α-SN incubated with dopamine, which makes stable oligomers (α-SNo), significantly reduced the spike frequency during current injection, elongated the duration of

spike afterhyperpolarization (AHP), and enlarged AHP current charge, when compared to application with α-SN incubated without dopamine. Pharmacological experiments indicated that this alteration mediated by α-SNo was dependent on the functional coupling of L-type Ca^{2+} channel, SK-type K^+ channel, and IP_3 receptor (IP_3R). α-SNo did not change Ca^{2+} current or IP_3 production, but intracellularly applied IP_3 mimicked and occluded the effect of α-SNo. These results suggested that the mechanism regulating IP_3R was targeted directly by α-SNo. Further observations using intracellularly applied Ca^{2+}-binding proteins regulating IP_3R opening or their antibodies, revealed that calcium binding protein 1 (CaBP1), but not calmodulin, was the key molecule involved with Ca^{2+}-induced Ca^{2+} release from IP_3 during spike trains mediated by α-SNo. Taken together, these findings revealed that α-SN oligomers hamper CaBP1-mediated inactivation of IP_3R and lead to spike-induced Ca^{2+} release from IP_3R without upregulating IP_3. This aberrant machinery may result in mitochondrial Ca^{2+} burden and be the molecular basis for neuronal vulnerability in PD/DLB.

Abstract: Lipids are abundantly present in the brain and play a critical role in its functioning. However, their involvement in neurodegenerative diseases is unclear. Recently parkin, a ubiquitin ligase whose mutations are causative of recessive Parkinson’s disease (PD), was shown to regulate brain lipid metabolism by modulating expression of CD36 (a fatty acid (FA) receptor) in the brain. Functionally, lipoprotein lipase (LPL-a rate limiting enzyme involved in FA

metabolism), is closely linked to CD36. Given this close functional link between CD36 and LPL in FA metabolism, we hypothesized that parkin may play a role in regulating brain LPL level. Accordingly, we explored the potential parkin-LPL link, with the view to understand its role in PD pathogenesis.
Using both parkin-deficient and parkin over-expression systems, we demonstrate that parkin indeed regulates LPL expression and this effect is consistent even at the transcript levels. Interestingly, this parkin mediated LPL regulation was independent of parkin's catalytic activity. Furthermore, our efforts to delineate the functional implications of parkin-LPL nexus demonstrated that lipid droplets (LDs- lipid rich intracellular organelles that regulate the storage and hydrolysis of neutral lipids) are significantly lower in parkin and LPL overexpressing cells in a toxin (rotenone) induced PD model. Given the extracellular role of LPL in mediating triglyceride hydrolysis and FA accumalation, this finding is indeed intriguing, and is suggestive of a novel intracellular role for LPL. Additionally, a significant increase in mitochondrial perimeter is observed in these cells, suggestive of a mitochondrial fusion phenotype in response to toxin-induced stress. Taken together, our results suggest a novel relationship between parkin and LPL. At the same time, our results also suggest a mechanism for the parkin-LPL nexus in the reduction of LDs via its effect on α-synuclein levels and subsequent mitochondrial fusion as a response to LD reduction.

Title: Lipid induced relief of N terminal mediated autoinhibition of ATP13A2/PARK9.

Authors: *S. VAN VEEN[1], S. MARTIN[1], T. HOLEMANS[1], C. VAN DEN HAUTE[2], V. BAEKELANDT[2], P. VANGHELUWE[1];
[1]Cell. and Mol. Med., [2]Dept. of Neurosciences, KU Leuven, Leuven, Belgium

Abstract: ATP13A2/PARK9 is a lysosomal P-type transport ATPase of unknown function which has been implicated in Parkinson's disease (PD) and Kufor-Rakeb syndrome, an early-onset atypical parkinsonism. Interestingly, ATP13A2 confers protection against α-synuclein, Mn^{2+} and Zn^{2+} toxicity in various model organisms. Recently, we demonstrated that ATP13A2 undergoes auto-phosphorylation like other P-type ATPases, which can be stimulated by the lipids phosphatidic acid (PA) and phosphatidyl inositol (3,5) bisphosphate (PI(3,5)P2) by interacting at the N-terminus. Our biochemical analysis further showed that ATP13A2 resides in an inactive conformation and awaits activation by PA and PI(3,5)P2. In SHSY5Y neuroblastoma cells ATP13A2 activity is required to provide protection in conditions of mitochondrial stress (rotenone/MPP+) and heavy metal (Mn^{2+}, Zn^{2+}, Fe^{3+}) toxicity. However, when the formation of PA and PI(3,5)P2 is inhibited, the protective effect of ATP13A2 is abolished. This indicates that in cells ATP13A2 also resides in an inactive state, pending lipid-dependent activation during specific stress conditions.
To further test this model, we generated stable SHSY5Y cell lines expressing WT ATP13A2 or mutants of the three putative N-terminal lipid binding sites (LBS1-3). At the biochemical level, the LBS mutants lost the ability to auto-phosphorylate and are considered to be catalytically dead. Consequently, the LBS mutants failed to protect against both mitochondrial and metal toxicities. In contrast to WT the LBS2 and LBS3 mutants responded poorly to pharmacological inhibition of respectively PI(3,5)P2 and PA formation. Thus, our data support the view that the ATP13A2 N-terminus acts as an auto-inhibitory domain that can be relieved by binding of PI(3,5)P2 to LBS2 and of PA to LBS3. Most interestingly, mutations of LBS2 and LBS3, but not LBS1, exert a dominant negative effect on the endogenous ATP13A2 in SHSY5Y cells. In agreement, purified N-terminal protein fragments of the LBS2/3 mutants stably interact with full length ATP13A2 protein and inhibit ATP13A2 activity. These findings indicate that the dominant negative phenotype of LBS2/3 may result from a direct and stable interaction on an intramolecular inhibitory binding site of ATP13A2.
We conclude that the N-terminus emerges as a key to unlock ATP13A2's lysosomal activity and suggest that the N-terminus may serve as a novel therapeutic target to activate ATP13A2 for reducing metal and mitochondrial toxicity in PD.

Title: ATP13A2/PARK9 protects against mitochondrial stress and metal toxicity by maintaining mitochondrial network functionality.

Authors: *S. MARTIN[1], S. VAN VEEN[1], T. HOLEMANS[1], C. VAN DEN HAUTE[2], V. BAEKELANDT[2], P. AGOSTINIS[1], P. VANGHELUWE[1];
[1]Dept. of Cell. and Mol. Med., [2]Dept. of Neurosciences, KU Leuven, Leuven, Belgium

Abstract: ATP13A2 (PARK9) is a P-type transport ATPase residing in the late endosomes and lysosomes that is implicated in Parkinson's disease (PD)[1]. The function of ATP13A2 remains unknown, yet it plays important roles in cellular homeostasis, underlying a pro-survival phenotype in both *in vitro* and *in vivo* models of PD exposed to heavy metals[1], mitochondrial (mito) toxins as well as alpha synuclein. Previous research demonstrated that ATP13A2 regulates autophagy, exosome biogenesis and mito/lysosomal functionality[1,2]. Recently, we showed that ATP13A2, like other P-type ATPases, undergoes auto-phosphorylation[2]. Moreover, the stress inducible lipids phosphatidic acid (PA) and phosphatidyl inositol (3,5) bisphosphate (PI(3,5)P2) modulate this activity by interacting at the level of the N-terminus, activating ATP13A2 responses[2]. Our biochemical analysis further showed that ATP13A2 resides in an inactive conformation and waits for further activation by PA and PI(3,5)P2[2], potentiating a pro-survival phenotype against various cellular insults and mito dysfunction[2]. Using stable SHSY5Y cell models of ATP13A2 overexpression *vs.* knockdown, we demonstrated a significant role of ATP13A2 in the maintenance of functional mitochondria, compared to control (fluc). Upon exposure to classical PD inducers (*e.g.* rotenone, MPP+, 6-OHDA) or heavy metals (Zinc, Manganese, Iron), we identified a significant protective effect of ATP13A2 on mito membrane potential and ATP output, which correlated inversely with the generation of reactive oxygen species (ROS). This ATP13A2-mediated protective effect was directly related to ROS, as its removal by the addition of anti-oxidants quenched the phenotype. Upon blockage of the functionality of the lysosomes by the addition of bafilomycin, we observed a re-sensitization of ATP13A2 overexpression towards mito toxicity and subsequent cell death. Moreover, in ATP13A2 knockdown cells we observed an increase of the mito unfolded protein response (HSP60, CHOP, CEBPβ), under both basal and rotenone-induced stress conditions, that was diminished by ATP13A2. Finally, using ATP13A2 loss-of-function patient-derived fibroblasts, we recapitulated our findings generated in the SHSY5Y cell models. In conclusion, our results provide further validity for the role of ATP13A2 in mito homeostasis and emphasize the importance of ATP13A2 activating compounds for PD prevention and protection. **References** 1. Title: Cloning the n27 dopamine cell line to improve a cell culture model of parkinson’s disease

Authors: *L. GAO;
Shanghai Med. School, Fudan Univ., Shanghai City, China

Abstract: Parkinson’s disease is the second most common neurodegenerative disease characterized by the death of dopamine neurons in the substantia nigra. To understand the molecular mechanisms of the disease, an *in vitro* model is important. In the 1990’s, we developed a dopaminergic cell line named as N27 cells from fetal rat mesencephalic dopamine neurons immortalized with the SV40 large T antigen. Because the original N27 cell line has been passaged many times, the line has become a mixture of cell types expressing highly variable levels of tyrosine hydroxylase (TH), a primary phenotypic marker for dopamine neurons. In this study, we performed multiple rounds of cell clonal cultures and finally identified a clone expressing high level of TH and dopamine transporter (DAT). Nearly 100% of cells in this purified N27 cells express TH, DAT and Tuj1. Western blot also confirmed that the purified N27 cells had three to four times level of TH and DAT than unpurified N27 cells. In addition, the purified N27 cells also express transcription factors of authentic dopamine neurons, such as Nurr1, En1, FoxA2 and Ptx3. As a dopaminergic cell line, the purified N27 cells were more sensitive to 6-hydroxydopamine induced toxicity as compared to unpurified N27 cells, while both cells had similar response to hydrogen peroxide induced toxicity. We conclude this purified N27 cells express high levels of dopamine neuron markers, which should provide an improved *in vitro* model for Parkinson’s research.

Abstract: Patient-derived primary dermal fibroblasts are accessible peripheral cells that recapitulate the Parkinson's disease (PD) chronological and epigenetic aging history, and provide a useful system to study the disease. Here, we utilized dermal fibroblasts from late onset sporadic PD and age-matched control patients, and systematically examined the morphology, growth dynamics, response to stress, as well as mitochondrial and autophagy-related function of these cells. It was found that fibroblasts from PD patients were significantly ($p<0.05$) smaller and more circular than control cells. In terms of growth dynamics, PD fibroblasts grew faster and showed higher cell density at time of passage relative to the control cells. In addition, PD cells showed specific patterns of spatial organization in culture, which were different from control fibroblast lines. When the response of the fibroblasts to ultraviolet radiation (specifically UVA)-induced stress was examined, higher reactive oxygen species (ROS) production, particularly mitochondrial ROS (MitoSOX™ Red assay), was observed in PD cells compared to controls. To further analyze this effect, we subjected the PD and control lines to a mitochondrial stress test using the Seahorse Mito Stress Kit and Extracellular Flux analyzer. Preliminary data indicate that in comparison to control fibroblasts, respiratory control rate (RCR), proton leak, and coupling efficiency were negatively altered in the cells from individuals diagnosed with PD. Furthermore, given that increased expression of alpha-synuclein (α-syn), a substrate of autophagy, was observed in PD fibroblasts via immunocytochemistry, we analyzed specific autophagy marker proteins (LAMP1, p62, LC3-I, LC3-II) via immunoblot analysis. Preliminary data from these experiments suggest that autophagy may be impaired in the PD cells relative to controls. Currently, mitochondrial dynamics and autophagy function are further being analyzed in the patient cells. In summary, these studies indicate that patient-derived primary skin fibroblasts can act as a powerful model to study sporadic PD, and glean insights into mechanisms underlying the PD pathogenesis.

Title: Anterior cerebellar degeneration impairs feedforward control in spinocerebellar ataxia type 6

Authors: *N. KANG, D. E. VAILLANCOURT, A. CASAMENTO-MORAN, S. H. SUBRAMONY, E. A. CHRISTOU;
Univ. of Florida, Univ. of Florida, Gainesville, FL

Abstract: The cerebellum has been implicated with both feedforward and feedback motor control. Spinocerebellar ataxia type 6 (SCA6), is a genetic disorder that results in the loss of Purkinje cells in the cerebellum, and loss of pyramidal track cells in the motor cortex. The purpose of this study was to investigate whether cerebellar degeneration in SCA6 influences the control of tasks that are primarily controlled by feedforward or feedback process. Fifteen individuals diagnosed with SCA6 performed fast goal-directed (feedforward) or constant force (feedback) isometric contractions with ankle dorsiflexion. Surface electromyography (EMG) and single and multi-motor unit recordings were recorded from the tibialis anterior muscle during the tasks. Moreover, we collected diffusion magnetic resonance imaging data to quantify free-water accumulation and free-water corrected fractional anisotropy in the cerebellar cortex and cerebellar peduncles, in order to examine the relation of the microstructural diffusion with force control, EMG burst activity, motor unit firing properties, and ataxia clinical assessments. Three novel findings were identified: (a) during the feedforward force control task, the SCA6 patients exhibited higher force error as well as greater EMG burst in the tibialis anterior than age-matched healthy controls (n = 9), (b) during the feedback force control task, there was no significant difference in force control and motor unit discharge rate properties between the SCA6 and control groups, and (c) elevated free-water values in the dentate, cerebellar peduncles, cerebellar lobules I-VI, vermis were found in the SCA6 group. Greater free-water in the lobule I-IV was associated with greater force error during feedforward motor control and more severe ataxia. These findings indicate that the anterior cerebellum degeneration that occurs with SCA6 interferes with feedforward motor control but not with feedback motor control.

Title: Combining Atm and Wrn deficiencies in mice leads to cerebellar deterioration

Authors: *O. BIHARI[1], N. KAMINSKY[2], R. GALRON[2], B. F. JOHNSON[4], E. PIKARSKY[5], Y. SHILOH[3], A. BARZILAI[2];

Med., Univ. of Pennsylvania, Philadelphia, PA; [5]Immunol. and Cancer Res., Hebrew University-Hadassah Med. Sch., Jerusalem, Israel

Abstract: The primary cause of Ataxia Telangiectasia (A-T) is *ATM* mutations. The ATM protein is a multifunctional, homeostatic protein kinase with a major role in maintaining genome stability, primarily in the response to DNA double-strand breaks (DSBs). It is still unclear which ATM functions are those whose loss leads to the major symptom of A-T - cerebellar atrophy. We suggest that a critical function of ATM in this regard is its involvement in many DNA repair pathways and other aspects of genome stability. The loss of this ATM function might be particularly deleterious to the ability of Purkinje neurons to cope with excessive wear and tear on their DNA due to the unique combination of their high metabolic activity, special chromatin organization, and finite non-regenerative state. In this scenario, the critical DNA lesions are those formed during ongoing DNA transactions or induced by endogenous oxygen radicals, with DSBs having a minor share in the broad spectrum of this DNA damage.
We are using mouse models to substantiate this contention. The cerebellar abnormalities observed in *Atm*-knockout (*Atm*-KO) mice are extremely mild over the lifetime of this mouse model. However, it does enable examining additional pressure on genomic stability that might enhance the deterioration of the Atm-deficient cerebellum and make it visible within the animal's life span. Presuming that this could be abrogation of the response to the ongoing damage and aberrations of the DNA, we combined a *Wrn* null allele with Atm loss. *Wrn* encodes the murine ortholog of the human gene, *WRN*, which is mutated in the premature aging disease,

Werner syndrome (WRN) . Wrn is a bifunctional helicase/nuclease that is involved in numerous DNA transactions and DNA repair mechanisms and in the resolution of non-canonical DNA structures. *Wrn*-knockout (*Wrn*-KO) mice were reported to show no discernible phenotype. Notably, the double-knockout genotype (*Atm*-/-//*Wrn*-/-) turned out to be embryonic lethal. A viable genotype of particular interest is *Atm*-/-//*Wrn*+/-, in which a mere heterozygosity at the *Wrn* locus is added to Atm loss. Other than premature aging signs, such as early graying, cracked skin and kyphosis, these animals exhibit neuromotor dysfunction from one year of age. Histopathological examination revealed various degrees of cerebellar degeneration, with atrophy in both the neuronal cell layer and supporting astroglia. Importantly, Purkinje neurons were deformed, with heteropycnotic nuclei. This mouse model is being further developed using conditional *Atm* ablation in the CNS combined with *Wrn*-KO. This mouse is likely to provide a much needed animal model of the degenerating ATM-deficient cerebellum.

Title: An miRNA-mediated therapy for SCA6 blocks IRES-driven translation of the CACNA1A second cistron

Authors: *Y. MIYAZAKI[1], X. DU[1], S.-I. MURAMATSU[2], C. GOMEZ[1];
[1]Dept. of Neurol., The Univ. of Chicago, Chicago, IL; [2]Div. of Neurol., Jichi Med. Univ., Shimotsuke, Japan

Abstract: Spinocerebellar ataxia type 6 (SCA6) is a dominantly-inherited neurodegenerative disease characterized by slowly progressive ataxia and Purkinje cell degeneration. SCA6 is attributable to a polyglutamine repeat expansion within a second *CACNA1A* gene product, α1ACT. α1ACT expression is under the control of an internal ribosomal entry site (IRES) present within the *CACNA1A* coding region. While SCA6 allele knock-in mice show indistinguishable phenotypes from wild-type littermates even at late phase, expression of SCA6-associated α1ACT ($\alpha1ACT_{SCA6}$) driven by Purkinje cell-specific promoter in mice produces slowly progressive ataxia and cerebellar atrophy. Here, we used *CACNA1A* IRES-driven $\alpha1ACT_{SCA6}$ expression by an adeno-associated virus (AAV)-based gene delivery system to develop an early onset ataxia model with a more pronounced phenotype, more suitable for testing *CACNA1A* IRES-targeted potential therapies. AAV9-mediated somatic gene transfer of *CACNA1A* IRES-driven $\alpha1ACT_{SCA6}$ caused expression throughout mouse brain and cerebellum. Mice expressing AAV9-delivered *CACNA1A* IRES-driven $\alpha1ACT_{SCA6}$ exhibit an early onset ataxia, motor deficits, and Purkinje cell degeneration in cerebellum from early age. We also found miR-3191-5p targeting *CACNA1A* IRES preferentially blocks the *CACNA1A* IRES-driven translation of α1ACT in an Argonaute (Ago) protein-4-dependent manner. miR-3191-5p bound to Ago4 selectively inhibits the translational initiation of α1ACT by eukaryotic initiation factors, eIF4AII and eIF4GII, which directly act on *CACNA1A* IRES to enhance α1ACT translation. Furthermore, AAV9-mediated delivery of miR-3191-5p protects from the ataxia, motor deficits, and Purkinje cell degeneration caused by *CACNA1A* IRES-driven $\alpha1ACT_{SCA6}$ in mice. Our results establish the proof of principle that therapeutic intervention with viral delivery of a disease-specific miRNA rescues SCA6 phenotypes in a mouse model that expresses *CACNA1A* IRES-driven $\alpha1ACT_{SCA6}$.

Title: 4-Aminopyridine alleviates ataxia and reverses cerebellar cortical output deficiency in a mouse model of spinocerebellar ataxia type 6

Authors: *S. JAYABAL[1,2], H. CHANG[3], K. E. CULLEN[3], A. J. WATT[1];
[1]Dept. of Biol., [2]Integrated Program in Neurosci., [3]Dept. of Physiol., McGill Univ., Montreal, QC, Canada

Abstract: Spinocerebellar ataxia type 6 (SCA6) is a mid-life onset progressive neurodegenerative disease that affects motor coordination and gait and has no known treatment. This autosomal dominant disease is caused by a CAG repeat expansion in the *CACNA1A* gene; most affected people have only one copy of the mutated gene. Here to evaluate the role of cerebellar Purkinje cell firing in SCA6 pathophysiology, we studied a hyperexpanded (84Q) mouse model of SCA6.

Purkinje cell firing was first measured non-invasively with extracellular recordings in acute slices made from heterozygous $SCA6^{84Q/+}$ mice at an age when motor coordination deficits were observed (19 months). We found reduced spike timing precision compared to litter-matched wildtype (WT) cells, reflected in an enhanced coefficient of variation (CV) of interspike intervals ($P = 0.0047$) without a significant change in firing rate ($P = 0.071$). Then to determine whether homozygous $SCA6^{84Q/84Q}$ mice, which develop motor deficits earlier (7 months) are a good model for SCA6, we measured Purkinje cell firing properties from acute slices of 7-month old cerebellum. Homozygous $SCA6^{84Q/84Q}$ Purkinje cells also displayed reduced spike timing precision compared to age-matched WT cells ($P < 0.0001$), suggesting that homozygous mice are a good and practical model for SCA6.

Since the FDA-approved potassium channel blocker 4-aminopyridine (4-AP) has been shown to improve ataxia and Purkinje cell firing abnormalities in mouse models of other forms of ataxia, we acutely applied 4-AP to $SCA6^{84Q/84Q}$ Purkinje cells in acute slices and found that it improved spike timing precision ($P = 0.003$) without affecting firing rate ($P = 0.15$). To determine if 4-AP might alleviate ataxia in SCA6 mice, we provided 4-AP in drinking water to 7-month-old $SCA6^{84Q/84Q}$ and WT mice. 4-AP produced a significant partial rescue of motor coordination in $SCA6^{84Q/84Q}$ mice after a week ($P < 0.0001$), without affecting WT motor performance. This improvement lasted as long as we tested (up to 3 months). Finally, to add further support to our hypothesis that changes in Purkinje cell firing contribute to disease onset in SCA6 mice, we completed *in vivo* single unit recordings, and found that spike timing precision was indeed reduced in untreated $SCA6^{84Q/84Q}$ mice ($P = 0.04$); it could then be rescued to WT levels following 2 weeks of chronic 4-AP (not significantly different from WT, $P = 0.21$), without significant changes in firing rates ($P > 0.05$). Taken together, our results provide a novel therapeutic approach for the treatment of SCA6 with 4-AP.

Res. Inst. (ICVS), Univ. of Minho, Braga, Portugal; [5]Degenerative Processes, Stress and Aging, Univ. Paris Diderot, Paris, France

Abstract: Spinocerebellar ataxia type 3 (SCA3) or Machado-Joseph disease (MJD) is an autosomal-dominantly inherited neurodegenerative disorder caused by a CAG expansion in the *ATXN3* gene leading to a polyglutamine expansion in the encoded ataxin-3 protein. Characteristic for SCA3 and other polyglutamine diseases are the so called neuronal intranuclear inclusion bodies (NII). As ataxin-3 is predominantly located in the cytoplasm, the formation of protein aggregates in the nucleus require a nucleocytoplasmic shuttling of ataxin-3. We demonstrated *in vivo* that the toxicity of expanded ataxin-3 depends on its intracellular localization: While nuclear ataxin-3 gave rise to a strong phenotype in transgenic mouse models with a high number of protein aggregates, purely cytoplasmic ataxin-3, however, even with a highly expanded polyglutamine repeat, was not able to induce a phenotype and even did not aggregate. We further identified and characterized intracellular transport signals (two nuclear export signals, NES, and one nuclear localization signal, NLS) within the coding sequence of ataxin-3. Therefore, it is evident that proteins involved in the nucleocytoplasmic transport machinery recognize these localization signals, control the intracellular localization of ataxin-3, thereby influence the toxicity and aggregation of ataxin-3 and, thus, the pathogenesis of SCA3. We now identified a transport protein which is critically involved in the nucleocytoplasmic

shuttling of ataxin-3 and impacts typical pathogenic mechanisms of SCA3 (like the formation of aggregates) as well as the phenotype induced by expanded ataxin-3. While the overexpression of this protein moved ataxin-3 into the nucleus, its downregulation kept it out of the nucleus. We replicated this correlation *in vivo* in *Drosophila* and observed a clear link between the intracellular localization of ataxin-3 and its toxicity i.e. its ability of induce neurodegeneration and a behavioral phenotype. Likewise we even confirmed in a mouse model of SCA3 the importance of the identified transport protein as its knockout largely prevented ataxin-3 from aggregating and alleviated behavioral and movement deficits. Our results demonstrate that transport proteins are involved in the intracellular localization of ataxin-3 and the neurodegenerative processes in SCA3. The insights into the mechanisms behind the intracellular transport of ataxin-3 give us clues into the pathogenic functions of expanded ataxin-3 and ways to mediate the progression of neuronal degeneration in SCA3 patients.

Title: ASO-mediated reduction of ATXN2 expression after motor phenotype onset in SCA2 mice restores cerebellar Purkinje cell electrophysiological phenotypes

Authors: *D. R. SCOLES[1], P. MEERA[2], M. SCHNEIDER[1], K. FIGUEROA[1], F. RIGO[3], F. BENNETT[3], T. OTIS[2], S. PULST[1];
[1]Dept. of Neurol., Univ. of Utah, Salt Lake City, UT; [2]Univ. of California Los Angeles, Los Angeles, CA; [3]Ionis Pharmaceuticals, Carlsbad, CA

Abstract: Spinocerebellar ataxia type 2 (SCA2) is caused by CAG repeat expansion in the ATXN2 gene resulting in polyglutamine expanded ATXN2 protein and pathogenic gain of toxic function. By screening 152 antisense oligonucleotides (ASOs) targeting ATXN2 we identified

ASO7 that lowered ATXN2 expression with long lasting effects without toxicity. We have characterized two SCA2 animal models, one expressing ATXN2-Q127 in Purkinje cells (PCs), the other a BAC-ATXN2-Q72 (Hansen et al., 2013, Dansithong et al., 2015). **Objective:** To demonstrate that lowering ATXN2 expression modifies the motor phenotypes of two SCA2 mouse models and to compare the ASO effects between the two mouse models for modifying neurophysiological phenotypes. **Methods:** SCA2 mice were treated by intracerebroventricular (ICV) injection of ASOs. The effects of ASO treatments on motor phenotypes were verified by rotarod testing, cerebellar molecular phenotypes were determined by qPCR, and PC firing frequencies (FFs) were determined by extracellular recordings in acute cerebellar slices. **Results:** Both ATXN2-Q127 mice and BAC-ATXN2-Q72 mice exhibit progressive age-dependent rotarod phenotypes. ATXN2-Q127 mice treated ICV with ASO7 at 8 wks of age had a significantly improved rotarod performance at 18 weeks of age vs. saline treated control mice (n=15 mice per group, $P<0.01$). At the endpoint, PC FFs were 16±1 Hz for saline treated mice, and 42±2 Hz for ASO7 treated mice (mean±SEM, per group n=2 mice, 102-107 neurons. $P<0.001$), which is similar to age-matched wildtype mice. For BAC-ATXN2-Q72 mice injected with ASO7 at 8 wks of age, we also observed a significantly improved rotarod performance at 18 weeks of age vs. saline treated mice (n=11-14 mice per group, $P<0.01$). BAC-ATXN2-Q72 mice have no PC FF phenotype until age 24 wks. Therefore, to evaluate the effect of ASO7 on BAC-ATXN2-Q72 mice we injected mice at age 30 wks, well after motor phenotype onset, and evaluated PC FFs at age 40 wks. We observed PC FFs of 49±1 Hz for ASO7 treated mice and 36±1 Hz for saline treated mice (mean±SEM, per group n=3-4 mice, 134-148 neurons. $P<0.001$). In both models, ASO7 engaged the target well resulting in reduction of hATXN2 by up to 80%. **Conclusions:** A single treatment of ASO7 lowered ATXN2 expression resulting in restoration of PC FF even well after onset of SCA2 mouse motor phenotype and significantly improved the rotarod phenotype in both mouse models.

Title: The role of alpha1ACT in the early stage development of the cerebellum

Authors: *X. DU, C. GOMEZ;
Univ. Chicago, Chicago, IL

Abstract: The spinocerebellar ataxia 6 (SCA6) gene, *CACNA1A*, encodes two proteins: the calcium channel, α1A, and α1ACT, a novel transcription factor. α1ACT is critical for neurite outgrowth and cerebellar cortical development by coordinating expression of Purkinje cell genes in concert with α1A and bears an expanded polyQ in SCA6. Using RNA-seq, the global gene expression profile of α1ACT revealed that there were 166 and 717 differentially expressed transcripts in PC12 cells over-expressing α1ACT at 6 hrs and 10 days, respectively. Additionally, 39 common differentially-expressed genes were identified over 4 time points. Furthermore, ChIP-seq and RNA-seq analysis revealed an enrichment of α1ACT binding around transcription start sites and a positive correlation between α1ACT genomic occupancy and the expression of many associated genes. Gene ontology and network analysis further demonstrated that differing functions of the identified specific genes were associated with neurogenesis and neuronal differentiation in early time points, and cell cycle in late time points. Using animal models we found that a humanized exon-47 mouse *CACNA1A* allele was a hypomorph, and mice bearing a second null *CACNA1A* allele (KIKO) had delayed cerebellar development, decreased survival, and impaired motor behaviors before 12 months old of age. Transgenic expression of α1ACT in KIKO background (KIKO/PC-α1ACT) restored cerebellar development, increased survival, and improved the impaired motor behavior. The α1ACT target gene expression was decreased in KIKO mice but restored in KIKO:PC-α1ACT mice, suggesting that α1ACT directly regulates genes important for orchestrating early postnatal stages of neural development. Absence or delay of α1ACT expression leads to dysregulated expression of common target genes and cerebellar development in the mouse model. These results reveal time-dependent expression profiles for α1ACT in global transcriptional regulation and have implications for understanding mechanisms underlying function of α1ACT *in vitro* and *in vivo* relevant to developing therapies for SCA6.

Title: Early cerebellar mitochondrial deficits in a frataxin-deficient mouse model of Friedreich's ataxia

Authors: *H. LIN[1], C. LAO-PEREGRÍN[2], E. M. CLARK[3], Y. DONG[1], A. J. RATTELLE[1], J. MAGRANÉ[2], D. R. LYNCH[1,3];
[1]Neurol. and Pediatrics, The Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Weill Cornell Med. Col., New York, NY; [3]Perelman Sch. of Med. Univ. of Pennsylvania, Philadelphia, PA

Abstract: Frataxin is a highly conserved small mitochondrial protein crucial for iron-sulfur cluster formation and ATP production. Frataxin deficiency in Friedreich's ataxia (FRDA) causes a complex neurological and pathological phenotype of peripheral and central nervous systems. Postmortem studies show degeneration of the cerebellum within dentate nucleus in FRDA patient brain samples. However, the contribution of mitochondrial pathophysiology in cerebellar degeneration of FRDA at early stage of disease remains largely uncharacterized. Here we report early cerebellar mitochondrial deficits at presymptomatic ages in a frataxin-deficient FRDA mouse model, frataxin knockin/knockout (*KIKO*) mice. In *KIKO* double transgenic mice expressing the fluorescent protein Dendra targeted to mitochondria in neurons (*mitoDendra-KIKO)*, while the cerebellar levels of frataxin were significantly reduced, the number and levels of mitochondria labeled with Dendra in the cerebellum were significantly decreased compared with control mice at presymptomatic ages. The levels of mitochondrial respiration chain complex II protein succinate dehydrogenase subunit A (SDHA) and mitochondrial heat shock protein mortalin/GRP75 were also significantly reduced in the cerebellum of *KIKO* and *mitoDendra-KIKO* mice compared with control mice at presympotmatic ages. More interestingly, the levels of mitochondrial biogenesis master regulator PGC-1α and mitochondrial fusion protein mitofusin were markedly reduced in the cerebellum of *KIKO* and *mitoDendra-KIKO* mice at presymptomatic ages, suggesting that frataxin deficiency may lead to disruption of cerebellar mitochondrial biogenesis and network at early stage of disease in FRDA. Our findings thus demonstrate early cerebellar mitochondrial deficits in a FRDA mouse model, which may contribute to progressive ataxia that could be reversible by restoring frataxin or mitochondria integrity in FRDA patients.

Title: ATM kinase activity is required to maintain mitochondrial integrity

Authors: *R. P. HART[1], H. CHOW[2], K. HERRUP[2];
[1]Rutgers Univ., Piscataway, NJ; [2]Hong Kong Univ. of Sci. and Technol., Clearwater Bay, Hong Kong

Abstract: Ataxia-telangiectasia (A-T) is one of the most prominent inherited neuropathological disorders caused by defects in the DNA damage response (DDR) pathway. While neurodegeneration in A-T has been attributed to defective DDR or to epigenetic regulation, recent reports on the role of ATM in redox signaling also suggest enhanced oxidative stress and reduced anti-oxidative defense may contribute to the neurodegenerative phenotype. We have previously reported a missense mutation 7181C>T which translates to an ATM S2394L protein variant, which exhibited little or no ATM kinase activity. This variant was identified in induced pluripotent stem cells (iPSC) derived from an A-T subject having later-onset, milder symptoms. Together with an unaffected single nucleotide polymorphism (SNP), which translates to an ATM L2037F protein and is hypothesized to have a protective effect in neurodegeneration, we tested effects of each variant on mitochondrial integrity. Our preliminary data show that when overexpressed in $ATM^{-/-}$ mouse astrocytes, ectopic expression of the S2394L mutant protein resulted in enhanced mitochondrial oxidation, fragmentation, and loss of mitochondrial potential; whereas expression of the L2037F mutant showed the opposite effect. Similar experiments in A-T iPSC-derived human neurons will extend these results to a neuronal background. These results suggest that functional ATM kinase activity is indispensable for the maintenance of mitochondrial structure and function.

Title: Dysfunction of mGluR1 signaling as a potential cause for ATX2-mediated purkinje neuron death in a spinocerebellar ataxia 2 mouse model

Authors: *P. MEERA[1], S. M. PULST[2], T. S. OTIS[1];
[1]Neurobio., Univ. of California Los Angeles, Los Angeles, CA; [2]Neurol., Univ. of Utah, Salt Lake City, UT

Abstract: Spinocerebellar ataxia 2 (SCA2) is an autosomal dominant neurodegenerative disorder, characterized by progressive ataxia and cerebellar atrophy, affecting primarily cerebellar Purkinje neurons (PNs) and is caused by an expansion of triplet CAG repeats (>31 triplet repeat) in the Ataxin 2 (ATXN2) gene coding region. In our earlier work, we performed a detailed characterization of the SCA2 mouse model generated by the Pulst laboratory, where full length ATXN2-Q127 was expressed under the control of a PN specific promoter (SCA2-Q127, Hansen, Meera et al., 2013). Here, we explore molecular mechanisms that underlie SCA2 pathophysiology in this SCA2-Q127 mouse model using simultaneous electrical recording and Ca^{2+} imaging. Using two photon microscopy and the Ca^{2+} dye Oregon Green BAPTA 1(OGB1), loaded into the PNs with the recording pipette, we find that the basal Ca^{2+} levels in PNs of SCA2 mice are increased when compared to WT PNs. To further elucidate potential mechanisms of SCA2 pathology, we focused on mGluR1-mediated signaling. The mGluR1 agonist DHPG leads to an age-dependent progressive increase in SCA2 PN firing frequency with only minimal effects on WT PNs. We also show that Parallel Fiber (PF)-mediated mGuR1 Ca^{2+} signals are dramatically and progressively enhanced in SCA2-Q127 mice. We further show that synaptic mGluR1 EPSCs are determined by internal free [Ca^{2+}]. Clamping [Ca^{2+}] close to 100 nM leads to indistinguishable EPSCs both in WT and SCA2 and raising internal Ca^{2+} close to 500 nM increases peak mGlur1 EPSCs in WT, similar to those found in SCA2. These findings support our overarching hypothesis that a key aspect of SCA2 pathology involves positive feedback between elevated basal Ca^{2+} and mGluR activity. Ca^{2+} elevations are known to potentiate mGluR function in PNs, suggesting that chronically elevated Ca^{2+} levels caused by hyperactive IP3Rs could lead to enhanced mGluR function. Such changes would be expected to exacerbate the elevated Ca^{2+}, and possibly lead to decreased firing frequency through the activation of SK channels, and eventually contribute to PN death. This PN cell loss likely leads to cerebellar circuit dysfunction responsible for the behavioral signs of ataxia characteristic of the disease.

Abstract: Spinocerebellar ataxia type 3 (SCA3) is a progressive, fatal neurodegenerative disorder caused by a repeat expansion of the trinucleotide sequence CAG encoding the amino acid glutamine. In SCA3, the mutant polyglutamine expansion occurs in the gene ATXN3 encoding the deubiquitinating enzyme ATXN3. Currently there is no effective treatment or cure for SCA3. Given the still limited understanding of specific pathogenic processes leading to neuronal loss, disease protein-lowering strategies have emerged as a powerful potential therapeutic strategy to prevent or slow genetic neurodegenerative diseases through targeted suppression of mutant protein expression. Here we tested target engagement and potential toxicity of antisense oligonucleotides (ASOs) targeting human ATXN3 in two transgenic mouse models of SCA3, the YACQ84.2 model expressing the full human disease gene with 84 CAG repeats and the CMV-MJDQ135 model expressing the human ATXN3 cDNA with 135 CAG repeats. Anti-ATXN3 ASOs were administered via a unilateral intracerebroventricular bolus injection. Histological analysis confirmed widespread delivery of ASOs throughout the brain, including regions highly affected in SCA3 such as pontine nuclei and deep cerebellar nuclei, with no evidence of ASO toxicity at effective doses. ASO candidates achieved knockdown of mutant ATXN3 in cervical spinal cord, cerebellum, brainstem and forebrain by western blot and histochemical analysis four weeks following delivery, and one ASO exhibited even greater

ATXN3 knockdown at 8 weeks post operation. We are currently further investigating ASOs in both mouse models and in a novel SCA3 disease-specific human embryonic stem cell line and derived neuronal populations. Our results demonstrate that an ASO strategy to reduce mutant ATXN3 levels effectively lowers ATXN3 in relevant tissues.

Title: Impact of ataxin-1 expression during postnatal cerebellar Purkinje neuron development and the role of metabotropic glutamate receptor type 1 for progression of SpinoCerebellar Ataxia Type 1

Authors: ***E. M. POWER**, M. F. IBRAHIM, R. M. EMPSON;
Dept. of Physiol., Univ. of Otago, Dunedin, New Zealand

Abstract: Spino-cerebellar ataxia type 1 (SCA1) is an incurable, autosomal dominant neurodegenerative motor disorder resulting from a CAG trinucleotide expansion of ataxin-1. In this study, we use a conditional transgenic mouse model of SCA1, where the CAG repeat expansion is restricted to cerebellar Purkinje neurons (PNs) and can be repressed via administration of doxycycline (doxy) in the food.

SCA1 mice exhibited a disruption of motor performance on the accelerating rotarod compared with controls at six weeks of age (two-way-ANOVA, $F_{1,25} = 5.78$, $P < 0.024$), and as the disease progresses motor performance becomes further impaired. However, when mutant ataxin-1 is repressed via doxy for the first 6 weeks of life there is a marked improvement in motor performance, compared to WT, up to 24 weeks of age (2-way-ANOVA, $P=0.071$, $F_{1,29} = 3.50$). This highlights the impact of mutant ataxin-1 expression during early postnatal cerebellar PN development.
PNs from pre-symptomatic doxy treated SCA1 mice at 12 weeks of age (Doxy administration in utero and for the first 6 weeks of life) exhibited intact dendritic morphology (Sholl analysis) (two-way-ANOVA $F_{96, 1536} = 2.36$, $P < 0.0001$) and normal phasic firing (one-way-ANOVA, $F_{2, 36} = 17.73$, $P < 0.0001$) when compared with PNs from 12 week SCA1 and WT doxy treated mice. The PNs did however demonstrate a significantly lengthened Parallel fibre evoked mGluR1-dependent current (one-way-ANOVA $F_{2,15} = 6.75$, $P = 0.008$) that may arise from early loss of the PN glutamate transporter EAAT4 occurring at 3 weeks of age in these SCA1 mice. Our results emphasize the importance of early intervention to prevent the progression of SCA1 and highlight mGluR1 receptors as a potential target for future therapies.

Abstract: Friedreich's ataxia (FRDA) is a rare recessive genetic disorder caused by a trinucleotide repeat expansion in the frataxin gene (FXN), which results in FXN deficiency. We studied gene expression profiles in peripheral blood in 392 patients, 217 carriers, and 80 controls, the largest FRDA cohort ever collected. Rich phenotypic data is available for most of

these subjects, and longitudinal data is available for a subset. Data analysis included correlation with expansion length, differential expression, network analysis, and machine learning approaches. We identified a robust peripheral signature associated with disease which partially overlaps with published datasets from both human FRDA patients and animal models of frataxin deficiency. A subset of transcripts showed longitudinal changes over time. Enriched ontologies and pathways in our signature included protein translation, mitochondrial metabolism, inflammation and cell stress. These findings will contribute to the identification of biomarkers for use in diagnostics and therapeutics.

Title: ATM is located on synaptic vesicles and its deficit leads to failsures in synaptic plasticity

Authors: *A. CHENG[1], G. VAIL[2], T. ZHAO[1], Y. HAN[2], S. DU[1], M. LOY[1], K. HERRUP[1], M. PLUMMER[2];
[1]HKUST, Kowloon, Hong Kong; [2]Rutgers Univ., New Brunswick, NJ

Abstract: Ataxia-telangiectasia is a multi-systemic disorder that includes a devastating neurodegeneration phenotype. The ATM (ataxia-telangiectasia mutated) protein is well-known for its role in the DNA damage response. Yet ATM is also found in association with cytoplasmic vesicular structures - endosomes and lysosomes as well as neuronal synaptic vesicles. In keeping with this latter association, electrical stimulation of the Schaffer collateral pathway in

hippocampal slices from ATM-deficient mice does not elicit normal long term potentiation (LTP). The current study was undertaken to assess the nature of this deficit. Theta burst-induced LTP was reduced in Atm-/- animals with the reduction most pronounced at burst stimuli that included six or greater trains. To assess whether the deficit was associated with a pre- or post-synaptic failure, we analyzed paired-pulse facilitation and found that it too was significantly reduced in Atm-/- mice. This indicates a deficit in presynaptic function. As further evidence that these synaptic effects of ATM deficiency were presynaptic, we used stochastic optical reconstruction microscopy (STORM). Three-dimensional reconstruction revealed that ATM is significantly more closely associated with Piccolo (a pre-synaptic marker) than with Homer1 (a post-synaptic marker). These results underline how, in addition to its nuclear functions, ATM plays an important functional role in the neuronal synapse where it participates in the regulation of presynaptic vesicle physiology.

Title: A new simple automatic and non invasive method for measurement of chemically induced tremors in rats

Authors: *D. AMRUTKAR, T. A. JACOBSEN, K. S. NIELSEN;
Saniona A/S, Ballerup, Denmark

Abstract: Essential tremor (ET) is regarded as one of the most common neurological disorders with a prevalence similar to or greater than that of stroke, Alzheimer disease, migraine and lumbosacral pain syndromes and is as much as 20 times more prevalent than Parkinson's disease. The incidence of ET increases with advancing age, but it is fairly common in all age groups and almost equal in men and women. Due to lack of understanding of the basic mechanism, origin of tremors and predictive animal models, it is difficult to develop and screen novel pharmacological agents with selective and specific antitremor activity. A new simple method of quantifying harmaline induced tremors in male Sprague-Dawley (SD) rats is described. Tremor activity (shaking movement of fore paws) is detected by movement of small metal band placed on one of the fore limb of the rats. A signal is generated as the band breaks the electromagnetic field of a loop antenna located under the rat and processed through an algorithm that determines tremor

activity using 1) amplitude, 2) zero-voltage crossing, and 3) signal duration. Tremors are summed and stored over a selected collection interval throughout the assay for later analysis as described by Yaksh TL. et al (2000). Harmaline induced significant tremors at 10mg/kg upon intraperitoneal administration. The method is validated by propranolol, diazepam and primidone, drugs used in the clinic to treat ET. The reliability and robustness of the automatic method is confirmed by manual visual assessment. In addition, riluzole, a neuroprotective, sodium channel stabilizer potently and dose-dependently inhibited the harmaline induced tremors as previously shown in the literature. The advantages of the method are: 1) It is less labour intensive as compared to manual evaluation of tremor activity 2) The data can be collected for longer periods of time and 3) The animals are not restrained and can move freely in the glass chamber unlike for instance tremor boxes. A limitation of the method is, that only fore limb tremors are counted and not the whole body tremors. In conclusion, a new simple automatic and non-invasive method for measurement of chemically induced tremors in rats can be useful for developing and screening novel treatment for human movement disorder. Keywords: Tremors, GABA, harmaline

Title: Use of the scale for the assessment and rating of ataxia (sara) in healthy volunteer and subjects with schizophrenia.

Authors: S. SYED[1], N. SHAAFI KABIRI[2], T. BALI[3], D. KARLIN[4], B. BINNEMAN[4], Y. TAN[5], *K. THOMAS[2];
[1]Tufts Med. Center, Pfizer Neurosci. and Pain Res. Unit, Boston, MA; [2]Anat. and Neurobio., Boston Univ. Sch. of Med., Boston, MA; [3]Dept. of Neurol., Massachusetts Gen. Hosp., Boston, MA; [4]Pfizer Neurosci. and Pain Res. Unit, Cambridge, MA; [5]Pfizer Inc. Res. Statistics, Worldwide Res. & Develop., Cambridge, MA

Abstract: Objective: Schizophrenia is associated with soft neurological signs and symptoms, including motor incoordination. The Scale for the Assessment and Rating of Ataxia (SARA) is a semi-quantitative assessment that is used to evaluate impairment level of cerebellar ataxia. The

goal of these studies was to assess the inter-subject variability and inter-rater reliability of SARA in a Healthy Volunteer (HV) group and subjects with Schizophrenia (SCZ).
Methods: Two studies were completed to collect SARA scores, in a HV group and in a stable SCZ group receiving background maintenance atypical antipsychotic monotherapy. The HV study was approved by Schulman Associates Institutional Review Board, Inc., and the SCZ study by Boston University School of Medicine Institutional Review board; both studies conformed to the Declaration of Helsinki. 177 HVs (18-65 years) and 16 SCZs (18-58 years) provided written consent and were assessed using the SARA. Of 177 HV subjects, 88 had test-retest (within 3 days of initial visit) while all 16 SCZ had three test-retest performances (within a 14 days of initial visit).
Results: For the HV group, the mean score for SARA on visit-1 was 0.38±0.70, and 0.34±0.61 for visit-2. The Pearson Correlation Coefficient between visit-1 and visit-2 was 0.686. For the SCZ group, the mean score for SARA on visit-1 was 0.6±0.65, and 0.8±1.19 for visit-2, and 0.8±0.94 for visit-3. The Pearson Correlation Coefficient between visit-1 and visit-2 was 0.655, between visit-1 and visit-3 was 0.663 and between visit-2 and visit-3 was 0.761.
Conclusions: When comparing across these 2 studies, the HV group demonstrated minimal symptoms of ataxia, similar to the SCZ group. The HV group also demonstrated similar inter-subject variability to the SCZ group. Acceptable inter-rater reliability was observed within the HV and SCZ groups respectively.

Title: A CK2 dependent phosphorylation mechanism is required to trigger attacks in an episodic ataxia type 2 mouse model.

Authors: *A. VITENZON, K. KHODAKHAH;
Albert Einstein Col. of Medicince, Bronx, NY

Abstract: Episodic ataxia type 2 (EA2) is a neurological disorder caused by mutations in the *CACNA1A* gene in which patients exhibit transient attacks of severe ataxia and dyskinesia triggered by different stressors such as, physical or emotional stress and caffeine or alcohol consumption. The *tottering* mouse, which carries a spontaneous loss-of-function mutation in the *CACNA1A* gene, is a well-established rodent model of EA2 that, like patients, exhibits motor attacks induced by stress, caffeine and alcohol. Work from our lab and others have shown that the cerebellum plays a critical role in the pathology of EA2. Expressing the human *CACNA1A* mutation only in Purkinje cells (PC) of wild-type mice is sufficient to recapitulate all the symptoms of the disorder, while killing the PCs of *tottering* mice alleviates much of the motor symptoms. Previous work in our lab has shown that the motor attacks in *tottering* mice are correlated with aberrant output from the cerebellum driven by high frequency burst firing of PCs, which normally fire regularly at 50 spikes per second *in vivo*. *CACNA1A* encodes the pore forming subunit of the P/Q type calcium channel ($Ca_v2.1$). The tonic firing pattern of PCs is partially governed by the tight coupling of $Ca_v2.1$ channels to SK2 channels that contribute to the after-hyperpolarization of PCs. It has been shown that block of SK2 channels promotes burst firing of wild type PCs. Thus, we hypothesized that attacks in the *tottering* mice might be a consequence of a further reduction in SK2 activity in PCs. One mechanism by which the activity of SK2 channels is modulated is their phosphorylation. Casein kinase 2 (CK2) is part of a protein complex that resides on the intracellular domains of SK2 channels and phosphorylates the calmodulin associated with SK2 thereby reducing its affinity for calcium, thereby decreasing SK2 channel open probability. We thus explored whether a decrease in the SK channel conductance by its CK2-dependent phosphorylation triggers Purkinje cell burst firing and attacks of dyskinesia in the tottering mice. To test this hypothesis, we used short hairpin RNA (shRNA) to knock down CK2. We find that knocking down CK2 in the cerebellum of *tottering* mice with two different shRNAs is sufficient to prevent attacks induced by stress, caffeine or ethanol. These data suggest that motor attacks in *tottering* mice are triggered by a reduction in SK2 activity by a CK2 dependent phosphorylation mechanism. This finding further delineates the events which mediate the episodic motor attacks in EA2 and opens new potential targets for drug intervention.

Title: Impact of SNX14 mutations on endocytic trafficking and autophagy

Authors: *D. T. BRYANT[1], C. DEMETRIOU[1], E. PESKETT[1], M. ISHIDA[1], M. SEDA[1], D. JENKINS[1], R. SCOTT[2], S. SOUSA[3], M. BITNER-GLINDZICZ[1,2], G. MOORE[1], P. STANIER[1]; [1]Inst. of Child Hlth., Univ. Col. London, London, United Kingdom; [2]Great Ormond Street Hosp., London, United Kingdom; [3]Hosp. Pediátrico de Coimbra, Coimbra, Portugal

Abstract: A large number of conditions have been described where severe intellectual disability and ataxia are found in patients with cerebellar hypotrophy. Individually, most types are rare and without known molecular pathology. Mutations in SNX14 have recently been reported to cause a distinct autosomal-recessive cerebellar ataxia with moderate to severe intellectual disability, early-onset cerebellar atrophy, sensorineural hearing loss and coarsened facial features. Patient-derived fibroblasts were acquired from individuals of three unrelated consanguineous families in Turkey and Portugal. These cell lines have mutations that result in either truncation or loss of the SNX14 protein. The SNX14 protein contains a Phox (PX) domain and a regulator of G protein signalling (RGS) domain. In one patient, loss of a single exon (containing the PX-domain) alone was sufficient to result in the associated pathology. This suggests that the PX domain is critical for normal SNX14 function. SNX14 mutations lead to the accumulation of vesicular inclusions in patient cells, indicating that there is a disturbance in protein metabolism and-/-or vesicle mediated transport. Analysis of cellular processes associated with autophagy provides additional evidence of this. However, the precise function of SNX14 remains unknown. We are currently investigating the precise role of SNX14 in subcellular trafficking by monitoring these processes in cell based models of the disease. Loss of SNX14 appears to impact cholesterol distribution and we are investigating the events leading to this. Additionally, we are examining zebrafish with homozygous null mutations in the snx14 gene to establish it as a research platform with which to explore therapeutic intervention into the neurological deficits associated with the disease.

Title: Simultaneus ablation of polyamine catabolizing enzymes Spermine/Spermidine-N^1-Acetyltransferase and Spermine Oxidase causes cerebellar injury and ataxia

Authors: *M. SOLEIMANI[1], M. BROOKS[1], S. L. BARONE[1], T. MURRAY-STEWART[2], C. DESTEFANO-SHIELDS[2], J. L. CLEVELAND[3], R. A. CASERO[2], K. ZAHEDI[1];
[1]Med., Univ. of Cincinnati Med. Ctr., Cincinnati, OH; [2]Johns Hopkins Sch. of Med., Baltimore, MD; [3]The Moffitt Cancer Ctr. & Res. Inst., Tampa, FL

Abstract: Polyamines, spermidine and spermine, are aliphatic cations with multiple indispensable roles in the regulation of DNA structure, protein-nucleic acid interactions, and cell growth and viability. The cellular content of polyamines is tightly regulated through the balance of their synthesis, degradation, import and export. Catabolism of polyamines is accomplished via their back conversion through the activity of spermine/spermidine-N^1-acetyltransferase (SSAT)/acetylpolyamine oxidase enzyme cascade, and the oxidation of spermine, by spermine oxidase (SMO). The expression of SSAT and SMOX increases in injured tissues and contributes to the induction of organ damage and dysfunction in response to a variety of insults (e.g. ischemia/reperfusion, traumatic and toxic). The importance of polyamine catabolic enzymes and their role in maintenance of tissue polyamine levels under normal conditions is not completely defined. In order to address this, we developed SSAT/SMO double knockout (SSAT/SMOX-dKO) mice. Examination of the SSAT/SMOX dKO mice did not reveal any overt growth or developmental deficits. These mice also have a build up of polyamines in the organs that were examined. The SSAT/SMOX dKO mice begin to develop neural deficits at approximately 3 months of age (average ataxia score of 5.07+/-0.26), while WT, SSAT KO and SMOX KO mice do not show any neural deficits (average ataxia scores of 0.51+/-0.07, 0.86+/-0.17 and 0.66+/-0.12). The comparison of brain and spinal cord histology of WT and SSAT/SMOX dKO mice revealed an increase in the presence of intensely stained contracted nerve cell clusters, and abnormalities (vacuolization) in the granular layer and white matter of the cerebellum. Furthermore, our results show that compared to WT mice, calbindin-1 staining of SSAT/SMOX dKO Purkinje cells is significantly increased. The increase in calbindin-1, in addition to amplified polyamine levels and their established role in the regulation of $[Ca^{2+}]_i$ suggests that there is an increase in $[Ca^{2+}]_i$ flux in SSAT/SMOX dKO mice that is being buffered by increased levels of calbindin-1. Further studies to examine the $[Ca^{2+}]_I$ levels, Lewy Body formation and the excitotoxic effect of polyamine accumulation in SSAT/SMOX dKO animals are underway. The results presented here indicate that polyamine catabolism is important in the maintenance of normal cellular polyamine levels, and that accumulation of polyamines due to the disruption of their catabolism is cytotoxic, especially in nerve cells. These disturbances to the polyamine catabolic pathway manifest with histological alterations in the cerebellum, as well as overt ataxia, in SSAT/SMOX dKO mice.

Title: Progressive impairment of metabotropic glutamate receptor (mGluR)-mediated signaling and cerebellar synaptic plasticity in spinocerebellar ataxia type 1 (SCA1) model mice

Authors: *N. HOSOI[1], A. SHUVAEV[2], H. HIRAI[1];
[1]Dept. of Neurophysiol. and Neural Repair, Gunma Univ. Grad. Sch. of Med., Maebashi, Japan;
[2]Krasnoyarsk State Med. Univ., Krasnoyarsk, Russian Federation

Abstract: Spinocerebellar ataxia type 1 (SCA1) exhibits cerebellar ataxia and progressive atrophy of Purkinje cells (PCs). SCA1 is an inherited progressive neurodegenerative disease caused by abnormal CAG repeat expansion (polyglutamine tract) in the gene of Ataxin-1. Ataxin-1 interacts indirectly with a transcriptional factor, retinoid-related orphan receptor α (RORα), and abnormal disease-causing mutant Ataxin-1 is suggested to disrupt RORα-mediated gene regulation. Our previous study has shown that RORα-deficient ataxic mice lack functional metabotropic glutamate receptor type 1 (mGluR1)-mediated signaling in the cerebellum. Moreover, previous molecular studies indicated that SCA1 involves downregulated expression of the metabotropic glutamate receptor type 1 (mGluR1), which is indispensable for synaptic plasticity and motor coordination. Thus, considering a shared signaling pathway between Ataxin-1 and RORα, we hypothesize that abnormal mGluR signaling underlie SCA1 pathology. However, it remains unknown whether mGluR-mediated signaling is functionally abnormal in SCA1 and which synaptic defect contributes to SCA1 pathology in the cerebellum. Using transgenic SCA1 model mice carrying the disease-causing mutant ataxin-1 with expanded polyglutamine tract, we show that those mice develop progressive deficits in mGluR-mediated signaling at cerebellar parallel fiber (PF)-PC synapses. SCA1 mice older but not younger than 5 weeks, exhibited impaired mGluR-mediated slow synaptic responses, loss of endocannabinoid-mediated retrograde short-term synaptic plasticity and lack of long-term synaptic depression (LTD). These types of synaptic plasticity are known to require mGluR1-mediated Ca^{2+} signals in PC dendrites. Our fast confocal Ca^{2+} imaging revealed that mGluR-mediated dendritic Ca^{2+} signals are also progressively impaired in PCs of SCA1 model mice older than 5 weeks (still prior to PC death). Interestingly, reduction in the dendritic Ca^{2+} signals in SCA1 mice were linearly correlated with small but substantial progressive PC atrophy, which was detected by measurement of the PC membrane capacitance (i.e. the cell surface area). These results suggest

that disruption of mGluR signaling including slow synaptic responses, dendritic Ca^{2+} signals and synaptic plasticity such as LTD at PF-PC synapses may underlie cerebellar ataxia in SCA1 pathology, and that progressive impairment of dendritic mGluR1-mediated Ca^{2+} signaling might accompany slight progressive PC atrophy in SCA1.

Abstract: The *Fragile X Mental Retardation (FMR1)* gene codes for the Fragile X Mental Retardation protein (FMRP) which is essential for proper neuronal development and function. A CGG trinucleotide sequence is located in the 5'UTR of *FMR1* and is normally repeated 5-54 times. Carriers of the Fragile X premutation (PM) have the CGG repeat sequence expanded to between 55-200 and are at risk for developing the late onset Fragile X-associated tremor/ataxia syndrome (FXTAS). Carriers of the full mutation have CGG repeat sequences over 200 and develop Fragile X syndrome (FS). In the brain, intranuclear inclusions that stain for ubiquitin are considered to be a pathological hallmark of FXTAS and are observed in both astrocytes and neurons. In order to examine the contribution of neuronal pathology to overall FXTAS pathology we developed a doxycycline (dox)-inducible mouse that expresses a CGG90 repeat sequence limited to neurons using the CaMKII-rtTA promoter in mice expressing a TetO-CGG(90)-eGFP transgene. By exposing inducible mice to dox at different ages, and then removing the dox, we are able to assess FXTAS disease progression (comparing 8 vs 20 wks on) and the potential for

disease reversibility (8 wks on, followed by a 12 wk off). Mice were tested using a battery of behavioral assays and subsequently characterized using immunohistological, stereological and western blot techniques. Inducible CGG(90) mice show behavioral deficits after exposure to dox (8 or 20 weeks), including increased anxiety related behaviors, hyperactivity and impaired cognitive abilities. After only 8 wks of dox treatment, neuron-specific expression of the ectopic CGG(90) was widespread and sufficient to produce the FXTAS-associated intranuclear inclusions. Brain atrophy is associated with FXTAS, and consistent with this finding the dox-inducible CGG(90) mice show significant cell loss in key brain regions, including the ventral and dorsal lateral geniculate nucleus. Western blot analyses showed that 8 wks of dox treatment was sufficient to lead to alterations in NR2A and GAD2 expression levels in key brain regions of the CGG(90) mice, which suggested an excitation/inhibitory imbalance in brain activity. Collectively, these results indicate that ectopic CGG(90) expression in neurons is sufficient to produce key elements of FXTAS-associated pathology in mice.

Title: Rapid atrophy and hyperexcitability in cerebellar Purkinje cells expressing infant-onset spinocerebellar ataxia type 13 Kv3.3. mutation

Authors: *D. M. PAPAZIAN[1], B. N. ULRICH[2], J.-Y. HSIEH[2], F. A. ISSA[2], B. BROWN[2], M.-C. A. LIN[2];
[2]Physiol., [1]Geffen Sch. Med. UCLA, Los Angeles, CA

Abstract: Spinocerebellar ataxia 13 (SCA13) is caused by mutations in Kv3.3, which promotes rapid firing in neurons and contributes to spontaneous tonic firing and complex spiking in cerebellar Purkinje cells (PCs). Different Kv3.3 mutations cause distinct forms of SCA13 that

differ in the age of onset. Infant-onset SCA13 is typified by severe cerebellar atrophy early in life, persistent motor problems, and cognitive impairment, whereas adult-onset SCA13 is characterized by progressive cerebellar degeneration and ataxia beginning in adulthood. Infant-onset mutations alter channel gating whereas the adult-onset mutation suppresses current amplitude without altering functional properties. To test the hypothesis that infant- and adult-onset mutations have distinct effects on PC excitability and viability, we expressed two S4 voltage sensor mutations, R3H and R4H, which cause adult- and infant-onset SCA13, respectively, in cerebellar PCs in zebrafish; membrane-bound EGFP (mEGFP) was co-expressed. Zebrafish PCs are born at 3 days post-fertilization (dpf) and begin firing spontaneously within hours. By 5 dpf, PCs receive parallel and climbing fiber input, and exhibit regular tonic firing and complex spiking. Expression of the R4H infant-onset mutation causes dramatic hyperexcitability by 4 dpf. In contrast, the R3H adult-onset mutation does not alter basal firing properties, but reduces excitability when PCs are driven by mossy fiber input. The effects of R3H and R4H on PC morphology were characterized by live confocal imaging starting at 3.5 dpf. PCs expressing the infant-onset R4H mutation lacked branched processes and dendritic spines, rapidly atrophied, and disappeared by ~4-5 dpf. In contrast, PCs expressing the adult-onset R3H mutation, exogenous wild-type Kv3.3, or mEGFP alone developed extensive, branched arbors and numerous spines, with no indication of reduced viability. To determine the role of hyperexcitability in the degeneration of R4H-expressing PCs, we treated zebrafish with NS13001, an SK channel agonist, or co-expressed $K_{IR}2.1$. Preliminary results suggest that reducing the excitability of R4H-expressing PCs stabilizes processes and increases cell survival. Our data suggest that in infant-onset SCA13, hyperexcitability triggers PC atrophy and death.

Title: PTBP1 and PTBP2 regulate conserved and nonconserved cryptic exons.

Authors: *R. CHHABRA[1], J. P. LING[1], J. D. MERRAN[2], P. M. SCHAUGHENCY[3], S. J. WHEELAN[3], J. L. CORDEN[4], P. C. WONG[1,4];
[1]Dept. of Pathology, [2]Mol. Biol. and Genet., [3]Oncology Biostatistics and Bioinformatics, [4]Neurosci., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: RNA splicing is essential for gene regulation and tightly controlled with nucleotide precision. It is thus not surprising that interruption of this delicate system underlies a variety of human diseases. In addition to their role in mRNA regulation and gene expression, various studies have revealed that the RNA binding proteins, polypyrimidine tract-binding protein 1 (PTBP1) and its neuronal homolog polypyrimidine tract-binding protein 2 (PTBP2), act as splicing factors. PTBP1 and PTBP2 both contain four RNA-recognition motifs (RRMs) with high affinity for CU-rich sequences. Intriguingly, the expression pattern of PTBP1 and PTBP2 are mutually exclusive, whereby PTBP1 downregulates PTBP2 by repressing exon 10 in PTBP2 leading to nonsense mediated decay of its transcript. PTBP1 is highly expressed in most of the tissues except certain organs such as brain, where PTBP2 is highly expressed. We previously reported that TDP-43, an RNA binding protein involved in a variety of neurodegenerative diseases, binds to UG dinucleotide repeats to repress nonconserved cryptic exons. As PTBP1 and PTBP2 are also splicing repressors, which binds to CU dinucleotide repeats, we reasoned that these two splicing factors might also repress cryptic exons. We performed RNA-seq analysis in PTBP1/2 knockdown HeLa and HEK 293 cells and searched for previously unidentified cryptic exons. Furthermore, we examined RNA-seq data set from brain of mice lacking *ptbp2* in neurons. Our results revealed that PTBP1 and PTBP2 bind CU dinucleotide repeats to regulate both conserved and nonconserved cryptic exons. Moreover, PTBP1 and PTBP2 seem to promote neuronal differentiation by governing the extent of CU repeat-associated repression. Together, our results establish that PTBP1 and PTBP2, along with TDP-43, belong to a novel family of cryptic exon repressors that serve to maintain the integrity of introns.

Title: Exploring G4C2 repeat expansions using long-read next generation sequencing

Authors: ***J. GREGORY**[1], K. KANG[1,2], G. DEIKUS[2,3], M. HARMS[3], N. SHNEIDER[3], R. SEBRA[2], H. PHATNANI[1];

[1]New York Genome Ctr., New York, NY; [2]Icahn Sch. of Med. at Mt. Sinai, New York, NY; [3]Columbia Univ. Med. Ctr., New York, NY

Abstract: We are developing methods to sequence and assemble the G_4C_2 hexanucleotide repeat expansion (RE) in chromosome 9 open reading frame 72 (C9orf72), which is the most common hereditary cause of familial ALS-FTD. In control populations, the RE is relatively short and can be identified with routine molecular biology and sequencing. However, ALS-FTLD patients have 100's to 1000's of repeats and, unfortunately, high throughput methods to determine the exact length, sequence, and heterogeneity of the C9orf72 RE do not currently exist; the current state-of-the-art uses laborious protocols that yield only gross approximations. The 100% GC content, length, and repetitive nature of the expansion have been particularly difficult to overcome for sequencing applications. There is considerable clinical heterogeneity in age of onset, severity, and clinical symptoms among C9orf72 RE carriers, some of which may be explained by differences in the C9orf72 repeat expansion. Preliminary data from PacBio and Oxford Nanopore sequencing using novel enrichment strategies for targeted sequencing of G_4C_2 repeat expansions will be discussed.

Title: Investigating effects of TDP-43 on metabolic gene expression in a *Drosophila* model of amyotrophic lateral sclerosis

Authors: *J. BARROWS[1], E. MANZO[1], A. JOARDAR[1], A. COYNE[1,2], D. C. ZARNESCU[1,2,3];
[1]Mol. and Cell. Biol., [2]Neurosci., [3]Neurol., Univ. of Arizona, Tucson, AZ

Abstract: Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease that primarily affects motor neurons, disrupting muscle function, which eventually leads to death by respiratory failure. TDP-43, a DNA/RNA binding protein that plays numerous roles in RNA processing, has been associated with RNA stress granule pathology in over 95% of ALS cases. TDP-43 has also been linked to dysregulation of specific mRNA targets at both the transcriptional and translational levels. Metabolomic analyses demonstrated that several metabolites in glycolysis and the TCA cycle are altered in *Drosophila* larvae expressing human TDP-43 compared to controls, suggesting that enzymes within these metabolic pathways are being affected in ALS. To confirm this hypothesis, we are using the GAL4-UAS system in *Drosophila* to express TDP-43 specifically in the motor neurons or glia. Indeed, transcriptional profiling shows that phosphofructokinase (PFK; Pfk in *Drosophila*) and glucose-6-phosphate dehydrogenase (G6PD; Zw in *Drosophila*) expression levels are altered in the context of TDP^{WT} or disease associated TDP^{G298S}. These findings are consistent with increased glycolysis and high levels of pyruvate identified using metabolomics in TDP-43 expressing flies. Current experiments are aimed at identifying additional transcriptional and translational alterations in metabolic pathways that control cellular energetics. Next, we will use genetic approaches to reduce (in the case of upregulation) or increase (in the case of downregulation) the expression levels of metabolic genes in the context of TDP-43. These experiments will determine whether restoring specific targets can rescue TDP-43 dependent phenotypes. This combination of molecular and genetic analyses will establish physiologically significant targets of TDP-43 that can be used for developing novel therapeutic strategies in the future.

Title: V2a neurons drive accessory respiratory muscle activity and degenerate in mouse models of ALS

Authors: *V. N. JENSEN[1], S. H. ROMER[2], K. SEEDLE[2], S. M. TURNER[2], S. A. CRONE[2]; [1]Grad. Neurosci. Program, Univ. of Cincinnati, Cincinnati, OH; [2]Neurosurg., Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: Respiratory failure is the leading cause of death in amyotrophic lateral sclerosis (ALS) and the only current treatment to improve breathing is mechanical ventilation. Despite progressive degeneration of phrenic motor neurons innervating the diaphragm, ALS patients and rodent models are able to maintain ventilation at early stages of disease, but experience a sharp decline at late disease stages. The mechanisms that maintain ventilation at early stages or lead to ventilation failure at late disease stages are unknown. We propose that compensatory mechanisms including recruitment of accessory respiratory muscles (ARMs) help to maintain ventilation at early stages of disease. Using a customized system for simultaneous non-invasive measurement of ARM electromyograph (EMG) activity and breathing (whole body plethysmography), we demonstrate that ARMs are recruited in early stage ALS model mice and increase ventilation. Surprisingly, ARMs are not used for breathing at late disease stages, even though they are used to perform other motor functions. In addition, we have identified a glutamatergic neuron class in the spinal cord and brainstem, the V2a class, that is able to drive accessory respiratory muscle activity and that degenerates in mouse models of ALS. These results support the hypothesis that a central deficit in respiratory circuitry underlies the failure to activate ARMs at late stages of disease. Our studies suggest that therapies to protect, replace, or improve the function of V2a neurons could help to restore or maintain ventilation in patients with ALS, other neuromuscular diseases, or spinal cord injury.

Title: Mechanisms of RAN translation in a C9orf72 heterologous expression system

Authors: *E. L. DALEY, J. A. ORTEGA, D. SANTOS, E. KISKINIS;
Neurosci., Northwestern Univ. - Chicago, Chicago, IL

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disorder that is characterized by degeneration of motor neurons and for which there is no effective therapy. Recently, the hexanucleotide repeat expansion GGGGCC within the first intron of C9*orf*72 was discovered to be the largest genetic contributor to ALS. Toxic mechanisms underlying pathogenesis driven by this mutation include C9*orf*72 haploinsufficiency, the accumulation of C9*orf*72 mRNA repeat transcripts and subsequent sequestration of RNA binding proteins, and production of dipeptide repeat proteins (DPRs) by the mechanism of repeat-associated non-ATG (RAN) translation. There is much that is still unknown about RAN translation. Past studies have demonstrated that RAN translation machinery likely varies based on location within the mRNA transcript, frame position, constituent bases comprising the repeat, and secondary structures formed by repeat nucleotide interactions. The current study sought further mechanistic understanding underlying RAN translation in the context of the GGGGCC repeat. Here, we report the development of a heterologous expression system in which 58 GGGGCC repeats, in the absence of an ATG and a Kozak sequence, stably expressed in HEK293 cells, demonstrated the accumulation of RNA foci and DPRs associated with this mutation. We report on the preliminary data of an unbiased genetic screen that identifies proteins necessary for RAN translation to occur within this system.

Title: Environmental toxicants upregulate TDP-43 expression through the Aryl Hydrocarbon Receptor

Authors: *P. E. ASH[1], E. A. STANFORD[2], G. J. MURPHY[3], D. H. SHERR[2], B. WOLOZIN[1]; [1]Dept of Pharmacol., Boston Univ. Med. Ctr., Boston, MA; [2]Dept. of Envrn. Hlth., Boston Univ. Sch. of Publ. Hlth., Boston, MA; [3]CReM, Boston Univ., Boston, MA

Abstract: Amyotrophic lateral sclerosis (ALS) is a debilitating neurodegenerative condition that is pathologically characterized by progressive loss of motor neurons and the accumulation of aggregated TAR DNA Binding Protein-43 (TDP-43). The causes of ALS are poorly understood, but environmental factors are established contributors to the risk of ALS. Recent epidemiological studies identified environmental toxicants, such as dioxins and polychlorinated biphenyls (PCBs), as a risk factor for ALS. Dioxins activate the aryl hydrocarbon receptor (AHR), which is a ligand-activated transcription factor. The TAR DNA Binding Protein (*TARDBP*) promoter contains clusters of AHR response elements. We report that ligands of the AHR, including known dioxin family toxicants, acutely increase *TARDBP* transcription, while AHR knockdown prevents such increases. Chronic treatment with AHR agonists for 1 week leads to over a 2-fold accumulation of soluble TDP-43 in cultured neuroblastoma cells. Similar sustained treatment of human iPSC-derived neurons (from an ALS patient carrying the *TARDBP* G298S mutation) increases the accumulation of insoluble monomeric, high molecular weight and C-terminal fragments of TDP-43. TDP-43 levels increase in the murine brain following intraperitoneal injection of an agonist of the AHR, demonstrating CNS penetration of these toxicants. These results provide the first lines of evidence that dioxins can increase levels of the principle pathological protein associated with ALS, which suggest a novel mechanism through which dioxins might contribute to the risk of ALS. The widespread distribution of dioxins and other AHR ligands across industrialized societies raises the possibility that these environmental toxicants might represent a significant public health concern for the risk of ALS.

Title: Phosphorylation of the intrinsically disordered domain of fused-in-sarcoma inhibits aggregation

Authors: *Z. MONAHAN[1], V. RYAN[2], K. BURKE[2], F. SHEWMAKER[1], N. FAWZI[2]; [1]Pharmacol., Uniformed Services Univ. of the Hlth. Scienc, Bethesda, MD; [2]Dept. of Mol. Pharmacology, Physiology, and Biotech., Brown Univ., Providence, RI

Abstract: Mutations of the RNA-binding protein fused-in-sarcoma (FUS) correlate with familial amyotrophic lateral sclerosis (ALS), a fatal motor neuron disease for which there is no effective treatment. Diseased motor neurons show a classic pattern of FUS cytosolic aggregation. Intriguingly, FUS contains a long N-terminal intrinsically disordered region of low sequence complexity, resembling the amino acid composition of canonical yeast prion proteins as well as other aggregation-prone human proteins implicated in numerous neurodegenerative diseases. These "prion-like" domains (PLDs) are characterized by an abundance of uncharged, hydrophilic amino acids, and propensity toward forming self-propagating aggregates. Here, we show that FUS is phosphorylated by the nuclear kinase DNA-PK *in vitro* and that the N-terminal PLD of FUS is specifically phosphorylated in mammalian cell culture following cell stress, thus reducing the prion-like character of the domain and its propensity to aggregate. Moreover, we show that specifically targeted phosphomimetic substitutions on serine or threonine residues within the PLD of FUS is correlated with a reduction in aggregation and cytotoxicity in a *Saccharomyces cerevisiae* model system. Although nuclear magnetic resonance spectroscopy demonstrates that the intrinsically disordered structure of the domain is preserved after phosphorylation, self-interaction of the prion-like domain is inhibited by phosphorylation. Conversion of *in vitro* liquid phase-separated FUS to solid aggregates is completely abrogated by phosphomimetic substitution in the prion-like domain. These results suggest that phosphorylation of prion-like low-complexity domains reduces protein aggregation propensity and cytotoxicity. Hence, post translational modification may be a mechanism by which cells control physiological assembly and prevent pathological protein aggregation, offering potential treatment pathway amenable to pharmacologic modulation.

Title: In the superoxide dismutase 1 ($hSOD1^{G93A}$) mouse model, cortical glucose metabolism is impaired while astrocytic TCA cycling is unaffected at onset of disease

Authors: *T. W. TEFERA, K. BORGES;
Sch. of Biomed. Sci., The Univ. of Queensland, Brisbane, Australia

Abstract: Altered glucose metabolism has been shown in various brain regions and spinal cord of patients with amyotrophic lateral sclerosis (ALS). However, the specific biochemical changes in neuronal and astrocytic glycolytic and TCA cycle pathways were unknown. We therefore investigated [1-^{13}C] glucose and [1,2-^{13}C] acetate metabolism in neurons and astrocytes in brain extracts from cortex of $hSOD1^{G93A}$ mice at onset of disease (80 days). Wild-type (n=15) and $hSOD1^{G93A}$ mice (n=10) at onset were simultaneously injected with 543 mg/kg [1-^{13}C]glucose and 504 mg/kg [1,2-^{13}C]acetate (i.p.) followed by microwave fixation of the head 15 minutes later. Cerebral cortices were removed and extracted with methanol-chloroform. The total concentrations of metabolites, amino acids and ^{13}C labelling in cortex extract were quantified using high-pressure liquid chromatography (HPLC), ^{1}H and ^{13}C nuclear magnetic resonance (NMR) spectroscopy. Levels of various glycolytic derived metabolites were reduced in $hSOD1^{G93A}$ mice, namely [3-^{13}C]lactate by 53%, total lactate by 43%, [3-^{13}C]alanine by 45% and total alanine by 20% ($p<0.03$). This signifies impairment in the glycolytic pathway in $hSOD1^{G93A}$ mice. We also found reductions in the amounts of glutamate by 27% and succinate by 23% in $hSOD1^{G93A}$ mice cortex compared to control mice ($p=0.02$), while, other total metabolite levels including those of glutamine, aspartate and GABA were unchanged. In addition, the labelling in glutamate ([4-^{13}C]glutamate), glutamine ([4-^{13}C]glutamine) and GABA ([2-^{13}C]GABA) from [1-^{13}C] glucose was diminished by 30% ($p<0.04$). This could be explained by the impairments in glycolysis, however additional abnormalities in TCA cycle reactions or enzymes metabolizing 2-oxoglutarate cannot be ruled out. Astrocytic metabolism of ^{13}C-acetate was unchanged as evidenced by unaltered incorporation of ^{13}C in [4,5-^{13}C]glutamate and [4,5-^{13}C]glutamine from [1,2-^{13}C]acetate. However, we found reduced labelling in [1,2-^{13}C]GABA, indicating that metabolism in GABAergic neurons is impaired, which can contribute to excitotoxicity in these mice. In conclusion, glucose metabolism is compromised in glutamatergic and GABAergic neurons, while astrocytic TCA cycling and glutamine-glutamate shuttling appears to be normal in the $hSOD1^{G93A}$ mouse model of amyotrophic lateral sclerosis at onset of

disease. These results justify additional research into alternative fuels to glucose to delay progression of ALS.

Title: Pharmacologic and pathophysiologic readouts of c9orf72 therapy in iPS neurons

Authors: *L. R. HAYES[1], T. GENDRON[2], L. PETRUCELLI[2], M. DISNEY[3], J. ROTHSTEIN[1]; [1]Sch. of Med., Johns Hopkins Univ., Baltimore, MD; [2]Dept. of Neurosci., Mayo Clin., Jacksonville, FL; [3]Departments of Chem. and Neurosci., The Scripps Res. Inst., Jupiter, FL

Abstract: A hexanucleotide repeat expansion in *C9ORF72* is now regarded as the most common genetic cause of ALS and FTD. Antisense oligonucleotide (ASO) therapy and small molecule agents are in development for C9*,* and have shown promising results in vitro and in vivo. Our early data show that ASO treatment of C9 iPSN ameliorates glutamate toxicity and deficits in nucleocytoplasmic transport. We have also demonstrated that glycine-proline (GP), one of six *C9ORF72* repeat-associated, non-ATG initiated (RAN) proteins, provides a dose-dependent readout of ASO efficacy in culture media from induced pluripotent stem cell-derived neurons (iPSN). We are in the process of working out the correlates between these pathophysiologic and pharmacodynamic readouts, which will be critical for understanding how to titrate therapy. Efforts are underway to carry out a systematic characterization of time- and dose-dependent effects of ASO and small molecule therapy on RAN protein levels in the culture media and measures of C9 toxicity, including sensitivity to glutamate, ER stress, nucleocytoplasmic transport defects, and nuclear pore pathology. These results will provide important preclinical data to help move these agents forward to clinical trial.

Title: Assessing the role of Nurr1 in a murine model of amyotrophic lateral sclerosis

Authors: ***M. M. BOIDO**, V. VALSECCHI, M. GUGLIELMOTTO, N. GIONCHIGLIA, E. TAMAGNO, A. VERCELLI;
Univ. of Turin, Orbassano (TO), Italy

Abstract: The nuclear receptor related 1 protein (Nurr1), also known as NR4A2, belongs to the steroid nuclear hormone receptor class, but it is considered an orphan receptor since its activity is not regulated by ligands. The role of Nurr1 is still debated, but it seems implicated both in neuroprotection and immunomodulation in different neurodegenerative diseases, as Parkinson's disease and multiple sclerosis. By cooperating with the CoREST complex, Nurr1 can repress the activity of the pro-inflammatory transcription factor NF-kB, therefore playing an anti-inflammatory role. Neuroinflammation is a pathological hallmark of many neurodegenerative diseases including amyotrophic lateral sclerosis (ALS): here we aimed to unravel the role of Nurr1 in ALS, in order to identify a new therapeutic target.
By following the progression of disease in SOD1 G93A mice (the most widely used animal model of ALS), we have correlated the Nurr1 expression with the severity of the disease, compared to age-matched WT mice that were considered as the baseline. Behavioral tests (rotarod and paw grip endurance test) have been employed to identify three different phases of the disease (pre-symtomatic, early and late symptomatic). RT-PCR showed that Nurr1 mRNA expression is strongly up-regulated at the onset of the pathology and decreases in the last phase. Moreover in nuclear extracts from the lumbar spinal cord of SOD mice, we measured a decreased level of NF-kB subunits (in particular the P50 one) in the early symptomatic phase. We also evaluated the Nurr1 expression by immunofluorescence reactions, in order to clarify which cells were specifically involved in this pathway: our results revealed a significant contribution of astroglial cells. Finally we quantified motoneuron number and astro/microgliosis, correlating this parameters to the progression of the disease.
Our overarching hypothesis is that Nurr1 activation aims to modulate neuroinflammation and to protect motor neurons, at least at the onset of disease. Our observations, in association with the

pharmacological modulation of Nurr1, could clarify the role of Nurr1 in such devastating disease.

Title: Cellular and Molecular Analysis of Corticospinal Motor Neurons that become vulnerable due to hTDP-43^{A315T} mutation

Authors: ***M. GAUTAM**[1], L. A. LABOISSONNIERE[3], M. KANDPAL[2], J. H. JARA[1], Y. BI[2], K. D. KIM[1], J. M. TRIMARCHI[3], R. V. DAVULURI[2], P. H. OZDINLER[1];
[1]Neurol., [2]Preventive Medicine-Health and Biomed. Informatics, Northwestern Univ., Chicago, IL; [3]Dept. of Genetics, Develop. and Cell Biol., Iowa State Univ., Ames, IA

Abstract: Corticospinal motor neurons (CSMN) are unique in their ability to collect and integrate signals from different regions of the cerebral cortex, and to transmit this information to distinct segments of the spinal cord. Their proper function is thus pivotal for motor functions, and CSMN degeneration is an important aspect of motor neuron diseases, in which voluntary movement is impaired. Transactive Response (TAR) DNA binding protein 43 (TDP-43) is an evolutionarily conserved DNA/RNA binding nucleoprotein involved in various functions, most importantly in RNA metabolism. Numerous mutations in the conserved region of TDP-43 have been detected in sporadic and familial cases of ALS patients. Of all the mouse models generated to date, the one overexpressing the hTDP-43^{A315T}mutation under the control of the prion promoter recapitulates many aspects of ALS pathology. Here, we investigate the health and stability of CSMN that express mutant TDP-43 and display TDP-43 pathology. We previously generated and characterized UCHL1-eGFP mice, in which CSMN are genetically labelled with eGFP expression that is stable and long lasting. Now, in an attempt to distinguish CSMN from other neurons and cells in the cerebral cortex, and to study their cell biology with high precision

and clarity, we generated a CSMN reporter line of *TDP-43^{A315T}* by crossing *UCHL1-eGFP* and hTDP-43^{A315T} mice. Our ongoing studies suggest that CSMN undergo progressive degeneration in the presence of TDP-43 pathology, and CSMN loss is accompanied by compromised motor behaviour, such as poor performance on a rotating rod and weak hind limb strength. Increased astrogliosis and microgliosis display an evoked immune response in the motor cortex, and immunohistochemistry coupled with electron microscopy reveals mitochondrial aggregation as well as cyto-architectural defects. RNA-Seq analysis of FACS purified healthy and diseased CSMN provides unique insights into the differentially regulated gene pathways in diseased CSMN, and enables identification of canonical pathways that are selectively modulated with respect to TDP-43 pathology, as well as potential alternative splice variations of key genes. Upon completion, our studies will reveal the unique importance of the *TDP-43^{A315T}* mutation on CSMN vulnerability and progressive degeneration.

Title: Investigating the role of a novel variant in the copper transporter ATP7A detected in an ALS patient-parent trio

Authors: *A. P. STARR[1], Z. T. MCEACHIN[2], N. BAKKAR[1], I. LORENZINI[1], D. C. ZARNESCU[3], G. J. BASSELL[2], C. M. HALES[2], W. ROSSOLL[2], R. SATTLER[1], N. M. BOULIS[2], R. BOWSER[1];
[1]Div. of Neurobio., Barrow Neurolog. Inst., Phoenix, AZ; [2]Emory Univ., Atlanta, GA; [3]Univ. of Arizona, Tucson, AZ

Abstract: Copper regulation is vital to the operation of a number of cellular processes, including mitochondrial electron transport, iron transfer, and antioxidant activity. The copper transporting P-type ATPase (ATP7A) is known to function in most human cell types in two primary ways; it chaperones copper to proteins in the trans-Golgi apparatus and exports excess copper at the plasma membrane. Mutations in the ATP7A gene are responsible for a number of neurological

disorders including Menkes' disease, occipital horn syndrome, and distal motor neuropathies. Here, we report a case of a male patient presenting with brachial amyotrophic diplegia, an atypical form of amyotrophic lateral sclerosis (ALS). Whole genome sequencing of the proband and his parents revealed a maternally inherited variant of unknown significance in the X-linked ATP7A gene. The hemizygous c.3931A>G variant results in a nonsynonymous p.M1311V substitution. This amino acid alteration occurs next to the ATP binding site of the protein. Given the frequency of neurological symptoms in ATP7A-related diseases and ATP7A's function as a copper chaperone to the ALS-associated enzyme superoxide dismutase (SOD1), we investigated the effect of this mutation on ATP7A expression, location, and activity. In patient-derived fibroblasts, ATP7A transcript and protein expression levels showed no difference from control fibroblasts. Similarly, no change was observed in cell viability, SOD activity or cytochrome c oxidase function. Immuno-colocalization analysis, however, did show that ATP7A relocation in response to elevated copper levels was reduced in patient fibroblasts. Patient-derived induced pluripotent stem cells (iPSCs) differentiated into neurons and *Drosophila* models overexpressing ATP7A-M1311V are being generated to further investigate the role of ATP7A-M1311V in more disease-relevant models.

Title: Complement and microglia mediate sensory-motor synaptic loss in Spinal Muscular Atrophy

Authors: *A. VUKOJICIC[1,2], N. DELESTREE[1,2], E. V. FLETCHER[1,2], S. SANKARANARAYANAN[3], T. YEDNOCK[3], B. A. BARRES[4,3], G. Z. MENTIS[1];

Abstract: Spinal muscular atrophy (SMA) is a neurodegenerative disease caused by reduced levels of the ubiquitously expressed SMN protein. The hallmarks of SMA are loss of motor neurons and abnormal postural reflexes. We have previously shown that decreased number of select synapses and sensory-motor circuit dysfunction precedes motor neuron loss. The mechanisms leading to this selective synapse loss on SMN deficient motor neurons remain unknown. Here we investigated whether complement-dependent pathways are activated and cause synapse elimination in SMA. Immunohistochemical assays in a mouse model of SMA, revealed that C1q, the initiating protein of the classical complement cascade, associates abnormally with excitatory - but not inhibitory - synapses on motor neurons. We show further that both C1q and C3, a downstream complement protein, are tagging proprioceptive (VGluT1+) synapses on vulnerable motor neurons. Furthermore we show that synaptic elimination is mediated by phagocytic activity of reactive microglia. Additionally, we find that microglia is the major source of C1q in the SMN deficient spinal cord. Finally, we asked whether immunotherapy by *in vivo* blockade of C1q with a monoclonal anti-C1q antibody, rescues synapses destined to be eliminated and whether prevention of early synaptic loss alleviates the severe SMA mouse phenotype. Strikingly, behavioral and morphological analysis revealed significant rescue of proprioceptive synapses, improved righting times, posture and lifespan. Importantly, functional assays employing the spinal cord *ex vivo* preparation demonstrated that synapses rescued from elimination are functional, providing further evidence that SMA is a disease of motor circuits. Collectively, our findings suggest that aberrant activation of classical complement pathway and microglial phagocytic activity mediate synaptic loss in a mouse model of SMA and identify blockade of C1q as a novel therapeutic target.

Title: Blood-CSF barrier disruptions in ALS

Authors: *N. BAKKAR, R. KOTHUR, R. BOWSER;
Gregory W. Fulton ALS and Neuromuscular Res. Ctr., St Joseph Hosp. and Med. Center/Barrow Neurolog. Inst., Phoenix, AZ

Abstract: The blood-CSF (BCSF) barrier is structurally comprised of an endothelial cell layer and a polarized epithelial cell layer named the choroid plexus (CP). The BCSF barrier lines the inside of the brain ventricles, separating the blood in the vascular system from the cerebrospinal fluid (CSF) that is in direct contact with neurons. The CP mainly functions in CSF production and turnover as well as selective transport of nutrients from the systemic compartment, removal of metabolic products out of the brain, regulation of cell trafficking into the CSF. Under inflammatory conditions, the CP epithelium expresses factors involved in mediating an immune response thus serving as a primary point of entry of immune cells into the nervous system. Aging and neurodegeneration have been reported to affect CP morphology and function, decreasing CSF production and turnover by as much as 50%, altering levels of proteins involved in energy production and free radical scavenging, and increasing protein leakage from blood to the CSF. ALS is similarly associated with increased oxidative stress markers, neuronal loss, and metabolic disturbances that may also impede CP function. Our group and others have reported increased levels of many proteins in CSF from ALS patients, including inflammatory targets, cytoskeletal and extracellular matrix proteins, as well as aggregated proteins. Having these proteins and factors abnormally localized to the CSF compartment suggests impaired BCSF barrier permeability, increased protein leakage from blood to the CSF and decreased clearance of metabolic products pointing to a dysfunctional BCSF barrier. To date, there have been few studies investigating BCSF barrier or CP alterations in ALS patients. We hereby have investigated BCSF integrity in ALS. We hypothesized that this physical barrier is disrupted in ALS possibly via excess metalloproteinase (MMP) activation, thus allowing an influx of immune cells into the CSF and conversely into the nervous system**.** We have investigated the morphology and distribution of various cell junction and cell adhesion proteins such as cadherins, occludins, and claudins in ALS CP compared to control CP by immunohistochemistry. We show that levels and distribution of many of these markers is altered in ALS. Results were confirmed by real-time PCR analysis. In addition, we have examined levels of various MMPs in ALS CP compared to controls, as a potential cause for BCSF barrier breakdown. By investigating BCSF barrier disruption in ALS patients, our study provides novel mechanisms of how toxic metabolites and immune modulators spread to the CSF potentially providing new targets for therapy development.

Title: TDP-43 overexpression leads to the repression of conserved exons

Authors: *J. P. LING, W. W. TSAO, P. C. WONG;
Johns Hopkins Univ., Baltimore, MD

Abstract: Cytoplasmic aggregation of transactivation response element DNA-binding protein 43 (TDP-43) is a key pathological hallmark of amyotrophic lateral sclerosis and frontotemporal dementia (ALS-FTD). We recently discovered that TDP-43 plays an important role in repressing the splicing of nonconserved cryptic exons. Furthermore, we demonstrated that restoring the repression of cryptic exons rescues cells from cell death induced by TDP-43 loss of function. However, strong overexpression of TDP-43 in animal models also leads to cellular toxicity—the mechanisms of which remain poorly understood. Here, we suggest that under conditions of TDP-43 overexpression, excess amounts of TDP-43 protein may bind to suboptimal UG repeats on conserved exons to induce exon skipping. Repression of conserved exons may explain the toxicity observed with TDP-43 overexpression.

Title: Alterations in protein-protein interactions caused by ALS associated mutations in Matrin 3

Authors: *A. BOEHRINGER[1], K. GARCIA[2], P. PIRROTTE[2], R. BOWSER[1];
[1]Barrow Neurolog. Inst., Phoenix, AZ; [2]Translational Genomics Inst., Phoenix, AZ

Abstract: We and others have recently reported mutations in the RNA binding protein Matrin 3 in amyotrophic lateral sclerosis (ALS) patients. ALS is a fatal, progressive, neurodegenerative disease resulting in loss of motor neurons and consequently progressive weakness and paralysis. As the mechanism by which Matrin 3 mutations result in ALS is currently unknown, we sought to identify protein-protein interactions (PPIs) with Matrin-3 and to determine if these associations are altered by mutations in the MATR3 gene. Altered PPIs caused by mutations may identify pathways that contribute to disease. We performed immunoprecipitation followed by mass spectrometry in NSC-34 cells stably expressing either human wildtype Matrin 3 or one of four ALS associated mutations in Matrin 3 (S85C, F115C, P154S and T622A). All experiments were performed in triplicate and each experiment repeated twice. Approximately 300 Matrin 3 interacting proteins were identified in each experiment. Proteins identified were further scored by probability of interaction using SAINTexpress. On average across all experiments, 50 protein binding partners were identified at medium confidence, and 20 binding partners at high confidence. A subset of these putative Matrin 3 interactors were confirmed by western blot and found to co-localize with Matrin-3 using immunocytochemistry. These two methods also highlighted differences in protein interactions with wildtype Matrin 3 as compared to ALS associated mutants. Putative binding partners were subjected to pathway analysis with the most significant pathway among wildtype and mutant being eukaryotic initiation factor 2 (eIF2) signaling. Otherwise, pathways differed greatly between wildtype and mutant Matrin 3, with some pathways found only in either wildtype or mutant experiments. Gene ontology annotation highlighted binding partners predominately involved in RNA processing and RNA splicing, though the number of proteins in each category and the specific RNA functions differed between wildtype and mutant.

Title: Rescue of neurotoxicity in a TDP-43-based *Drosophila* model of ALS by a 4-aminoquinoline analog

Authors: *B. ZAEPFEL[1], A. COYNE[1], J. A. CASSEL[2], A. B. REITZ[2], D. C. ZARNESCU[1]; [1]Univ. of Arizona, Tucson, AZ; [2]ALS BioPharma, LLC, Doylestown, PA

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a neurodegenerative disease affecting upper and lower motor neurons. TAR DNA-binding protein (TDP-43) is an RNA and DNA binding protein that has been implicated in ALS, both as a causative factor and at the level of pathology. Although TDP-43 has been shown to play a key role in RNA metabolism, its mechanism is not fully understood. Specifically, evidence has shown that TDP-43 binds TG-rich sequences within RNA targets. In the context of disease, this binding can lead to alterations in splicing and/or proper regulation of its targets, and is partially responsible for the neurotoxicity that is associated with ALS. A 4-aminoquinoline analog (i.e. AAQ-2) has been shown to inhibit the binding of TDP-43 to TG oligonucleotides. To evaluate the effect of this small molecule in vivo, we administered AAQ probes to larvae expressing wild-type or mutant TDP-43 in motor neurons (D42 GAL4>TDP-43). Our experiments show that feeding of AAQ-2, but not a structurally similar negative control (AAQ-9), rescues the lethality caused by overexpression of TDP-43 in motor neurons. Additionally, AAQ-2 feeding also leads to improved locomotor function of larvae, as well as increased lifespan of flies overexpressing both wild-type and mutant TDP-43. In exploring the role of TDP-43-associated proteins in mediating the protective effect of AAQ-2 in motor neurons, we find that rescue of TDP-43-induced neurotoxicity by AAQ-2 is dependent in Fragile X Mental Retardation Protein (FMRP) in a TDP-43 variant-dependent manner. Currently, experiments are being performed to determine the effect of AAQ-2 on the solubility of full-length TDP-43 and its cleaved C-terminal fragment within motor neurons. These results provide insight into the role of TDP-43 in RNA metabolism, as well as suggest a possible therapeutic strategy for TDP-43-based ALS and related neurodegenerative diseases.

Title: A computational model for investigating early alterations in motor neuron and reflex excitability in amyotrophic lateral sclerosis

Authors: ***S. VENUGOPAL**, S. CHANDLER;
Integrative Biol. and Physiol., Univ. of California Los Angeles, Los Angeles, CA

Abstract: We recently showed complex changes in excitability of disease vulnerable trigeminal motor neurons (TMNs) at early postnatal stage (P8-P12) in the $SOD1^{G93A}$ mouse model for Amyotrophic Lateral Sclerosis (ALS). The observed changes in excitability were specific to putative motor unit types and there appeared to be a homeostatic dysregulation of proportions of TMNs with distinct discharge patterns in jaw closer motor pools. Additionally we have noted hyper-excitable shifts in sensory Mesencephalic (Mes V) neurons. Similar studies on brainstem and spinal MNs showing early excitability changes together suggest multiple channelopathies and homeostatic dysregulation of membrane properties in sensorimotor circuits. Such changes representing some of the earliest abnormalities in animal models of ALS could lead to dysfunctional reflex control and neuromuscular system. Furthermore, channelopathies leading to dysregulation of intracellular calcium can lead to abnormalities in a variety of cellular functions involving metabolism, neuroprotection and excitability. We begin an integrative approach to track progressive abnormalities in disease development and their behavioral consequences with the development of a computational reflex circuit model that incorporates known ionic currents in TMNs and Mes V neurons of the brainstem trigeminal system. The conductance-based TMN models reproduce the heterogeneous discharge properties (Type I: Linear, Type II: Adapting, Type III: Sustained Linear, Type IV: Hysteretic) and Mes V model reproduces complex burst firing. The TMNs form a trigeminal jaw closer motor pool consisting of putative fast and slow motor units distinguished based on their recruitment thresholds and input resistance. The sensory Mes V neurons drive the TMN motor pool that in turn drives a simplified muscle model. Using this reflex circuit model, we examined consequences of altered ionic conductances involving persistent inward currents, calcium-activated potassium currents in TMNs as well as persistent

and resurgent sodium currents in Mes V neurons. Our model results reproduce experimentally observed changes in TMN rheobase, input resistance and proportions shifts in turn predicting correlative changes in ionic conductances and their consequences on reflex excitability and muscle force development.

Title: Identification of therapeutic targets for cytoskeletal defects in amyotrophic lateral sclerosis

Authors: *A. JAVAHERIAN[1], P. GOYAL[1], K. SHAH[1], E. MOUNT[1], M. HSIAO[1], S. BROSKI[1,2], C. FALLINI[2], E. DANIELSON[2], J. LANDERS[2], S. FINKBEINER[1]; [1]Gladstone Inst., San Francisco, CA; [2]Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract: The pathogenesis of ALS and the mechanisms that lead to selective motor neuron degeneration are still unknown. This lack of knowledge hinders the development of an effective therapy to prevent or stop progression of the disease. Identification of ALS causative genes has helped to identify potential pathogenic pathways involved in the development of familial and sporadic ALS that can be targeted for therapeutic intervention. We recently identified mutations in two cytoskeletal genes, the actin binding protein profilin 1 (PFN1) and the microtubule subunit α-tubulin 4A (TUBA4A) as causative for familial ALS. These observations suggest that alterations affecting the cytoskeleton architecture, dynamics, and function are important in ALS pathogenesis. Our central hypothesis is that alterations to cytoskeleton structure and dynamics disrupt essential cellular functions, such as synaptic plasticity, vesicle recycling, axonal transport, and neuronal plasticity, which are necessary for the maintenance of motor neurons. We

have developed novel primary neuron cellular models of ALS based on TUBA4A and PFN1 mutations using a custom-built automated longitudinal imaging platform. We apply these cellular models to screen a subset of the druggable genome siRNA library focused on cytoskeletal genes and genes that have direct interactions with known ALS-linked cytoskeletal genes. Screening this RNAi library allows us to identify genes that play a role in the cytoskeleton pathway and act as disease modifiers. We have found several modifiers that rescue neurodegeneration caused by mutant PFN1, TUBA4A and TDP43 and could reveal common mechanisms underlying neurodegeneration caused by these mutations. Furthermore, these genes could serve as potential therapeutic targets.

Abstract: Among the growing number of known amyotrophic lateral sclerosis (ALS) disease proteins, TAR DNA binding protein 43 (TDP-43) has emerged as a key player. Nearly all sporadic and familial ALS cases are characterized by cytoplasmic aggregations of hyper-phosphorylated, ubiquitinated, and cleaved TDP-43 fragments and the loss of nuclear TDP-43. Although the specific composition of these detergent-insoluble inclusions may hold important clues to the pathological process in TDP-43 proteinopathies, it was previously unknown.
To address this question, we have adapted a new technique for proximity-dependent biotin-labeling and identification of proteins (BioID). This approach is based on the expression of a fusion protein of a promiscuous biotin ligase (BirA*) to the target protein. Our results show that

addition of excess biotin led to efficient biotinyation of endogenous proteins that were co-aggregating with BirA*-TDP-CTF in live cells. This novel application of the BioID method allowed us to efficiently isolate biotinylated proteins present in detergent-insoluble pathological aggregates by affinity capture under denaturing conditions, and to identify them via mass spectrometry.
Quantitative proteomics and gene ontology analysis show that the TDP-CTF interactome can be functionally categorized in translation, RNA processing, protein degradation, and intracellular transport. Immunofluorescence experiments confirmed the co-aggregation of TDP-CTF with numerous highly disordered proteins involved in intracellular transport pathways. Our findings demonstrate that expression of TDP-CTF and full length TDP-43 carrying ALS-specific point mutations cause defects in the localization of proteins within the cell. This is further supported by genetic interaction data from a Drosophila model of TDP-43 proteinopathy and staining of human brain tissue. Taken together, our data show that TDP-43 toxicity causes the disruption of intracellular transport pathways may contribute to the neurodegeneration observed in ALS/FTD, and potentially other neurologic disorders.

Title: Glua2 editing deficiency and synaptic dysfunction in C9orf72 als and ftd.

Authors: ***I. LORENZINI**[1], E. MENDEZ[2], I. VARELA[2], J. ROTHSTEIN[2], J. CHEW[3], L. PETRUCELLI[3], R. SATTLER[1];

[1]Neurobio. Div., Barrow Neurolog. Inst., Tempe, AZ; [2]Neurol., Johns Hopkins Univ., Baltimore, MD; [3]Neurosci., Mayo Clin., Florida, FL

Abstract: The hexanucleotide repeat expansion GGGGCC (G4C2) in the noncoding region of the C9orf72 (C9) gene represents the most common cause of sporadic and familial amyotrophic lateral sclerosis (ALS) and of frontotemporal dementia (FTD). Recent studies proposed a deficit in nuclear-cytoplasmic trafficking of RNA and nuclear proteins as a disease mechanism for mutant C9orf72. In agreement with these findings, we discovered a significant mislocalization of the RNA editing enzyme ADAR2, which is known to edit the glutamate receptor subunit GluA2 at its Q-R site. Analysis of C9 patient postmortem brain and spinal cord tissue samples, C9 human induced pluripotent stem cell (hiPSC) derived motor neurons and a novel C9 mouse model confirmed this mislocalization and the subsequent misediting of the GluA2 Q/R site. Lack of editing at the GluA2 Q/R site leads to increased Ca^{2+} permeability of AMPA receptors, which has been shown to regulate surface expression of GluA2 containing receptors. Changes in AMPA receptor trafficking and localization are known to play a significant role in synaptic transmission and plasticity, and aberrant AMPA receptor function is therefore thought to lead to synaptic dysfunction and cognitive impairment in C9 patients. When analyzing C9 hiPSC neurons for signs of synaptopathy, we found a significant decrease in spine density and dendritic branching proximal to the neuronal cell body when compared to healthy control hiPSC neurons. In addition, we see a decrease in presynaptic marker protein expression synapsin 1 and VGlut1. Based on these results we propose that the C9orf72 mutation leads to GluA2 editing deficiency via mislocalization of ADAR2, which results in dendritic remodeling, cortical dysfunction and may therefore contribute to the development of cognitive impairment observed in C9ORF72 ALS and FTD patients.

Abstract: Amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD) are progressive neurodegenerative diseases with substantial clinical, pathological, and genetic overlap. A hexanucleotide repeat expansion in the C9orf72 gene is the most frequent reported genetic cause of ALS and FTD. The objective of this study was to identify pathways involved in disease pathogenesis that are unique to each clinical phenotype and those that are similar across this spectrum. We performed an unbiased, quantitative proteomic screen using post-mortem brain tissue from patients clinically diagnosed with ALS (n=19), FTD (n=12), and patients who had both ALS and FTD (n=10), compared to normal (without neurological disease) controls (n=10). Patient tissue included those with and without the C9orf72 expansion mutation. Our data identified several pathways that differentiated these four clinically defined groups using weighted correlation network analysis. These included RNA binding proteins, astrocytic markers, proteins involved in nucleocytoplasmic transport, and synaptic proteins amongst other pathways. Using principal component analysis, we found that the proteomic signatures segregated out by clinical diagnosis. The presence of a C9orf72 expansion mutation was not identified as an independent variable associated with proteomic differences. Future detailed validation of these observed differences will clue us into the molecular underpinnings of these overlapping diseases. Based on our findings, we conclude that there are overlapping cellular pathways implicated in the diseases along this spectrum but also specific differences unique to clinical phenotypes separating ALS, FTD and ALS-FTD.

Title: Functional screening of ALS and ALS-dementia-linked Ubiquilin 2 (UBQLN2) mutations

Authors: *K. N. MCFARLAND[1], Y. ZHANG[2], D. RYU[2], C. CEBALLOS[3], D. RINCON-LIMAS[2], N. MCFARLAND[2];
[1]Dept. of Neurol., McKnight Brain Institute, Univ. of Florida, Gainesville, FL; [2]Neurol., [3]Neurosci., Univ. of Florida, Gainesville, FL

Abstract: Multiple mutations in *Ubiquilin 2* (*UBQLN2*) are found in individuals with X-linked amyotrophic lateral sclerosis (ALS), fronto-temporal dementia (FTD) or a combination of both (ALS-FTD). Since the initial study that identified a link between UBQLN2 and ALS/FTD, over 20 UBQLN2 mutations have been identified in familial as well as sporadic ALS/FTD patients. While initial mutations were identified in the proline-rich region of UBQLN2, additional mutations are scattered throughout in multiple domains outside the PXX region. UBQLN2 is a member of the ubiquitin-like family of proteins and is implicated in the functioning of the ubiquitin proteasome pathway (UPS), and possibly also in autophagy and the regulation of ER-associated protein degradation (ERAD). Both viral-mediated and transgenic overexpression of identified ALS-linked UBQLN2 mutant proteins results in widespread neuronal inclusion pathology in mouse models. In addition, a number of ALS-linked proteins are found within UBQLN2 inclusions in pathological samples, including ubiquitin, p62, TDP-43, VCP and optineurin. Furthermore, ALS-linked proteins of the hnRNP family interact with UBQLN2. These studies suggest converging pathogenic mechanisms involving UBQLN2 for abnormal proteostasis and RNA metabolism in ALS and ALS-dementia. Yet, the pathological mechanisms of UBQLN2 and its ALS-associated mutants remain unclear. The goal of our study is to determine the role of UBQLN2 in normal cellular proteostasis and RNA metabolism and to determine whether identified UBQLN2 mutations alter this using a combined approach of cellular and in vivo models. A dominant-negative effect has been proposed for UBQLN2 mutants affecting UPS function, but recent studies suggest also a toxic gain-of-function. Indeed, in our cell models expression of different UBQLN2 mutants results in varied inclusion pathology and differential effects on proteasomal function. Results from these studies lend insight into the function of UBQLN2 in cellular proteostasis and RNA metabolism and could identify proteins for targeted interventions.

[3]2nd Fac. of Medicine, Charles Univ., Prague, Czech Republic

Abstract: Amyotrophic lateral sclerosis (ALS) is a progressive neurodegenerative disorder leading to the death of upper and lower motoneurons (MN). Cell therapy may present new possibilities to cure ALS by providing neurotrophic support to host MN, dysfunctional glial cells and by influencing the immune system. In our preclinical study human mesenchymal stem cells (hMSCs), were delivered intrathecally into symptomatic SOD1 G93A transgenic rats (n=11). Survival in the hMSC-treated group was prolonged by 13.6 days compared with the sham-treated group (n=9). We found that the cell-treated rats showed significantly better motility and grip strength. Quantitative analyses of wisteria floribunda (WFA) fluorescence intensity measured in the ventral horns of the spinal cord, revealed significantly greater numbers of perineuronal nets (PNNs) in the hMSCs-treated animals. The clinical study (sponsored by Bioinova) was designed as a prospective, non-randomized, open-label study (phase I/IIa, EudraCT No. 2011–000362–35) to assess the safety and efficacy of autologous multipotent bone marrow (BM) MSCs in the treatment of ALS. Investigational product (IP) with $15\pm4.5\times10^6$ of MSCs (manufactured by Bioinova) was applied via lumbar puncture into the cerebrospinal fluid. During the 18 month follow-up period potential adverse reactions were assessed by clinical, laboratory and MR examination. The clinical outcome was evaluated using the ALS functional rating scale (ALSFRS), Norris spinal and bulbar scale (NSS and NSB), forced vital capacity (FVC) and weakness scale (WS). To date, 26 patients were enrolled in the study. One quarter (27%) of these patients experienced mild/moderate headache resembling headache after standard lumbar puncture. No suspected serious adverse reactions (SUSAR) were observed. In the group of 19 patients suitable for efficacy analysis a significant reduction in the ALSFRS decline at 3 months ($p<0.01$) and at 6 months ($p<0.05$) after IP application was found. Moreover, stabilization of FVC decline between 3 and 6 months was observed. A subgroup of 14 patients, with remarkable pretreatment decline in functional scales (ALSFRS + NSS), had significant reduction/stabilization in their functional scales decline at 3 months after IP application ($p<0.001$ in ALSFRS, $p<0.05$ in NSS), which was less pronounced at 6 months ($p<0.05$ in ALSFRS, $p<0.07$ in NSS) and at 9 months ($p<0.05$ in ALSFRS + NSS). In this group we also observed stable WS values for a time period of 3 months after application. Our results demonstrate that the intrathecal application of BM-MSC in ALS patients is safe and can, at least temporarily, slow progression of the disease.

Title: Selection and prioritization of candidate drug targets for amyotrophic lateral sclerosis through a meta-analysis approach

Authors: *G. MORELLO[1], A. SPAMPINATO[1], F. CONFORTI[2], V. D'AGATA[3], S. CAVALLARO[1];
[1]ISN, CNR, Catania, Italy; [2]ISN, CNR, Mangone (CS), Italy; [3]Dept. of Biomed. and Biotechnological Sciences, Section of Human Anat. and Histology, Univ. of Catania, Catania, Italy

Abstract: Amyotrophic lateral sclerosis (ALS) is a progressive and incurable neurodegenerative disease. Although several compounds have shown promising results in preclinical studies, their translation into clinical trials has failed. This clinical failure is likely due to the inadequacy of the animal models that do not sufficiently reflect the human disease. Therefore, it is important to optimize drug target selection by identifying those that overlap in human and mouse pathology. We have recently characterized the transcriptional profiles of motor cortex samples from sporadic ALS (SALS) patients and differentiated these into two sub-groups based on differentially expressed genes, which encode 70 potential therapeutic targets. To prioritize drug target selection, we investigated their degree of conservation in superoxide dismutase 1 (SOD1) G93A transgenic mice, the most widely used ALS animal model. Interspecies comparison of our human expression data with those of eight different SOD1G93A datasets present in public repositories revealed the presence of commonly deregulated targets and related biological processes. Moreover, deregulated expression of the majority of our candidate targets occurred at the onset of the disease, offering the possibility to use them for an early and more effective diagnosis and therapy. In addition to highlighting the existence of common key drivers in human and mouse pathology, our study represents the basis for a rational preclinical drug development.

Title: Microneurotrophins improve survival in motor neuron-astrocyte co-cultures but do not improve disease phenotypes in a mutant SOD1 mouse model of Amyotrophic Lateral Sclerosis

Authors: *K. E. GLAJCH[1], L. FERRAIUOLO[2], K. A. MUELLER[1], A. GRAVANIS[3], P. J. SHAW[2], G. SADRI-VAKILI[1];
[1]Dept. of Neurol., Massachusetts Gen. Hosp., Charlestown, MA; [2]Sheffield Inst. of Translational Neurosci., Univ. of Sheffield, Sheffield, United Kingdom; [3]Dept. of Pharmacology,, Univ. of Crete, Sch. of Med., Crete, Greece

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a neurodegenerative disease caused by loss of motor neurons. ALS patients experience rapid deterioration in muscle function with an average lifespan of 3-5 years after diagnosis. Currently, the most effective therapeutic only extends lifespan by a few months, thus highlighting the need for new and improved therapies. Neurotrophic factors (NTFs) are important for neuronal development, maintenance, and survival. NTF treatment has previously shown efficacy in pre-clinical ALS models. However, clinical trials using NTFs produced no major improvements in ALS patients, due in part to the limited blood brain barrier (BBB) penetration. In this study we assessed the potential neuroprotective effects of a novel class of compounds known as MicroNeurotrophins (MNTs). MNTs are derivatives of Dehydroepiandrosterone (DHEA), an endogenous neurosteroid that can cross the BBB and bind to tyrosine kinase receptors mimicking the pro-survival effects of NTFs. Here we sought to determine whether MNTs were neuroprotective in two different models of ALS. Our results demonstrate that BNN27 (10 μM) attenuated loss of motor neurons co-cultured with astrocytes derived from human ALS patients with SOD1 mutations. Additionally, in the G93A SOD1 mouse, BNN27 (10 mg/kg) treatment attenuated motor behavioral impairment in the paw grip endurance and rotarod tasks at postnatal day 95 in female but not male mice. In contrast, BNN27 (10 mg/kg and 50 mg/kg) treatment did not alter any other behavioral outcome or neuropathological marker in male or female mice. Lastly, BNN27 was not detected in post-mortem brain or spinal cord tissue of treated mice and *in vitro* experiments demonstrated that BNN27 is metabolized at a faster rate by mouse hepatocytes relative to human hepatocytes. Together, these findings demonstrate that BNN27 treatment failed to yield significant neuroprotective effects in the G93A SOD1 model likely due to its rapid rate of metabolism in mice.

Title: The effects of different applications of mesenchymal stem cells in the treatment of amyotrophic lateral sclerosis

Authors: ***P. JENDELOVA**[1,2], M. SENEKLOVA[1,2], S. FOROSTYAK[1,2], Y. PETRENKO[1], E. SYKOVA[1,2];
[1]Inst. of Exptl. Medicine, ASCR, Prague 4, Czech Republic; [2]2nd Fac. of Medicine, Charles Univ., Prague, Czech Republic

Abstract: Amyotrophic lateral sclerosis (ALS) is characterized by the degeneration of upper and lower motor neurons, muscle atrophy and paralysis. Although the mechanisms responsible for motor neuron degeneration in ALS remain unclear, mesenchymal stem cell (MSC) transplantation is considered a promising approach for promoting neuroprotective and neuroregenerative repairs. However, the stem cells exert their effects in different manners depending on the way they are applied. In the first group, symptomatic SOD1 G93A transgenic rats received 2 injections of 10^5 cells MSCs intraspinally at the Th 10 level and $2x10^6$ intravenously (i.v.). The second group of rats received $5x10^5$ human MSCs (hMSCs) suspended in 50µl of growth media intrathecally (via the cistern magna) in a single injection, or repetitively 3 times via lumbar puncture. The third group of animals received 3 times 50µl of hMSC conditioned medium (CM-MSC). The fourth group of rats received hMSCs intramuscularly (three injections of $2x10^5$ cells into m. quadriceps femoris into both hind limbs) to prevent axonal degeneration. Sham operated animals were injected with growth media, using the same delivery route. The time course of the disease and functional scores after cell transplantation were tested behaviourally by BBB score, rotarod test, gript strength tests and motorater data analysis. We followed body weight and performed immunohistochemical analysis. Quantitative

polymerase chain reaction (qPCR) was used to evaluate the expression of growth factors in spinal tissue, apoptosis-related genes (BAX, BCL-2 and Casp-3) and necroptosis-related genes (RIP1, RIP3, MLKL). In comparison with the sham-treated group, overall survival in the i.v. MSC-treated group was prolonged by 11 days, a single intrathecal dose of hMSCs increased survival by 13.6 days and repetitive hMSCs application resulted in prolonged life spam by 19.6 days. All cell-treated rats showed significantly better motility and grip strength than controls. In the implanted rats we found a greater number of MNs at the thoracic and lumbar level and the apoptotic process assessed by the intensity of TUNEL staining decreased. CM-MSC or hMSCs intramuscular injection did not significantly prolong the life spam of SOD1 animals. Our results suggest that MSC application slows down disease progression and repeated application prolongs the effect. It is therefore reasonable to assume that repeated application can be more beneficial for potential clinical study in ALS patients.

Title: Therapeutically targeting the motor cortex in ALS using human neural progenitor cells expressing GDNF

Authors: *G. M. THOMSEN, A. MA, P. AVALOS, P. HARO, O. SHELEST, C. N. SVENDSEN;
Cedars-Sinai Med. Ctr., West Hollywood, CA

Abstract: Recently, there has been an increased focus on the role of the motor cortex in amyotrophic lateral sclerosis (ALS). We have shown that the transplantation of human neural progenitor cells expressing glial cell line-derived neurotrophic factor (hNPC-GDNF) into the motor cortex of the SOD1 rat model of ALS leads to a delayed disease onset and extension in survival. Here, we show that this targeting strategy also leads to enhanced survival of large spinal motor neurons in both the lumbar and cervical spinal cord in SOD1 rats transplanted with hNPC-GDNF relative to non-injected rats when euthanized at ~165 days of age. The difference in spinal motor neurons was not evident when rats were euthanized at endpoint, which is

unsurprising given that rats are at a similar anatomical disease state. Analysis of L5 ventral root axons was not significantly different in those rats receiving injections of hNPC-GDNF in the brain relative to non-injected controls at either time point. Variability in data suggests, however, that there may be a dose-response range whereby the extent of injected cell survival and migration throughout the cortex influences the magnitude of downstream effects, the delay in disease onset and the extension in survival. Assessment of graft survival and GDNF expression in one rat surviving 273 days (3.9 standard deviations above the mean survival of 182 +/- 23 days in non-injected SOD1 rats in this study) has revealed robust cell survival, high GDNF expression, and widespread migration throughout the rostral-caudal axis of the motor cortex. Cells in these long-term grafts primarily differentiated into GFAP-expressing astrocytes, with a number of them appearing morphologically as mature astrocytes. Additionally, host cells in the transplanted regions appeared to take-up GDNF. Two SOD1 rats that received cortical injections of hNPC-GDNF in this study are currently surviving at 315 days of age. Transplanted cells in all rats are assessed for survival, migration, differentiation and GDNF expression, and these parameters are correlated with disease onset and lifespan. Transplanting hNPC-GDNF into the motor cortex has significant beneficial functional effects in a rat model of ALS. As such, studies with a single non-human primate are underway to test the safety of delivering hNPC-GDNF to the motor cortex in a large animal model. Collectively, these preclinical studies should permit translation of targeting the brain with these cells to treat ALS. This promising treatment could involve targeting the brain alone, or in combination with spinal cord and/or muscle.

Title: A personalized gene therapy approach for charcot-marie-tooth disease type 2d

Authors: *K. H. MORELLI[1,2], J. S. DOMIRE[3], N. PYNE[3], A. FOWLER[3], S. HARPER[3], R. BURGESS[1,2];

Abstract: Charcot-Marie-Tooth disease is a collection of inherited polyneuropathies caused by at least 80 loci in the human genome. To date, thirteen different mutations in *GARS (*glycyl-tRNA synthetase, GlyRS*)* have been identified in patients with autosomal dominant CMT Type 2D (CMT2D). Although, the mechanisms through which mutant forms of GARS cause axon degeneration remain controversial. Preliminary data from CMT2D patients and mouse models of the disease ($Gars^{C201R/+}$ and $Gars^{P278KY/+}$) are consistent with the expression of mutant GlyRS causing toxic gain-of-function or dominant negative effects in peripheral nerves. These data suggest that the selective silencing of mutant *GARS* expression should be of therapeutic benefit for patients with this disorder. However, considering there are currently no strategies for accomplishing this pharmacologically, we have developed a gene therapy strategy that reduces mutant *Gars* transcripts through allele-specific RNAi. To test the proof-of-principle of this approach, microRNA vectors that specifically target the mutant mouse *Gars* allele, P278KY (mi-P278KY) have been developed and cloned into self-complementary adeno-associated viral vectors (scAAV9) for *in vivo* delivery. Preliminary data suggest that when injected at birth, AAV9-mi-P278KY leads to significantly improved gross motor function and nerve conduction velocity in $Gars^{P278KY/+}$ mice. Treated mice will be further evaluated for additional primary outcome measures of neuropathy, including axon atrophy, axon loss, and neuromuscular junction abnormalities to confirm the efficacy of the gene therapy approach. Future directions for this study include testing the ability of AAV9-mi-P278KY to arrest or reverse the neuropathy when delivered post onset in $Gars^{P278KY/+}$ mice, and to test efficacy of patient-specific vectors in "humanized" mouse models that have CMT2D-patient-associated mutations introduced into the mouse *Gars* gene. Success with this approach would provide a promising avenue for treatment of CMT2D and other dominantly inherited neuromuscular diseases.

Title: Il37 reduces inflammation and ameliorates pathophysiology in amyotrophic lateral sclerosis

Authors: *A. MARTINEZ-MURIANA[1], C. A. DINARELLO[2,3], R. LOPEZ-VALES[1];
[1]Cell biology, physiology and immunology, Univ. Autonoma De Barcelona, Bellaterra, Spain; [2]Div. of Infectious Dis., Univ. of Colorado Denver, Aurora, CO; [3]Dept. of Med., Radboud Univ. Med. Ctr., Nijmegen, Netherlands

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a fatal neurodegenerative disorder that affects upper and lower motor neurons (MNs). MNs loss results in skeletal muscle weakness, spasticity and eventual paralysis, leading to the death of patients by respiratory failure 3 to 5 years after diagnosis. As occurs in several neurological disorders, inflammation is a hallmarks also found in ALS patients. Several reports provide evidence that glial cells accelerate the course of the disease in animal models of ALS, suggesting that therapies aimed at targeting inflammation may be a valuable approach for the treatment of ALS. IL-37 is a member of the IL-1 family that exerts broad anti-inflammatory effects over innate and acquired immunity. Transgenic mice for human IL-37 (hIL-37tg) exhibit reduced disease severity in models of endotoxemia, acute lung injury, chemical colitis, myocardial ischemia, and sleep disturbance. We have demonstrated for the first time that this cytokine mediates marked anti-inflammatory actions in the injured central nervous system, and leads to reduced tissue damage and functional deficits in a mouse model of spinal cord contusion injury. However, whether IL-37 also exerts similar beneficial effects in neurodegenerative conditions is not known yet. In the present study, we investigated whether IL-37 suppresses inflammation and slows the clinical course of the disease in a mouse model of ALS ($SOD1^{G93A}$ mouse). Since IL-37 is not expressed in the mouse, we crossed hIL-37tg mice with $SOD1^{G93A}$ mice. Our data reveals that transgenic expression of IL-37 resulted in reduced microgliosis and astrogliosis in the lumbar spinal cord of $SOD1^{G93A}$ mice. Interestingly, we also observed that IL-37 slowed ALS disease progression and increased lifespan of these mice, which correlated with an increased preservation of spinal MN. Our findings provide the first evidence of the anti-inflammatory and beneficial actions of IL-37 in a neurodegenerative disease, and supports the therapeutic potential of this cytokine for the treatment of ALS.

Title: Gene therapy for familial amyotrophic lateral sclerosis using adeno-associated virus serotype-9 mediated silencing of mutant SOD1

Authors: *T. IANNITTI[1], J. M. SCARROTT[1], I. R. P. COLDICOTT[1], B. K. KASPAR[2], L. FERRAIUOLO[1], P. J. SHAW[1], M. AZZOUZ[1];

Abstract: Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disorder resulting in death of brain and spinal cord motor neurons. Some familial cases are caused by missense mutations in the gene encoding the Cu/Zn superoxide dismutase 1 (SOD1) conferring a toxic gain of function to this protein. We hypothesised that specifically silencing expression of the mutant form of the human SOD1 gene would alleviate SOD1-linked ALS symptoms. The aim of our study was to evaluate the therapeutic efficacy of clinical AAV9-shRNA mediated SOD1 silencing in the SOD1G93A mouse model. Animals were treated either at postnatal day 1 (P1, pre-onset) or P40 (onset). scAAV9-hSOD1si or scrambled control scAAV9-hSOD1ssi were delivered using 2 routes of delivery, facial vein or cisterna magna. Mice were then tested using behavioural tests including weekly rotarod runs, neurological scoring and CatWalk gait analysis. Weekly body weight was also collected. We observed an improvement in rotarod performance in mice treated with scAAV9-hSOD1si when compared to scAAV9-hSOD1ssi and untreated controls. Survival analysis revealed that a therapeutic dose of $2.5x10^{13}$vg/kg body weight increased median survival from 129 days, to a maximum survival of over 240 days. Clinical AAV9-shRNA vector mediated SOD1 silencing through cisterna magna improved motor performance and led to remarkable life span extension in the SOD1G93A mouse model. Our gene therapy approach offers promising strategy for clinical application in SOD1-linked familial ALS.

Title: Artificial microRNA silences C9ORF72 variants and decreases dipeptides in BAC transgenic mouse

Authors: *G. TORO[1], O. M. PETERS[2], T. F. GENDRON[4], C. MUELLER[3], R. H. BROWN, Jr[2];

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a fatal neurodegenerative disease that targets upper and lower motor neurons causing progressive muscle weakening. Respiratory failure is the common cause of death approximately 2-5 years after symptom onset. An expanded hexanucleotide repeat located in chromosome 9 open reading frame 72(C9ORF72) accounts for the majority of familial ALS cases as well as frontotemporal dementia (FTD) cases. Post mortem patient brain tissues have shown that in the presence of the expansion, C9ORF72 mRNA is reduced and RNA sequences complimentary to the expansion aggregate into nuclear foci. Simultaneously, this expanded RNA can be translated into long dipeptide chains by non-ATG repeat associated (RAN) translation. These findings have led to three hypotheses on the pathogenesis of C9ORF72: 1) haploinsufficiency, postulating that decreased levels of mRNA lead to insufficient gene product; 2) adverse effects of intranuclear RNAi foci (eg. protein sequestration); 3) RAN translation from the repeat expansion generating toxic poly-dipeptide proteins. Our group has generated 2 lines of mice containing a bacterial artificial chromosome (BAC). The first line is composed of exons 1-6 of the human C9ORF72 gene and a 500 repeat hexanucleotide expansion. The second is composed of all 12 exons and a smaller, 100 repeat expansion. These mouse models recapitulate the major histopathological features seen in human ALS/FTD caused by C9orf72 mutations: lower levels of C9ORF72 mRNA, RNA nuclear foci, and the RAN translation products. We have used these mice as a platform in which to test RNAi therapeutic strategies. We have designed artificial microRNAs that target the human C9ORF72 gene with the purpose of decreasing the mRNA levels, the toxic RNA foci and/or RNA dipeptide proteins. We packaged our lead microRNA into a recombinant adeno-associated virus (rAAV) serotype 9 to use with primary neuron cultures and *in vivo* experiments. Silencing was initially validated in primary cortical neurons from the first C9ORF72 mouse line. Our results suggest

that AAV9-mediated microRNA not only reduced the mRNA levels of C9ORF72 but also the most abundant poly dipeptide (GP). Experiments are now underway to silence C9ORF72 *in vivo* via intracranial ventricular (ICV) injection of this microRNA into C9ORF72 transgenic pups; results will be presented.

Title: Antisense oligonucleotides-based strategy as a therapy for the development of genetic Motor Neuron Diseases Antisense oligonucleotides-based strategy as a therapy for the development of genetic Motor Neuron Diseases

Authors: M. NIZZARDO[1], M. BUCCHIA[2], A. RAMIREZ[2], F. RIZZO[2], M. RIZZUTI[2], P. RINCHETTI[2], G. ULZI[1], A. BORDONI[2], N. BRESOLIN[1], *G. P. COMI[1], S. CORTI[1]; [1]Univ. of Milan, Ospedale Maggiore Policlinico, Milan, Italy; [2]Univ. of Milan, Milan, Italy

Abstract: Motor neuron diseases (MNDs) are fatal incurable disorders characterized by relentless motor neuron (MN) degeneration. No effective approved treatments are presently available. The genetic MNDs forms can offer a solid ground for research since, at least in these cases, the etiopathogenetic primum movens is identified. In this study, we developed novel

oligonucleotides with morpholino (MOs) chemistry designed to reduce the synthesis of human SOD1 and C9ORF72, the most frequent Amyotrophic Lateral Sclerosis (ALS) causative genes, or to up-regulated the SMN full length level, the causative molecular defect of Spinal Muscular Atrophy (SMA). To investigate the effectiveness of MO approach in a human model, we treated human familial (f)ALS (SOD1/C9ORF72) and SMA induced pluripotent stem cell (iPSC) and their derived motor neurons with MOs. The oligonucleotides can effectively modulate the expression of the target protein downregulating SOD1/C9ORF72 in fALS and up-regulating SMN protein level in SMA cells. Indeed, after treatment, SOD1 and SMA motor neurons displayed increased survival and reduced expression of apoptotic markers, while C9ORF72 cells showed a significant reduction of toxic dipeptides accumulation. At the same time, we studied the efficacy of the already validated MO sequence targeting (MO-10-34) SMN2 in vivo in the SMAΔ7 mouse model after its conjugation with four cell-penetrating peptides (Tat, R6, r6 and (RXRRBR)2XB) to increase the cellular and tissue uptake and pharmacological profile. The compounds obtained were administered in a small pilot group of pre-symptomatic SMA mice to determine the best one by its ability to rescue the SMN protein levels by western blot and to perform further studies in presymptomatic and symptomatic SMA mice to assess MO therapeutic potential. Overall, our results support the efficacy of MO-mediated therapeutic strategy in MND models, opening the path for human development of this approach.

Title: Mitigation of TDP-43 proteinopathy through recombinant single chain antibodies.

Authors: *S. POZZI, S. S. THAMMISSETTY, C. GRAVEL, J. KRIZ, J.-P. JULIEN; CRIUSMQ, Québec, QC, Canada

Abstract: A landmark in ALS was the discovery in 2006 of TDP-43 as a major component of ubiquitinated inclusions in ALS cases. TDP-43 is predominantly a nuclear protein that has been implicated in regulating mRNA splicing, stability and gene transcription but the pathogenic pathways of TDP-43 in ALS are not well understood. We discovered that TDP-43 acts as a co-activator of p65 subunit of nuclear factor kappa B (NF-kB). p65 interacts with the RNA recognition motif 1 (RRM1) domain of TDP-43. We propose to develop a therapy for ALS based on the delivery of single chain (scFv) antibodies that can target specifically the TDP-43 RRM1 domain with the dual action to block the TDP-43 interaction with p65 NF-κB and to attenuate formation of TDP-43 aggregates. From monoclonal antibodies, specifically binding the RRM1 domain of TDP-43, we generated vectors expressing two recombinant scFv antibodies. Vectors include a human myc epitope as a localization signal and an IgK domain which allows scFv secretion. We transfected cells with scFv expressing vectors and verify the ability of scFv to recognize TDP-43, disrupt TDP-43/p65 interaction and reduce TDP-43 aggregation. We finally generated scAAV2/9 viral vectors producing the single chain antibodies, injected them in the frontal cortex of mice expressing mutant TDP-43 and analysed the disease progression in terms of motor performances and cognitive impairments. ScFv can be produced and released in the medium of transfected cells and are able to bind recombinant TDP-43 fragment and to disrupt TDP-43/p65 interaction. Experiments in BV2 microglial cells provide evidences that scFv antibodies can attenuate the activity of p65/NF-kB and modulate cytokine expression levels after LPS induction. Moreover, transfection of scFv antibodies into Hek293 attenuates TDP-43 insolubility after treatment with Ethacrynic Acid. Mutant TDP-43 mice, injected with the virus expressing scFv antibodies, show improvements in cognitive behavioural tests like novel object recognition and open field test. These results support the feasibility to use these scFv antibodies for attenuating TDP-43 proteinopathy.

Title: Development of clinical grade neurotrophic factor secreting autologous mesenchymal stem cells for treatment of amyotrophic lateral sclerosis

Authors: *S. RAMESH, N. N. MADIGAN, K. J. CLARK, M. J. POLZIN, S. P. EKKER, A. J. WINDEBANK, N. P. STAFF;
Mayo Clin., Rochester, MN

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disorder affecting the motor neurons leading to progressive paralysis. In most cases, the cause is sporadic (90%) and leads to death within 3-5 years after disease onset. Recent work has shown that delivery of mesenchymal stem cells (MSCs) to the spinal cord is safe and could potentially slow motor neuron degeneration. Neurotrophic factors (NTFs) have long been considered neuroprotective in animal models of motor neuron disease. However, in human clinical trials NTFs have not been beneficial for ALS possibly due to poor central nervous system penetrance. Based on previous work, we hypothesize that controlled release of NTFs in an autologous MSC based delivery system could be a potential therapeutic solution for patients suffering from ALS. Our objective is to conduct targeted gene insertion in patient adipose derived MSCs at 'safe-harbor' sites using transcription activator like effector nuclease technology (TALEN). NTF secreting MSCs (MSC-NTFs) will then be evaluated for safety and efficacy in *in vitro* ALS models. Two pair of TALENs for each of the two safe-harbor sites (AAVS1 and CLYBL) was cloned. Various delivery methods including nucleofection and polyethylenimine based transfection systems were explored in this study. One TALEN pair for AAVS1 was chosen and cell viability, transformation efficiency, and TALEN pair cutting efficiency was measured 48 hours after nucleofection. We aim to develop clinical grade NTF-secreting adipose-derived MSCs that can be delivered back to ALS patients in a safe manner. Development of this system may be beneficial not only to treat ALS but potentially could also be used to treat other neurodegenerative disorders that are responsive to NTFs.

Abstract: Amyotrophic Lateral Sclerosis (ALS) is an incurable disease that targets motor neurons (MNs). Non cell-autonomous mechanisms, particularly micro and macro-gliosis are implicated in MNs degeneration. We describe here the results from studies testing the ability of human neural stem cells (hNSCs) – whose clinical GMP-status was granted by the Italian Medicines Agency (AIFA) – to elicit anti-inflammatory effects upon transplantation in the SOD1

rat ALS model and data emerging from a standardized phase I clinical trial on ALS patients. SOD1 experiments: hNSCs were injected bilaterally into the anterior horns of the spinal cord (4 grafts; L3-L4 tract) of early symptomatic SOD1 rats (n=15). Control groups: HBSS treated SOD1 (HBSS, n=15) and untreated ones (Ctrl, n=22). hNSCs migrated rostro-caudally up to 3.27±1.05 cm differentiating into neurons and glia. At late-symptomatic stage, hNSCs SOD1 displayed higher spinal MNs density (L3-L4) and reduced astroglial and microglial cell numbers ($p \leq 0.05$ vs HBSS and $p \leq 0.01$ vs Ctrl). hNSCs slowed body weight loss and motor performances deterioration ($p \leq 0.05$ vs HBSS and $p < 0.0001$ vs Ctrl). hNSCs SOD1 (n=5) survived more respect to HBSS (n=5, HR: 0.08 95%CI=0.01-0.72 p=0.024) and Ctrl (n=14, HR: 0.08 95%CI=0.01-0.65 p=0.018). Phase I clinical trial: In 2012 the Italian Institute of Health (ISS) and competent ethical committees approved a phase 1 clinical trial (*EudraCT* Nr 2009-014484-39) to assess the safety and feasibility of intraspinal transplantation of hNSCs in 18 ALS subjects. The trial has now been completed. Stereotactic microinjection procedures (n=6 thoracolumbar [T10/11], n=12 cervical [C3-5]) delivered hNSCs into definite ALS patients (5F and 13 M, Median age 49yrs), in three cohorts. Each injection series comprised 3 injections of 15 µl of 50,000cells/µl suspension. All patients were immunosuppressed for 6 months after surgery and are monitored monthly by both clinical and radiological standardised assessment. No patients manifested severe treatment-related adverse events (post-surgical mild pain disappearing in ~4days), no structural changes (including tumor or syrinx formation) and no evidence of acceleration of disease progression due to the treatment has been evidenced so far. Eleven patients showed a transitory improvement of MRC score respectively in the leg and in the arm. Nine patients died 8-35 months after surgery due to natural history of the disease. This study confirms the safety of this procedure and shows no evidence of immediate or delayed toxicity related to hNSCs. Based on these results we are now submitting to the ISS a request to proceed with a phase II trial examining therapeutic efficacy.

Title: Cryptic exon repression by tdp-43 as a novel approach to a disease modification biomarker in als, ftd, and ad

Authors: *R. KESILMAN (KORN);
Early Discovery Neurosci., Merck & Co., Inc., West Point, PA

Abstract: Dysregulation of transactivation response element DNA-binding protein 43 (TDP-43) is a common pathophysiological hallmark of Amyotrophic lateral sclerosis (ALS) and Frontotemporal dementia (FTD). Cytoplasmic mislocalization and aggregation of TDP-43 is distributed across distinct populations of neurons and is thought to reflect the pathological progression of ALS -FTD. Recently it was discovered that TDP-43 functions to repress cryptic exon expression in pre-mRNA transcripts of key target genes. Cryptic exons are small intronic regions of DNA normally removed by the spliceosome prior to mature mRNA production. A loss of TDP-43 function, resulting from nuclear mislocalization, truncation, or aggregation during the disease process, is proposed to cause abnormal inclusion of cryptic exons in target proteins. The purpose of the experiments described in this presentation was to validate cryptic exon expression following TDP-43 knock-down in a human neuroblastoma cell line, and in human post-mortem disease tissue. Data from these experiments confirmed and extended initial findings and demonstrated that TDP-43 knock-down in SH-SY5Y cells results in a robust increase in cryptic exon expression in key target mRNA. In most cases, cryptic exon incorporation results in premature stop codons and nonsense mediated decay of RNA. However, cryptic exons can also be spliced in-frame and result in translation of a cryptic peptide sequence. To explore this, cryptic peptide expression following TDP-43 knock-down in SH-SY5Y cells is being explored using mass spectrometry to characterize novel disease-specific biomarkers. Finally, we continue to evaluate and characterize cryptic exon and cryptic peptide expression in post-mortem disease brain tissue, plasma, and csf to determine the robustness and reliability of expression in patients versus control tissue. Together, these findings point to a novel biomarker of TDP-43 proteinopathy, and may be used to develop PET ligands, antibody or mass spectrometry-based biomarker assays of disease progression.

Title: Chronic laryngeal nerve stimulation to improve swallow function and survival in an ALS mouse model

Authors: M. M. HANEY[1], K. L. ROBBINS[2], J. H. ALLEN[3], A. THIESSEN[3], I. DENINGER[2], K. FLYNN[2], V. CAYWOOD[2], A. MOK[1], D. OHLHAUSEN[2], N. KHODAPARAST[4], *T. E. LEVER[3];
[1]Vet. Pathobiology, [3]Otolaryngology - Head and Neck Surgery, [2]Univ. of Missouri Columbia, Columbia, MO; [4]Nuviant Med., Dallas, TX

Abstract: Objectives: Many neurologic diseases, such as amyotrophic lateral sclerosis (ALS), result in swallowing impairment, also known as dysphagia. Dysphagia is highly correlated with malnutrition and aspiration pneumonia, leading to poor quality of life and increased morbidity and mortality. Current treatments are palliative and target the clinical symptoms of dysphagia. There are little to no treatments that address the underlying neuro-pathophysiology responsible for dysphagia. To address this, we have developed an experimental protocol to investigate the efficacy and safety of chronic superior laryngeal nerve (SLN) stimulation to improve swallow function and survival in the low copy number (LCN) *SOD1-G93A* transgenic ALS mouse model that has phenotypic variation relative to limb paralysis. This experiment is based on our previous experiments using acute SLN stimulation to immediately rescue swallow function in end-stage *SOD1-G93A* mice, enabling dysphagic mice to swallow at stimulus frequencies similar to control mice.
Methods: 80 mice (40 *SOD1-G93A* and 40 controls) underwent a freely-behaving videofluoroscopic swallow study assay to characterize dysphagia over the lifespan. 20 additional control mice were utilized for surgical protocol development for chronic SLN stimulation with a custom made nano-cuff electrode.
Results: *LCN-SOD1-G93A* mice develop dysphagia at 6 months of age that worsens with disease progression; however, dysphagia severity is worse for mice with predominant forelimb paralysis. At dysphagia onset, mice are undergoing our surgical protocol for nano-cuff placement that includes an anterior cervical approach. The SLN is isolated and the nano-cuff is positioned around the nerve to stimulate swallowing. A micro-patch electrode is placed on the anterior digastric muscle for EMG detection of swallows. Electrode leads are tunneled subcutaneously and attached to a skull-mounted head stage and connected to an electrical stimulator and bioamplifier. Using this protocol, we are establishing optimal SLN stimulation parameters that evoke swallowing in freely-behaving mice.
Conclusions: If ALS-affected mice maintain healthy swallow function and survive significantly longer as a result of chronic SLN stimulation, this study will lay the groundwork for using an implantable SLN stimulator for long-term treatment of dysphagia in patients with ALS and other chronic neurological conditions. While we hypothesize this novel treatment strategy will improve swallow function regardless of ALS phenotype, we expect mice with predominant forelimb paralysis (i.e., the most severe dysphagia) will demonstrate the best treatment outcomes.

Title: 3a-diol is neuroprotective and attenuates pro-inflammatory cytokines in the brain following soman exposure in mice.

Authors: ***K. LAITIPAYA**, J. K. CHANDLER, T. M. FERRARA-BOWENS, J. F. IRWIN, D. D. PALMER, L. J. SHUMWAY, E. A. JOHNSON;
USAMRICD, Gunpowder, MD

Abstract: Severe neuropathology and behavioral impairment result from prolonged status epilepticus (SE) caused by organophosphorus nerve agents such as soman (GD). GD, a potent acetylcholinesterase inhibitor, causes prominent cell death in the hippocampus, thalamus, piriform cortex, and amygdala, leading to the activation of the neuroinflammatory cascade. Neuroinflammation can exacerbate tissue injury or promote healing, depending on the intricate interaction of multiple cells, inflammatory factors, and receptors as the injury progresses. Few studies have explored the effects of the neuroendocrine system on brain injury caused by SE. Prior studies have shown that reductions in neuroinflammation can confer neuroprotection and that androgen therapy also has neuroprotective properties. In particular, testosterone and its metabolites dihydrotestosterone (DHT) and 3α-androstanediol (3α-diol) have been shown to attenuate seizure probability and damage caused by GD insult while also increasing seizure threshold. We have previously shown that pretreatment with 3α-diol prior to GD exposure, outperforms testosterone and testosterone with letrozole in those regards. In this study, the effects of 3α-diol on numerous pro- and anti-inflammatory markers in specific brain regions via fluorescent detection quantifiable multiplex speed assay were investigated to elucidate the possible mechanisms of 3α-diol neuroprotectivity. Brain regions protected by 3α-diol also have attenuated levels of well-known pro-inflammatory markers, such as interleukin-1 beta (IL-1β), interleukin-6 (IL-6), and tumor necrosis factor alpha (TNFα).

Title: Increased amyloidogenic processing of APP potentially induced by the cyclooxygenase product of inflammation prostaglandin J2

Authors: *T. JEAN-LOUIS[1,2], P. ROCKWELL[1], M. FIGUEIREDO PEREIRA[1];
[1]Biol. Sci., Hunter Col., New York, NY; [2]The Grad. Center, CUNY, New York, NY

Abstract: Senile plaques (SP) are pathological hallmarks of Alzheimer disease (AD). The main component of SPs is Aβ, generated via cleavage of the amyloid precursor protein (APP) by β- (BACE) and γ-secretases in the amyloidogenic pathway. Alternatively, APP processing by α- and γ-secretases in the non-amyloidogenic pathway prevents Aβ formation. The upstream events that regulate APP processing by the amyloidogenic and non-amyloidogenic pathways are poorly defined. We propose that inflammation contributes to the shift in balance towards APP amyloidogenic processing. Inflammation plays a major role in AD. Investigating how specific factors of inflammation mediate neurodegeneration in AD is crucial. Our studies focus on prostaglandin products of cyclooxygenases, which are key enzymes in inflammation and highly relevant to AD. In particular, we are investigating how the neurotoxic prostaglandin J2 (PGJ2) alters processing, trafficking, and post-translational modifications of APP. Neuronal APP occurs as mature forms exhibiting both *N*- and *O*-glycosylation, as well as an immature form displaying only *N*-glycosylation. Our previous studies with rat cerebral cortical neuronal cultures showed that PGJ2 induces a significant decrease in the *O*-glycosylated forms of APP. Our current data demonstrate that this decline in *O*-glycosylation is not due to PGJ2 stimulating APP cleavage by cellular proteases, such as proteasomes, lysosomal proteases, calpains and caspases, or by the α and γ secretases. Instead, PGJ2-treatment altered APP trafficking along the secretory pathway

and neuronal processes. Accordingly, PGJ2 induced a decline in APP levels at the ER and Golgi, as well as the accumulation of APP into large clusters at neuronal processes. Moreover, APP trafficking from the trans-Golgi network (TGN) to the cell surface is known to decline when its *O*-glycosylation is impaired. Deficits in APP *O*-glycosylation promote its trafficking to early endosomes, where APP is degraded by BACE and γ-secretase to produce Aβ and sAPP, which can then be secreted. These data together with our finding that PGJ2 alters APP *O*-glycosylation suggests that PGJ2 could promote the amyloidogenic processing of APP by re-directing its trafficking to early endosomes, where APP processing by BACE and γ-secretase would increase secreted Aβ levels. Since upregulation of cyclooxygenase-2 has emerged as an important determinant of the cytotoxicity associated with neuroinflammation, our studies address a mechanism possibly linking neuroinflammation with increased Aβ production in AD.

Title: Tumor necrosis factor-α enhances vascular cell adhesion molecule-1 expression and promotes monocyte adhesion in human glioblastoma cells

Authors: *Y.-S. LIU[1], C. LIN[2], C.-F. TSAI[3], D.-Y. LU[4];
[1]Grad. Institue of Basic Med. Sci., China Med. Univ., Taichung, Taiwan; [2]Dept. of Physiology, Sch. of Medicine, China Med. Univ., Taichung, Taiwan; [3]Dept. of Biotechnology, Asia Univ., Taichung, Taiwan; [4]Dept. of pharmacology, Sch. of Medicine, China Med. Univ., Taichung, Taiwan

Abstract: Cytokines are abundantly in tumor microenvironment and involve in tumor progression. Vascular cell adhesion molecule-1 (VCAM-1) is a cytokine-induced adhesion molecule whose expression on the surface of cancer cell and interact with various immune cells. However, the role of VCAM-1 in monocyte/macrophage adhesion to human glioblastoma (GBM) is mostly unknown. Analysis of GSE4290 glioma patient dataset showed that VCAM-1 expression was correlated with clinicopathologic grade of gliomas. TNF-α induced VCAM-1 expression and thus promoted human monocyte adhesion to GBM. Knockdown of VCAM-1 abolished TNF-α-enhanced monocyte adhesion to GBM. In immunohistochemistry staining, the expression of VCAM-1 in glioma patients was correlated with tumor stage and higher than that in the normal brain tissue. The inductive effect of EGFR phosphorylation was observed time-

dependently after TNF-α stimulation. In addition, induction of TNF-α-enhanced monocyte adhesion to GBM was antagonized by treatment of EGFR inhibitor. TNF-α decreased miRNA-181a/b expression in GBM. Moreover, transfection with miRNA-181a/b mimics reversed the TNF-α-induced VCAM-1 expression. On the other hand, miRNA-181a/b reduced the PP2A phosphatase activity in GBM. TNF-α-induced VCAM-1 expression and monocyte adhesion were antagonized by using the PP2A pharmacological inhibitor okadaic acid (OA) or small interfering RNA (siRNA) against PP2A. Taken together, these results indicate that TNF-α-induced VCAM-1 expression through miRNA-181a/b, PP2A, and EGFR resulting in contributing to the human monocytes adhesion to GBM and promote GBM invasion. These results suggested that VCAM-1 is a potential target for improving GBM therapy.

Title: The brain penetrant phosphodiesterase-4 inhibitor, ABI-4, blocked endotoxin and age related pro-inflammatory effects in the plasma and CNS

Authors: *J. R. HEDDE;
Neurosci. & Pain Res. Unit, Pfizer Global Res., Cambridge, MA

Abstract: Inhibitors of phosphodiesterase-4 (PDE4) have been approved for the treatment of peripheral inflammatory disorders. There is a remarkably high incidence of co-morbid depression-like symptoms in patients suffering from disorders such as psoriasis which could reflect a central component of inflammation. Furthermore, symptoms of apathy and amotivation affect many healthy elderly people and are common in patients suffering from neurodegenerative disorders. In the current studies we have investigated the potential for the novel brain penetrant PDE4 inhibitor, ABI-4, to attenuate neuroinflammation and thus differentiate from the 2 approved PDE4 inhibitors which have poor CNS permeability. The anti-inflammatory effects of PDE4 were initially evaluated in vitro. Incubation of human primary blood monocytes (PBMCs) and primary murine microglial cells with lipopolysaccharide (LPS, 100 ng/ml) caused TNF-α release that was inhibited by co-incubation with PDE4 inhibitors (IC50: roflumilast 4.2 nM, rolipram 35.6 nM, ABI-4 14.7 nM). The effects of LPS (1 or 10 mg/kg i.p.) in CNS and periphery, and their modulation by PDE4 inhibition were also evaluated in vivo. LPS caused robust increases in plasma and brain TNF-α, IL-6 and IL-1β in mice. ABI-4 (0.1- 1 mg/kg s.c.)

reduced LPS-induced brain and plasma cytokines. Repeated administration of LPS (0.32 mg/kg i.p.) for 5 days resulted in microglial activation, assessed by ex vivo binding of a translocator protein (TSPO) ligand. This increase in TSPO binding in the brain was prevented by co-administration of ABI-4 (1 mg/kg s.c.). Central administration of LPS (2 ng, i.c.v.) stimulated cytokine levels in mouse brain and plasma 4 h later. Administration of ABI-4 attenuated the pro-inflammatory effects of LPS in the brain. The brain impaired PDE4 inhibitor, roflumilast, did not attenuate the CNS or systemic effects of centrally administered LPS. In naïve aged mice administration of ABI-4 (0.32 mg/kg, s.c. x 14 days) significantly decreased the plasma and brain levels of the proinflammatory cytokines TNF-α and IL-1β. These data indicate that the PDE4 inhibitor ABI-4 blocked the in vitro, and in vivo induction of proinflammatory cytokines by LPS, in brain and plasma. These data suggest that ABI-4 could represent a novel approach to achieving anti-inflammatory effects which could abrogate CNS consequences associated with inflammation.

Title: Emergence of CNS biomarkers for lysosomal abnormalities in aging progranulin deficient mice

Authors: ***L. H. MARTENS**[1], F. ALBAYYA[1], J. H. SOPER[1], V. KING[1], D. E. SLEAT[2], P. LOBEL[2], M. TOWNSEND[1], L. LEVENTHAL[1], G. KOENIG[1], H. PATZKE[1];

Abstract: Loss of function mutations in the progranulin (*GRN*) gene cause frontotemporal dementia (FTD). FTD is the second most common neurodegenerative disorder and is characterized by alterations in behavior and/or language. In patients, the disease is caused by haploinsufficiency of progranulin protein (PGRN) resulting in extensive neuronal loss, TDP-43 pathology, and gliosis. Patients homozygous for PGRN mutations develop a lysosomal storage disorder (LSD) at a young age that results in vision impairment and ataxia. Several mouse models of PGRN deficiency have been developed by knocking out the *Grn* gene. The haploinsufficent/heterozygous mice that mimic the decrease PGRN levels of patients appear relatively normal at the molecular and pathological level. The PGRN knockout mice consistently

exhibit a hyperactivation of the inflammatory response and lysosomal abnormalities, thereby closely mimicking the human LSD disease state. Here we report a chronology of molecular and pathologic phenotypes that emerge with age in PGRN deficient mice. As previously shown, accumulation of lipofuscin becomes apparent in discreet brain regions by 6.5 months in *Grn* knockout mice. This corresponds with dysregulation of expression of several lysosomal proteins in the brain including; v-ATPase, Cathepsin D, and other lysosomal proteins. However, lipid profiling of mouse brain revealed little significant change between genotypes. Mass spectrometry analysis of cerebrospinal fluid from PGRN deficient mice revealed alterations in the lysosomal protein, SPARCL1. PGRN has been shown to act as an immunomodulatory molecule and PGRN deficient mice have increased gliosis with age. Associated with increased gliosis, the inflammatory protein osteoactivin/GPNMB was found to be upregulated in the brain of aged animals. All of these abnormalities can be linked to lysosomal dysfunction and are characteristic of LSDs. These results provide a series of disease biomarkers that can be evaluated for reversal by restoring expression of progranulin.

Title: The therapeutic role of recombinant IL-1 signaling inhibition on behavioral functioning of nerve agent soman-exposed mice in the shuttle box apparatus

Authors: *D. D. PALMER, J. K. CHANDLER, T. M. FERRARA-BOWENS, J. F. IRWIN, K. LATIPAYA, J. L. LANGSTON, T. M. MYERS, E. A. JOHNSON;
US Army Med. Res. Inst. of Chem. Def., Gunpowder, MD

Abstract: Exposure to soman (GD), a chemical warfare nerve agent that acts as a potent acetylcholinesterase inhibitor, causes status epilepticus (SE), leading to impaired behavioral functioning and widespread neuronal death throughout several regions of the brain. The activation of multiple neuro-inflammatory cytokines, including the pro-inflammatory cytokine IL-1, initiates a detrimental neurodegenerative cascade exacerbating neuropathology. While most

treatments following GD exposure serve to ameliorate SE, currently no approved treatment counters the neurodegenerative process. Previous research has identified the pro-inflammatory cytokine interleukin-1 (IL-1) as a key component of the neurodegeneration and inflammation that occurs after exposure to GD. Therefore, inhibition of IL-1 may be therapeutically beneficial to preserve neuronal tissue and improve behavioral functioning after exposure to GD. Kineret (anakinra), a recombinant form of the natural IL-1R inhibitor IL-1Ra, was used in this study as a possible neuroprotective treatment for GD exposure. WT mice were treated with HI-6 dichloride 5 minutes prior to a 1.6 LD_{50} subcutaneous administration of GD. Treatment via repeated subcutaneous administration of anakinra began one hour after seizure onset and concluded 12 hours later. One week after exposure, behavioral experimentation was conducted using the shuttle box apparatus to evaluate learned avoidance behavior, anxiety levels, mobility and overall cognitive functioning. Additionally, neuropathology was evaluated. This study investigated the overall therapeutic role of recombinant IL-1 inhibition in reversing behavioral deficits and improving pathology after nerve agent exposure. The views expressed in this talk are those of the author(s) and do not reflect the official policy of the Department of Army, Department of Defense, or the U.S. Government. The experimental protocol was approved by the Animal Care and Use Committee at the United States Army Medical Research Institute of Chemical Defense and all procedures were conducted in accordance with the principles stated in the Guide for the Care and Use of Laboratory Animals and the Animal Welfare Act of 1966 (P.L. 89-544), as amended. These studies were funded by the Defense Threat Reduction Agency (DTRA).

Title: Rat model of neuroinflammation exhibiting parkinsonian-like pathology induced by prostaglandin J2 a product of the cyclooxygenase pathway

Authors: C. CORWIN[1,3], *M. NUNEZ SANTOS[2], A. NIKOLOPOULOU[4], Y. KANG[4], S. VALLABHAJOSULA[4], P. SERRANO[1], J. BABICH[4], M. FIGUEIREDO PEREIRA[1]; [2]Biol. Sci., [1]Hunter Col., New York, NY; [3]The Grad. Center, CUNY, New York, NY; [4]Dept. of Radiology, Weill Cornell Med., New York, NY

Abstract: Upregulation of cyclooxygenase-2 has emerged as an important determinant of the cytotoxicity associated with neuroinflammation in Parkinson's Disease (PD). Moreover, epidemiological studies strongly support that chronic treatment with low levels of cyclooxygenase inhibitors (i.e., NSAIDs), lowers the risk for PD. Thus, NSAIDs are so far the only approved clinical drugs that prevent or delay the onset of PD. Prostaglandins (PGs) are major products of cyclooxygenases, but their role in neurodegeneration is poorly understood. PGD2 is the most abundant prostaglandin in the brain, increases the most under pathological conditions, and leads to the highly neurotoxic prostaglandin J2 (PGJ2) by spontaneous dehydration. To study the *in vivo* effects of PGJ2 we established a rat model of neuroinflammation. PGJ2 (or vehicle) was unilaterally injected into the right *substantia nigra* (SN) of adult Sprague Dawley male rats for two and four weeks (once per week). The rats were analyzed for motor deficits (cylinder test and open field), dopaminergic neuronal loss (tyrosine hydroxylase immunostaining quantified by stereology), and microglia activation (Iba1 immunostaining and μPET/CT imaging with the TSPO radioligand [^{11}C]PK11195). The rats that received four PGJ2-injections were analyzed four weeks after the last injection. Compared to vehicle controls, the PGJ2-treated rats exhibited significant motor deficits concomitant with dopaminergic neuronal loss in the impaired SN. The rats that received two PGJ2 injections were analyzed four and eight weeks after the last injection to determine the progression of neuronal damage. Compared to vehicle controls, these rats showed increased microglial activation (higher [^{11}C]PK11195 uptake) accompanied by significant loss of dopaminergic neurons in the impaired SN, as well as motor deficits. To determine the efficacy of NSAID therapeutic intervention in our model, a group of rats that received two PGJ2 injections were given 40mg/kg body weight/day of ibuprofen in their food, from the day after the first surgery until 4 weeks post-injection. The ibuprofen treatment appears to prevent the motor impairment developed by the PGJ2-treated rats. In conclusion, our newly developed PGJ2-induced rat model of neuroinflammation exhibits parkinsonian-like pathology correlating with in vivo PET imaging of neuroinflammation. We propose that this pre-clinical rat model is highly valuable to identify and optimize therapeutics that suppress the neurotoxic effects of inflammation as a strategy to prevent or delay the progression of PD. This model can also aid in testing novel PET ligands of neuroinflammation.

Title: Inhibition of IL-1 signaling provides neuroprotection following seizurogenic exposure to the nerve agent soman (GD) in mice.

Authors: *J. IRWIN[1], T. M. FERRARA-BOWENS[2], J. K. CHANDLER[2], D. D. PALMER[2], K. LAITIPAYA[2], M. WEGNER[3], E. A. JOHNSON[2];
[2]Res. Div., [3]Res. Support Div., [1]USAMRICD, Gunpowder, MD

Abstract: Exposure to organophosphates, such as soman (GD), causes cholinergic crisis from the accumulation of acetylcholine (ACh) at the synapse. Without intervention, GD rapidly and irreversibly binds to acetylcholinesterase (AChE) and will result in status epilepticus (SE), which can lead to severe neuropathology. Interleukin 1 (IL-1) signaling has a known proinflammatory role in the CNS and is involved in seizure development and maintenance. IL-1 signaling upregulates multiple proinflammatory cytokines and is naturally attenuated by the IL-1 antagonist IL-1Ra. A GD model was developed using wild type and IL-1 signaling knockout mouse strains (i.e., IL-1R1 and IL-1Ra) to validate the role of IL-1 signaling in brain damage after exposure to a seizurogenic dose of GD. In addition, the anti-IL-1 signaling drug anakinra was used as a treatment in wild type mice. Molecular and histological approaches were used to investigate the role of IL-1 in seizure propagation, neuroinflammation, and neuropathology. Multiplex bead assays allowed for the quantification of inflammatory markers and furthermore for the examination of the relationship between IL-1 signaling and the propagation of the neuroinflammatory cascade. H&E staining of the brains and physiological measurements obtained during the exposure allowed for evaluation of neuropathology, sickness, and the rates of convulsion and mortality. Neuroprotection was observed in strains with impaired IL-1 signaling, while a significant increase in multiple proinflammatory markers and neuropathology was observed in strains with enhanced IL-1 signaling. These results show that IL-1 signaling plays an acute role the progression of neuropathology and physiological outcomes and that regulation of this pathway may be beneficial in recovery after GD exposure.

Title: Suppression of seizure-induced glial activation in the hippocampus using a novel N-acylethanolamine acid amidase inhibitor

Authors: *C. B. MERRILL[1], T. BANDIERA[2], F. BERTOZZI[2], D. PIOMELLI[3];
[1]Anat. and Neurobio., Univ. of California Irvine Dept. of Anat. and Neurobio., Irvine, CA; [2]Drug Discovery and Develop., Inst. Italiano di Tecnologia, Genoa, Italy; [3]Univ. of California-Irvine, Irvine, CA

Abstract: Palmitoylethanolamide (PEA) is one of several biologically active fatty acid ethanolamides in the brain. These molecules, which include the endocannabinoid anandamide, have demonstrated marked anti-inflammatory activity in animal models of neurological diseases such as Alzheimer's, multiple sclerosis, and epilepsy (Centonze D, et al., Trends Pharmacol Sci. 2007 Apr; 28(4): 180-7). PEA activates the nuclear receptor PPARα, which modulates in turn the activity of pro-inflammatory regulators such as NF-κB (D'Agostino G, et al., Eur J Pharmacol. 2009 Jun 24; 613(1-3): 54-9). Therefore, enhancement of PEA levels has recently been proposed as a potential anti-inflammatory target, due to its ability to modulate pro-inflammatory cascades in the brain. We have recently developed a novel inhibitor directed toward *N*-acylethanolamine acid amidase (NAAA), the lysosomal cysteine hydrolase that degrades PEA. The compound, called ARN16186, inhibits human NAAA with an IC_{50} of 83 nM and has adequate pharmacokinetic properties and brain penetration in mice.
In the present study, we used kainic acid-induced seizures to initiate pro-inflammatory cascades in the brain and tested the ability of ARN16186 to prevent glial activation and neuroinflammation. The NAAA inhibitor was administered by intraperitoneal administration (10 mg/kg) prior to kainic acid injection and twice daily for the four following days. We measured fatty acid ethanolamide levels by liquid chromatography/mass spectrometry, and examined astrocyte and microglial activation by immunostaining GFAP and IBA_1, respectively, within the hippocampus, a focus of several neurological diseases. We found that blocking NAAA activity decreases glial activation within the hippocampus four days after i.p. injection of kainic acid. These results suggest that PEA plays a significant anti-inflammatory role within the central nervous system and that enhancing PEA levels through NAAA blockade may represent a potential therapy to ameliorate neuroinflammation, which may exacerbate progression of neurological disease.

Title: Interactions of peripherally derived macrophages and microglia after spinal cord injury

Authors: *A. D. GREENHALGH[1], S. DAVID[2];
[1]McGill Univ., Montreal, QC, Canada; [2]Res. Inst. of McGill Univ. Hlth. Ctr., Montreal, QC, Canada

Abstract: Microglia and infiltrating monocyte derived macrophages (MDMs) play pivotal roles in inflammation during CNS injury and disease. Microglia and MDMs are distinct, based on their ontogeny and transcriptional profiles; however, it is not known whether these two cell types influence each other's functions in areas of CNS damage. We have previously reported that after traumatic spinal cord injury, phagocytosis of tissue debris by microglia is reduced after macrophage infiltration. Therefore, we hypothesised that MDMs enter the injured CNS and signal to microglial cells to stop phagocytosis. To test this, we cultured adult primary microglia under conditions in which they retain a similar transcriptional profile to freshly isolated adult microglia, together with bone marrow derived macrophages, in a tiered Banker system. We assessed the expression of several microglial 'signature' genes and inflammatory cytokines with RT-qPCR. Under inflammatory conditions (LPS), the presence of macrophages did not affect the expression of a panel of microglial signature genes in microglia. However, the presence of macrophages significantly suppressed the pro-inflammatory cytokine, TNF, in microglia, while the presence of microglia significantly increased the pro-inflammatory cytokine, interleukin-1β, in macrophages. We also assessed the ability of microglia and macrophages to influence each other to phagocytose myelin using pHrodo-labelled myelin. Flow cytometry revealed that macrophages suppressed microglial phagocytosis of myelin while the presence of microglia increased macrophage phagocytosis of myelin, as compared to cells in isolation. These studies reveal that microglia and macrophages differentially affect each others' inflammatory cytokine expression and phagocytic function. Studies are now underway to identify the soluble mediators responsible for these interactions and assess these mechanisms in *in vivo* models of CNS injury.

Title: Gene expression profiling of the interlukin-1 inflammatory pathway in knockout mice following soman exposure

Authors: *J. K. CHANDLER, T. M. FERRARA-BOWENS, J. F. IRWIN, K. LAITIPAYA, D. D. PALMER, H. M. HOARD-FRUCHEY, E. A. JOHNSON;
US Army Med. Res. Inst. of Chem. Def, Aberdeen Proving Ground, MD

Abstract: Soman, an organophosphorus (OP) compound, is a potent acetylcholinesterase inhibitor. The accumulation of acetylcholinesterase leads to convulsions, prolonged seizures, and neuropathology which can result in death. Previous studies have shown that changes in inflammatory signaling pathways, such as the IL-1 pathway, exacerbate neuronal damage and elicit long term cognitive deficits after OP poisoning. Using microarray, we analyzed gene expression changes across multiple mouse strains to further understand the pathways involved in neuroinflammation and their relationship to OP poisoning. Piriform cortex samples were collected at 1, 3, 6, 12, 24, and 48 hours following soman exposure in IL-1R1 knockout mice, IL-1Ra knockout mice, and background matched wild-type mice (C57BL/6J). Analysis of the individual gene expression profiles of each strain identified similar changes in canonical pathways and gene networks across all three mouse strains. Further investigation into these pathways will help identify potential therapeutic targets for effective mitigation of OP poisoning effects.

Title: Is progranulin deficiency in microglia alone sufficient to cause microglia activation and neurodegeneration?

Authors: *M. CAHILL[1], J. ZHANG[1], H. LUI[1,2], E. J. HUANG[1];
[1]Pathology, Univ. of California San Francisco, San Francisco, CA; [2]Sch. of Publ. Hlth., Univ. of California, Berkeley, Berkeley, CA

Abstract: Global progranulin (PGRN [protein], *Grn* [gene]) deficiency leads to an age-dependent activation of microglia, which promotes complement-mediated synaptic pruning that acts as a major driver of neurodegeneration in frontotemporal dementia. Given the abundant PGRN expression in microglia, these results lead to the hypothesis that PGRN deficiency in microglia alone should be sufficient to cause aberrant microglia activation and consequently neurodegeneration. To test this hypothesis, we generated the *Cx3cr1-Cre;Grn*$^{fl/fl}$ mice, in which *Grn* is selectively deleted in microglia. Surprisingly, unlike *Grn*$^{-/-}$ mice, *Cx3cr1-Cre;Grn*$^{fl/fl}$ mice

only show very modest age-dependent microglial infiltration in the ventral thalamus and no detectable increase of astrogliosis or loss of synapses at 12-month-old. Consistent with these results, *Cx3cr1-Cre;Grn*$^{fl/fl}$ mice also do not exhibit OCD-like excessive grooming behavior. These results indicate that loss of PGRN in microglia alone is not sufficient to recapitulate the global loss of PGRN phenotypes and further suggest that cross talk between microglia, astrocytes and neurons is needed in order to fully activate *Grn* deficient microglia. In support of this idea, *CaMKII-Cre;Grn*$^{fl/fl}$ mice also show no evidence of microglial infiltration, astrogliosis, excessive synaptic pruning or OCD-like grooming behaviors during the aging process, further supporting that loss of PGRN in microglia, astrocytes and neurons is required to fully recapitulate global PGRN deficiency phenotype. These unexpected findings represent an important conceptual advance that a homeostatic loop exists between neurons and glia and that dysfunction of this loop only occurs when PGRN is absent from both neurons and glia. We are in the process of developing microglia-astrocyte-neuron co-cultures to further test this hypothesis.

Title: An immunohistochemical analysis of inflammation-driven changes in synaptic plasticity: the combined effects of aging and an immune challenge

Authors: V. G. ROMETT, C. W. MOODY, N. TANAKA, L. R. PEACH, *S. L. PATTERSON;
Biol., Temple Univ., Philadelphia, PA

Abstract: Mounting evidence suggests that the peripheral immune system not only has extensive communication with the central nervous system (CNS), but also has a significant effect on behavior and cognition. Interestingly, cognitive vulnerabilities to immune challenges (e.g. injury, illness, surgery) seem to increase with age. Even cognitively sound elderly individuals who experience a significant immune challenge often experience an abrupt cognitive dysfunction, termed delirium, which is associated with increased probabilities of eventually developing dementia, even when the delirium is transient. In rodent models of this phenomenon, it has been shown that a peripheral immune challenge produces a more robust and longer lasting response in

the CNS of older rats. This exaggerated CNS immune response correlates strongly with deficits in hippocampal-dependent learning and memory. Investigations by our lab have found that immune challenged older rats have deficits in Brain-derived neurotrophic factor (BDNF) signaling, with less mature BDNF in hippocampal synapses; they also have deficits in hippocampal late-phase long-term potentiation (L-LTP). As L-LTP requires intricately orchestrated reciprocal communication between neuronal processes and the nucleus, an understanding of where and how this dialogue is disrupted is integral for understanding the detrimental effects of dysregulated immune responses on memory. To investigate these questions, immunohistochemistry was used to look at the association between inflammatory markers, such as activated microglia and complement system components, and the distribution of molecules essential for intracellular communication and synaptic remodeling, such as immediate-early gene products and proteins involved in signal transduction. By looking at different age groups of rats at different time points of immune response (following *E. coli* injection) and the responses of these groups to pharmacological LTP stimulation, we have disentangled some of the complex effects of ageing and neuroinflammation on synaptic plasticity. This study may provide important insights for understanding the genesis of early failures of synaptic plasticity in neuroinflammatory conditions such as Alzheimer's disease (AD), multiple sclerosis (MS), and traumatic brain injuries (TBIs), and may aid the development of novel treatment options.

Title: Inhibition of monoacylglycerol lipase prevents HIV gp120-induced synapse loss by decreasing prostaglandin production

Authors: *X. ZHANG[1], S. THAYER[2];
[1]Pharmacol., [2]Univ. of Minneasota, Minneapolis, MN

Abstract: About half of HIV infected patients develop HIV-associated neurocognitive disorder (HAND). Cognitive decline in HAND patients correlates with deficits in synaptic structure and

function. Previous studies from our lab showed that treating rat hippocampal cultures with 600 pM HIV envelope protein gp120, a potent neurotoxin, induced synapse loss through an interleukin-1β (IL-1β) mediated neuroinflammtory pathway. Activation of cannabinoid type 2 (CB2) receptors on microglia prevented gp120-induced synapse loss by blocking IL-1β release. Monoacylglycerol lipase (MAGL) degrades the endocannabinoid 2 arachidonoylglycerol (2-AG) to arachidonic acid. Inhibition of MAGL with the selective inhibitor, JZL 184, increases 2-AG levels and decreases arachidonic acid, the precursor for brain prostaglandins. Thus, MAGL inhibition might reduce neuroinflammation and prevent synapse loss induced by gp120. Here, we tested the effect of MAGL inhibition on gp120-induced synaptic changes using confocal imaging of an enhanced green fluorescent protein fused to an intrabody that binds to endogenous postsynaptic density protein 95. Treatment with JZL 184 completely blocked synapse loss induced by gp120. Synapse loss results from the potentiation of N-methyl-D-aspartate (NMDA) receptors. The potentiation of NMDA-evoked Ca^{2+} influx induced by gp120 was also blocked by JZL 184. Quantitative real-time PCR measurement of IL-1β mRNA indicated that JZL 184 blocked gp120 triggered production of IL-1β. The CB2 receptor antagonist, AM630, failed to attenuate the inhibition of IL-1β production caused by JZL 184, suggesting that elevated 2-AG levels were not activating CB2 receptors on microglia. In contrast, dimethyl-prostaglandin E2 (dmPGE2), an analog of prostaglandin E2 increased gp120-induced IL-1β production in the presence of JZL 184. These data suggest that the protective effect of JZL 184 is likely through decreased prostaglandin production. MAGL is a promising therapeutic target for neuroinflammatory conditions such as HAND. While modulation of endocannabinoid and prostaglandin levels could both potentially contribute to the neuroprotective effect of JZL 184, in this in vitro model of gp120 evoked synaptic injury, reduction of prostaglandins is the predominant effect.

Title: Immune sensitization in sequential stem cell transplantation in the spinal cord

Authors: *M. S. TORA[1,3], J. J. LAMANNA[1], J. GUTIERREZ[1], L. N. URQUIA[2], C. MORETON[1], J. L. WAGNER[1], T. FEDERICI[1], N. M. BOULIS[1];

[1]Neurosurg., [2]Emory Univ. Sch. of Med., Atlanta, GA; [3]Biomed. Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: Stem cell transplantation is under investigation in both animal models and clinical trials for the treatment of spinal cord disease such as Amyotrophic Lateral Sclerosis (ALS). However, there is a poor understanding of the immunological barriers to successful stem cell engraftment. Importantly, it is not known if multiple transplants over time will sensitize the immune system and impair stem cell survival. In a Phase I/II clinical trial conducted by our group, ALS patients received stem cell transplantation into the lumbar spine and later received transplantation to the cervical spine. The effect of multiple transplantations on cell survival is unknown as there is currently no method to quantify stem cell graft survival in these patients. We hypothesized that the initial stem cell transplantation would sensitize the immune response and lead to decreased stem cell survival in subsequent transplantation.

To assess this in an animal model, female Göttingen minipigs (n=5/group) first received ten thoracolumbar spinal cord injections of either porcine neural progenitor cells (pNPC) or vehicle (Sham). Three weeks after initial transplantation, both groups received pNPC transplants into the cervical spine. Three weeks after the second transplantation, the pigs were sacrificed and the spinal cords were sectioned and stained for pNPCs, Iba-1 (activated microglia), CD8, and CD4. The pigs were maintained on IV tacrolimus (0.005 mg/kg/day) for the duration of the study. pNPC Grafts were quantified for cell survival and microglial activation, summarized in Table 1. Interestingly, there was no statistically significant difference in survival between the sensitized group (Graft + Graft) and non-sensitized group (Sham + Graft). However, there is a statistically significant increase in Iba-1 staining in the sensitized group compared to the non-sensitized ($p < .05$), indicating increased microglial activation with previous cell transplantation. Quantifications of CD8+ and CD4+ infiltrating cells are ongoing. These data suggest that, while there does not seem to be a change in graft survival at three weeks, there may be an increased immune response which may impact long term cell graft survival and therefore therapeutic efficacy.

Table 1. Summary of Stem Cell Graft Survival and Microglial Response

Group	% Graft Survival		Iba-1 Staining [a]	
	Mean (STDEV)	Range	Mean (STDEV)	Range

Title: APOBEC1-mediated RNA-editing of LAMP2 in microglia is linked to lysosomal accumulation in hippocampus and impaired cognitive decline in middle-aged Apobec1$^{-/-}$ mouse

Authors: K. GAGNIDZE[1], D. COLE[1], K. HAJDAROVIC[1], F. N. PAPAVASILIOU[3], T. A. MILNER[4], V. RAYON-ESTRADA[5], *K. BULLOCH[2];
[2]Labs of Endocrinol. and Mol. Immunol., [1]The Rockefeller Univ., New York, NY; [3]The Rockefeller.edu, New York, NY; [4]Weill Cornell Med. Col., New york, NY; [5]The Rockefeller, New York, NY

Abstract: Microglia (MG), the resident immune macrophages in the CNS, play important roles in brain homeostasis and neuronal plasticity. Under steady state conditions, MG aid synaptic stripping and clearing of cellular debris, while supporting myelination, and promote growth, survival and maintenance of neurons. MG also serve as immune sentinels that quickly become activated during brain pathogenic or traumatic insult, produce pro-inflammatory cytokines and recruit circulating monocytes(dendritic cells and macrophage) to the site of damage. Here we report that mice lacking the RNA editing enzyme, APOBEC1, in MG have marked pathophysiology. This is characterized in the male middle-aged (9-12 mo) APOBE1$^{-/-}$ mouse at the organismal level by aberrant behaviors and at the light and ultrastructural level by clustering of activated MG, increased inflammation, demyelination and accumulation of lysosomes noted within hippocampal neurons and microglia. Conversely, we have demonstrated in the wildtype mouse brain that APOBEC1-mediated RNA editing occurs within microglia, in analogy with editing functions for APOBEC1 in bone marrow derived macrophages. To determine the impact of RNA editing may have on lysosomal function within MG we isolated two subsets defined as CD45^{int}CD11b^{hi}CD11c^{neg} (*CD11c^{neg} MG)* and CD45^{int}CD11b^{hi}CD11c^{+} (*CD11c^{+} MG)*, from wildtype and knockout middle aged mouse brains and performed RNAseq followed by an analysis of RNA editing events. These data show that the lysosomal-associated membrane protein (L*AMP2)* is edited in wildtype microglia, and the loss of its editing reduces the abundance of this protein. Thus, loss of *LAMP2* editing in the APOBEC1$^{-/-}$ mouse brain may be

related to the accumulation of lysosomes and autophagic vesicles, as the lack of LAMP2 results in similar pathology. Since this neuropathology phenotype is common to lysosomal storage disease and age-related neurodegeneration these findings may open up new avenues of therapeutic strategies to address both heritable neurological diseases and those of previously unknown etiology.

Title: A mouse model of Gulf War Illness reveals a primed neuroinflammatory response to subsequent systemic inflammatory challenge.

Authors: *K. A. KELLY[1], A. R. LOCKER[1], L. T. MICHALOVICZ[1], J. A. VRANA[1], S. VASHISHTHA[2], G. BRODERICK[2,3,4], D. B. MILLER[1], J. P. O'CALLAGHAN[1]; [1]CDC-NIOSH, Morgantown, WV; [2]Univ. of Alberta, Edmonton, AB, Canada; [3]Dept. of Med., Univ. of Miami, Miami, FL; [4]Inst. for Neuro Immune Med., NOVA Southeastern Univ., Fort Lauderdale, FL

Abstract: Gulf War Illness (GWI) is a multi-symptom disorder diagnosed by a phenotype which includes persistent headaches, chronic fatigue, memory loss, confusion, skin and gastrointestinal problems. These features are characteristic of persistent sickness behavior, which is known to result from underlying neuroinflammation. Chronic exposure to corticosterone (CORT), at levels associated with high physiological stress, can prime the CNS to mount an exacerbated neuroinflammatory response, indicated by an increase in proinflammatory cytokines/chemokines, following systemic exposure to neurotoxicants and inflammagens. By mimicking the stresses of war with exogenous CORT (200 mg/L 0.6% EtOH in drinking water) for 7 days prior to exposure to sarin surrogate acetylcholinesterase inhibitor (AChEI), diisopropyl fluorophosphate (DFP; 4 mg/kg, i.p.), heightened neuroinflammatory responses were observed without astrogliosis or neurodegeneration from 6 to 72 hours after DFP exposure. While these observations recapitulated early symptoms of GWI, the essential pathobiology of this illness is persistence of heightened responses to external stimuli for 20+ years. Here, we

employed episodic exposure to CORT in drinking water of male C57Bl6/J mice for up to 90 days (CORT drinking water for 4 or 7 days every other week) to emulate episodic stress incurred by ill veterans following their exposures to multiple AChEI agents in theater. Since the GWI phenotype is punctuated by symptom flare-ups, systemic exposure to lipopolysaccharide (LPS - a bacterial mimic), at sub- and neuroinflammatory doses (0.5 or 2 mg/kg, s.c., respectively), was used to challenge the GWI phenotype. While CORT pretreatment primes the neuroinflammatory response to produce augmented LPS-induced inflammation, a single dose of DFP significantly exacerbated this effect. Using a comprehensive survey of molecular markers, blood cytokine expression profiles of ill veterans compared to our GWI mouse model revealed a significant overlap of the phenotype between man and mouse. This correlation supports the hypothesis that exposure to sarin, or a similar AChEI, in theater served as a major precipitating factor for the development of GWI. Overall, we have demonstrated that a paradigm of CORT in the drinking water with a single DFP exposure followed by episodic CORT instigates a primed neuroinflammatory phenotype similar to that of Gulf War Illness. An LPS challenge in our model results in an exacerbated inflammatory response, recapitulating the flare-up of symptoms seen in affected patients. Together, these data suggest that GWI is a chronic, stressor primed, neuroinflammatory condition.

Title: Complement activation due to HexB deficient microglia targets neurons: implications for Sandhoff and Tay-Sachs disease

Authors: *N. SASIDHARAN, B. JUN, Y. GONG, F. EICHLER;
Harvard Med. Sch. / Massachusetts Gen. Hos, Boston, MA

Abstract: G_{M2} gangliosidoses (Tay-Sachs Disease, TSD; Sandhoff Disease, SD) are caused by an inherited deficiency of the lysosomal enzyme β-hexosaminidase. In humans, mutations in the

α-subunit (HexA) and the β-subunit (HexB) lead to TSD and SD respectively. Microglial cells have been shown to express high levels of both HexA and HexB, with expression of HexB to be 6 fold higher than HexA. Despite marked microglial activation in mouse models and human patients, the role of these resident macrophages during neurodegeneration remains poorly understood. The complement immune response, largely elicited by glial cells in the CNS, has been identified as putative contributor of neuronal loss. To determine the role of the complement system in G_{M2} gangliosidoses, we examined a $HexB^{-/-}$ mouse model, human post-mortem SD brain tissue and a CRISPR/CAS9 edited HexB (-/-) microglial cell line. In $HexB^{-/-}$ mouse brain, mRNA expression of complement factors—C1q, C3a, and C5a—was significantly increased. Primary cells isolated from these mice, revealed that microglia were a major source of those complement factors, which were pathologically upregulated in primary $HexB^{-/-}$ microglia. Furthermore, C1q expression was localized to apoptotic and G_{M2}-bearing neurons in the $HexB^{-/-}$ mouse suggesting that neurons are the primary target of complement activation. Examination of post-mortem SD and TSD patient brain tissue confirmed elevated expression of C1q in human cells. Analysis of CRISPR/CAS9 edited HexB (-/-) cell lines, showed changes in microglial morphology suggesting a primed state. These cells displayed an increase in the expression of C3 receptor, but little or no change in inflammatory and other complement markers. Interestingly, co-culture experiments of CRISPR/CAS9 edited HexB (-/-) microglia with differentiated neurons reveal a significant increase in inflammatory marker IBA1. Furthermore, GM2 staining in CRISPR/CAS9 edited HexB (-/-) microglia revealed no changes in ganglioside levels *in vitro*. Taken together these results suggest that complement upregulation is a cell non-autonomous response that only occurs *in viv*o due to contact with other cell types in the brain. This study implies a novel role of complement activation during microglia-neuron interactions in the pathology of G_{M2} gangliosidoses.

Title: Neuroinflammation in vervet brains following chronic dietary exposures to a cyanobacterial toxin

Authors: *D. A. DAVIS[1], A. DELLE DONNE[2], S. A. BANACK[3], R. PALMOUR[4], W. G. BRADLEY[2], P. A. COX[3], D. C. MASH[2];
[1]Dept. of Neurol., [2]Neurol., Univ. of Miami, Miami, FL; [3]Neurochemistry, Inst. of Ethnomedicine, Jackson Hole, WY; [4]McGill Univ., Montreal, QC, Canada

Abstract: Alzheimer's disease and amyotrophic lateral sclerosis (ALS) are characterized by the appearance of reactive microglial and astroglial cells. Astrocytes and microglial are highly reactive to environmental insults. We have recently reported that dietary exposure to beta-methylamino-alanine (L-BMAA), produced by cyanobacterial blooms, triggers AT8-positive neurofibrillary tangles (NFT) and sparse β-amyloid inclusions in vervet brain (Cox et al., 2016). To investigate the effects of BMAA on microglia and astrocytes, we examined the brain and spinal cord from vervet monkeys fed oral doses of L-BMAA (210 mg/kg/day for 140 days; N=12). Formalin fixed brain sections were stained with antibodies to glial fibrillary acidic protein (GFAP) and microglial/macrophage membrane protein (Iba1) (Neuroscience Associates, Knoxville, TN). The distribution of immunostained microglia and astrocytes was mapped using a Huron Digital Pathology Scanner and nonbiased image analysis software (ImageJ; NIH). Chronic dietary exposure to L-BMAA induced AT8-immunopositive glial lesions similar to those reported in the brain of Guamanian ALS PDC patients, including plaques, tufts, granular hazy astrocytic inclusions, coiled bodies and crescent inclusions. GFAP-positive astrocytes were observed in the amygdala, entorhinal, insular and motor cortices where AT8-positive NFTs were abundant. BMAA is known to target motor neurons and GFAP reactivity was robust in primary motor cortex and in the vicinity of the anterior horn cells of the lumbar spinal cord. Activated microglia were observed within the midbrain and brainstem at the level of corticospinal tract. These observations suggest that BMAA causes early microglia activation in upper motor neurons in the absence of cell loss. The neuroinflammatory reaction may represent an early stage of BMAA pathology in vervets following chronic dietary exposure.

Title: Type I interferon response in alzheimer's disease pathology

Authors: A. CARRANO[1], C. VERBEECK[2], *P. DAS[1];
[1]Neurosci., [2]Mayo Clin., Jacksonville, FL

Abstract: Type I interferon (IFN-I) responses are an early immune-mediated defense mechanism against microbes. Although the IFN-I associated anti-microbial activities are well characterized, the IFN-I responses in the aging brain and in correlation with neurodegeneration is not well still not elucidated. Recent studies have shown that Type I interferon responses are up-regulated in the aged brain and in the Alzheimer disease (AD) brains, although the consequence of this up-regulation is not clear. In this study we have tested the effects of Abeta and tau on the activation of IFN-I responses in neuronal and microglial cell lines in vitro. In response to pathological Aβ and tau, we observed activation of the IFN-1 signaling pathways in both cell lines, as measured by an activation of transcription factor IRF7. In addition, activation of the IFN-I pathway affected cell susceptibility to Abeta and tau exposure. Our next aim is to determine whether blocking IFN-1 signaling can lead to beneficial outcomes in AD pathologies using IFN-1 knock out cell lines and siRNA techniques. These studies have revealed that the inflammatory Type I interferon responses may be detrimental in AD pathogenesis and blocking this pathway could lead to novel therapeutic options for the treatment of Alzheimer’s disease.

Title: Detecting gangliosides expression profile changes during microglial activation

Authors: *M. M. ALSHAIKH[1], G. LAJOIE[2], S. WHITEHEAD[1];
[1]Anat. and Cell Biol., [2]Biochem., Western Univ., London, ON, Canada

Abstract: With aging, our brains become more susceptible to diseases and injuries. Different brain regions have differing levels of vulnerability to stress and injury, and this brain region dependent variability to vulnerability could be partly explained by the existence of glycosphingolipids within the cell's plasma membrane called gangliosides. Gangliosides are expressed predominantly within the brain and play various roles within the central nervous system including development, differentiation and neural regeneration. Moreover, it has been shown that different species of gangliosides are associated with specific roles within the brain. For instance, several studies demonstrated the importance of GM1 gangliosides in neural repair and cell survival. Simple gangliosides GM2 and GM3, on the other hand, have been associated with neurodegeneration in animal models of stroke and Alzheimer's disease. Our lab has demonstrated that gangliosides can shift their composition from GM1 back to GM2 and GM3 following stroke in rats indicating a role for simple gangliosides in the neurodegenerative process. Interestingly, the transient increase in GM2 and GM3 occurred within 3 and 7 d post stroke-reperfusion indicating that these changes may be part of a neuroinflammatory cascade. It is therefore possible that the observed increases in GM2 and GM3 in the mouse stroke model may have occurred in glial cells; in particular, microglia. Microglia are the innate immune cells of the brain. In response to injury, microglia exhibit functional and morphological changes, and transform into either the classical M1 phenotype or the anti-inflammatory M2 phenotype.
Based on the literature and preliminary studies conducted in our lab, we hypothesize that GM2 and GM3 gangliosides will increase following microglial activation, while GM1 ganglioside will decrease. BV2 microglia were cultured and activation were induced by either LPS for 24 and 48 h or IL-4 for 24 h to induce M1 and M2, respectievly . Immunofluorescence was used to stain for GM1, GM2 and GM3 species. To identify different microglial activation states, OX-6 and CD206 antibodies were used as markers for M1 and M2, respectively. electrospray ionization mass spectrometry (ESI-MS) was used to quantify the gangliosides expressed within these activated microglia.
Both MS and immunofluorescence results revealed that GM2 and GM3 increased during microglial activation while there were no significant changes for GM1 expression. This increase in GM2 and GM3 following activation *in vitro* support the idea that microglia can be the source of the increase in GM2 and GM3 found in animal models of neurodegeneration.

Col. of Med., Seoul, Korea, Republic of

Abstract: In patients with ocular toxoplasmosis, disruption of retinal pigment epithelium is frequently observed. The retinal pigment epithelial layer constitutes outer blood retinal barrier (BRB) that lies between retina and leaky choroidal vasculature. In this study, we investigated the effect of monocytes infected with *Toxoplasma gondii* on *in vitro* model of outer BRB. Retinal pigment epithelial cells, ARPE-19, were cultivated on transwell to form a confluent monolayer. Then, human monocytic cells, THP-1, infected with *Toxoplasma gondii* or their conditioned medium were treated and the barrier function was evaluated by measurement of transepithelial electrical resistance (TEER) and immunocytochemistry of tight junction proteins. Additional treatment with neutralizing antoby against CXCL8 or FAK inhibitor (PF-573228) was performed to investigate the associated signaling pathway. Six hours after the treatment with infected monocytes could disrupt tight junction protein. The disruption was not restricted to the area adjacent to the cells but was happening widely. To evaluate the paracrine effect of the infected monocytes, their conditioned media alone were treated and found to decrease TEER and disrupt tight junction protein as well. To figure out the factors in the conditioned media mediating the disruption, CXCL8 was selected based on the microarray data regarding gene expression of *Toxoplasma gondii*-infected monocytes. Although the effect of neutralizing antibody against CXCL8 was nor remarkable to restore disrupted barrier but inhibition of downstream signaling pathway by additional treatment with FAK inhibitor could attenuate the decreased TEER and disrupted tight junction protein. In conclusion, monocytes infected with *Toxoplasma gondii* can impair outer BRB paracrinely. The paracrine effect of *Toxoplasma gondii*-infected monocytes is mediated by FAK signaling partly activated by CXCL8.

Title: The galectin-1 and -3 participate in the neuroinflammation-induced by the administration amyloid-β (25-35) into hippocampus of rats

Authors: *E. RAMIREZ[1], L. MENDIETA[2], M. A. MAYORAL[3], I. MARTINEZ[4], F. LUNA[5], I. D. LIMÓN[6];
[1]Benemérita Univ. Autónoma De Puebla, Puebla, Mexico; [2]Neurofarmacologia, Benemerita Univ. Autonoma de Puebla, Puebla, Mexico; [3]Medicina, Univ. Autonoma Benito Juarez, Oaxaca, Mexico; [4]Neuroquimica, [5]Neuroendocrinologia, [6]Neurofarmacologia, Benemérita Univ. Autónoma de Puebla, Puebla, Mexico

Abstract: The galectins are animal lectins that bind to β-galactosides, such as lactose and N-acetyllactosamine, contained in glycoproteins or glycolipids. Galectin 1 (Gal-1) and Galectin 3 (Gal-3) are involved in different pathologies associated to inflammatory process as well as in cell proliferation, production of cytokines, cell adhesion, migration and apoptosis. Amyloid-β 25-35 ($A\beta_{25-35}$) is able to cause memory impairment and neurodegenerative events. Recent evidences have shown that the administration of $A\beta_{25-35}$ into the hippocampus of rats increases the inflammatory response. However, the relation how the galectins are participating in the neuroinflammation process and that could be involved in the progression of $A\beta_{25-35}$ toxicity it is unclear. Our aim was to evaluate the expression of Gal-1 and Gal-3 in the neuroinflammation after administration of $A\beta_{25-35}$ into the hippocampus. We examined the spatial memory in the Morris water maze. After behavioral test in the day 32 the hippocampus was assessed for astrocytes (GFAP), microglia (Iba1), Galectin-1 (Gal-1) and Galectin-3 (Gal-3) by immunohistochemical analysis. The administration of $A\beta_{25-35}$ in the day 31 the animal was tested for spatial memory in the Morris Water Maze. Behavioral performance showed that inflammation evoked by $A\beta_{25-35}$ impaired spatial memory, because animal showed a major time to find the platform during the task that the control groups. Our results showed a significant increase of reactive gliosis (GFAP and Iba1) in the hippocampus (CA1, CA3 and DG) of $A\beta_{25-35}$ treated rats. The expression of Gal-1 and Gal-3 was detected predominantly in most of the Iba1-positive microglia and in GFAP-positive astrocytes of the hippocampus. Therefore, we suggest that Gal-1 and Gal-3 is involved in the inflammatory process of neurodegenerative disorder induced by administration of the $A\beta_{25-35}$.

Title: Cofilin mediates LPS-induced microglial cell activation & associated neurotoxicity through NF-κB & JAK-STAT pathways

Authors: ***Q. M. ALHADIDI**[1], Z. A. SHAH[2];
[1]Medicinal and Bioloogical Chem., [2]Medicinal and Biol. Chem., Univ. of Toledo, Toledo, OH

Abstract: Microglial cells are activated in response to different types of injuries or stress in the CNS. Such activation is necessary to get rid of the injurious agents and restore tissue homeostasis. However, excessive activation of microglial cells is harmful and contributes to secondary injury. Pertinently, microglial cell activity was targeted in many preclinical and clinical studies but such strategy failed in clinical trials. The main reason behind the failed attempts is the complexity of the injury mechanisms which needs either a combination therapy or targeting a process that is involved in multiple pathways. Cofilin is a cytoskeleton associated protein involved in actin dynamics. In our previous study, we demonstrated the role of cofilin in mediating neuronal apoptosis during OGD conditions. Previous studies on microglia have shown the involvement of cofilin in ROS formation and phagocytosis. However, additional studies are needed to delineate the role of cofilin in microglial cell activation. Therefore, in the current study, we investigated the role of cofilin in LPS-induced microglial cell activation using cofilin siRNA knockdown paradigms. The viability of differentiated PC12 cells was used as a measure of the neurotoxic potential of conditioned medium derived from cofilin siRNA-transfected and LPS-activated microglial cells. Cofilin knockdown significantly inhibited LPS-induced microglial cell activation through NF-κB and JAK-STAT pathways. The release of proinflammatory substances (NO, TNF-α, IL-1β, iNOS and COX2) as well as microglial proliferation and migration rates were significantly reduced by cofilin knockdown. Furthermore, differentiated PC12 cells were protected from the neurotoxicity induced by conditioned medium derived from cofilin-transfected and LPS-activated microglial cells. In conclusion, we demonstrated that cofilin is involved in the cascade of secondary injury in microglia and further

validates our previous study on cofilin's role in mediating neuronal apoptosis. Together, our results suggest that cofilin could present a common target in neurons and microglial cells during stroke and might prove to be a promising therapy. Keywords: Cofilin; Microglia; LPS, Inflammation

Title: Inflammation induces a biphasic nuclear Nrf2 translocation activation in neuronal cells

Authors: S. KREPEL, *T. B. KUHN;
Dept Chem. & Biochem., Univ. Alaska Fairbanks, Fairbanks, AK

Abstract: Persistent inflammatory and oxidative stress (IOS) is largely responsible for the progressive loss of neuronal integrity and connectivity underlying the continuous decline of cognitive function associated with most chronic CNS disorders as well as normal aging. The transcription factor Nrf2 plays a pivotal role in the antioxidant defense of non-neuronal and neuronal cells. Nrf2 remains sequestered in the cytosol of cells under basal conditions tightly bound to its repressor Keap1. Upon oxidative stress, Nrf2 dissociates from Keap1 and translocates into the nucleus to stimulate transcription of antioxidant defense mechanisms. It is not yet clear how duration and extent of IOS impact Nrf2 activation and nuclear translocation in neuronal cells. Exposure of SH-SY5Y human neuroblastoma to 200 ng/ml TNFα caused a time dependent Nrf2 translocation (2 fold increase) into the nucleus peaking 4 h after addition. However, nuclear Nrf2 decreased and remained at 50% of peak maximum for a prolonged time period. A presence of 50 ng/ml TNFα resulted in the highest accumulation of Nrf2 in the nucleus compared to higher concentrations (100 to 400 ng/ml). Immunocytochemistry against Nrf2 corroborated these findings. Additionally, prolonged exposure of SH-SY5Y cells to TNFα (24 h) at concentrations 200ng/mL or higher resulted in significant cell death due to oxidative stress. Together these findings suggest that Nrf2-mediated antioxidant defenses in response to TNFα

were insufficient. One of the many health benefits of nutrition rests on the capacity of distinct botanicals, in particular polyphenols, to directly act on biochemical mechanisms rather than through passive antioxidant capacities. We demonstrated that supplementation of SH-SY5Y neuroblastoma cells with extracts obtained from Alaska wild bog blueberries (5 μg/ml) increased neuronal viability in the prolonged presence of 200 ng/mL TNFα. Surprisingly, blueberry extracts prevent Nrf2 nuclear accumulation upon exposure to TNFα. Understanding the regulation of Nrf2 through botanicals could provide vital insight for developing neuroprotective strategies applicable to an array of neurodegenerative diseases.

Title: Quantification of brain acetylcholine in a mouse model of Gulf War Illness using HILIC-UPLC-MS/MS

Authors: *J. A. VRANA[1], A. R. LOCKER[1], K. A. KELLY[1], L. T. MICHALOVICZ[1], R. F. LEBOUF[2], J. P. O'CALLAGHAN[1], D. B. MILLER[1];

Abstract: Approximately 30% of veterans from the 1991 Persian Gulf War suffer from an exaggerated and persistent form of sickness behavior, classified as Gulf War Illness (GWI). Numerous studies on GWI have suggested that exposure to cholinergic-acting organophosphates (OP) in-theater, such as the irreversible acetylcholinesterase (AChE) inhibitor and chemical warfare agent, sarin, as well as other pesticides and insecticides, may have contributed to GWI symptomatology. Additionally, concomitant exposure to physiological stressors in-theater may have been involved in the initiation of the GWI phenotype. Traditionally, inhibition of AChE and the subsequent accumulation of acetylcholine (ACh) result in the activation of the cholinergic anti-inflammatory pathway. However, the association of GWI with neuroinflammation appears to contradict this effect of AChE inhibitors. Therefore, it is possible that exposure to OPs (e.g.,

sarin, chlorpyrifos) both alone and with corticosterone (CORT) pretreatment to mimic physiological stress targets biomolecules other than AChE to induce the neuroinflammatory effects seen in our mouse model of GWI. To further investigate this phenotype, adult male C57BL/6J mice were exposed to CORT (400mg/L in 1.2% ethanol) in the drinking water for four days. On the fifth day, mice were exposed to a single dose of a sarin surrogate, diisopropyl fluorophosphate (DFP; 4.0mg/kg, i.p.). To fully evaluate the impact of DFP on AChE, AChE activity and ACh concentrations were measured in the brain. Here, DFP decreased AChE activity, while CORT pretreatment ameliorated this effect. Quantification of ACh in brain homogenates has been difficult due to brain matrix effects, polarity of neurotransmitters, neurochemical derivatization requirements, and endogenous AChE activity occurring after euthanasia. To overcome these effects, we have developed a simple and high-throughput method for ACh quantification from brain homogenates using hydrophilic interaction liquid chromatography (HILIC) with ultra-performance liquid chromatography (UPLC)-tandem-mass spectrometry (MS/MS). Also, to ensure rapid inactivation of AChE, mice were euthanized using focused microwave irradiation. ACh concentrations were inversely related to AChE activity with the highest ACh concentration observed in the striatum, followed by the hippocampus and cortex. From these datasets, the alterations in AChE activity and ACh in the brain do not appear to correspond with the exacerbated neuroinflammation induced by CORT and DFP exposure, suggesting that the symptomatology of GWI may be due to the organophosphorylation of currently unidentified biomolecular targets.

Title: Using novel ALDH1L1 bacTRAP technology to evaluate the astrocyte-specific responses to Gulf War Illness-related exposures

Authors: *L. T. MICHALOVICZ[1], K. A. KELLY[1], A. R. LOCKER[1], J. A. VRANA[1], G. BRODERICK[2,3,4], D. B. MILLER[1], J. P. O'CALLAGHAN[1];

Abstract: A central problem in neurobiology is the ability to reliably assess cell-specific expression profiles in response to various conditions, such as development, disease, or exposure. Specifically, it is challenging to elucidate a particular cell's *in vivo* response without affecting it's interaction with other cells in the brain. To overcome this issue, Heintz and Greengard (2008) developed bacTRAP (translating ribosome affinity purification) technology which allows for the evaluation of the actively translating transcriptome of a particular cell type, as directed by a cell-specific gene sequence. Thus, using the astrocyte-specific housekeeping gene, Aldh1l1, it is possible to extract the astrocytic response to various conditions. Here, we have characterized the ALDH1L1 bacTRAP mouse using the dopaminergic neurotoxicant, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP; 12.5 mg/kg, s.c.), and expanded upon these observations to evaluate the effects of Gulf War Illness (GWI)-related exposures on astrocytes. Using our published animal model of GWI, which models the exposures experienced by GWI suffering veterans during the 1990-1991 Persian Gulf War (O'Callaghan *et al.*, 2015), we evaluated the astrocyte-specific response of ALDH1L1 bacTRAP mice to corticosterone (CORT) in the drinking water (200 mg/L in 0.6% EtOH) for 4 days followed by a single exposure to the sarin surrogate, diisopropyl fluorophosphate (DFP; 3 mg/kg, s.c.). Overall, in comparison to C57BL/6J (wild-type) mice, ALDH1L1 bacTRAP mice had a significantly higher neuroinflammatory response to CORT DFP exposure. Illumina RNAseq analysis identified 703 unique, differentially expressed genes (DEGs, FC>1.5) in the cortical astrocytes of CORT DFP exposed mice, over all control conditions. Furthermore, 211 DEGs were found to be enriched in the astrocytes of CORT DFP exposed mice, displaying a 5-fold greater mRNA expression over total "unTRAPed" cortex. Subsequent gene ontology and pathway analysis of the two DEG sets indicated that most of the genes were related to inflammation and cell death. Specifically, cytokine-cytokine receptor interaction and the complement cascade pathways were identified in both gene sets. Interestingly, we have found that despite causing neuroinflammation and altering mRNA expression in astrocytes, exposure to these GWI conditions do not result in astrogliosis. By understanding cell-specific responses, especially in disease states, it is not only possible to identify the cell-types responsible for cellular and molecular features, but it also creates the potential to specifically target therapeutics to affected cells and avoid off-target effects.

Title: Initial characterization of 11C-GSK1482160 as radioligand for P2X7 receptors.

Authors: J. S. PETERS, *J. A. MEYER, A. A. RILEY, B. P. MCCARTHY, M. GAO, M. WANG, Q.-H. ZHENG, G. D. HUTCHINS, P. R. TERRITO;
Radiology and Imaging Sci., Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Neuroinflammation is an essential step in the progression of brain diseases [1] in which pro-inflammatory cytokines play a central role [2]. Recent work has shown that the pathogenesis of neuroinflammation is mediated in part by the release of adenosine/uridine derivatives from the damage site, involving a family of ionotropic purinergic receptors including P2X7 with elevated receptor expression [3], microglial proliferation and phagocytosis of the injured site [4, 5]. This mechanism is common amongst a wide array of neurodegenerative inflammatory diseases including Alzheimer's, Parkinson's, and Huntington's Diseases, frontotemporal dementia, Atrophic Lateral Sclerosis, Multiple Sclerosis, and Traumatic Brain Injury [6-8]. The P2X7 receptor represents a novel molecular target for imaging neuroinflammation via PET. The compound GSK1482160 is an ideal starting point for evaluation of the P2X7 receptors, has high receptor affinity and ideal blood-brain barrier penetration [9]. Moreover, recent work from our institution has radiolabeled this compound [^{11}C]-GSK1482160 [10] yielding a potential biomarker for neuroinflammation, of which saturation kinetics revealed a B_{max} and K_d of 923fmol/mg and 1.1nm in hP2X7R-HEK cells, respectively. Association kinetic determination of K_{on}, K_{off}, and B_p in hP2X7R-HEK cells were 0.231/min*nM, 0.272/min, and 0.91, respectively. These results were confirmed via P2X7 binding and IFA in hP2X7R-HEK cell blocks with secondary and tertiary confirmation in western blot and IHC using a lipopolysaccharide (LPS, 5mg/kg IP) neuroinflammation mouse model. Biodistribution of [^{11}C]-GSK1482160 showed a time dependent tissue distribution in all tissues studied with the liver, intestines, and kidney, showing the highest uptake by 30min. The brain, blood, heart, lung, spleen and skeletal muscle all had uptake which showed similar temporal patterns and uptake levels. To characterize tracer kinetics, in vivo PET/CT [^{11}C]-GSK1482160 was performed in mice administered saline or LPS (5mg/kg IP) and kinetically modeled for 1 cortical and 1 hippocampal brain region. Total volumes of distribution (V_t) for 6 of 8 all brain regions were statically significantly elevated ($p<0.05$, n=3/treatment). We report the initial physical and biological characterization of this novel ligand, which shows high affinity

and favorable association/disassociation kinetics and was confirmed via multiple in vitro assays. In vivo biodistribution indicated that the liver, intestine and kidney uptake were maximal by 30min and in vivo PET/CT tracer kinetic modeling indicated that V_t followed expected trends for mice treated with LPS.

Abstract: Objective Bone marrow stromal cells (BMSCs) transplantation is an important strategy for treatment of ischemic stroke. But there are no crucial method to guide BMSCs toward the lesion site. In this study, we investigated the effect of electrical stimulation on BMSCs migration in ischemic model of rats. **Methods** Adult male Wistar rats weighing 200 to 250g received right middle cerebral artery occlusion (MCAO) for 90 minutes. BMSCs (2.5×10^5cells/ 4μl PBS) were stereotaxically injected into the left corpus callosum at 1day after MCAO. After BMSCs injection, plate electrode with diameter 3mm which connected to the implantable electrical stimulator was placed on the right frontal epidural space and then counter electrode was placed extra-cranial space. Electrical stimulation, at preset current (100μA) and frequency (100Hz), was performed for two weeks. Behavioral tests were performed at1, 4, 8, 15 days after MCAO using the Modified Neurological Severity Score (mNSS) and cylinder test. Rats were euthanized at 15 days after MCAO for evaluation of infarct volumes and the migration distance and area of BMSCs found in the brain tissue. **Results** Behavioral test at 4, 8, and 15days after MCAO revealed that stimulation group displayed the significant improves in mNSS compared to control group ($p<0.05$). Similarly, the infarct volumes of stroke rats in stimulation group were significantly decreased compared to control group ($p<0.05$). Migration distance and area of transplanted BMSCs were significantly longer and wider respectively in stimulation

group. **Conclusions** These results suggest that electrical stimulation enhances migratory ability of transplanted BMSCs in stroke model of rats. If we can direct the implanted BMSCs to the site of interest, it may have a greater therapeutic effect.

Title: Development of optimized hematopoietic stem cell gene-therapy approaches for treatment of infantile neuronal ceroid lipofuscinosis.

Authors: *M. PEVIANI[1], U. CAPASSO[2], R. MILAZZO[3], V. CIPOLLA[1], S. GATTI[2], D. MOSCATELLI[2,4], A. BIFFI[1];
[1]Cancer and Blood Disorders Center, Gene Therapy Program, Dana-Farber/Boston Children's, Boston, MA; [2]Dept. di Chimica, Materiali ed Ingegneria Chimica, Politecnico di Milano, Milan, Italy; [3]Tiget-DIBIT1, San Raffaele Scientific Inst., Milan, Italy; [4]Inst. for Chem. and Bioengineering, Dept. of Chem. and Applied Biosci., ETH Zürich, Zürich, Switzerland

Abstract: Infantile neuronal ceroid lipofuscinosis (INCL), caused by defects in CLN1 gene coding for palmitoyl protein-thioesterase-1 (PPT1), is one of the most severe forms of NCLs, leading to progressive vision loss, dementia, epileptic seizures and loss of motor coordination, culminating in premature death. Although gene-therapy is a promising therapeutic option for these pathologies, insufficient delivery of PPT1 activity to the central nervous system (CNS) remains an issue that hindered successful clinical application of the approaches tested by now. Exploiting the reconstitution of brain-resident microglia as local source of the wild type hydrolase, by transplantation of gene-corrected hematopoietic stem cells (HSCs) in myeloablated recipients, may represent an alternative strategy to obtain widespread distribution of wild type PPT1 in the CNS. We highlighted that systemic treatment with busulfan, an alkylating agent capable of ablating brain resident microglia progenitors, is instrumental to foster efficient turnover with donor-derived progenitor cells administered systemically. We hypothesized that CNS-directed delivery of the chemotherapeutic drug and injection of HSCs in the cerebrospinal

fluid may work as optimized approach to favor the engraftment of donor-derived gene-corrected microglia progenitors in the brain, potentially speeding up enzyme activity reconstitution within the CNS without exposure to the side effects associated with the myeloablative chemotherapy administered systemically. As first steps to reach this goal, here we present the development and characterization of a new drug delivery biodegradable and biocompatible nanocarrier for busulfan, based on polymeric nanoparticles (NPs), able to selectively target CNS microglia/macrophages. By analyzing the biodistribution of microglia-targeted NPs after intra-cerebroventricular administration in mice, we observed prominent localization in proliferating cells localized in brain regions lining the lateral ventricles and CNS stem/progenitor cells niches. These regions are also the first to be colonized by donor-derived HSCs soon after transplant, which suggests that targeting these specific CNS niches with cell-selective chemotherapy may create space for efficient engraftment of donor derived HSCs. Modification of the NPs core with functional groups selected according to their affinity for busulfan, led to improved drug-loading, within a range of biologically active concentrations. Experiments are now on-going to optimize NPs dosing and timing/route of HSC administration to obtain improved engraftment in healthy and INCL mouse brain.

Abstract: Transplantation of neural progenitor cells (NPCs) is a promising strategy to replace, repair and bridge the injured spinal cord. Transplants of human iPSC derived NPCs (iPSC/NPCs) are clinically relevant because of the potential for using patients own cells. In the present study, we examined the survival and differentiation of transplanted human iPSC/NPCs (Haidet-Phillips et al., Stem Cells Transl Med, 2014 3(5):575-585) following grafting into the intact and injured spinal cord of rats. We initially examined the survivability and phenotypic repertoire of transplanted cells in the intact spinal cord, derived either directly from frozen stock or after culturing. Cells harvested from frozen stocks demonstrated few surviving cells at 1 week, and no survival at 3 and 5 weeks post-transplantation. In contrast, transplants survived much better when the cells were cultured for 2 days. The cells differentiated into neurons and astrocytes by 3 and 5 weeks post-transplantation. Next, we examined the fate of cells transplanted into the injured spinal cord using two distinct models: C4 dorsal column and lateral funicular lesions. Transplanted cells from a frozen stock into an acute lesion did not survive at the lesion site, but survived near the lesion area. In contrast, cultured cells survived within the lesion as well as around lesion, but failed to fill the entire lesion area even at 5 weeks post-transplantation. In both cases, the transplanted cells differentiated into neurons and astrocytes. Human iPSC/NPCs from a frozen stock transplanted after a 2 week delay survived within and near the lesion but did not fill the entire lesion area. In a separate experiment, human iPSC/NPCs from a frozen stock were enriched with GRP-derived astrocytes (prepared from the same iPSC cell line) and transplanted after a 2-week delay. Similar to grafts of human iPSC/ NPCs alone, these grafts survived within the lesion, but again failed to fill the entire lesion area. Transplanted cells also differentiated into neurons and astrocytes 5 weeks post-transplantation within the lesion site. These results indicate that transplants of human iPSC/NPCs can generate neurons and therefore be used to form relays to reconnect the injured spinal cord, but they require additional care to improve survival for efficient replacement of lost tissue.

Title: Survival of iPSC-derived grafts within the striatum of immunodeficient mice: importance of developmental stage of both transplant and host

Authors: *C. TOM, S. YOUNESI, E. MEER, V. B. MATTIS;
Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: Degeneration of the striatum can occur in multiple disorders and these lesions have devastating consequences for the patients. For example, infantile infections with streptococcus, measles or herpes cause striatal necrosis associated with dystonia or dyskinesia. Additionally, in Huntington's disease the striatum undergoes massive degeneration and presents with behavioral, psychological and movement issues, ultimately resulting in death. Currently, only supportive therapies are available for striatal degeneration. Clinical trials have shown some efficacy using transplantation of fetal-derived primary striatal progenitors. For transplantation therapy to be a reality, large banks of fetal progenitors that give rise to the primary neuron of the striatum (medium spiny neuron (MSN)) are needed. However, fetal tissue is of limited supply, has ethical concerns and requires patient use of immunosuppressive drugs, due to the risk of rejection. Another potential source of MSNs is from induced pluripotent stem cells (iPSCs), adult somatic tissues reprogrammed back to a stem cell fate. Multiple publications have demonstrated the ability to differentiate MSNs from iPSCs.
Previous publications reveal that the graft survival of fetal progenitors is critically dependent upon the age of the donor embryo. With the advent of iPSC technology, the question regarding "age" of the graft is even more essential, since transplanting pluripotent cells has an inherent risk of overproliferation and teratoma formation, but has gone largely unanswered. iPSCs were therefore transplanted at different stages along a paradigm of striatal differentiation into the striatum of both the neonatal and adult immunodeficient mice. This study aims to examine the importance of both the developmental age of the transplant and recipient for graft survival, migration and immunohistochemical expression of cell markers in iPSC-derived striatal cell transplants.

Abstract: Huntington disease (HD) is a fatal late-onset neurodegenerative disorder caused by the degeneration of medium spiny neurons in the striatum region of the brain. The main cause of the disease is the CAG repeat expansion on the Huntingtin gene (HTT) leading to poly glutamine tract which is toxic to the cells. To date, there is no cure or effective treatment for this disease. Previous studies have shown the therapeutic effects of bone marrow and umbilical cord derived mesenchymal stem cells (MSC) on the motor deficits of HD. However, a very recent study has indicated that the therapeutic effect of MSCs for HD depends on how many times the cells have been passaged prior to transplantation. It was shown that higher passaged MSCs (P40 to P50) delayed the onset of motor, cognitive, and neuropathological loss in HD mouse models, most likely through the release of neurotrophic factors, specifically the brain derived neurotrophic factor (BDNF). However, there is also evidence showing that the higher passaged MSCs may not demonstrate an acceptable safety profile, due to accumulation of chromosomal abnormalities that may occur over several passages. Hence, higher passage MSCs may not confer optimal clinical utility. Previous studies have revealed synergistic effects of donor age and passage number. Given this, the present study examined these two critical aspects - the donor age and the passage number of the bone marrow derived MSCs in the context of alleviating motor deficits in R6/2 mouse model of HD. Our findings indicates that donor ages of 5 weeks, 6 months and 10 months of the MSCs and the number of passages prior to transplantation, ranging from lower passage (P3 to P8), intermediate passage (P20 to P30) and high passage (P40 to P50) can affect therapeutic efficacy. *Support for this study was provided by the Neuroscience program, the College of Medicine, the Field Neurosciences Institute, and the John G. Kulhavi Professorship in Neuroscience at CMU*

Title: The significance of HLA matching in allogeneic human iPS cell-derived neural stem/progenitor cell transplantation for spinal cord injury

Authors: *M. OZAKI[1], A. IWANAMI[1], J. KOHYAMA[2], N. NAGOSHI[1], G. ITAKURA[2], H. IWAI[1], M. MATSUMOTO[1], H. OKANO[2], M. NAKAMURA[1];

Abstract: Background
Aiming at a first-in-human trial of human iPS cell-derived neural stem/progenitor cell (iPSC-NS/PC) transplantation for spinal cord injury, it would be realistic to use allogeneic human leukocyte antigen (HLA)-matched iPSC-NS/PCs from the viewpoint of quality control and cost performance. The purpose of this study is to determine the clinical significance of HLA matching on post-transplant immunoreaction using mixed lymphocyte reaction (MLR).
Materials and Methods
1×10^5 peripheral blood mononuclear cells (PBMCs) from volunteers were co-cultured with 1×10^5 irradiated iPSC-NS/PCs from a HLA-A, -B, and -DRB1 loci homozygous donor. The proliferative activities of PBMCs were measured by incorporation of ^{3}H-thymidine represented as counts per minute (CPM). HLA genotyping of iPSC-NS/PCs and their PBMCs was performed prior to the mixed culture. Stimulation index (SI) was calculated as the CPM of stimulated PBMCs divided by the CPM of the unstimulated PBMCs. Cut off value for immune rejection was defined as SI = 2.
To assess the immune suppressive effect of iPSC-NS/PCs on PBMCs proliferation, 5×10^4, 1×10^5 or 2×10^5 HLA homozygous iPSC-NS/PCs were co-cultured with 1×10^5 allogeneic PBMCs stimulated by allogeneic antigens.
Subsequently, the expression of immune-related antigens on iPSC-NS/PCs was analyzed using flow cytometry. To mimic an inflammatory environment at the injured spinal cord, iPSC-NS/PCs were exposed to IFN-γ and/or TNF-α for 48 hours prior to the analysis.
Results
Allogeneic HLA-A, -B, -DRB1-mismatched response was equivalently low as allogeneic HLA-A, -B, -DRB1-matched response (mean SI: 1.14 ± 0.19 vs. 1.20 ± 0.14 p=0.802). Furthermore, allogeneic response was also similar to autologous response (mean SI: 0.96 ± 0.15 vs. 0.85 ± 0.23 p=0.807). 2×10^5 iPSC-NS/PCs significantly suppressed the proliferation of stimulated allogeneic PBMCs compared to 5×10^4 (p=0.001) or 1×10^5 iPSC-NS/PCs (p=0.017). The

expression of HLA-DR, CD40, CD80 and CD86 on iPSC-NS/PCs was not elevated even in the presence of IFN-γ and/or TNF-α.

Conclusions

Immunological examination using MLR revealed no significant differences in immune response between HLA-matched and -mismatched conditions. Furthermore, the stimulation indexes in both two conditions were less than 2, suggesting that the immure response in iPSC-NS/PC transplantation could be unexpectedly low. Taken together, the immune suppressive effect and the low antigen presenting function of iPSC-NS/PCs could affect low immune response even in allogeneic HLA-mismatched setting.

In the near future, it is crucial to further verify whether these results could be reproduced in the clinical setting.

Title: Grafted glutamatergic neuronal precursors integrate into the postnatal cerebral cortex and promote functional recovery after targeted neuronal apoptosis

Authors: J. MIHHAILOVA, V. PETRENKO, P. CONSTANTHIN, A. CONTESTABILE, R. BOCCHI, K. EGERVARI, P. SALMON, *J. Z. KISS;
Univ. of Geneva, Dept. of Neurosciences, Geneva, Switzerland

Abstract: Transplantation of appropriate neuronal precursors after neuronal injury holds promises for reconstruction of cortical circuits. However, the efficiency of these approaches for neuronal replacement *in vivo* remains yet very limited. Here we studied the sequential events that characterize the integration of grafted neuronal precursors into the injured neocortex. We took advantage of a new, highly reproducible model of neuronal ablation utilizing a diphtheria toxin/diphtheria toxin receptor system to induce synchronized apoptotic death of the layer II/III neurons in the rat somatosensory cortex at postnatal day 16 (P16). Transplantation of embryonic

progenitors was carried out 4 days after the lesion that was followed by the analysis of transplanted grafts and somatosensory behavior tests at 7, 14 and 30 days after transplantation. Our results indicate long-term survival (up to 180 days) and good tissue integration of donor cells. Transplanted precursors differentiated into glutamatergic neurons, sent long distance projections into the recipient cortex and received thalamocortical as well as GABAergic innervation. Moreover, neurons in the graft were engaged in synaptically interconnected networks with the host circuits. Compared to transplants into the intact cortex, grafts in the environment of the apoptotic injury showed earlier maturation, increased dendritic tree complexity and accelerated development of GABAergic innervation. Finally, transplantation of neuronal precursors significantly attenuated the apoptotic injury-induced functional deficits in behavior tests. The model provides new possibilities for exploring the synaptic integration of transplanted cells and their impact on functional recovery.

Title: Human-porcine chimerism and the use of blastocyst complementation to generate a source of nigral dopamine precursors suitable for transplantation

Authors: ***A. CRANE**[1,2], P. SWAMINATHAN[1], H. HEWITT[1,3], F. XIAO[1,3], V. SAVANUR[1], J. VOTH[1], Z. SCHULTZ[1], D. CARLSON[4], S. FAHRENKRUG[1,4], J. DUTTON[1], W. LOW[1,3]; [1]Stem Cell Inst., [2]MinnCResT Program, [3]Neurosurg., Univ. of Minnesota, Minneapolis, MN; [4]Recombinetics Inc., St. Paul, MN

Abstract: Ethical considerations and limited tissue availability represent a significant hurdle in transplantation of human fetal midbrain dopamine (mDA) progenitors for patients with Parkinson's disease. Blastocyst complementation can provide an alternative source of tissue, a process in which human pluripotent stem cells (PSCs) are introduced into genetically engineered organogenesis-disabled porcine blastocysts. Through normal development, injected PSCs can potentially fill the niche and fully develop into a human organ. The goal of our research is to obtain genuine human fetal mDA progenitors grown within the porcine midbrain. In the current

study, our first experiment represents a proof-of-concept for human-porcine chimerism. *In vitro* observations of human induced pluripotent stem cells (hiPSCs) and human cord blood stem cells (hUCBSCs) injected into wild-type porcine blastocysts indicate human cells can incorporate and proliferate within the porcine inner cell mass. Furthermore, human cells were widely present in E30 porcine fetuses derived from hUCBSC injected blastocysts, following transfer to surrogate sows. Subsequent experiments examined the ability to complement *PITX3* knockout porcine embryos with hUBSCS or hiPSCs to generate a human substantia nigra within the porcine midbrain. Examination of *PITX3*-knockout fetuses at E62 demonstrate a reduction in tyrosine hydroxylase (TH) immunoreactivity within the developing substantia nigra as well as a closed-eye phenotype, which were attenuated through blastocyst complementation. Interrogation of fetuses complemented with either hiPSCs or hUCBSCs failed to identify any human cells present throughout the fetus. In a subset of complemented animals, intermediate phenotypes were observed in the morphology of the retina or an increase in TH immunoreactivity within the substantia nigra. As no human cells were observed in the target tissue, further studies will interrogate porcine-porcine chimerism as well as the mutation of additional genes earlier in the development of the ventral mesencephalon. This study represents the first attempt in human-porcine chimerism, providing the groundwork for generating exogenic human mDA progenitors in swine.

Title: hESC-derived dopaminergic grafts improve L-DOPA induced dyskinesia in a rat model of Parkinson’s disease

Authors: *O. F. ELABI[1], A. KIRKEBY[2], M. PARMAR[2], E. LANE[1];
[1]Sch. of Pharm. and Pharmaceut. Sci., Cardiff Univ., Cardiff, United Kingdom; [2]Dept. of experimental Med. Sci., Lund stem cell centre, Lund, Sweden

Abstract: Human embryonic stem cell derived dopaminergic neurons are currently the best candidates to supersede primary dopaminergic neurons as a source of cells for transplantation in the treatment of Parkinson's disease. However, although studies have now demonstrated survival of these cells in rodent models of the disease, there has been debate about the interaction of anti-parkinsonian drugs with the grafts. This is critical, given that patients will be taking dopaminergic medication (L-DOPA or dopamine agonists) prior to, during and following transplantation. Furthermore, long term treatment provokes L-DOPA induced dyskinesia, and may precipitate graft-induced dyskinesia (a side effect of the transplantation procedure). It is therefore essential to determine how grafts respond in the presence of these medications. Five groups of female Sprague Dawley rats (n=8-9) received unilateral infusions of 6-hydroxydopamine (6OHDA) into the median forebrain bundle to selectively kill the nigro-striatal dopaminergic neurons. hESC-derived dopaminergic neurons were transplanted into the dopamine depleted striatum of 4 groups while one group was a lesion only control. Two transplanted groups received chronic L-DOPA treatment for 4 weeks before transplantation and 16 weeks after transplantation. One L-DOPA and one non-L-DOPA treated groups were administered exendin-4 (0.5ug/kg twice daily) starting immediately after transplantation. Behavioural assessments were performed prior to transplantation and at repeated intervals post-transplantation: amphetamine induced rotations test and other simple hand motor tests (stepping, whisker and cylinder) were performed. L-DOPA induced dyskinesia side effect were measured weekly from starting L-DOPA treatment by using the AIMs rating scale as described by Breger,L. et al 2013 . Brains were then be harvested for histological analysis. All transplanted groups showed a significant improvement in amphetamine rotation test at week 12 of transplantation. Exendin-4 with and without L-DOPA significant improved rats' performances in whisker test since week 8 post transplantation compared to the lesion control group. AIMs scoring and L-DOPA induced rotations were significantly reduced from 6 weeks post transplantation. This study demonstrates for the first time that hESC derived dopaminergic neurons are able to ameliorate L-DOPA induced dyskinesia. We also found that L-DOPA had no detrimental effect on the ability of the graft to improve motor performance and that exendin-4 may support graft function and integration. Histological analysis will further these findings.

Title: Transplanted embryonic neurons integrate adequately into adult neocortical circuits

Authors: *S. GRADE[1,4], L. DIMOU[1,4,2], K. CONZELMANN[3], M. GÖTZ[1,4,2];
[1]Physiological Genomics, [2]SYNERGY, Excellence Cluster of Systems Neurol., [3]Max von Pettenkofer Inst. and Gene Ctr., Ludwig-Maximilians Univ., Muenchen, Germany; [4]Inst. of Stem Cell Res., Helmholtz Ctr. Munich, Neuherberg, Germany

Abstract: Neuronal connectivity forms the structural foundation underlying neural function, as brain circuits restrain or even define the functional neuronal networks that act together in a sophisticated and highly coordinated fashion to express motor, sensory or cognitive behavior. Transplantation strategies aiming at replacing neurons lost upon brain injury or disease have been thriving in the last decades, however, it remains elusive whether new neurons can faithfully integrate and wire into the existing circuits. Herein, we induced cell death of upper layer projection neurons in the primary visual cortex (V1) of adult mice and transplanted neurons from the embryonic mouse neocortex. Our data show that the new neurons display the appropriate upper layer neuron identity, acquire mature morphologies by extending axons and dendrites through the host brain parenchyma, and develop synaptic specializations on those arbors. Using monosynaptic tracing based on a modified rabies virus and brain-wide analysis, we show here that transplanted neurons receive area-specific, afferent projections matching those of endogenous pyramidal neurons in the primary visual cortex. These comprise a number of sensory and associative cortices, as well as subcortical regions including the dorsal lateral geniculate nucleus (dLGN), the relay nucleus of the retino-geniculate-cortical pathway. Interestingly, connectivity ratios are comparable to the ones found endogenously, and the new geniculate-cortical connections respect the topographic maps that are established during development of the mouse visual system, revealing accurate pairwise connections and maintenance of neighbor to neighbor relationships between subregions of the visual thalamus and the V1. Excitingly, transsynaptic tracing after transplantation in a highly inflammatory injury as a stab wound, reveals as well a broad and V1-specific connectome, raising prospect for the success of neuronal replacement in conditions where environment is highly changed by reactive glia and infiltrating immune cells. Similarly to what we observed in both lesion models, neurons transplanted in the intact brain establish mostly adequate connections, however considerably fewer connections per cell, far below the connectivity ratio existing endogenously. Altogether our data indicate that

transplanted neurons can integrate with great specificity into already existing neocortical circuits, which normally do not harbor new neurons, a critical question for functional reconstruction in the adult brain.

Sch. of Med., New Haven, CT

Abstract: The hallmark motor symptoms of Parkinson’s disease (PD) are attributable to the loss of midbrain dopaminergic (DA) neurons projecting from the substantia nigra pars compacta (SNpc) to the striatum. Replacing these neurons by cell transplantation is an attractive strategy for restoring dopaminergic dysfunction and modifying disease progression in patients. Recent advances in developing robust cell culture protocols for directed differentiation of human pluripotent stem cells (hESCs or hiPSCs) to near pure populations of SNpc (A9-type) DA neurons has heightened the prospects for PD cell therapy. However, some of the remaining challenges include: risk of hyperproliferation/tumor formation of the grafts, generation of unwanted side populations (e.g., 5-HT neurons that may contribute to graft-induced dyskinesia), and limited graft survival. Directly addressing these issues, we report a novel genetic-programming strategy in hESCs using a constitutively-active form of the transcription factor MEF2C, combined with the floor plate DA neuronal differentiation protocol of Lorenz Studer’s group, in order to yield cultures that contain a nearly pure population of DA neurons expressing A9-type markers and electrophysiological properties by patch-clamp recording and without 5HT expression. Additionally, we have shown that expression of MEF2C, which is known to be

dysfunctional in at least some forms of PD (Ryan et al. *Cell*, 2013), is anti-apoptotic and drives BDNF expression. Direct comparison of gene expression profiles by RNAseq of these MEF2C-engineered cells with non-engineered cells reveal that the MEF2C-cells are substantially more similar to human brain-derived A9 DA neurons. Transplantation of the engineered cells into the striatum of the 6 hydroxydopamine-lesioned rat and MPTP monkey models of PD showed significant motor behavioral improvement. This was accompanied by long-term (>1 year) survival of the grafts containing DA neurons, as analyzed by SPECT scan, robust innervation of A9 targets, and complete absence of hyperproliferation. These results support the robustness and translational readiness of our approach toward developing a human stem cell-based PD therapeutic.

Title: An immortalized cell line from the motor cortex of an adult rat as a model of cell transplant therapy in rats subjected to cortical ischemia. Survival, phenotype and functionality post grafting

Authors: A. ARMIJO[1], *C. F. ARRIAGADA[2,4], R. CAVIEDES[3], P. CAVIEDES[3]; [1]Program of Anat. & Devel. Biol., [3]Program of Molec. & Clin. Pharmacol., [2]ICBM, Fac. Med, Univ. Chile, Santiago, Chile; [4]Program of Anat. & Devel. Biol., ICBM, Fac. of Medicine, Univ. of Chile, S, Chile

Abstract: Transplant models using stem cells have resulted in survival and differentiation of engrafted cells in models of cerebral ischemia. Therapeutic developments have been limited due to reduced quantities of procurable cells, variable phenotypes, potential tumorogenesis in cells transfected with oncogenes, and the ethical dilemma on the origin of the stem cells. An alternative source are immortalized cell lines, per the experience with the implant of a human immortalized cell line, hNT, in the cerebral cortex of patients with permanent ischemic damage.

We present our work evaluating the engraftment of an immortalized cell line, named RCCCM, derived from the motor cortex of an adult Fisher 344 rat, in the brain of rats subjected to temporary brain ischemia. Four Fisher 344 rats previously subjected to brain ischemic lesions by occlusion of the middle cerebral artery, were transplanted with the RCCCM cell line transfected with enhanced green fluorescent protein (RCCCMt) along three sites of stereotactic coordinates in the primary motor cortex, in a density of 100.000 cells/µl. 12 weeks post-surgery, the animals were euthanized and the brains fixated. Engrafted RCCCMt cells were immunodetected with either diaminobenzidine (DAB) against EGFP or immunofluorescence. Maturation and phenotype of grafted RCCCMt cells were evidenced by colocalization experiments with immunofluorescent labeling against Ki67, βIII-tubulin, MAP-2, NT3 and GFAP. DAB labelling was visualized through light microscopy and double labeling was confirmed using confocal microscopy. RCCCMt cells were found at the bottom of the implantation sites, where they exhibited a round, immature shape with signs of migration through the ipsilateral corpus callosum. RCCCMt cells were also encountered in Layers 4 and 5 of the cerebral cortex, where they exhibited a rounded and pyramidal shape, with long processes. βIII-tubulin (7,72%), MAP-2 (18,12%) and NT3 (17,79%) were present in RCCCMt cells, whereas labeling against Ki67 and GFAP was absent. Hence, RCCCMt cells survived in the host brain tissue even in the proximity of a damaged cerebral cortex, and they could migrate from this site or the end of the needle tract and localize in layers 4 and 5. Immunofluorescent colocalization analysis confirmed that RCCCMt cells maintained their neuronal phenotype and developed two stages of differentiation in the host tissue, immature and mature, as expressed by the presence of βIII-tubulin and MAP-2 and NT3, respectively Further, no cells in undifferentiated/proliferative stages were found The results strongly suggest that RCCCMt cells can survive after grafting in the brain, migrate and maintain neuronal traits.

Title: Embryonic stem cell transplants as a therapeutic strategy in a rodent model of autism

Authors: *J. J. DONEGAN[1], A. M. BOLEY[2], D. J. LODGE[2];
[1]Pharmacol., Univ. of Texas Hlth. Sci. Ctr. At San Antonio, San Antonio, TX; [2]Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: Autism is a neurodevelopmental disorder characterized by disruptions in three core behavioral domains: deficits in social interaction, impairments in communication, and repetitive and stereotyped patterns of behavior or thought. There are currently no drugs available for the treatment of the core symptoms of ASD and drugs that target comorbid symptoms often have serious adverse side effects, suggesting an urgent need for new therapeutic strategies. The neurobiology of autism is complex, but converging evidence suggests that ASD involves disruptions in the inhibitory GABAergic neurotransmitter system. Autistic patients show reductions in GABA itself, in the GABA synthesizing enzymes, GAD65 and GAD67, and in subunits of the $GABA_A$ receptor. Post mortem studies demonstrate that these reductions may be due to an actual loss of GABAergic interneurons, specifically the parvalbumin (PV)-positive subtype. PV-positive interneurons play a critical role in regulating pyramidal cell excitability and synchronizing coordinated network activity. Autistic patients show hyperexcitability and reduced coordinated activity in the prefrontal cortex (PFC) and this dysregulated PFC activity has been associated with autism-like behaviors, including reduced social interaction and cognitive inflexibility. Therefore, we hypothesize that restoring PV interneuron function will normalize aberrant cortical activity and ultimately abolish the behavioral deficits associated with autism. To induce an autism-like phenotype, pregnant rats were injected with the viral mimetic Poly I:C (7.5 mg/kg) on gestational day 12. To restore interneuron function, we used a mouse embryonic stem cell line containing dual reporters (Lhx6::GFP and Nkx2.1::mCherry) to grow PV-positive interneurons. Cells were sorted using flow cytometry, then injected into the mPFC of Poly I:C- or saline-treated offspring. After a 30 day recovery period, during which time the transplanted cells migrate and integrate into the mPFC circuitry, we measured social interaction, ultrasonic vocalizations, attentional set-shifting, and pyramidal cell activity in the mPFC. PV-positive transplants into the mPFC of Poly I:C-treated rats increased social interaction time, improved cognitive flexibility, and normalized pyramidal cell function, suggesting that targeting PV-positive interneurons in the mPFC may be a novel and effective treatment strategy to reduce the core symptoms of autism.

Title: Potential of induced pluripotent stem cells (iPSCs) and iPSC-derived neural stem cells (iNSCs) for treatment of the behavioral and neuropathological deficits in the YAC128 mouse model of Huntington's disease

Authors: *A. AL-GHARAIBEH[1,5,2], R. CULVER[2,5], A. CRANE[2,5], R. WYSE[2,5,3], A. ANTCLIFF[2,5,3], B. SRINAGESHWAR[2,5], N. KOLLI[2,5], L. FROLLO[2,5], D. STORY[4,5,2], G. PATRICIA[2,5], S. MOORE[2,5], O. LOSSIA[2,3], A. EICKHOLT[2], G. DUNBAR[2,6,5,4], J. ROSSIGNOL[2,5,3];

Abstract: There is no cure or effective therapy for Huntington's disease (HD), and the only FDA-approved treatment for this disorder has only palliative effects. However, stem cell therapy holds significant promise for HD patients, but more research is needed to test the safety and efficacy of this approach in order to determine the optimal stem cell type for transplantation. The goal of the current study was to assess the efficacy of intra-striatal transplantation of induced pluripotent stem cells (iPSCs) and iPSC- derived neural stem cells (iNSCs) as a treatment for HD. For this purpose, we developed mouse adenovirus-generated iPSCs and transplanted them into striata of wild-type (WT) and HD YAC128 mice. Also, we differentiated the iPSCs into neural stem cells *in vitro*, and then transplanted them into striata of WT and HD YAC128 mice. We tested the efficacy of these transplanted iPSCs or iNSCs for their ability to survive and differentiate into neuronal phenotypes, and their ability to reduce the significant behavioral deficits observed in this mouse model of HD. To analyze the functional efficacy of iPSC and iNSC transplantation, 10-month old male and female WT and HD YAC128 mice were given bilateral intra-striatal transplants of iPSCs or iNSCs, pre-labelled with Hoechst, or given injections of vehicle control. Measures of accelerod, open field, and clasping behaviors were made one day before the transplantation, and then weekly for 10 weeks. Our results revealed an amelioration of locomotor deficits for the HD groups that received iPSC or iNSCs transplantation, but no between-group differences were observed on measures of open-field activity levels or the amount of clasping at baseline and week 10. Ten weeks following

transplantation, the mice were perfused, and their brains were frozen, sectioned and analyzed by immunohistochemistry. The results from our histological examinations revealed that iPSCs in both WT and HD mice had survived and showed evidence of differentiation into neuronal phenotypes, with co-labelling of Hoechst with Tuj1 and NeuN. Further analyses of this tissue is aimed at measuring the extent of potential differentiation of the transplanted cells into region-specific (e.g., DARPP-32) neurons, detection of any early signs of tumor formation, markers for inflammation and mutant *huntingtin* aggregate formation. Collectively, our present histological and behavioral data suggest that adenovirus-generated iPSCs or iNSCs may provide a safe and effective option for neuronal replacement therapy.

Title: Growth, differentiation and connectivity of implanted human neuronal precursor cells in the mouse visual cortex

Authors: ***J. BENOIT**[1], H. WU[2], V. BRETON-PROVENCHER[1], J. P. K. IP[1], D. FELDMAN[1], S. CHOU[1], R. JAENISCH[2], M. SUR[1];

Abstract: The use of induced pluripotent stem cells (iPSCs) to recapitulate the effect of human genetic diseases in an experimentally tractable system requires both a rich genomic as well as cellular context. Current models for neurological diseases generally consist of human induced-neuronal (iN) cells engineered with the specific mutations of interest, or derived from patient cells with those same mutations, and grown *in vitro* in a 2D culture. In order to create a more natural and 3D environment in which to grow and assess human iNs, we differentiated "wild-type" AAVS1-CAG-tdTomato human neuronal precursor cells (NPCs) which were then transplanted into the mouse cortex to form a "humanized" functional network in a model system. We injected approximately 10,000 NPCs into the primary visual cortex (V1) of SCID immunodeficient mice at P21 and then using a craniotomy, examined their morphological development *in vivo* from 6 weeks post-injection onwards. Of the injected NPCs, several hundred survived and were localized mainly to the injection tract although some cells in deeper layers (~300 um from pia) were well-intercalated between endogenous mouse cells within several hundred um of the injection. NPCs sent wide-ranging projections, some of which reached to adjacent cortical areas and extended beyond the craniotomy (1.5 mm lateral distance) in some cases. We found evidence of filopodia and potential immature spines on human dendrites which suggests that the NPCs have differentiated into a neuronal phenotype and may be forming synapses with endogenous mouse neurons. We are currently examining calcium responses in these cells to determine if they possess functional contacts with the mouse cortical circuit and are therefore responsive to visual input. We posit that this system represents a more realistic environment with superior experimental validity in which the development of normal and patient-derived human neurons can be studied.

Title: Optogenetics stimulation improves stem cell engraftment after transplantation into neonatal rats with focal ischemic stroke

Authors: *Z. WEI[1], A. GANGAL[1], X. GU[1], D. CHEN[1], C. LIU[1], Z. LI[1], K. BERGLUND[2], S. YU[1], L. WEI[1];

Abstract: Neonatal ischemic stroke is a devastating disorder affecting 1/4000 infants worldwide and clinically applicable treatment is very limited. Currently, there is no effective acute treatment or regenerative therapy to repair the damaged brain tissue following ischemic stroke in neonates. In animal models, intracranial delivery of neuronal precursors has been tested and shown beneficial effects of brain repair and stimulating endogenous neurogenesis. However, whether transplanted cells can reconnect to the surviving or new generating neurons through synaptic formation following ischemia has rarely been verified. Utilizing a neonatal stroke model in the present study, we investigated intracranial delivery of neural progenitor cells derived from mouse induced pluripotent stem cells (iPSCs). Before transplantation, iPSCs were genetically modified to express ChR2 or VChR1 channels that can be selectively activated by optogenetics stimulation using blue laser light or luciferin-luciferase. Neonatal P7 rats were subjected to a focal ischemia targeting the right sensorimotor cortex. Neural progenitor cell transplantation was performed at 7 days after stroke; optogenetics stimulation (15 min/day) was carried out from 14 days after stroke until sacrifice. This transplantation and stimulation paradigm increased the expression of synaptic proteins including PSD-95, SNAP-25, SYN-1 and synaptophysin in immunohistochemical assays and Western blot analysis. In functional assessments, cell transplantation and optogenetics stimulation improved the performance of stroke mice in whisker-touching test, sensorimotor function evaluation, computer-based automated homecage behavioral analyses, and neurocognitive tests. Optogenetics stimulation also showed significant increases in MBP expression, DCX-expressing neuroblasts and Glut-1+/BrdU+-colabeled small vessels in the penumbra region. Our finding demonstrates that optogenetics activation and transplantation of iPSC-derived neural progenitor cells act synergistically to augment neural network repair and provides an exciting opportunity to improve cell therapies for neonatal ischemic stroke.

Title: Chronically reduced adult neurogenesis in the mouse hippocampus contributes to functional deficits following soman-induced status epilepticus

Authors: K. M. HOFFMAN[1], K. L. SCHULZ[1], E. K. JOHNSON[1], J. K. CHANDLER[1], *P. M. MCNUTT[2];

Abstract: *Status epilepticus* (SE) resulting from central exposure to organophosphorus nerve agents causes devastating damage to the brain, including acute neurotoxicity and impaired brain function. In most cases cognitive and behavioral deficits do not resolve, and the only treatment option is supportive care. The hippocampal formation is a primary target of nerve agents, and the acute loss of pyramidal CA neurons is a well-described outcome of nerve agent-induced SE (NASE). However the contributions of other hippocampal pathologies to aberrant cognition have yet to be described. Here we evaluated the effects of NASE on functional neurogenesis in the subgranular zone (SGZ) of the hippocampus. SGZ-derived newborn neurons integrate into the dentate gyrus within 2-3 wk and are functionally important for certain types of memory. In preliminary studies, immunohistochemistry revealed a 90% reduction in doublecortin-expressing immature neurons at 21 and 56 d (but not at 1 d) after soman exposure as compared to age-matched, vehicle-treated controls. To evaluate the functional consequences of reduced neurogenesis on hippocampal function, high frequency stimulation (HFS) of the medial perforant pathway was used to induce long-term potentiation (LTP) in DG neurons. While robust LTP was observed in all vehicle control mice and in soman-exposed mice at 1 d, LTP was completely eliminated in soman-exposed mice at 21 and 56 d. These data suggest that impaired hippocampal neurogenesis has both delayed and chronic effects on DG function in NASE survivors. Ongoing studies are focused on determining the precise mechanism(s) and timing of impaired neurogenesis.

Title: Histological characterization of stem-cell derived 3D retinal progenitor sheet transplants in an immunodeficient retinal degenerate rat model

Authors: A. MATHUR[1], B. T. MCLELLAND[1], M. SARY[1], J. WAN[1], G. NISTOR[3], I. NASONKIN[4], R. ARAMANT[1], H. S. KEIRSTEAD[3], *M. J. SEILER[2];

Abstract: Incurable eye diseases such as age related macular degeneration (AMD) and retinitis pigmentosa (RP) are characterized by retinal degeneration (RD). While current therapies aim to delay photoreceptor death, replacement with retinal progenitor sheets has the potential to restore vision. The current study investigated whether transplants of human stem cell (hESC) derived retinal progenitor sheets could replace the degenerating cells of the host retina and make functionally relevant connections (see abstract Thomas et al.). Our RD model is an immunodeficient (nude) rho SS34ter-line3 rat (will not reject human cells) in which most of the outer nuclear layer (ONL) is absent by P30. hESCs were differentiated into retinal organoids (retinoids) following a protocol similar to Zhong et al. 2014 (Nature Communications 5:4047). One set of transplants was differentiated after Singh et al. 2015 (Stem Cells & Development 24:2778). These 3D retinoids (differentiation day 30-63) were dissected into sheets and then transplanted into the host subretinal space (P25-30). Cryostat sections through the transplants 50-300 days post-surgery (DPS) were stained with hematoxylin and eosin (H&E), or processed for immunohistochemistry to label human donor, retinal cells and synaptic markers using light and confocal microscopy. RD sham surgery eyes (150+ DPS) had a complete loss of ONL, however the inner nuclear (INL), plexiform (IPL) and ganglion cell layers (GCL) appeared intact. Transplanted progenitor sheets developed a rosetted morphology in vivo, with a distinct ONL and photoreceptor inner and outer segments located in the center of the rosettes. Transplants (stained with human marker SC-121) extended processes into the host IPL and GCL. Outer segments clearly stained for rhodopsin within the rosettes. The mature retinal markers PKCα (rod bipolar), recoverin (rods and cones, cone bipolar) or rhodopsin (rod outer segments) showed less expression in younger (<100 DPS) than in older (150+ DPS) transplants (labeled with either

SC-121 or Ku80). Neuronal processes of human donor cells (human neurofilament) were dense within the transplant area and extended into the host IPL in all transplants. The labeling of synaptic markers (bassoon and synaptophysin) indicated the presence of functional connections, possibly between the transplant and host retina. In summary, hESC-derived retinal progenitor sheet transplants develop mature retinal cell subtypes including photoreceptors and integrate with the RD host retina.

Abstract: Cortical interneurons originate from either the medial ganglionic eminence (MGE) or from the caudal ganglionic eminence (CGE). Previous studies have shown that transplanted MGE precursors can migrate and functionally integrate into a variety of heterochronic environments. It is not known whether heterochronic transplantation of CGE precursors can induce similar gains, or whether CGE precursors can survive, disperse, and laminate appropriately. We show that CGE cells transplanted into the postnatal visual cortex survive, disperse widely, and adopt laminar locations and overall dendritic morphology appropriate for their lineage. In addition, the mature cells demonstrate immunocytological markers characteristic of their pretransplant fate. We further show that anatomically isolated CGE transplants contain a subpopulation of MGE cells. We used a genetic approach for the elimination of MGE-derived interneurons from CGE transplants by expressing a diphtheria toxin alpha subunit in *Nkx2.1*-expressing neurons. These genetically purified CGE transplants disperse and laminate nearly identically to the anatomically isolated CGE transplants, without the PV- and SST-expressing interneurons ordinarily seen following transplantation of anatomically isolated CGE. This work shows that heterochronically transplanted CGE neurons can integrate appropriately into visual cortex and that they retain the lamination and immunocytological fates of their lineage.

Abstract: Maturation of inhibitory GABAergic cortical circuits regulates experience-dependent plasticity. We recently showed that the heterochronic transplantation of interneurons from the medial ganglionic eminence (MGE) reactivates ocular dominance plasticity (ODP) in the postnatal mouse visual cortex. Genetic deletion of parvalbumin (PV) or somatostatin (SST) expressing interneurons from those transplants demonstrated that PV and SST cells each have the capacity to reactivate ODP. Might other types of interneurons similarly induce cortical plasticity? Here we establish that although heterochronic transplantation of anatomically isolated caudal ganglionic eminence reactivates ODP, genetic elimination of the small fraction of MGE cells (which are normally present in anatomically isolated CGE, as they migrate through the CGE en route to caudal cortex) eliminates the ability of CGE transplants to induce ODP. We use brain slice recording techniques to demonstrate that CGE transplants develop diverse active and passive physiological properties consistent with CGE lineage interneurons. In addition, we demonstrate that interneurons derived from hetereochronic CGE transplantation demonstrate orientation selective visual responses and are synaptically coupled to local excitatory and inhibitory neurons, consistent with their CGE lineage fate. These findings demonstrate that genetically purified heterochronically transplanted CGE cells can functionally integrate into host visual cortical circuits without allowing heterochronic ODP, thus illustrating the unique role of MGE lineage neurons in transplant induced ODP.

Title: Restoration of visual cortical responses after retinal sheet transplantation in rats with retinal degeneration

Authors: *A. T. FOIK[1], G. A. LEAN[1], B. T. MCLELLAND[2], A. MATHUR[2], R. B. ARAMANT[2], M. SEILER[2], D. C. LYON[1];
[1]Anat. and Neurobio., [2]Dept. of Physical Med. & Rehabil., Univ. of California, Irvine, CA

Abstract: Age-related macular degeneration and retinitis pigmentosa lead to a profound loss of vision in millions of people worldwide. Many of these patients lose both retinal pigment epithelium (RPE) and photoreceptors. Fetal-derived retinal progenitor sheets have been successfully transplanted into both rodents (*review: Seiler and Aramant, 2012 Prog Retin Eye Res, 31:661-87*) and humans (*Radtke et al, 2008 Am J Ophthalmol, 146:172-182*). In several models of retinal degeneration (RD), transplants restore rudimentary responses to flashes of light in a region of the superior colliculus (SC) corresponding to the location of the transplant in the host retina; and synaptic connectivity between transplant and RD host retina has been confirmed. However, in order to determine the quality and accuracy of visual information provided by the transplant, here we study visual responsivity at the level of visual cortex where higher visual perception is processed. Specifically, we used the transgenic *Rho S334ter-3* RD rat, which begins to lose photoreceptors at an early age, becoming blind shortly after 1 month post-natal. Between 24-40 days of age, RD rats received fetal rat retinal sheet transplants in one eye. Donors were rats expressing human placental alkaline phosphatase in all cells. Three to ten months following surgery, we found several neurons in the region of primary visual cortex (V1) matching the transplanted portion of the retina that were well tuned to stimulus orientation, size, contrast, and spatial and temporal frequency. Each of these response features are considered fundamental properties of V1 neurons that are necessary building blocks for higher level visual processing, such as shape and motion perception. In addition, we find that these response properties are absent in non-transplanted and sham-transplanted RD rats, but are on par with normal age-matched controls that do not suffer from RD. Moreover, in rats with normal retinas and RD rats with retinal transplants spontaneous firing rates were low, whereas in the RD rats without transplants, spontaneous firing rates were often higher, indicating abnormal function in the absence of visual input. In conclusion, our data thus far indicate that fetal rat retinal sheet transplants can restore visual cortical responses in transgenic *Rho-S334ter-3* RD rats. This restoration of 'normal' cortical physiology in a rat model represents a critical step towards developing an effective remedy for the visually impaired human population.

Abstract: Retinal degeneration (RD) diseases such as Age-related Macular Degeneration (AMD) and Retinitis Pigmentosa (RP) affect millions of people worldwide. Most treatment strategies can only delay the progression of the diseases. Our goal is to repair the damaged retina and restore the lost vision by transplanting stem-cell derived, 3D retinal organoid (retinoid) sheets. Based on qPCR and immunohistochemistry, we have shown previously that the human embryonic stem cell (hESC) derived retinoids develop retinal markers and lamination over time (McLelland et al Neuroscience abstract 2015). The data suggested a gene expression pattern similar to the developing human fetal eye. We hypothesize that after transplantation into immunodeficient rho S334ter line-3 RD rats (nude RD rats) - that do not reject human cells - the hESC derived retinal progenitor tissue will create new photoreceptors for the host and generate new synaptic connections for phototransduction processing leading to visual function. To test this, stem-cell derived 3D retinoids, created based on a protocol modeled after Zhong et al. 2014 (Nature Communications 5:4047), were transplanted unilaterally into the subretinal space of 24-30 day old RD nude rats. One set of transplants was differentiated after Singh et al. 2015 (Stem Cells & Development 24:2778). Transplants were routinely imaged by optical coherence tomography (OCT) at 2-4 weeks after transplantation and then in 2-month intervals, and were selected for functional testing based on OCT. Optokinetic testing of visual acuity (= OKN) and superior colliculus (SC) electrophysiology was performed at 4 - 9 months after transplantation. In OCT imaging, transplants developed layers, integrated with the host and photoreceptor rosettes were recognizable in transplants 4-6 months after transplantation. Histological analysis showed that transplants developed photoreceptors in rosettes (see abstract by Mathur et al.). OKN testing demonstrated significant improvement in visual acuity of the hESC-derived retinoid

transplanted rats ($P<0.05$ for months 3-5, paired t test, transplanted eye vs non-surgery eye). Electrophysiological recordings from the SC showed that visual function was observed in the majority of the RD nude rats after hESC-derived retinoid transplantation (4/6) whereas age-matched RD controls had no visual responses. Based on these data, it may be concluded that hESC-derived retinoid transplants in rho S334ter line-3 nude rats can integrate with the host retina and support improved visual function.

Title: Fear erasure facilitated by immature inhibitory neuron transplantation

Authors: ***Y.-C. YU**, W.-Z. YANG, T.-T. LIU, J.-W. CAO, L.-Y. LIU;
Inst. of Brain Sci., Fudan Univ., Shanghai, China

Abstract: Transplantation of embryonic GABAergic interneurons has been demonstrated to modify disease phenotypes in rodent models of neurologic and psychiatric disorders. However, whether transplanted interneurons can modulate fear memory remains largely unclear. Here, we show that transplantation of embryonic interneurons into the amygdala does not alter host fear memory formation. However, approximately two weeks after transplantation, but not earlier or later, extinction training produces a marked reduction in spontaneous recovery and renewal of fear response. Further analyses reveal that transplanted interneurons robustly form functional synapses with neurons of the host amygdala and exhibit similar developmental progresses as endogenous amygdala interneurons. Importantly, transplanted immature interneurons reduce the expression of perineuronal nets, promote long-term synaptic plasticity, and modulate amygdala circuit dynamics. Our findings demonstrate that transplanted immature interneurons modify amygdala circuitry and suggest a previously unknown strategy for the prevention of extinction-resistant pathological fear.

Title: Spontaneous neuronal repopulation within the dorsal hippocampus following an acute kainic acid-mediated excitotoxic injury

Authors: *Y. YIN[1,2], L. M. KONEN[2], C. W. VAUGHAN[1], B. VISSEL[2,3,4];
[1]Kolling Inst. of Med. Res., Univ. of Sydney, Sydney, Australia; [2]Dept. of Neurosci., Garvan Inst. of Med. Res., Sydney, Australia; [3]Fac. of Sci., Univ. of Technol., Sydney, Australia; [4]Fac. of Med., UNSW Australia, Sydney, Australia

Abstract: Excitotoxicity is a contributing factor to a variety of neurodegenerative disorders and acute brain injuries. Additionally, neuronal repopulation outside of well-established neurogenic regions is highly controversial. The assumption that the central nervous system (CNS) has a poor capacity for recovery after injury has led to the view that only exogenous interventions can drive CNS repair. The present study aims to demonstrate the extent to which spontaneous neuron

repopulation of the CA1/CA3 dorsal hippocampal regions is possible following an acute excitotoxic injury, based on varying degrees of induced injury.
Excitotoxic neurodegeneration was induced by stereotaxic injection of kainic acid (KA; 1μg/μl) in one of several discrete locations (intrahippocampal-dorsal, intrahippocampal-ventral, intracerebroventricular (ICV) and amygdalar) in male C57BL/6 mice. Vehicle controls were injected with sterile phosphate buffered saline (PBS) at the same coordinates. Mice were perfused with 4% paraformaldehyde at 2 and 8 weeks post-injection (wpi), and brains were removed. The level of neuronal injury and regeneration was assessed in the CA1 and CA3 by immunohistochemistry, using NeuN as a marker of mature neurons. Non-fluorescent quantification of neuron populations was performed using StereoInvestigator7.
ICV injection of KA produced profound loss of neurons in the CA1 ($p<0.001$) and CA3 ($p<0.05$) regions, ipsilateral to the site of injury at 2 wpi, as compared to vehicle treated controls. However, by 8 wpi, the CA1 neuronal population was significantly increased in KA treated mice compared to 2 wpi, and was not significantly different to vehicle treated controls. Furthermore, both the CA1 and CA3 neuronal populations quantified at 8 wpi were comparable to PBS-injected animals, suggesting repopulation of the CA1 and CA3 regions. KA injection into the other three locations resulted in varying degrees of observed damage with subsequent effects on the magnitude of neuronal repopulation within the CA1 and CA3 regions. The results from the present study suggest the existence of intrinsic mechanisms for spontaneous repair and recovery within the brain in the absence of exogenous interventions. By providing the framework for understanding the extent to which spontaneous neurogenesis can occur in the unperturbed brain, we hope to inform current and future therapies for treatment of acute brain injuries and disorders.

Title: Characterization of neural progenitor cell differentiation on poly (ε-caprolactone) microfibers

Authors: *B. B. PATEL[1,2], F. SHARIFI[3], D. P. STROUD[1], N. HASHEMI[3], D. S. SAKAGUCHI[1,2];

Abstract: Biomaterials have become increasingly important for development of novel biomedical and therapeutic applications. Poly (ε-caprolactone) (PCL) is a biodegradable synthetic polymer used for fabricating microfibers using a microfluidic approach. PCL fibers help align cells and may be used for applications in axon regeneration and directed cell migration. These microfibers may mimic the microenvironment and provide a more complex 3-D platform in which cells can differentiate and proliferate. Multipotent adult hippocampal progenitor cells (AHPCs) have the ability to differentiate into neurons, oligodendrocytes and astrocytes. In this project our goal is to investigate the adhesion, proliferation, and differentiation of rat AHPCs *in vitro* growing on PCL microfibers. A panel of cell type specific antibodies was used to identify neural progenitors, neurons and glial cells. Proliferating cells were immunolabeled with Ki67 antibody, neural progenitor/stem cells were detected with Sox2 and Nestin antibodies, neuronal cell differentiation characterized by TuJ1 and MAP2ab antibodies and glial cell differentiation characterized by GFAP antibody. Preliminary results have indicated that the PCL microfibers support cell adhesion, survival, proliferation and differentiation of the AHPCs based on immunolabeling experiments. AHPCs play an important role in adult neurogenesis and due to the limited capacity of CNS to regenerate, they may become an important cell population for transplantation and the development of brain repair strategies. Transplantation of neural progenitor/stem cells within a PCL microfiber scaffolding construct may provide important biological and topographic cues that facilitate the survival, differentiation and integration of transplanted cells.

Title: Combining optogenetics and *In vivo* two photon calcium imaging to explore the functional impact of newborn neurons in the mouse olfactory bulb

Authors: *C. FOIS[1], S. PÉRON[2], N. MARICHAL[2], P.-H. PROUVOT[1], B. BERNINGER[2], A. STROH[1];
[1]Inst. for Microscopic Anat. and Neurobio., Johannes Gutenberg Univ., Mainz, Germany; [2]Adult Neurogenesis and Cell. Reprogramming, Inst. of Physiological Chem., Johannes Gutenberg Univ. Mainz, Mainz, Germany

Abstract: In the mammalian brain, adult neurogenesis is maintained within two neurogenic niches located in the subgranular zone (SGZ) of the hippocampus and in the subventricular zone (SVZ) of the lateral ventricles. Neuroblasts migrate from the SVZ via the rostral migratory stream (RMS) towards the olfactory bulb where they integrate into the pre-exisiting neuronal circuitry. However, the functional impact of the newborn neurons - mainly GABAergic interneurons - to the OB microcircuitry of the mitral/tufted (M/T cells) cells layer, representing the main output of the OB, remains poorly understood. Here, we establish the combination of optogenetics, two-photon calcium imaging, immunohistochemistry and electrophysiology for a causal understanding of how the spontaneous activity and the odor processing of the M/T cells are modulated by the mature newly integrated neurons in the main OB. To specifically and precisely control adult-born OB neurons activity, an adeno-associated viral vector (AAV) encoding the hyperpolarizing opsin ArchT is delivered to the OB neuron progenitors that are located in the SVZ. To monitor M/T cells activity, a second AAV vector coding for the genetic calcium indicator (GECI) GCaMP6f is injected locally in the dorsal OB at the depth of 350-400 µm. Subsequently, a chronic optical window is implanted at the level of the dorsal OB to allow for repeated 2P imaging. Six weeks post-injections, the M/T cells strongly express GCaMP6f and the ArchT-expressing newborn neurons have migrated to the OB where they are becoming fully integrated and mature. A custom-made 2P microscope is then used to record spontaneous and odor-evoked activity of the M/T cells (30.5 Hz) with and without the functional contribution of the newborn neurons. A mix of several odorant molecules known to activate the dorsal glomeruli are presented to the mouse's snout to elicit odor-evoked responses in the M/T cells. To transiently optogenetically inhibit newborn neurons 552 nm light (green) is delivered by an optic fiber (200 µm diameter) to the ArchT-expressing interneurons during the odor processing. The challenging combination of these techniques will provide unprecedented levels of understanding of the functional role that a complex process such as neurogenesis plays in OB microcircuitry.

Title: Reduced binocular summation of fMRI responses to visual stimulation in ventral extrastriate cortex in anisometropic amblyopia is related to visual cortical GABA concentration

Authors: *K. N. BYRNE[1,2,3], E. YANG[2,3], L. LI[4], D. M. LEVI[1,2,5], M. A. SILVER[1,2,3,5]; [1]Vision Sci. Grad. Group, [2]Sch. of Optometry, [3]Henry H. Wheeler Jr. Brain Imaging Ctr., [4]Cognitive Sci. Program, [5]Helen Wills Neurosci. Inst., Univ. of California Berkeley, Berkeley, CA

Abstract: Background: Amblyopia is a neurodevelopmental disorder characterized by reduced visual acuity due to abnormal early visual experience. Previous brain imaging studies have yielded mixed results regarding visual cortical abnormalities in amblyopia, and none have compared responses to monocular, binocular (identical stimuli in the two eyes), and dichoptic (different stimulus in each eye) stimuli. Recent studies have linked occipital GABA levels with fMRI response amplitude in the visual cortex of healthy individuals. Here, we measured fMRI responses to binocular, monocular, and dichoptic stimulation to measure binocular summation in anisometropic amblyopes and healthy controls, and we correlated these measures with visual cortical GABA levels.
Methods: We recorded fMRI activity in retinotopically-defined early visual cortical areas in twelve subjects with anisometropic amblyopia and fifteen visually normal control subjects for four stimulus conditions: binocular, dichoptic (orthogonal orientations in the two eyes), monocular stimulation of the amblyopic eye (for controls, the non-dominant eye) (monocularAE), and monocular stimulation of the fellow non-amblyopic eye (for controls, the dominant eye) (monocularFE). In addition, magnetic resonance spectroscopy was performed in the absence of visual stimulation to measure resting GABA concentration in a 3 cm^3 voxel centered on the calcarine sulcus.
Results: We quantified binocular summation of visual cortical responses by comparing the amplitude of fMRI responses to binocular stimulation to the responses to dichoptic and to monocular stimulation. In cortical area V2v, we found significant differences between amblyopic and control subjects for binocular-monocularAE ($p=0.048$), binocular-monocularFE ($p=0.026$), and binocular-dichoptic ($p=0.005$), with amblyopes showing significantly less binocular summation than controls. Similar group differences were obtained in area V3v for binocular-dichoptic ($p=0.016$). In addition, visual cortical GABA concentration was inversely correlated with binocular-monocularAE in V1 ($p=0.005$) and V2v ($p=0.035$) and with binocular-dichoptic in V2v ($p=0.024$) in the combined group of subjects.
Discussion: Our results demonstrate reduced binocular summation of fMRI responses in ventral (V2v and V3v) but not dorsal (V2d and V3d) extrastriate cortex in anisometropic amblyopia. This finding may be related to the previously reported dorsoventral asymmetry in $GABA_A$ receptor density in V2 and V3 in healthy subjects. In addition, binocular summation was inversely correlated with visual cortical GABA levels across all subjects.

Title: Spatiotemporal excitation of the primary visual cortex induced by intracortical microstimulation in the Royal College of Surgeons rats

Authors: ***S. MIYAMOTO**, N. SUEMATSU, Y. UMEHIRA, Y. HAYASHIDA, T. YAGI; Grad. Sch. of Engin., Osaka Univ., Suita-Shi, Japan

Abstract: Visual prostheses by means of intracortical microstimulation has a potential to restore a certain degree of visual function in the patients suffering from acquired vision loss. However, there have been reports that the visual cortical excitability is likely to be reduced in the blind patients. Therefore, in order to design the best suitable stimulation for the prostheses, it is desirable to understand the quantitative relationship between the stimulus parameters and the induced responses in relevant animal models. Although the Royal College of Surgeons (RCS) rat has been known for several decades as an animal model with inherited retinal degeneration, little has been known about the neural responses to microstimulation in their visual cortex. Thus, in the present, we examined neural excitability of the visual cortex in the RCS rats by using the voltage-sensitive dye (VSD) imaging technique. The RCS rats used here were grouped into early (3-5 week-old, $n = 5$), middle (9-10 week-old, $n = 6$) and end (88-100 week-old, $n = 5$) stages. The neural responses to single-pulse current stimuli (cathodic-first biphasic, 0.2 msec/phase, 0.675-5.33 nC/phase) delivered through a metal-based intracortical electrode were recorded by means of the VSD fluorescence. As results, we found no statistically significant difference among the three groups in terms of the intensity-response (I-R) profiles measured in the electrode vicinity; namely 1) the threshold stimulus charges (in nC/phase) were 0.47/0-0.63 (median/1st-3rd quartiles) in the early, 0.62/0-0.71 in the middle, and 0.22/0-0.60 in the end stages, 2) the Hill coefficients of the I-R curves were 2.00/1.97-2.30 in the early, 1.55/1.34-2.00

in the middle, 1.75/1.00-2.08 in the end stages. On the other hand, spatial extents of the trans-synaptic responses changed in their shapes more elliptical with age; namely the spatial aspect ratios of the responding areas were 1.41/1.33-1.58 in the early, 1.52/1.38-1.62 in the middle, 1.62/1.51-1.94 in the end stages. These results suggested that although the synaptic connections could be remodeled with age in the RCS rats, yet the intracortical microstimulation is valid to induce the neural excitations even in the end stage of the retinal degeneration.

Title: A case report of visual and motor recovery after cognitive sensorimotor rehabilitation in a patient with cortical blindness

Authors: D. DE PATRE[1], C. PERFETTI[1], F. PANTE[1], C. RIZZELLO[1], M. ZERNITZ[1], *A. VAN DE WINCKEL[2];
[1]Ctr. Studi di Riabilitazione Neurocognitiva, Villa Miari, Santorso (Vicenza), Italy; [2]Dept. of Physical Med. and Rehabiltiation, Med. Sch., Univ. of Minnesota Twin Cities, Minneapolis, MN

Abstract: Background and purpose: Spontaneous partial visual recovery happens 1-6 months after onset of cortical blindness. Further recovery can occur with visual rehabilitation. However, currently there is no gold standard therapy; clinical outcomes are variable and rarely translate into improvements in daily life activities (ADL).
The purpose of this study was to demonstrate feasibility and potential value of cognitive sensorimotor rehabilitation in a patient with cortical blindness.
Case description: A 48 year old female patient, with severe cortical blindness and tetraplegia caused by hypoxia after cardiac arrest, was dependent in ADL and distinguished shapes and colors after 1.5 year of standard visual rehabilitation. She then started cognitive sensorimotor rehabilitation for 8 months, 5 days/week, 3 hours/day, consisting of discrimination exercises correlating sensory and visual information to reconstruct vision and improve daily life motor performance. Clinical assessments and PET imaging were performed before and after rehabilitation.
Outcomes: Visual performance significantly improved: Her field of view increased to 15*10cm; she recognized and described objects; watched television; and used her cell phone. She improved

45 points (65/100) on the “Barthel ADL index”, reflecting independence in self-care and improved walking. She increased 23 points (48/58) on the “Motor Evaluation of Upper Extremity in Stroke Patients” (MESUPES), i.e. she moved her arm and hand accurately. She improved 23 points (57/70) on the “Warwick-Edinburgh Mental Well-being Scale” (WEMWBS), i.e. she felt self-reliant.
Before rehabilitation, PET imaging confirmed reduced glucose metabolism in the visual cortex. After rehabilitation, glucose metabolism increased in the occipital, frontal and parietal cortex. Correlating sensory and visual information during rehabilitation possibly provides an alternative route to reactivate preserved visual areas.
Conclusions: This study demonstrates feasibility of cognitive sensorimotor rehabilitation in a patient with cortical blindness, who experienced an impressive clinical visual and motor recovery with marked ADL improvement, more than 2 years after onset.

Title: Sodium channel redistribution in the DBA/2J mouse model of glaucoma

Authors: *M. A. SMITH, G. N. WILSON, C. M. DENGLER-CRISH, J. R. RICHARDSON, S. D. CRISH;
Northeast Ohio Med. Univ., Rootstown, OH

Abstract: Axonopathy is an early pathology common to many chronic neurodegenerations. We have previously reported that semifunctional retinal ganglion cell (RGC) axons persist after anterograde axonal transport deficits in two mouse models of glaucoma, a group of optic neuropathies that make up the leading cause of irreversible blindness worldwide. In other neurodegenerative conditions that exhibit persistent axons, there are multiple alterations in axonal structure and physiology that can be protective or detrimental. The best characterized of these changes is in multiple sclerosis (MS) and its animal models, experimental autoimmune encephalomyelitis (EAE). In these disorders, there is extensive redistribution and differential expression of sodium channels (Nav) are thought to play a major role, both protective and

detrimental, in the course of the disease. Regarding glaucoma, Nav blockade has been reported to be neuroprotective in one model, but little is known about distribution of sodium channels in this disorder. Using tract tracing, immunofluorescence, and capillary-based electrophoresis we examined the nodes of Ranvier in a common mouse model of chronic glaucoma, the DBA/2J mouse. In agreement with previous work (and contrasting with MS/EAE) we did not find overt demyelination; however, RGC axons in pathological animals exhibited substantial expansion of the nodal region. Most intriguingly, as in MA/EAE, we found redistribution of the "mature node" sodium channel Nav1.6 and massive increases in the "premyelination channel" Nav1.2. These changes suggest that these persisting axons are actively undergoing compensatory processes that may lead to impaired neuronal signaling.

Title: Bioenergetic analysis of optic nerve mitochondria in the DBA/2J model of glaucoma

Authors: *L. L. COUGHLIN[1,3], P. T. KANG[2], D. M. INMAN[1];
[1]Dept. of Pharmaceut. Sci., [2]Integrative Med. Sci., Northeast Ohio Med. Univ., Rootstown, OH; [3]Sch. of Biomed. Sci., Kent State Univ., Kent, OH

Abstract: In glaucoma, retinal ganglion cell (RGC) axons that make up the optic nerve degenerate, leading to irreversible blindness. As with other neurodegenerative diseases, alterations in mitochondrial morphology, autophagy/mitophagy, and ATP production have been observed in glaucoma. Specifically, in the DBA/2J (D2) mouse glaucoma model, it has been observed that mitochondria in the optic nerve are both smaller in size and more numerous than in age-matched controls. In addition to the altered appearance of optic nerve mitochondria, optic nerves from aged mice with increased intraocular pressure (IOP) produce less ATP. Despite the changes in mitochondrial morphology and energy levels reported in aged D2 optic nerves, the functional capacity of optic nerve mitochondria has yet to be fully characterized. The purpose of this study is to determine when mitochondrial respiration differences in glaucoma occur, and how they relate to other known events in the development of glaucoma pathology. Visual

acuities, IOP, and anterograde transport were measured in 3, 6, and 10 month D2 and control strain DBA/2-$^{wt\text{-}gpnmb}$ (D2G) mice. To measure mitochondrial respiration, optic nerves were analyzed using a Seahorse XF24 flux analyzer. Optic nerves were freshly dissected, sectioned, and placed in a 24 well islet capture plate. Optic nerve mitochondria were subjected to a stress test that included sequential exposure to oligomycin (10μg/ml), FCCP (4μM), and antimycin-A (1μM); extracellular acidification rate (ECAR) was also measured as a readout for glycolysis. Differences in OCR and ECAR were compared between strains, across age groups, and with regard to anterograde axon transport status; these comparisons were correlated with IOP and visual acuity. This work is designed to give a novel and detailed time course of mitochondrial respiration in glaucomatous optic nerve and confirm the role of mitochondrial failure in early glaucoma development.

Title: Effects of IL-4 on inflammation in the visual projection of DBA/2J glaucomatous mice

Authors: *G. N. WILSON[1,2], M. A. SMITH[2], C. M. DENGLER-CRISH[2], J. R. RICHARDSON[2], S. D. CRISH[2];
[1]Kent State Univ., Akron, OH; [2]Pharmaceut. Sci., NEOMED, Rootstown, OH

Abstract: Glaucoma is a chronic neurodegeneration that is the leading cause of irreversible blindness worldwide. As with other neurodegenerations, neuroinflammation is a major component of the degeneration of retinal ganglion cells that characterize the disease. Indeed, we recently reported that neuroinflammation precedes overt degeneration in the DBA/2J mouse model of glaucoma, suggesting that anti-inflammatory treatment may be a viable target for intervention. Interleukin-4 (IL-4), an anti-inflammatory cytokine, has been shown to alter the microglial phenotype from a pro-inflammatory to anti-inflammatory state. Here, we injected recombinant IL-4 into the vitreal chamber of early glaucomatous (8-10 months old) and late glaucomatous (12-15 month old) DBA/2J mouse eyes. Forty-eight hours after IL-4 or vehicle

(1% BSA) injections, mice were anaesthetized, decapitated, and fresh retina, optic nerve (ON), and superior colliculus (SC) were dissected and immediately frozen on dry ice. Tissue was homogenized in T-Per buffer and cytokine levels were measured using bead-based multiplexing. We assessed levels of pro-inflammatory IL-1β, IL-6, TNF-α, and IL-12, as well as anti-inflammatory IL-10, and IL-4. Mirroring findings in other degenerative models, we found that IL-4 decreased pro-inflammatory cytokines within the treated projection (retina, optic nerve, and superior colliculus) when compared to vehicle injected projections. Anti-inflammatory IL-10 was significantly increased in treated projections. At older ages effects of IL-4 injection were not as prominent, suggesting that microglial phenotype may be less easily altered in aged animals or more effective in the earlier stages of degeneration. These findings suggest that exogenous application of IL-4 may be a viable mechanism to reduce inflammation and, potentially, neurodegeneration in glaucoma models.

Title: Cortical plasticity in retinitis pigmentosa

Authors: *L. BARONCELLI, T. BEGENISIC, M. CENNI, A. SALE, L. GALLI;
Neurosci. Institute, CNR, Pisa, Italy

Abstract: Retinitis Pigmentosa (RP) is a family of inherited disorders caused by the progressive loss of retinal photoreceptors. There is no cure for RP, but research aimed at preventing further photoreceptor loss, or substituting new light-responsive elements of biological or artificial nature, is generating hope for these patients. These strategies require that the visual system downstream of the photoreceptors is capable of elaborating visual signals. Anatomical and functional studies have shown that retinal and thalamic structure are well preserved with RP, but the effect of photoreceptor degeneration on the visual cortex is still unknown. Here, we studied how visual cortical processing changed during the course of progression of RP, and whether the visual cortex retained the capability of plastic remodelling. We performed in vitro electrophysiological recordings of field excitatory post-synaptic potentials in V1. Basic synaptic

transmission, as assessed by response vs stimulus amplitude, showed a significant shallower response in RP mice. Biochemical analysis suggests that this synaptic deficit could be related to the alteration of absolute levels of inhibition and excitation in the visual cortex, with an overexpression of inhibitory markers. These results suggest that cortical changes occur in the visual cortex that might further compromise vision by downregulating or suppressing visual processing, as the retinal input progressively deteriorates. This work is supported by Fondazione Roma.

Title: Differential changes in distribution of nitric oxide synthase at the central auditory relays after chronic injections of salicylate in rats

Authors: *T.-W. CHIU[1,2], C.-R. SOO[2], S.-T. HSU[1];
[1]Dept of Biol. Sci. and Technology, NCTU, Hsinchu, Taiwan; [2]Inst. of Mol. Med. and Bioengineering, Natl. Chiao Tung Univ., Hsinchu, Taiwan

Abstract: Tinnitus is a phantom perception of sounds in the absence of external acoustic stimuli. The effective cure remains unavailable since it underlying neural mechanisms remains unclear. Previous studies demonstrated the elevations in spontaneous and sound evoked neural activities at the central auditory relays in salicylate induced tinnitus animals. The increased activities was related to the excitation-inhibition imbalances but the causal link between the tinnitus generation and excitation-inhibition imbalances still unavailable. Nitric oxide (NO), a gas neurotransmitter, might be the key in the molecular signaling in the SS-tinnitus model since (i) the NO is function as a retrograde neurotransmitter to backward modulate the release of inhibitory neurotransmitter in long term potentiation; (ii) the neuronal form of nitric oxide synthase (nNOS) was widely expressed in the central auditory relays, and (ii) the number of NOS positive cells increased at the ventral cochlear nucleus of rats at after the acute salicylate treatment. However, it remains

unclear if the expression profile also changed in other central auditory relays (e.g., the auditory cortex) in chronic salicylate treated animals. Therefore, the aim of this study is to determine the expression and distribution profiles of NOS positive cells in chronic salicylate induced tinnitus rats.
Animals were randomly classified into control and experimental groups. The experimental rats were administrated with sodium salicylate injection (250mg/kg, i.p.) for five consecutive day. The controls were injected with same volume of phosphate buffer saline. On day 6, both control and experimental animals were placed inside a sound room for 8 h before sacrifice. Immunohistochemistry showed a significant increase in the number of nNOS positive cells at the ventral cochlear nucleus (VCN), auditory cortex (AC) and amygdala in salicylate treated rats. No apparent differences in nNOS positive neurons at the dorsal cochlear nucleus. Our results provide evidence to show changes of NOS positive cells at the amygdala and AC also have implications in the salicylate-induced tinnitus generation.

Title: Topographical functional connectivity patterns exist in the congenitally, prelingually deaf

Authors: *E. STRIEM-AMIT[1], J. ALMEIDA[3], M. BELLEDONNE[2], Q. CHEN[4], Y. FANG[5], Z. HAN[5], A. CARAMAZZA[2,6], Y. BI[5];

Abstract: Congenital deafness causes large changes in the auditory cortex structure and function, such that without early childhood cochlear-implant, profoundly deaf children do not develop intact, high-level, auditory functions. But how is auditory cortex organization affected by congenital, prelingual, and long standing deafness? Does the large-scale topographical organization of the auditory cortex develop in people deaf from birth? And is it retained despite cross-modal plasticity? We identified, using fMRI, topographic tonotopy-based functional connectivity (FC) structure in humans in the core auditory cortex, its extending tonotopic gradients in the belt and even beyond that. These regions show similar FC structure in the congenitally deaf throughout the auditory cortex, including in the language areas. The topographic FC pattern can be identified reliably in the vast majority of the deaf, at the single subject level, despite the absence of hearing-aid use and poor oral language skills. These findings suggest that large-scale tonotopic-based FC does not require sensory experience to develop, and is retained despite life-long auditory deprivation and cross-modal plasticity. Furthermore, as the topographic FC is retained to varying degrees among the deaf subjects, it may serve to predict the potential for auditory rehabilitation using cochlear implants in individual subjects.

Title: Disrupted auditory nerve activity limits peripheral but not central temporal acuity

Authors: *C. Q. PHAM[1,2], F.-G. ZENG[1,2,3,4,5];
[1]Anat. & Neurobio., [2]Ctr. for Hearing Res., [3]Otolaryngology-Head and Neck Surgery, [4]Biomed. Engin., [5]Cognitive Sci., Univ. of California Irvine, Irvine, CA

Abstract: Introduction. Auditory neuropathy refers to hearing pathologies affecting neural synchrony in the auditory nerve but sparing amplification in the inner ear. Patients with auditory neuropathy lack speech understanding despite having audibility. Neural discharges synchronized to frequencies up to several thousand Hz preserve the relative timing of action potentials propagated through several synaptic stages which encode auditory features for speech recognition. Auditory neuropathy subjects poorly recognize speech due to impaired temporal processing. The present study probed gap duration between 2 identical frequencies stimulating peripheral, overlapping nerve fibers and the same perceptual channel (within-channel; WC) or different frequencies stimulating non-overlapping nerve fibers and different perceptual channels (between-channel; BC). We intend to determine the contribution of neural synchrony to peripheral and central temporal acuity.
Methods. Three subjects pre-diagnosed with auditory neuropathy and 1 with an acoustic neuroma participated in the experiments. The subjects with auditory neuropathy had normal inner ear amplification (present cochlear nerve and outer hair cell responses) but absent/ abnormal auditory brainstem responses. The auditory neuropathy group had elevated audibility of octave frequencies 0.125 to 12 kHz, especially low frequency hearing loss as acoustic neuroma. Six subjects with audibility ≤20 decibels Hearing Level served as healthy, age- and gender-matched controls. A 3-interval forced choice, adaptive procedure measured subjects' just-noticeable-differences in gap (gap threshold) between two identical tone bursts (0.5:0.5; 2:2; 4:4 kHz; WC) and two different tone bursts (4:2 kHz; BC).
Results. Auditory neuropathy produce significantly impaired WC gap thresholds approximately an order of magnitude longer than the normal control. WC gap thresholds increased with increasing frequency and correlated significantly with the degree of hearing loss. Auditory neuropathy, however, produce normal BC gap thresholds.
Discussion. The present results suggest neural desynchrony due to auditory neuropathy decreases WC temporal acuity but produce no effect on BC temporal acuity. Peripheral machinery seems to limit WC processing on the order of several ms whereas central computations limit BC processing on the order of hundreds of ms. Auditory neuropathy appears to affect peripheral mechanisms producing a temporal delay of tens of ms, but central mechanisms remain unaffected. Differences in WC and BC gap detection can differentiate peripherally- vs. centrally-based temporal processing disorders.

Title: A simple method to detect noise-induced “hidden” hearing loss

Authors: *H.-B. ZHAO, L. MEI, Y. ZHU;
Dept of Otolaryngology, Univ. Kentucky Med. Sch., Lexington, KY

Abstract: Noise-induced hearing loss is a major form of hearing disorders. Long-term, intensive noise can produce permanent hearing loss causing permanent hearing-threshold shift (PTS), whereas short-term noise-exposure can lead to temporal hearing loss, i.e., temporal threshold shift (TTS). Such TTS is recoverable and has long-term been considered to be a safe procedure, since the regular audiogram examinations show normal after stop of noise exposure, even some patients may have complaints on difficulty in speech sensing in noisy environments. Recently, it has been found that even suffering from short-term noise exposure and there is no apparent hair cell loss, exposed animals could still have irreversible neural degeneration, in particular, losing of lower spontaneous rate (LSR) auditory nerves and their synapses with inner hair cells. This can eventually lead to difficulty hearing speech in noisy environments. Such ‘hidden’ hearing loss is not readily detectable by currently standard clinical auditory tests. In this study, we have developed a new, clinical-practicable method to detect such noise-induced “hidden” hearing loss. Auditory nerves can be divided into three groups based on spontaneous rate. Middle and higher spontaneous rate (M/HSR) fibers have low-threshold and their discharges are quickly saturated as sound intensity increases, whereas LSR fibers have high-threshold and their discharge rates can still increase at high intensity levels. In the study, we have used middle levels of white noise to saturate M/HSR fiber discharge and use another stimulus to examine the LSR fiber function. Auditory brainstem response (ABR) was recorded under both quiet and noisy environments. We found that ABR thresholds of noise-exposure group were significantly increased than that of normal control group without noise-exposure under noisy environment. However, distortion product acoustic emission (DPOAE), which mainly reflects outer hair cell function and active cochlear mechanics, in the noise-exposure group had no significant changes in comparison with that in the control group. These data suggest that our newly-developed method can detect the deficit of LSR fiber function and provide a practicable testing method in the clinic to detect noise-induced “hidden” hearing loss.

Title: Pharmacological activation of sphingosine 1-phosphate receptor 2 protects neural-derived cells from cisplatin toxicity by attenuating generation of reactive oxygen species

Authors: *D. R. HERR[1,2], M. J. Y. REOLO[1], Y. X. PEH[1], W. WANG[1];

Abstract: Ototoxic drugs, such as platinum-based chemotherapeutics, often lead to permanent hearing loss through apoptosis of neuroepithelial hair cells and afferent neurons of the cochlea. There is no approved therapy for preventing or reversing this process, but our data suggest that a G protein-coupled receptor, sphingosine 1-phosphate receptor 2 ($S1P_2$), may represent an effective drug target. We show that $S1P_2$ knockout mice uniformly display progressive degeneration of the cochlea which results in profound deafness by 4 weeks of age. This degeneration is preceded by accumulation of reactive oxygen species (ROS) and can be attenuated by administration of the antioxidant N-acetylcysteine. Since loss of $S1P_2$ leads to cochlear degeneration, we sought to determine whether activation of $S1P_2$ can protect against ototoxicity. We validated a chemical probe, CYM-5478, as an $S1P_2$-selective agonist and used it in a number of in vitro cell-based assays to evaluate cell viability, induction of apoptosis, and accumulation of ROS following activation of $S1P_2$ in the presence of cisplatin. We show that activation of $S1P_2$ increases cell viability and reduces cisplatin-mediated cell death in neural-derived cell lines by reducing ROS, but does not protect non-neural tumor-derived cell lines. Cumulatively, these results suggest that $S1P_2$ may serve as a therapeutic target for attenuating cisplatin-mediated ototoxicity without affecting the therapeutic efficacy of platinum-based chemotherapy.

Abstract: The glutathione transferase (GST) detoxification system converts an exogenous/endogenous toxic compound into a less toxic form by conjugating the toxic compound to reduced glutathione by a variety of GST enzymes. Studies using C.elegans, D.melanogaster, and dwarf mice suggest that enhanced GST detoxification is associated with exceptional longevity or protection against aging. In humans, epidemiological studies have detected polymorphisms of several GST enzymes in individuals with noise-induced hearing loss, age-related hearing loss, or cisplatin-induced hearing loss, suggesting that GST detoxification has a key role in maintaining auditory function. The goal of this project is to investigate whether GSTA4 (glutathione transferase α4) plays an essential role in maintaining cochlear and auditory function during aging and/or in eliminating ototoxic compounds. To investigate whether deficiency of GSTA genes promotes oxidative stress-induced cell death, we conducted in vitro oxidative stress tests using hydrogen peroxide in *Gsta1*-, *Gsta3*-, or *Gsta4*-knockdown mouse inner ear cell lines (HEI-OC1, House Ear Institute-Organ of Corti 1). We found that downregulation of *Gsta1*, *Gsta3*, or *Gsta4* isoform increased susceptibility to oxidative stress-induced cell death. We also found that treatment with cisplatin, a well-known cancer drug that causes cochlear damage and hearing loss, significantly increased mRNA levels of *Gsta1*, *Gsta2*, *Gsta3*, and *Gsta4* isoforms in cochlear organotypic cultures from 3-days-old C57BL/6 mice, suggesting that *Gsta* family enzymes play a role in detoxifying hydrogen peroxide (reactive oxygen species) or cisplatin (ototoxic drug) in mouse cochlear cells. These results suggest that GSTAs play a critical role in removing hydrogen peroxide or cisplatin in mouse inner ear cell lines. Currently, we are investigating the effects of *Gsta4* deficiency on cochlear and auditory function during aging or under cisplatin treatment using *Gsta4* knockout mice in the CBA/CaJ background.

Title: Auditory functional deficits < structures changes following blast shockwave exposure > mice

Authors: *Y. WANG[1], Y. WEI[1], S. VAN ALBERT[1], A. NORTHROP[2], R. URISTE[1], P. ARUN[1], D. WILDER[1], S. VENKATASIVASAISUJITH[1], I. GIST[1], S. MCLNTURFF[2], W. CHANG[2], T. FITZGERALD[2], M. KELLEY[2], J. LONG[1];
[1]Walter Reed Army Inst. of Res., Silver Spring, MD; [2]NIDCD/NIH, Bethesda, MD

Abstract: A high fidelity animal model is critical to define the mechanism(s) of blast-induced auditory injury and to develop therapeutic strategies. The Advanced Blast Simulator (ABS) incorporates design features which allow higher fidelity replication of the key features of blast wave flow conditions, including the negative phase and secondary shock. Using this device, the present research is aimed at producing a comprehensive characterization of auditory functional deficits and associated pathological changes in the central and peripheral auditory signal processing regions disrupted by exposure to blast shockwaves. isofluorane anesthetized CBA mice (male, 23 - 28 g) were exposed to blast overpressure (peak static pressure of 19 psi and 4 msec positive phase duration) generated by the ABS which consists of a 0.5 ft long compression chamber that is separated from a 21 ft long transition/expansion test section by rupturable Valmex membranes. A time-course of blast effects on auditory function was assessed by analyzing auditory brainstem response (ABR) and distortion product otoacoustic emission (DPOAE) under anesthesia. Data revealed that blast exposure caused significant elevations of ABR threshold, increased ABR wave latency, and reductions in ABR wave amplitude immediately following the blast shockwave insult. These changes were observed over the entire acoustic frequency spectrum and persisted over 14 days. DPOAE signals were undetectable immediately after blast exposure and their disappearance persisted over 14 days, suggesting significant damage to the inner ear. Immunostaining of Myo7a and Phalloidin in wholemount cochlea revealed appreciable damage to outer hair cells, inner hair cells, as well as to other structures in the inner ear. Silver staining of brain sections showed significant axonal degeneration in auditory and vestibular signal processing regions in brainstem and cerebellum. The results indicate that both peripheral and central auditory signal processing regions are vulnerable to blast overpressure exposure in the ABS. This mouse model of blast-induced auditory injury should provide a useful experimental tool for studying the mechanisms

underlying hearing impairment after blast exposure and for evaluating potential strategies for prevention and cure.

Title: Critical dynamics during processing of somatosensory input are maintained by interneuronal activity

Authors: *S. SESHADRI, D. PLENZ;
NIMH, Bethesda, MD

Abstract: Ongoing neuronal activity in cortex, whether recorded *in vitro* in acute slices and slice cultures or *in vivo* in rodents, non-human primates and humans, has been shown to organize as neuronal avalanches. Avalanche sizes, durations, waveforms and their temporal occurrences are governed by power laws, supporting the view that ongoing cortical dynamics is poised at criticality. Theory and experiments have shown that numerous aspects of information processing are optimized at or near criticality. However, it is currently not clear whether avalanche dynamics is maintained upon the transition from ongoing to sensory evoked cortical activity. Recent experimental work suggests a fast recovery towards avalanche dynamics after sensory stimulation, such as flash stimuli in visual cortex of the turtle (Shew et. al., 2015) or sensory processing in humans (Arviv et. al., 2015). While these studies suggest a transient deviation from avalanches during evoked activity, they lack cellular resolution to monitor the precise network changes during these transitions. We recently demonstrated (Bellay et. al., 2015) that spontaneous spiking activity in local groups of pyramidal neurons organizes at criticality *in vivo* in the awake resting state using genetically encoded calcium indicators (GECIs). Here, we combine this cellular approach with interneuron specific optogenetic modulation to examine avalanche dynamics during resting and sensory evoked activity.
We performed *in vivo* 2-photon imaging of layer 2/3 pyramidal neurons in primary

somatosensory cortex, through chronic cranial windows in awake, head-fixed Thy1-GCaMP6s transgenic mice positioned on a running wheel. For optogenetic modulation of interneurons, we crossed Thy1-GCaMP6s with PV-Cre or SOM-Cre mice respectively, and injected AAVs to obtain Cre-dependent expression of excitatory (C1V1) or inhibitory (NpHR3.0) opsins. Our preliminary results show that spiking activity increases with self-initiated locomotion. Yet, power laws in avalanche size distributions are maintained at rest as well as during locomotion. Power law slopes were shallower during periods of running, as predicted by the observed increase in spiking activity. The role of critical dynamics during sensory processing has been an outstanding question in the field of population coding. Our results address this question experimentally and elucidate the role of interneurons in maintaining critical dynamics.

Title: Membrane potential correlates of increased SNR and asynchronous cortical activity following activation of the nucleus basalis

Authors: *I. MEIR, Y. KATZ, I. LAMPL;
Neurobio., Weizmann Inst. of Sci., Rehovot, Israel

Abstract: The basal forebrain (BF) plays a major role in arousal, attention, learning and plasticity. BF neurons, mainly from the nucleus basalis (NB), send cholinergic, GABAergic and glutamatergic projections to the cortex. NB activation shifts cortical dynamics from synchronized to asynchronized mode and exerts profound effects on neuronal activity. In sensory cortices, NB activation improves the signal to noise ratio (SNR) of sensory responses. The underlying mechanisms, especially at the subthreshold level, remain unclear. We studied the effects of NB electrical stimulation on ongoing and sensory evoked activities of cortical cells in the mouse barrel cortex of lightly anesthetized mice, using LFP, extracellular and intracellular recordings. In agreement with previous studies, NB stimulation reduced low frequency

components in the cortical local field potential (LFP). In extracellular recordings, a prominent increased SNR to whisker stimulation was observed, accompanied by an increased latency of sensory response. The increased SNR was mainly due to reduced background firing, while the response magnitude remained unchanged. We used whole cell patch recordings to reveal the underlying effects of NB stimulation and found that it eliminates the large spontaneous synaptic fluctuations and hyperpolarizes the resting membrane potential. However, NB stimulation had negligible effect on the magnitude of the sensory evoked synaptic response and on its trial to trial variability. Simultaneous Vm-LFP recordings indicate that NB stimulation reduced the cross-correlation between these signals during ongoing activity and lowered the trial to trial correlation of sensory response. Taken together, we suggest that activation of the NB induces a significant hyperpolarization of cortical cells which in turn reduces the amount of spontaneous activity. This filtering effect can account for the increased sensory evoked response SNR and the longer latency, and explains the reduced correlation between cells. The combined effects of filtering and decorrelation, can promote sensory processing and are in line with the effects of attention.

Title: Slow asynchronous synaptic noise broadens the dynamic range of spiny stellate neurons in layer 4 of the mouse barrel cortex

Authors: O. REVAH[1], A. BINSHTOK[2,3], F. WOLF[4,5], A. NEEF[4,5], *M. J. GUTNICK[1]; [1]Koret Sch. of Vet Med, Hebrew Univ. Jerusalem, Rehovot, Israel; [2]The Hebrew Univ. Med. Sch., Jerusalem, Israel; [3]The Edmond and Lily Safra Ctr. for Brain Sci., Jerusalem, Israel; [4]MPI For Dynamics and Self-Organisation, Goettingen, Germany; [5]Bernstein Ctr. for Comput Neurosci, Goettingen, Germany

Abstract: Spiny stellate (SpSt) neurons, which are the prevalent excitatory cells in layer 4 of the rodent somatosensory cortex, are organized in ”barrels”. Each receives nearly all its excitatory

input from the thalamus and from other SpSt neurons in the same barrel. Because it is a primary thalamo-cortical target, the layer 4 circuit comprises a key gateway into the cortical circuit. It is therefore imperative that the layer 4 circuit responds rapidly to input. However, SpSt cells are very small, and there are strong theoretical reasons to suspect that their compact morphology could impair their capacity to encode high input frequencies and thus hamper the temporal fidelity of cortical processing. Here, we used whole-cell patch clamp to measure the temporal properties of asynchronous noise in SpSt cells as compared with the much larger layer 5 pyramidal (Pyr) cells, and characterize the capabilities of both cell types to encode high frequencies in a synaptically active-like environment. We find that individual SpSt cells indeed have a much narrower dynamic range than Pyr cells when probed with fluctuating inputs with identical correlation time. However, we show that the synaptic dynamics in SpSt cells, as evidenced by the correlation time of asynchronous noise, is much slower than that of Pyr neurons, and that slower correlation time is associated with significant broadening of the dynamic range of SpSt cells. We further show that this improvement in encoding bandwidth of sensory input depends on activation of potassium conductance, as it disappears when potassium channels are pharmacologically blocked.

Title: Cholinergic control of cortical circuit dynamics

Authors: *R. DASGUPTA, F. M. SEIBT, M. BEIERLEIN;
Neurobio. and Anatomy, McGovern Med. School, Houston, Univ. of Texas Hlth. Sci. Ctr. At Houst, Houston, TX

Abstract: Cholinergic neurons of the basal forebrain form extensive projections to neocortex and are critically involved in mediating numerous cognitive processes, including sensory processing, reward timing and fear learning. To understand how acetylcholine (ACh) shapes

cortical computations, it is critical to gain a better understanding of the underlying cellular and circuit mechanisms. While previous work has shown that cholinergic agonists can act on both nicotinic and muscarinic receptors expressed by distinct neurons and synapses throughout neocortex, how synaptically released ACh influences cellular targets and ultimately controls cortical circuit dynamics remains poorly understood. We addressed this question using a combination of *in vitro* electrophysiology and optogenetics in somatosensory (barrel) cortex of transgenic ChAT-ChR2-EYFP mice. We found that the activation of cholinergic afferents led to a strong reduction of evoked cortical activity, with nicotinic receptors (nAChRs) mediating fast and transient suppression, and muscarinic receptors (mAChRs) mediating delayed and sustained suppression. To investigate the underlying cellular mechanisms for ACh-mediated control of cortical activity, we characterized cholinergic synaptic inputs onto specific cell types in distinct layers. Postsynaptic cholinergic responses were prominent in layer 4 and were primarily mediated by mAChRs, with excitatory neurons showing long-lasting IPSCs and regular-spiking interneurons displaying EPSCs. In agreement, cholinergic suppression of cortical activity in the isolated layers 4-6 was entirely dependent on mAChR activation. In contrast, cholinergic responses in supragranular layers were predominantly mediated by nAChRs expressed by GABAergic interneurons. Taken together, our results show that cholinergic control of cortical network dynamics occurs over different time scales and is mediated by nAChR and mAChR-dependent mechanisms expressed in distinct cortical layers.

Title: Complementary connectivity defines two distinct networks of cortical somatostatin-expressing interneurons

Authors: *A. S. NAKA, B. SHABABO, B. SNYDER, H. ADESNIK;
UC Berkeley, Berkeley, CA

Abstract: Cortical computation depends critically on a diverse array of GABAergic interneurons. Parsing this diversity is essential for understanding cortical operation, since evidence indicates that the various types of interneurons are specialized for distinct functions. One such specialization is target selection; for example, many somatostatin (SOM) expressing interneurons target the distal apical dendrites of pyramidal cells in layer 1 where they can powerfully influence neuronal computation through dendritic inhibition. Gain and loss of function studies using optogenetic manipulations in SOM-cre transgenic lines have pointed to possible functional roles for SOM-mediated inhibition, but have often necessarily treated SOM cells as a homogenous group. However, SOM cells are heterogeneous with respect to their morphology, intrinsic properties, and connectivity. Using paired whole cell recording, two photon imaging, and optogenetic circuit mapping, we provide evidence that SOM cells can be subdivided functionally into at least two distinct networks, which are spatially intermingled, but have complementary and non-overlapping patterns of laminar connectivity. These networks are likely to have divergent influences on cortical computation.

Title: Diversity and connectivity of somatostatin interneurons in layer V of the mouse barrel cortex

Authors: *M. J. NIGRO, Y. HASHIKAWA, R. TREMBLAY, B. RUDY;
Dept. of Physiol., New York Univ., New York, NY

Abstract: Inhibitory interneurons represent about 10-15% of the neuronal population in the somatosensory cortex, and their activity powerfully shapes sensory information processing in the cortex. Despite being a relatively small neuronal population, GABAergic interneurons are very diverse, and three main classes have being defined according to developmental, molecular, morphological, electrophysiological, and synaptic features. Among these classes the

somatosatin-expressing GABAergic interneurons are specialized in dendritic inhibition. Somatostatin-expressing interneurons represent about 30% of the GABAergic population in the somatosensory cortex, and are localized mainly in infragranular layers. We performed whole-cell patch clamp experiments from slices of transgenic mice expressing td-Tomato in somatostatin-expressing interneurons to study the diversity and connectivity of these cells. Our morphological and electrophysiological analysis shows three main types of somatostatin interneurons: type I Martinotti cells have an ascending axon travelling across the cortical layers and branching upon arrival to layer I; type II Martinotti cells have an ascending axon that starts branching at the border between layer IV and II/III; non-Martinotti cells have an ascending axon that specifically targets layer IV. Type I Martinotti represent about 10% of the recorded interneurons and show high input resistance and rebound bursting. Type II Martinotti neurons are about 40% of the recorded interneurons and show an adapting firing pattern. Non-Martinotti cells are about 40% of the recorded population and show a quasi fast-spiking firing pattern. Using dual and triple recordings in brain slices we show that these morphological diversity correlates with specific connectivity patterns.

Title: Remodeling of dendritic inhibition during active wakefulness

Authors: ***W. MUNOZ**[1], R. TREMBLAY[1], D. LEVENSTEIN[2], B. RUDY[1];
[1]NYU Neurosci. Inst., New York, NY; [2]NYU Ctr. for Neural Sci., New York, NY

Abstract: How the brain processes information is contextually adjusted in order to optimize perception and behavioral performance. In neocortex, this is achieved by dynamically restructuring circuits. Recent experiments examining a variety of behavioral contingencies led to the discovery of a canonical disinhibitory circuit in which dendritic-targeting somatostatin-expressing (Sst) interneurons (INs) are suppressed during active wakefulness by the activation of VIP-expressing (Vip) INs. These observations have given rise to the notion that during active

states, the dendrites of pyramidal neurons are globally disinhibited, enhancing input responsiveness and serving important computational functions such as gating and gain modulation. Here, we challenge this concept by showing that during active whisking behavior, Sst IN-mediated dendritic inhibition is not globally suppressed throughout the cortical column, but rather remodeled. By examining the *in vivo* activity of Sst INs across the entirety of cortical columns in head-fixed mice, we discovered that while supragranular layer Sst INs are silenced, the majority but not all of granular and infragranular Sst INs are activated during whisking behavior depending on their subtype identity. These Sst IN subtypes with distinct axonal innervation domains and laminar distribution possess context-specific ability to differentially affect signaling in pyramidal neuron dendrites. Moreover, specific SST INs selectively receive Vip IN inhibitory inputs and cholinergic modulatory drive, which allow for their differential recruitment. Our study provides a novel framework for understanding the spatiotemporal control of neuronal excitability carried out by SST IN-mediated dendritic inhibition, emphasizing its potential interplay with the layer-specific organization of excitatory input lines and signaling zones in dendritic compartments of pyramidal cells in the mammalian neocortex.

Title: Dendritic dynamics in sensory perception

Authors: ***N. TAKAHASHI**, M. LARKUM;
Humboldt-Universität zu Berlin, Berlin, Germany

Abstract: Perception is a process that requires the matching of an internal representation of previous experience with real-world sensory data, for which the cellular mechanisms are poorly understood. There is abundant evidence that feedback information to primary sensory regions is integral to the perceptual process. Recent data suggest that feedback information activates dendritic processes in pyramidal neurons that are linked to cognitive function. Here, we show that calcium activity in the apical dendrites of a subset of layer 5 (L5) pyramidal neurons in

primary sensory cortex correlates with the threshold for perception of whisker stimulation in rodents. Another population of apical dendrites of L5 neurons is negatively correlated. The same positive and negative correlations are found for bursts of somatic spikes in L5 neurons that preceded the behavioral actions of the animals. Using pharmacological and optogenetic approaches, we show that the dendritic activity is causally linked to the animal's behavior, demonstrating that the perceptual process depends critically on activation of the apical dendrites of L5 pyramidal neurons in primary sensory cortex.

Title: *In vivo* monosynaptic excitatory transmission during active cortical states.

Authors: ***J. KREMKOW**[1,2,3], J.-S. JOUHANNEAU[2,1], A. L. DORRN[2,1], J. F. A. POULET[2,1]; [1]Cluster of Excellence NeuroCure, Neurosci. Res. Ctr., Charité-Universitätsmedizin Berlin, Berlin, Germany; [2]Dept. of Neurosci., Max-Delbrück Ctr. for Mol. Med. (MDC), Berlin, Germany; [3]Inst. for Theoretical Biol., Humboldt-Universität zu Berlin, Berlin, Germany

Abstract: In vivo, cortical neurons fire action potentials and perform synaptic transmission during network activity. While glutamatergic synaptic transmission has been studied in great detail in quiescent cortical slices, very little is known in active networks in vivo. Modeling and experimental studies have predicted that active cortical states can modulate subthreshold

computations underlying action potential generation to different extents. Some studies suggest that active states will cause a reduction in the amplitude of a unitary excitatory postsynaptic potential, whereas others suggest there will be no change. To understand how cortical neurons integrate synaptic input, it is therefore critical to investigate the properties of monosynaptic transmission in vivo, during active cortical states. We performed dual, triple and quadruple, two-photon targeted whole-cell patch-clamp recordings from monosynaptically connected somatosensory cortex layer 2/3 pyramidal neurons in anaesthetized mice. Under urethane anesthesia neurons oscillate between hyperpolarized Downstates with little network activity, and synaptically active, depolarized Upstates. We triggered single action potentials with brief current injection and identified a sparsely connected, structured network of small amplitude, reliable synaptic connections in the Downstate (Jouhanneau et al, 2015). We next compared the amplitude of connections between Up and Down states. Across the population, there was no overall change in amplitude, however, the ratio of Up to Down state unitary excitatory postsynaptic potential amplitude varied between individual connections. We provide a new approach to measure the impact of network activity on synaptic transmission and the processing of spontaneous and sensory input by connected, neighboring neurons in vivo.

Title: A quantitative morphological analysis of supragranular neurons of the barrel cortex and their connections

Authors: F. PALAGUACHI[1], M. C. ANAYA[2], C. TSE[3], S. SOSNOWIK[1], J. BRUMBERG[1], *A. TSIMOUNIS[2];

Abstract: A 'bottom-up' approach to resolving neuronal circuits involves deciphering their fundamental building blocks, the individual neurons. While specific morphologies have been correlated with specific circuit functions the number of functional classes of neurons remains unknown. For example, there are pyramidal neurons in the supragranular layers of the mouse barrel cortex that originate connections to the opposite hemisphere (callosal cells), the primary motor cortex (M1) and the secondary somatosensory cortex (S2), but what remains unanswered is whether these cells have similar or different intrinsic properties. We have been taking a morphological approach to understanding neuronal circuits in the primary somatosensory cortex, more specifically those associated with supragranular neurons in the barrel field (S1BF) of the mouse. After defining groups of neurons that are distinguished from one another based on morphological characteristics, our aim is to determine if specific morphological groups are associated with particular cortical connections. Individual neurons in brain sections from CD-1 mice are labeled using Diolistics and reconstructed from confocal images. Morphological measurements are analyzed using principal component analysis followed by cluster analysis, revealing distinct groups of neurons. Cortical connections are revealed by in vivo injections of fluorescent beads in synaptic target areas of S1BF. We show the distribution of neurons projecting to three different synaptic targets of S1BF (contralateral S1, ipsilateral M1 and ipsilateral S2) within the overall morphological classification dendrogram. These experiments show the correlation between anatomical classes of neurons and specific roles within the cortical circuit.

Title: Tactile noise improves somatosensory response in the injured rat brain

Authors: L. M. ANGUIANO-PACHECO[1], J. M. DUENAS-JIMENEZ[2], N. HUIDOBRO[4], P. LINARES[4], S. H. DUENAS-JIMENEZ[1], E. MANJARREZ[4], *B. Autónoma de Puebla, Puebla, Mexico

Abstract: Previously we demonstrated that tamoxifen can restore the electrocorticographic activity in the somatosensory cortex of the injured rat. These findings suggest that tamoxifen can preserve or restore the injured neural circuits (Franco y cols. 2013). The purpose of the present study was to evaluate, in injured tamoxifen treated rats, whether an optimal level of tactile noise can increase the barrel cortex Evoked Field Potentials (EFP´s). We obtained EFP´s from the barrel cortex of 15 rats which were divided in three groups: 5 injured rats treated with tamoxifen, 5 injured rats without treatment and 5 intact rats. The injury was performed in the barrel cortex using a thin needle with the support of a stereotaxic frame. The EFP´s where elicited 30 days after the lesion by protracting the whiskers using a mechanical transductor (Chubbuck). Simultaneously we delivered three levels of mechanical noise applied in the whiskers by means of the Chubbuck. MATLAB software was used to evaluate EFP´s amplitudes. For all subjects, we found that the quantitative analyses of the amplitudes exhibited an inverted U-like form as a function of the applied noise, being the intermediate level of noise which produces the higher EFP´s amplitude. However, in tamoxifen treated rats, we observed that the EFP´s exhibited higher amplitudes compare with the not-treated group. In order to evaluated the amplitudes between the Zero Noise (ZN), Optimal Noise (ON) and High Noise (HN) we applied the one way ANOVA test and to compare the amplitudes between the three conditions. After comparing between the noises conditions, we applied the one way ANOVA test to compare differences of the EFP´s amplitude in ON condition between the experimental groups (treated untreated and intact rats). A Bonferroni post hoc was applied for multiple comparisons. The results showed significant statistical differences between ZN and ON ($p<0.05$), also between ON and HN ($p<0.5$), but not between ZN and HN. This was observed in the three groups (treated, untreated and intact rats). When comparing the EFP´s amplitudes of the ON conditions between the experimental groups, we observed a significant statistical difference between the treated rats compared with the not treated ($p<0.05$); in contrast not significant differences were observed between the intact and the treated rats. These results suggest that tamoxifen can restore the functionality of the barrel cortex. Also, stochastic resonance phenomena improves the EFP´s response to almost normal values, which lead us to speculate that an optima level of noise applied in the injured brain can be a part of an integral treatment for traumatic brain injury.

Abstract: In spite of substantial efforts, the relevance and computational contribution of neuronal circuits in early sensory cortex of mammalian brains remains elusive. Even for the first stage of cortical processing, the transformation of sensory inputs arriving from the thalamus in layer 4 of sensory cortex is not understood. Hypotheses range from a simple amplification of the thalamic signals to a translation into a proprietory cortical signal code. Here we set out to test these hypotheses by combining in-vivo 2-photon calcium imaging of large populations of excitatory neurons in a “barrel” of a cortical column in mouse primary somatosensory cortex with connectomic analysis of the very same tissue volume. Using a simple correlation method, we detected at least 3 unique neuronal response classes in response to a realistic object-impact stimulus. We then exposed the same barrel to large-volume 3D EM using SBEM and reconstruct the underlying circuitry to ask what fraction of the functional responses can be explained by intracortical circuits - and thus decide whether the observed responses are purely an amplification of thalamic inputs or result from local intracortical computations.

Title: Connectomics of three-layered reptilian and mammalian cortices

Authors: P. BASTIANS[1,2], M. HELMSTAEDTER[2], G. LAURENT[2];
[1]MPI of Neurobio., Martinsried, Germany; [2]MPI for Brain Res., Frankfurt am Main, Germany

Abstract: Next to mammals, reptiles are the only other animal class possessing a cerebral cortex. Reptilian cortex is three-layered, similar to mammalian piriform cortex and hippocampus. While the overall cytoarchitectonic differences between three-layered cortex and mammalian 6-layered "iso"cortex are obvious, the organization of these cortices at the microcircuit scale is not known. Here, we set out to study the local innervation principles of three-layered cortices in turtle and mouse. We acquired local 3D EM datasets using SBEM and are currently analyzing the connectomic fingerprints of these cortices. First results indicate fundamentally different innervation principles especially with respect to inhibitory connections in the 3-layered reptilian dorsal cortex when compared to 6-layered mouse primary somatosensory cortex.

Title: Automated detection of glia cells for the analysis of connectome-specific neuron-glia interactions in cerebral cortex

Authors: *A. MOTTA, M. HELMSTAEDTER;
Connectomics, Max Planck Inst. For Brain Res., Frankfurt, Germany

Abstract: While the exact proportion remains debated, it is known that the mammalian cerebral cortex contains a substantial number of glial cells, possibly exceeding the number of neurons in some species. Glial cells have long been hypothesized to be involved in memory formation and it is speculated that they provide a correlate of local learning signals. Both hypotheses require specific interactions between glial cells and neurons that are related to the neuronal connectome rather than only to the tissue geometry. To test whether such specificity occurs in local circuits of mouse cerebral cortex, we developed a supervised machine learning classifier based on image and shape features for automatically detecting and reconstructing glial processes at high precision. We are currently analyzing the relation of glial processes to the connectomic structure.

Title: Automated synapse detection in large scale connectomics data

Authors: ***B. STAFFLER**[1], M. BERNING[1], K. M. BOERGENS[1], P. VAN DER SMAGT[2], M. HELMSTAEDTER[1];
[1]MPI Brain Res., Frankfurt, Germany; [2]TUM, Munich, Germany

Abstract: Nerve tissue contains a high density of chemical synapses, about 1 per μm^3 in the mammalian cerebral cortex. Thus, even for small blocks of nerve tissue, dense connectomic mapping requires the identification of millions to billions of synapses. While the focus of connectomic data analysis has been on wire reconstruction, synapse detection becomes limiting when datasets grow in size and dense mapping is required. Here, we report a method for automated synapse detection from 3D electron microscopy image stacks that scales to very large volumes: SynEM. The approach is based on a pre- segmentation of the image data and focuses on classifying borders between neuronal processes as synaptic or non-synaptic. SynEM yields 96% precision and 95% recall in realistic binary cortical connectomes with no user interaction; it provides full synaptic input maps of single neurons at 95% precision and 95% recall with human effort of about 7 work hours per neuron. We exemplify SynEM for a local connectome of 90 times 38 from mouse somatosensory cortex and the complete synapse input map of a local layer 4 spiny neuron comprising 1334 input chemical synapses. This first locally complete input weight distribution is best fitted by a lognormal distribution, with however a slightly stronger

tail. SynEM provides the tools required for large-scale synapse detection for connectomics in the cerebral cortex and beyond.

Title: Local connectomic patterns in septal versus barrel circuits

Authors: *P. LASERSTEIN, M. HELMSTAEDTER;
Max Planck Inst. For Brain Res., Frankfurt, Germany

Abstract: The projections from thalamus to cortex in primary somatosensory cortex of mouse distinguish “septal” regions in which projections from the posterior medial nucleus (PoM) dominate, and “barrel” regions in which projections from ventral posterio-medial nucleus dominate. Whether the local cortical circuit principles differ between septa and barrels is poorly understood. Here, we use EM-based circuit reconstruction to investigate the local connectomic patterns in septa and barrels of mouse P28 S1 cortex. We acquired a dataset sized 400 x 400 µm and comprising ~3000 sections (30nm) using serial block face electron microscopy (SBEM) and reconstructed 52 spiny and 12 interneurons located in septa and barrels. We then investigated the synaptic input to these, finding first evidence for separated local circuits.

Authors: *K. M. BOERGENS, M. BERNING, B. STAFFLER, A. MOTTA, S. LOOMBA, M. HELMSTAEDTER;
Max Planck Inst. of Brain Res., Frankfurt am Main, Germany

Abstract: The degree to which local circuits in the mammalian cerebral cortex are specific and the statistical order which these circuits obey are not known. Hypotheses range from random local wiring to high-order innervation precision. Here we set out to measure the local connectome statistics in volumes sized about $(100\ \mu m)^3$ acquired using SBEM. We first focused on two volumes from layer 4 and 2/3 of mouse barrel cortex. We used skeleton reconstruction, focused annotation, local automated volume segmentation and manual and automated synapse detection to obtain the first complete local cortical connectomes of datasets this size. Our analysis unravels highly specific pairwise innervation statistics for inhibitory axons that are selective for the nature of the postsynaptic dendritic targets

Title: Developmental analysis of cortical connectomes

Authors: *A. G. GOUR, M. HELMSTAEDTER;
Dept. of Connectomics, Max Planck Inst. For Brain Res., Frankfurt, Germany

Abstract: With the emergence of highly specific wiring principles in local circuits of adolescent (P28) mouse neocortex (Boergens & Helmstaedter) the question arises whether such wiring specificity is already present at the time of formation of first synapses in postnatal development (around P5-6). To what degree does the establishment of these wiring "rules" require pruning of previously existing connections? Is some fraction of the connectome specificity enhanced or created by sensory experience? As a first step towards answering these questions, we have acquired EM datasets using SBEM from barrels in mouse somatosensory cortex at postnatal days 9 and 14. First results from the P14 cortex indicate the inclusion of new innervation target for

Axon initial segments (AIS) innervating inhibitory axons in L4 when compared to P28. While we are still analyzing these developmental connectomes, preliminary data suggests the specificity of these circuits at P14 to be different with respect to P28.

Title: Exploring the role of BDNF in the organization of borders in adult cortical representations of S1

Authors: *L. GONZALEZ, P. W. HICKMOTT;
Psychology, UC Riverside, Riverside, CA

Abstract: The primary somatosensory area, S1, contains a topographical representation of the entire surface of the body. When assessed physiologically, discontinuities are found in the responsiveness of the cortical map, forming distinct borders that serve to constrain the spread of excitation between neighboring representations. Furthermore, the organization of the S1 map is dynamic, and can change in response to a variety of manipulations, notably changes in the patterns of incoming sensory activity to S1. These changes in large-scale organization result from changes in synaptic, intrinsic and anatomical properties of the intracortical circuit. However, little is known about the cues that link changes in activity to coordinated changes in circuit properties.
Research in developmental plasticity has found brain-derived neurotrophic factor, BDNF, to be released in the somatosensory cortex during changes in neural connectivity. BDNF has also been found to display activity dependent expression and release during developmental plasticity. These characteristics have suggested BDNF to be a possible contender for providing a link between the anatomical and physiological bias observed at representational borders. BDNF has been well studied in the developing brain; however, its effects on adult organization have not been heavily researched.
Our previous studies focused on the border separating the forepaw and lower jaw representations in S1. Recent work has found that the local field potential (LFP) of connections crossing a representational border (CB) are smaller than connections that project within a representation (NCB) in our mouse model. When BDNF was bath applied it was found to depress the LFP of CB and NCB populations. Additionally, BDNF had a greater depressing effect on NCB versus

CB synapses.
These results have formed a hypothesis that BDNF is involved in the depression of CB excitatory synapses or in the potentiation of inhibitory synapses. BDNF has previously been shown to be involved in both conditions. To verify the hypothesis, this project will focus on rapid changes in synaptic properties mediated by BDNF after NCB synapses have been depressed using a long –term depression (LTD) paradigm. The results of these studies will shed further light on the role BDNF has on the organization of borders in adult cortical representations of the primary somatosensory area.

Title: The effects of microstimulation on the behavioral report of single neuron stimulation

Authors: *G. DORON, M. BRECHT, M. VON HEIMENDAHL;
Humboldt Univ. of Berlin, Berlin, Germany

Abstract: The activation of individual neurons in the rat barrel cortex using nanostimulation can have an impact on behavioral responses in a detection task (Houweling and Brecht, 2008). Detectability of single neuron spiking depended on the regularity and frequency of the stimulus, as well as the type of the stimulated neuron (Doron et al., 2014). However, the mechanisms that underlie these effects of single neurons on sensation remain unknown. Here we examine the effect of microstimulation on the detectability of single regular spiking (RS) and fast spiking (FS) neurons in the rat somatosensory cortex. We juxtacellularly recorded and stimulated single RS and FS neurons using a combined tungsten electrode and glass pipette device and analyzed the behavioral report to nanostimulation. Interestingly, single neuron stimulation was likely to be detected when preceded by recent (less than 10s) microstimulation. Spectral analysis of the local field potential (LFP) 1 sec before and 1-4 seconds after the microstimulation revealed that perception of the stimulus was related to a significant decrease in delta power (1-4 Hz), as well as an increase in slow frequencies (6-30 Hz) and gamma power (40-100 Hz) within the first 3 seconds following stimulation, compared to no-stimulation trials. Surprisingly, examination of the effects of irregular nanostimulation pattern, which we previously reported to be the best perceived by the subjects, resulted in similar LFP patterns to those of microstimulation within the first 2 seconds following stimulation. These findings suggest that microstimulation as well as

certain single neuron stimulation patterns might influence the local network dynamics and alter their sensitivity to weak perturbations. We are currently assessing the effects of microstimulation on individual RS and FS spiking dynamics. Preliminary data suggest that firing rates are affected in these neuronal classes differently.

Title: Somatotopic organization within the rat trunk sensory cortex

Authors: *G. H. BLUMENTHAL, B. NANDAKUMAR, K. A. MOXON;
Sch. of Biomed. Engineering, Sci. & Hlth. Systems,, Drexel Univ. Sch. of Biomed. Engin. Sci. and Hlth. Systems, Philadelphia, PA

Abstract: In both human and animal studies, the intensity of chronic neuropathic pain (CNP) has been directly associated with the degree of reorganization in the primary somatosensory cortex (S1). In patients suffering from phantom or below-level pain after deafferentation injury, cortical representations surrounding the painful, deafferented regions tend to expand, but patterns of cortical reorganization with development of at-level pain are not as well characterized. Mid-thoracic spinal cord contusion in the rat is an appropriate model for studying at-level CNP, because animals can easily be tested for several phenotypes of neuropathic pain and be selected for at-level CNP only. Although mid-thoracic SCI in rats may produce a practical model for at-level pain, the S1 trunk cortex in the naive rat is not defined well enough to study detailed reorganization in that region. This study aims to develop a detailed somatotopic map of the trunk sensory cortex in the rat.
Naive female Sprague Dawley rats were anesthetized with 1.5 g / kg urethane and placed in a stereotaxic frame. A grid of 1 cm^2 squares were drawn on the shaved trunk. A craniotomy with the coordinates 1.5 - 4.5 mm rostral/caudal and 1.5 - 4.5 mm medial/lateral relative to bregma was performed, and a ground screw was inserted into the skull. Dura was removed, and a high-impedance tungsten microelectrode was slowly lowered through the cortex as single unit neurons were identified. Upon identification, the animal's skin was lightly stimulated with a cotton swab as the cell was classified as responsive or non-responsive to the stimulation. If responsive, the receptive field of the cell was determined in relation to the grid drawn on the animal. This process was repeated in several locations within and surrounding the trunk sensory cortex. In a

subset of animals, the single electrode was replaced with a multi-channel shank (NeuroNexus, A2x16), and sensory evoked potentials (SEPs) were recorded through all layers of the cortex simultaneously using electrical stimulation to the trunk.
Our results support a somatotopic organization of the trunk within the trunk sensory cortex, with a caudal to rostral sensory receptive field orientation over the medial to lateral cortical area, and a dorsal to ventral receptive field orientation over the caudal to rostral cortical area. Cortical locations related to specific dermatomes of the thoracic region were also identified. This work provides the basis for studying cortical remapping of specific areas of trunk sensory cortex which receive information from the areas of the body affected by at-level CNP after spinal cord injury.

Title: The role of mouse barrel cortex in tactile trace eye blink conditioning

Authors: ***J. I. HOFMANN**[1], B. JOACHIMSTHALER[2], C. SCHWARZ[2];
[1]Ctr. For Integrative Neuroscience; Ag Schwarz, Tuebingen, Germany; [2]Univ. Tübingen, Tübingen, Germany

Abstract: Mouse whisker-related primary somatosensory cortex (barrel cortex, BCx) is required to form an association between a behaviorally relevant tactile stimulus and its consequences, only if the first (conditioned stimulus, CS, here a single whisker deflection), and the latter (unconditioned stimulus, US, here a corneal airpuff) are separated by a brief memory period (‘trace’). We trained three mice on a tactile trace eye blink conditioning task (TTEBC) to assess learning related functional plasticity of BCx by recording LFPs and multi unit (MU) spiking from 4-shank laminar silicone probes (8 electrodes per shank, inter-shank distance 200 μm) spanning the depths of the principal barrel column and its neighbors. Current source density analysis (CSD) showed the known short latency sink in L4 and L6 during CS presentation but also a novel source at the same depthsduring the trace period. Both were consistently attenuated during TTEBC acquisition. Onset MU spike response to the CS (at a latency of <30 ms) was increased in some units while steady state CS-response (~50ms-250ms) typically decreased below the pre-learning level. Spiking during the trace period depressed as well during learning. These plastic changes were observed in neighboring shanks at a horizontal distance of up to 400μm. These findings show that BCx is functionally involved in TTEBC acquisition. We next

asked whether the involvement of BCx during the trace period has any causal role. We employed a well-established mutant mouse line that,due to expression of channelrhodopsin2 in inhibitory neurons (Guo et al., 2013), allows to block virtually all spikes in a column using illumination with blue light with great temporal precision. We found that BCx functionality was required during CS presentation. However mice learned normally when blocking BCx during the trace period. After learning, BCx activity during CS and trace was entirely dispensable for task performance. In summary, we demonstrate that the barrel column is tightly involved in acquiring the TTEBC association. Nevertheless, the plasticity of the neuronal response in the trace period is a non-causal reflection of learning, and after learning BCx is not needed for task performance at all. The role of BCx thus seems compatible with an instructor that couples other structures according to the task demands. We are currently investigating whether other tactile cortical representations are involved as well.

Abstract: Even the simplest stimuli evoke highly heterogeneous responses in thousands of neurons in the related primary sensory areas of the mammalian neocortex. This intracortical (IC) representation of the stimulus is integrated by specific output populations in cortical layer 5 (L5), which transmit the results of cortical sensory information processing to several distant brain areas. How local IC activity is transformed into cortical output, and whether the transformations are related to the specific long-range targets is unknown. Here we combined injections of retrograde tracer agents with *in vivo* recordings and computational modeling to determine relationships between local synaptic input and sensory-evoked responses of individual L5 neurons with identified subcortical targets. We found that cortico-subcortical (CS) neurons in L5 of rat primary somatosensory cortex (S1) are subdivided into four disjoint projection types, which are embedded into the cortical circuitry in a target-related manner. Our results demonstrate that several CS output channels, in parallel, transform IC activity into target-related spiking patterns, potentially to extract disjoint features from the same stimulus.

Title: Stochastic transitions in cortical ensemble dynamics can predict the timing of taste ingestion egestion orofacial behavior

Authors: *N. MUKHERJEE, J. WACHUTKA, D. B. KATZ;
Brandeis Univ., Waltham, MA

Abstract: Single neurons in the taste/gustatory cortex (GC) display temporally dynamic responses to taste stimuli. Their responses are seen to evolve gradually over time through a stereotypical series of 'epochs' (Katz et al., 2001, 2002), the last of which (~0.8 secs post stimulus) is rich in palatability (the ingest-egest decision variable)-related firing. However, using ensemble analysis techniques (Hidden Markov Models) to look at patterns of population firing, it turns out that the emergence of this epoch of decision-related firing is much more

sudden than revealed by trial-averaged single neuron responses. GC neural ensembles flip suddenly and spontaneously between a set of stereotypical population firing 'states', and the emergence of decision-related firing varies from trial-to-trial (Jones et al., 2007). Here we test the hypothesis that this sudden and variable emergence of palatability/decision related firing holds behavioral significance on single trials – using chronic, multi-electrode recordings of GC neurons (~5-30 neurons) in awake behaving rats, we show that the variability in palatability-related dynamics of GC ensembles, hitherto dismissed as 'noise', correlates strongly with the onset of ingestion-egestion related orofacial behavior on a trial-by-trial basis. We go on to test the functional significance of this brain-behavior correlation – we show that optogenetic inactivation of GC populations during taste processing affects the timing and probability of palatability-specific ingestion-egestion orofacial movements. Finally, we develop a novel optotrode system to probe the stochastic and dynamic states of GC ensemble activity with brief, targeted optogenetic inactivation and explore its behavioral consequences. All in all, our work starts to unravel the role of stochasticity in the processing of taste stimuli in GC ensembles and its behavioral significance in the context of brainstem controlled ingestion-egestion orofacial behavior.

Title: Gustatory cortical input onto the nucleus of the solitary tract refines neuronal firing patterns and enhances learning in the awake rat

Authors: ***J. D. SAMMONS**[1], C. E. BASS[2], J. D. VICTOR[3], P. M. DI LORENZO[1]; [1]Psychology, Binghamton Univ., Binghamton, NY; [2]Pharmacol. and Toxicology, Univ. at Buffalo, SUNY, Buffalo, NY; [3]Feil Family Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY

Abstract: Taste responsive neurons in the nucleus of the solitary tract (NTS, the first relay in the central gustatory pathway) are almost all broadly tuned across taste qualities. In addition to input from the tongue, the NTS receives centrifugal input from multiple brain regions including the gustatory cortex (GC). In the NTS, spike patterns (rate envelope and spike timing) are known to

convey more information about taste quality than spike count alone. However, whether direct GC-NTS input can shape spike patterns of NTS responses is unclear, as is its behavioral relevance. Here, we used optogenetic tools to manipulate GC-NTS input while recording from the NTS in awake, freely licking rats during taste-driven behaviors. We then used a Go-no-Go (GnG) paradigm to study the behavioral effects of selective enhancement or inhibition of GC-NTS input. We first infused viral constructs containing channelrhodopsin 2 or halorhodopsin genes bilaterally into the GC. After 2-4 weeks, we implanted an optrode consisting of a fiber optic implant attached to a bundle of 8 tungsten microwires into the taste responsive portion of the NTS. Following recovery, rats were moderately water deprived and placed in an experimental chamber where they experienced a "taste-only" or GnG paradigm. In the taste-only paradigm, trials of 5 consecutive licks (12μL/lick) of a tastant (0.1 M NaCl, 0.1 M sucrose, 0.1/0.01 M MSG/IMP, 0.01 M citric acid, 0.001 M quinine, or artificial saliva) were interspersed with 5 licks of artificial saliva presented on a VR5 schedule. After several days of taste-only recording, rats were switched to the GnG paradigm. Each trial in the GnG paradigm started with a single cue stimulus lick of 0.1 M NaCl followed by 5 dry licks and then 3 test stimulus licks (0.1 M MSG/IMP or 0.1 M KCl). If cue and test stimuli matched, continued licking produced a 3-lick 0.5 M sucrose reward; if cue and test stimuli differed, continued licking produced a 3-lick 2 mM quinine punishment. Withholding licking for 1 s enabled them to avoid this punishment. Incorrect responses also included a 5 s timeout. In a random half of each trial type, GC-NTS input was manipulated optically (25 Hz of 473 nm or 532 nm laser light at 8-10 mW) for a maximum 1 s following each test lick. Results show that stimulation or inhibition of GC-NTS input can change the temporal characteristics of taste-evoked spike trains in the NTS. Further, GC-NTS enhancement improved GnG learning only for difficult tasks while inhibition of GC-NTS input impaired GnG performance. These data demonstrate a role of direct GC-NTS input in shaping NTS firing patterns and that these changes are functionally expressed by changes in performance in a GnG paradigm.

Title: Patterned activation of amygdalo-cortical projections induces synaptic and intrinsic plasticity in rat primary gustatory cortex.

Authors: *M. HALEY, A. FONTANINI, A. MAFFEI;
SUNY At Stony Brook, Stony Brook, NY

Abstract: Projections from the basolateral amygdala (BLA) to the agranular portion of primary gustatory cortex (aGC) show laminar-specific and target-specific properties. Previous studies that used a combination of pharmacology, behavior, and extracellular recordings demonstrated that input from BLA to GC is necessary for learning about the hedonic value of a taste and predictive cues anticipating taste stimuli. These learning processes are hypothesized to induce plastic changes between BLA and GC, but the capacity for plasticity of BLA-GC synapses has not been investigated. Here we used whole-cell patch clamp in acute GC slices combined with optogenetic activation of BLA terminal fields to investigate 1) the patterns of BLA afferent stimulation that induce plasticity at BLA-GC synapses, 2) whether BLA-GC plasticity induction and expression may vary depending on target neuron identity and location. We show that LTD is the dominant form of plasticity induced at BLA inputs onto PYR neurons in supragranular GC (sGC). The magnitude of the LTD differed by induction paradigm (% changes, phasic bursts - 20Hz: -27.7 ± 3.3; 40Hz: -48.3 ± 9.8; Tonic firing for 6s: -43.3 ± 6.2). In infragranular GC (iGC), LTD was induced at BLA-PYR synapses using phasic busts at 20 and 40 Hz (% changes, phasic bursts - 20Hz: -28.0 ± 3.5; 40Hz: -36.5 ± 6.3). However, differently from PYRs in sGC, induction using tonic activation of BLA-GC afferents induced LTP (% change, tonic firing: 98.1 ± 19.0). We also report that in both sGC and iGC, tonic activation of BLA afferents induced intrinsic plasticity of PYR neurons, increasing their excitability. Our results indicate that BLA-GC synapses show laminar differences in their capacity for plasticity, suggesting that input from BLA to the superficial and deep layers of aGC may subserve different functions in taste learning.

Title: Layer specific sensorimotor activity in the gustatory cortex of licking mice.

Authors: *G. N. DIKECLIGIL, D. M. GRAHAM, I. M. PARK, A. FONTANINI;
Stony Brook Univ., Stony Brook, NY

Abstract: Gustatory Cortex (GC) neurons in alert rodents display rich temporal dynamics encoding the chemical and somatomotor features of a gustatory experience. How these dynamics are represented across layers and cell types in GC is unknown. Specifically, little is known on how patterns of somatomotor -related activity differ across elements in GC circuits.
To address this question we performed extracellular recordings targeted to deep (Layers 4-6) and superficial layers (Layer 2/3) of GC in head restrained mice engaged in a cued-licking paradigm. Mice received a single drop (~2 μL) of taste solution in each trial and were trained to continue licking at 7 Hz for 750 ms to ensure stereotyped somatomotor behavior across trials.
Isolated single units with narrow waveforms (peak to through 100-275 μs) were classified as putative inhibitory cells and those with wide waveforms (peak to through 300-500 μs) were classified as putative pyramidal cells. A total of 202 single units were recorded with 39/202 deep layer inhibitory cells (DI), 89/202 deep layer pyramidal cells (DP), 71/202 superficial layer pyramidal cells (SP) and 3/202 superficial inhibitory cells (SI). SI cells were not analyzed further due to small sample size.
Principal component analysis of normalized peri-stimulus time histograms revealed that DI cells display strong pre-stimulus modulations and tonic stimulus-evoked response profiles. DP cells show small pre-stimulus modulation with a mixture of rhythmic and tonic evoked responses. In contrast with deep layer cells, SP cells show very strong coupling to licking rhythm with negligible pre-stimulus modulations. The percentage of neurons that show a significant modulation in the pre-stimulus epoch (300 ms prior to first lick) is greater for DI cells compared to DP and SP cells ($p<0.05$, DI: 79% , DP: 47%, SP: 33%).
To relate pre-stimulus modulations to mouth movements we performed cross-correlations between continuous mouth movement signals (obtained by video analysis) and firing rates. 92% of pre-stimulus modulated neurons showed significant correlations with mouth movements. GC firing could both precede and follow mouth movements, suggesting that pre-stimulus activity could reflect both preparation and execution of licking.
Our data show that response dynamics of GC circuits are layer and cell type specific and this differentiation extends to periods prior to the arrival of taste stimuli. The bias of pre-stimulus activity to putative interneurons in deep layers suggests that inhibition may play an important role in preparing GC neurons for receiving taste and in shaping taste response dynamics.

Title: Holistic processing of taste mixtures in rat gustatory cortex

Authors: *J. WACHUTKA[1], N. MUKHERJEE[2], S. ZARMSKY[2], D. KATZ[2];
[1]Neurosci., [2]Brandeis Univ., Waltham, MA

Abstract: Taste plays a crucial role in the feeding behaviors of animals--acting as the last line of defense against ingestion of potentially harmful stimuli. We avoid bitter and sour foods that may be potentially harmful in favor of sweet, salty, or savory flavored foods—tastes generally associated with nutrients and calories that we require. However, natural foods rarely feature only one basic taste component, and there are some situations—when an animal encounters a sweet yet harmful fruit, for example—in which animals must learn to avoid foods due to physiological affects rather than discriminating by pleasantness of taste alone. This presents the taste system with a difficult problem: it must process a diverse range of sensory stimuli and post-ingestive memory in varying contexts while reliably producing the correct behavioral output. Here, we show that rats are capable of responding to a mixture of two taste cues in the opposite ingestive manner as they do to either taste when presented in isolation following conditioned taste aversion learning: taste mixtures can be processed not as a combination of component parts, but rather as a single unique, holistic entity. We hypothesize that this holistic processing leads animals to generalize taste learning to mixture components on the basis taste quality similarity, rather than processing the mixture as the co-occurrence of two independent features. Future electrophysiological work in rat gustatory cortex will explore single unit responses to binary taste mixtures and single tastes to test the prediction that mixture responses do not simply reflect the simultaneous activation of individual taste response patterns, but in fact reveal a unique pattern reflecting our observed holistic treatment of taste.

Title: Modification of the gustatory responses in rat insular cortex by the olfactory stimulation.

Authors: ***N. MIZOGUCHI**[1], M. KOBAYASHI[2], K. MURAMOTO[1];
[1]Meikai Univ. Sch. of Dent., Saitama, Japan; [2]Nihon Univ. Sch. of Dent., Tokyo, Japan

Abstract: Flavor is a sense that is important to identify foods in a mouth and is related to a good taste and the satisfaction of the meal. When eating foods, taste information is integrated with odor cues to form a flavor sensation in a certain brain region. Several studies reported previously that the insular cortex (IC) is received the olfactory input in addition to taste information. However, it has been unclear by what kinds of mechanism two chemical senses are integrated in the IC.
To address this issue, we examined the spatiotemporal dynamics of excitatory propagation in cerebral cortex induced by simultaneous electrical stimulation (5 train pulses at 50 Hz) of the chorda tympani nerve (CT) and main olfactory bulb (mOB). Rats were anesthetized by intraperitoneal injection of urethane, and cortical responses to stimulations of gustatory and/or olfactory pathways were observed by an *in vivo* optical imaging technique using a voltage sensitive dye. (RH1691). Our surgical operation permitted a clear visualization of cortical areas around the IC, including the ventral mOB, lateral olfactory tract, anterior and posterior PC. We observed the optical responses in these cortical regions to electrical stimulation of the CT and/or the ventral mOB. The principal responding region with the CT stimulation was located in the rostral part of the dysgranular IC (DI). On the other hand, ventral mOB stimulation evoked excitatory propagation that spread in the piriform cortex (PC) and the agranular region (AI), which locates ventrally adjacent to DI.
Next, we examined the effects of simultaneous stimulation of CT and ventral mOB on the IC response by changing an interval between two stimulations. Ventral mOB stimulation was applied at three timings: simultaneous, 150 ms before, and 150 ms after CT stimulation. Simultaneous stimulation of CT and ventral mOB additively increased the response-amplitude in AI, and shorten the time to peak of excitation in DI without changing its signal amplitude. Ventral mOB stimulation 150 ms before or after CT stimulation evoked the response that peaked just after CT stimulation in DI and after mOB stimulation in AI. These results suggest that DI principally responses to inputs from CT, and in contrast, AI is more sensitive to inputs from mOB than CT. It was showed that the short time lag between odor and taste inputs affected the

responses in the IC.
Our data suggest that the gustatory and the olfactory information is at least partially integrated in AI and DI to form flavor prior to the orbitofrontal cortex.

Title: Neural correlates of sweet taste intensity in the insular and orbitofrontal cortex

Authors: *E. G. FONSECA DE LA CRUZ[1,2], A. S. MATSUMOTO[4,2], M. VILLAVICENCIO[2], A. I. HERNANDEZ-COSS[3], S. A. SIMON[5], R. GUTIERREZ[2];
[1]Inst. De Fisiología Celular, UNAM, Mexico City, Mexico; [2]Dept. of Pharmacol., [3]Dept. of Bioelectronics, CINVESTAV - IPN, Mexico City, Mexico; [4]Fac. of Psychology, UNAM, Mexico City, Mexico; [5]Dept. of Neurobio., Duke Univ. Sch. of Med., Durham, NC

Abstract: Food consumption of any taste quality is modulated in an intensity dependent manner. Rodents taste intensity processing neural correlates has been described from the periphery to the insular cortex (IC). Nonetheless, methodological ways to measure taste sensitivity requires an improvement in order to assess neural correlates in freely moving animals which are actively acquiring sensory information to construct a taste percept. On the other hand, despite Orbitofrontal Cortex (OFC) is also known as secondary gustatory cortex its role in intensity processing has been left aside. To address this issues, we performed single unit recording in IC and OFC of rats trained in a novel sucrose intensity discrimination task that allow us to measure behavioral and neuronal taste identification sensitivity by using psychophysics. During training sessions subjects had to emit differential responses (left or right) according to the taste intensity cue received: low(3%) or high(18%). Once subjects learned the task, rats accessed classification session: rats had to classify different sucrose intensities (3, 4.75, 7.5, 11.75 or 18%) as “low” or “high”. Afterwards, rats were stereotaxically implanted with a 16 channel multielectrode array for recording single unit activity while they were performing in training and classification

sessions. The task was divided in the following epochs: 1) Cluster Start (CS), first dry lick, 2) Cue delivery, 3) Cluster End (CE) last after cue lick, 4) PreRew, 300 ms before reward delivery and 5) Reward delivery. Preliminary data from 538 (training) and 319 (classification) OFC neurons, and 80 (training) and 50 (classification) IC neurons has been obtained. IC and OFC neurons processed orosensory and motor information during different epochs, responding in an inhibitory, excitatory phasic, excitatory tonic or licking-coherent way. In training sessions, we found OFC neurons that discriminates between concentration during Cue, CE and PreRew epochs. OFC neurons responding in an intensity dependent manner were found. These intensity processing neurons classifies intensities in one of two ways: phasic/categoric or monotonic with gradual increases or decreases in their firing rate in an intensity dependent manner. Similar responses are expected to be seen in Insular Cortex. Neural sensitivity to identify sucrose intensities will be calculated for neurons in both areas using psychophysics approximation.

Abstract: Sensory thalamic nuclei display remarkable similarities in their inputs, intrinsic circuitry, synaptic organization, and neurotransmitters, the gustatory thalamus in particular remains the most sparsely studied sensory nuclei in the mammalian brain. We have recently provided the first characterization of the synaptic circuitry in the gustatory thalamic nucleus (VPMpc) in the rat (Holtz et al., 2015), including its primary input from parabrachial nucleus (PBN) and feedback projections from the insular cortex. We demonstrated that the synaptic circuitry in the VPMpc was unique compared to other mammalian thalamic nuclei: PBN axons synapse exclusively on proximal relay cell dendrites; glomerular organizations of primary inputs and triadic arrangements, two hallmark morphologies in the sensory thalamus, are missing; and dense core vesicles and CGRP label mark inputs from multiple origins. We argued that these unique properties of the rat gustatory thalamus were either specific for chemical senses, or they were a consequence of pathway differences between primates and rodents. In primates, the gustatory thalamus receives its primary input directly from nucleus of the solitary tract (NTS), whereas in rodents, the NTS instead projects to the PBN, which in turn, projects to the thalamus and amygdala. In order to test for these possibilities, we examined the gustatory thalamus in the tree shrew, a close relative to non-human primates. Indeed, while retrograde tracers in the VPMpc of rodents do not result in any label in the NTS, a similar injection in ventral thalamus of the tree shrew confirmed the presence of solitario-thalamic cells in the rostral NTS. Unlike in the rat, the tree shrew gustatory thalamus, the VPMP, has well differentiated cytoarchitectonic borders, delineated by myelin and cytochrome oxidase stains. Unlike in the rodent VPMpc, but similar to other mammals, the tree shrew VPMP is immuno-stained for VGluT2. Also unlike in the VPMpc, where CGRP is a marker for inputs including those from PBN, no CGRP+ terminals were encountered in the tree-shrew VPMP. Electron microscopy revealed that unlike in rodents, the VPMP in tree shrew contains triadic arrangements and glomeruli where VGluT2+ terminals are located. The characteristic morphology of PBN terminals mentioned above were not encountered in the tree shrew. Overall, our data confirm the hypothesis that the synaptic

organization of the rodent gustatory thalamus is substantially different than in the tree shrew, a species with a direct solitario-thalamic pathway, and suggest that rodent taste thalamus circuitry is not representative of the taste thalamus in primates.

Title: Pungency and pain and *In vivo* imaging of mouse trigeminal ganglion neurons

Authors: S. LEIJON[1], J. M. BREZA[2], N. CHAUDHARI[1], *S. D. ROPER[1];
[1]Dept. of Physiol. and Biophysics, Univ. of Miami Sch. of Med., Miami, FL; [2]Eastern Michigan Univ., Ypsilanti, MI

Abstract: Certain plant-derived compounds such as capsaicin, allyl isothiocyanate (AITC), and menthol add pungency to food and beverages and change the perception of oral thermal sensations. Capsaicin is an agonist of TRPV1, a channel that also transduces nociceptive stimuli. AITC stimulates TRPA1 and menthol activates TRPM8, both of which are associated with environmental cold. The trigeminal ganglion receives somatosensory signals from the oral cavity, including pain, pungency, and temperature. Neurons in this ganglion express TRPV1, TRPA1, and TRPM8, with many neurons co-expressing combinations of these channels (e.g. TRPV1/TRPA1). We are exploring the representation of pungency, pain and temperature in the trigeminal ganglion, imaged *in vivo*. Mice were deeply anesthetized and cortical tissue overlying area V3 of the ganglion (identified as containing neurons with receptive fields in the oral cavity) aspirated via a cranial window. Using confocal Ca^{2+} imaging in mice that express the Ca-indicator GCaMP3 in sensory neurons (Kim *et al*, *Neuron* **81**:873, 2014), we could monitor up to 800 trigeminal ganglion cells simultaneously to record orally-evoked neuronal responses. Artificial saliva containing capsaicin (10 to 1000 μM), menthol (1-5 mM), AITC (20 mM), or artificial saliva alone at temperatures ranging from nociceptive cold (2^{o}) to nociceptive hot (45^{o}) were delivered retrogradely via a catheter inserted through the esophagus as 10 second oral lavages. All stimuli elicited responses in neurons having significantly smaller diameters (mean =

19.2 ± 0.4 μm, n=73) than the average diameter of trigeminal neurons (24.5 ± 0.4 μm, n=204; $p<0.0001$), consistent with nociceptors and thermoreceptors. Capsaicin, AITC, and menthol elicited responses in distinct populations of ganglion neurons, despite there being overlapping co-expression of TRPV1 and TRPA1 channels. Interestingly, nociceptive cold (2^{o} C) applied orally stimulated a different subset of neurons than the same stimulus (in Tyrode buffer) applied topically onto the trigeminal ganglion. There was only 6% overlap between these two subsets. Capsaicin (100 μM) applied orally produced a long-lasting (minutes) enhancement of responses to oral lavage with warm stimuli. Menthol (1-3 mM) appeared to have a similar effect for cold stimuli. In addition to exploring the neural basis of everyday somatosensory experiences during food intake, this preparation lends itself as a promising tool for studying orofacial pain, such as thermal allodynia and inflammatory evoked hyperalgesia.

Title: Developmentally dependent microglia increase following chorda tympani transection in rats

Authors: *A. J. RIQUIER, S. I. SOLLARS;
Univ. of Nebraska At Omaha, Omaha, NE

Abstract: The taste system provides a useful model for the study of neuroplasticity, due in part to the dynamic and relatively rapid changes that occur as a result of normal development and in response to injury. The chorda tympani (CT) is a gustatory nerve that transmits information from taste buds in fungiform papillae to the rostral nucleus of the solitary tract (rNTS) in the brainstem. Transection of the CT (CTX) performed at various ages in the rodent model is a

paradigm used to examine adaption to neural insult of both developing and mature gustatory systems. Since the CT runs ipsilaterally from the taste buds to the rNTS, the side contralateral to a CTX is often used as a control. Adult (≥ 40 days of age) CTX results in temporary loss of taste buds and moderate changes to rNTS terminal fields. Previous work from our lab showed that CTX performed in neonatal rats (≤ 10 days of age) results in profound and permanent loss of taste buds, fungiform papillae, and rNTS terminal fields. While the mechanisms underlying this terminal field loss are unknown, microglia have been shown to increase in number in the rNTS four days following unilateral CTX in adult mice (Bartel, 2012). However, microglia response to CTX performed at pre-adult ages has not been examined. In the present study, four rats received unilateral CTX at 10, 25, or 50 days of age and were sacrificed four days later. Animals were perfused and brains extracted, post-fixed in 4% paraformaldehyde, and sectioned horizontally at 40 μm on a vibratome. Sections were processed for the microglia marker ionized calcium-binding adapter molecule 1 (Iba1). Iba1+ cells in the rNTS were counted using the program Neurolucida (MBF Bioscience). Microglia density was calculated by dividing the number of Iba1+ cells by the area of the rNTS. An ANOVA revealed a significant main effect of both age ($p < .05$) and surgery ($p < .05$). Paired-samples t-tests were used to compare the number of microglia in the rNTS on the transected side to the contralateral intact side. Microglia increased in number in the rNTS when CTX was performed at 50 ($p < .01$), 25 ($p < .01$), or 10 ($p < .05$) days of age. The percentage increase was calculated for each age to allow for comparisons across age conditions. While CTX performed at 25 or 50 days of age elicited a similar microglia response ($p > .05$), 10-day CTX resulted in significantly less response in comparison to 25 ($p < .05$) and 50 ($p < .01$) CTX. These findings show that, although microglia increased in number following CTX in all ages tested, the magnitude of the increase differed between the youngest and the two older ages. These findings may shed light on the developmentally differing degree of terminal field loss observed following CTX.

Title: Transganglionic degeneration of the chorda tympani nerve terminal field following neonatal denervation

Authors: *L. J. MARTIN[1], K. K. SAMSON[2], A. H. ORAND[1], S. I. SOLLARS[1];
[1]Univ. of Nebraska At Omaha, Omaha, NE; [2]Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Taste afferents project to the nucleus of the solitary tract (NTS) where their terminal fields overlap considerably - creating the opportunity for competition between nerves. We have found that chorda tympani transection (CTX) in rats leads to reorganization of glossopharyngeal and greater superficial petrosal nerve terminal fields when surgery occurs at postnatal day 5 (P5), such that both of these nerves have a larger volume in the dorsal NTS. This effect does not occur following CTX at P10. Since the chorda tympani (CT) does not regenerate if CTX occurs at P10 or earlier, it is unclear why the extent of reorganization differs between these surgical ages. To understand how this altered projection pattern relates to CT degeneration, we analyzed CT terminal field volumes after CTX at P5 or P10. The CT was first accessed in neonatal rats (n=5/surgical group) and either transected (CTX) or left intact (Sham). Following 50-51 days survival, the CT was cut in the tympanic bulla (central to the initial transection) and biotinylated dextran amine was applied to the proximal end of the nerve. Animals were perfused 48 hr later and brain tissue was sectioned at 50 μm in the horizontal plane. Sections were processed using diaminobenzidine (DAB) to visualize the CT terminal field. Images were taken of each section containing CT terminal field, and a pixel analysis (ImageJ) was performed to determine terminal field volumes. Transection of the CT at either age resulted in a significantly lower terminal field volume relative to controls; CTX at P5 and P10 led to CT terminal field volumes that were 12% and 24% of sham volumes, respectively. The loss of terminal field is much greater than that observed after adult CTX (Reddaway et al., 2012). While there was a tendency for terminal field volumes to be smaller after P5 CTX relative to transection at P10, this difference was not statistically significant (p = .08). After CTX at P5 or P10, CT volumes were significantly lower than Sham volumes in the dorsal, intermediate, and ventral NTS. CT volumes following CTX at P5 were not significantly different from those of P10 CTX rats for any zone of the NTS. Volumes in the dorsal zone in particular were very similar after CTX at P5 or P10 - representing 13% and 14% of sham volumes, respectively - suggesting that the CT degenerates to a similar extent following denervation at these ages. Thus, the expansion of the glossopharyngeal and greater superficial petrosal nerves into the dorsal zone following CTX at P5 appears to be caused by factors other than CT retraction alone. These findings suggest that there may be a sensitive period whereby nerves are best equipped to reorganize in response to degeneration of an adjacent nerve.

Title: Thermal and tactile responses of the rat chorda tympani nerve

Authors: Y. YOKOTA, A. KUMARI, C. M. MISTRETTA, *R. M. BRADLEY;
Univ. Michigan Sch. Dent., Ann Arbor, MI

Abstract: Previous investigations of the properties of primary afferent neurons of the chorda tympani nerve (CT) have emphasized responses to stimulation of the anterior tongue with chemicals. However it has been known for some time that the CT also responds to thermal and tactile stimulation of the tongue dorsum. Recently we have shown that inhibiting Hedgehog signaling using a pharmacological blocker treatment in mice results in loss of taste bud integrity and CT electrophysiological responses to chemical stimulation (Kumari et al. J. Neurophysiol. 2015). However, CT responses to tactile and cold stimuli are retained indicating that these two modalities are mediated by different sensory receptors than taste. We have investigated the receptive field properties of geniculate ganglion/chorda tympani (GG/CT) neurons using extracellular recordings and stimulation of the tongue with chemicals (Yokota and Bradley, J. Neurophysiol. 2016). Currently we are characterizing the cold and tactile responses of GG/CT neurons. Receptive field location and size of the neurons were determined by electrical stimulation of individual fungiform papillae. To date 7 GG/CT neurons have been isolated that responded only to cold stimulation of the tongue. Receptive field size of these neurons was 1.6 ± 0.5 (mean, S.D) papillae, significantly smaller than average field size of neurons responding to chemical stimulation. The thermal responding papillae were located at the tongue tip. We have also isolated GG/CT neurons that innervate fungiform papillae responding exclusively to mechanical stimulation. These neurons also have small receptive fields consisting of 1 or 2 papillae. While receptor mechanisms of tongue chemoreceptors have been extensively investigated little is known about the identity of the thermal and mechanosensitive lingual receptors innervated by the CT. Experiments are in progress to identify possible receptors by evaluating the effect of receptor antagonists on GG/CT responses. In recent experiments we have used TRPA1 receptor antagonists AP18 and HC-030031 injected into the tongue to explore a possible role in the CT response to 4ºC water. Based on all results it is apparent that fungiform papillae are complex sensory organs responding to multiple modalities that can serve a role similar to the finger tips as an oral organ of sensory exploration.

Title: Metabolic syndrome is associated with altered functional connectivity of the primary and secondary taste cortices and eating disinhibition

Authors: ***E. E. PONGPIPAT**, A. JACOBSON, C. MURPHY;
San Diego State Univ., San Diego, CA

Abstract: Metabolic Syndrome (MetS) is a cluster of risk factors that increases the risk of heart disease, stroke, diabetes, and late-life cognitive impairment and dementia. The risk factors include hypertension, elevated resting blood sugar/insulin resistance, hypertriglyceridemia, abdominal obesity, and abnormal cholesterol levels. The present study examined the indirect relationship of MetS risk factors and eating disinhibition mediated by the functional connectivity of primary and secondary taste cortices in middle-aged adults. Thirty-four middle-aged adult participants between the ages of 43 and 54 years underwent functional Magnetic Resonance Imaging (fMRI) while tasting and rating the pleasantness of sucrose after a 12-hour fast. The functional connectivity was analyzed and obtained using psychophysiological interaction methods. Additionally, participants completed the Three-Factor Eating Questionnaire (TFEQ) to measure eating behavior such as eating disinhibition. A path-analytic model tested the indirect relationship from the number of MetS risk factors to the eating disinhibition score from the TFEQ via the functional connectivity of primary and secondary taste cortices (i.e. right frontal operculum and left caudolateral orbitofrontal cortex, respectively) as a mediating variable. The target model fit well statistically, ($\chi^2(1, N=28) = 1.465$, $p = .226$) and descriptively (CFI = .956, RMSEA = .129, SRMR = .061). With respect to the relationship specified within the model, individuals were significantly more likely to have an increased positive functional connectivity of primary and secondary taste cortices as the number of MetS risk factors increased ($r = .417$, $p < .015$). The eating disinhibition score was also significantly more likely to increase as the functional connectivity of primary and secondary taste cortices increased ($r = .461$, $p = .006$). For middle-aged adults, these findings suggest that the relationship of eating disinhibition in individuals with MetS may be mediated by an altered functional connectivity of primary and

secondary taste cortices. Future studies may consider examining whether behavior modifications such as healthy eating, exercise, or medication and surgery can ameliorate MetS and its downstream effects of altered functional connectivity of primary and secondary taste cortices and eating disinhibition. Title: Differences in neural gustatory processing between lean and obese individuals revealed by evoked responses.

Authors: *S. HARDIKAR[1], R. WALLROTH[2], A. VILLRINGER[1], K. OHLA[2];
[1]MPI for Human Cognitive and Brain Sci., Leipzig, Germany; [2]German Inst. of Human Nutr., Nuthetal, Germany

Abstract: The sense of taste serves to help us in identifying nutritional food sources and avoiding harmful ones. The sensory appeal of food, including taste, motivates food intake even after satiation, leading to over-nutrition. Yet, little is known about the relationship between taste perception and obesity. Especially the spatio-temporal processing of gustatory stimuli has never been explored in relation to Body Mass Index (BMI). In this study, we presented two suprathreshold intensities of sweet (10 g/100 mL and 5 g/100mL sucrose) and salty (2.5 g/100mL and 1.25 g/100mL NaCl) tastants to 30 lean (BMI < 25) and 24 obese (BMI > 30) individuals using a gustometer suited to elicit gustatory evoked responses without concomitant somatosensory activation, while recording head-surface electroencephalography (EEG) from 62 channels.
All participants rated intensity as higher and pleasantness as lower for high compared to low taste intensities. Global Field Power (GFP) was higher in lean than in obese, and for salty than for sweet taste in both groups, which is in line with previous reports of an increased signal-to-noise ratio for salty compared to sweet taste responses; no effect of intensity modulation was

found. Electric field distributions for all conditions differed significantly between lean and obese (130-158 ms, and from 430 ms onward) as well as showing a group*taste quality interaction (from 196 ms onward), indicating differential neural networks in both groups.
Between-subjects multivariate pattern analysis was used to examine group-specific properties in the neural processing of taste by training shrinkage Linear Discriminant Analysis (LDA) classifiers to discriminate between lean and obese participants for each of the tastes and intensities separately. Model performance was evaluated with data from participants not part of the training set. Significant decoding performance for group membership was observed for all tastes starting at 370 ms and mainly driven by salty taste for which significant group decoding was found at both high and low concentrations beginning as early as 190 ms.
The results suggest that lean and obese individuals process sweet and salty tastes differently, although the behavioural consequences of these differences remain to be explored.

Title: Cortical correlates of metabolic syndrome risk factors and hunger in middle aged and older adults

Authors: ***R. B. VERTREES**[1], E. E. PONGPIPAT[1], E. MCINTOSH[1], C. MURPHY[1,2,3]; [1]San Diego State Univ., San Diego, CA; [2]SDSU/UCSD Joint Doctoral Program in Clin. Psychology, [3]UCSD, San Diego, CA

Abstract: Metabolic syndrome (MetS), which affects nearly 35% of U.S. adults and 50% of older adults (60+), is defined as the assemblage of risk factors for development of cardiovascular disease and type 2 diabetes. The risk factors are composed of 5 elements (i.e. high blood pressure, high triglyceride level, low HDL cholesterol level, raised fasting glucose, and abdominal obesity) as defined by the Joint Scientific Statement by K. Alberti et al., *Circulation (*2009). Possessing 3 of the 5 risk factors qualifies an individual for a diagnosis of MetS. The purpose of the current study was to examine the effect of MetS risk factors on hunger (as measured by the Three-Factor Eating Questionnaire) and how this relationship is affected by structural brain changes within taste cortices in middle-aged and older adults. The primary taste

cortex is located within the insula and is responsible for intensity and identification of taste. The secondary taste cortex, which includes the orbital frontal cortex (OFC), evaluates the reward and pleasantness of taste. Both taste cortices contribute to an individual's food selection, and are, therefore, crucial to issues of unbalanced energy intake/ expenditure such as exhibited in individuals with MetS. Analyzing 33 middle-age and 32 older adult participants using structural MRI, the study found that, for both middle aged and older adults, the greater the number of MetS risk factors, the higher their score on the hunger scale of the TFEQ. For middle aged adults, individuals with greater OFC thickness exhibit a weaker relationship between number of MetS risk factors and hunger ratings ($p=.038$, $\eta^2=.141$). For older adults, individuals with greater insula thickness exhibit a weaker relationship between number of MetS risk factors and hunger ratings ($p=.021$, $\eta^2=.177$). These findings suggest an important interaction between cortical thickness and risk factors of MetS on feelings of hunger, and suggest the importance of further study of taste cortical structure and MetS correlates.

Title: Sucrose binge eating selectively alters taste palatability but not sweet taste identification

Authors: *A. S. MATSUMOTO[1,2], E. G. FONSECA[3,5], S. A. SIMON[6], R. GUTIERREZ[4]; [1]Pharmacol., Ctr. De Investigación Y De Estudios Avanzados De, Distrito Federal, Mexico; [2]Fac. of Psychology, UNAM, Mexico, Mexico City, Mexico; [4]Pharmacol., [3]Lab. of Neurobio. of

Appetite, Dept. of Pharmacology, CINVESTAV-IPN, Mexico City, Mexico; [5]Inst. of Cell. Physiology, UNAM, Mexico, Mexico City, Mexico; [6]Duke Univ. Sch. of Med., Durham, NC

Abstract: Binge eating (BE) is characterized by the consumption of highly caloric food in a brief period of time (≤ 2h). This pathological feeding pattern might be due to an altered taste perception. However, it is not clear whether sweet intensity sensitivity (SIS) and/or palatability responses are affected by BE development. Although this 2 process normally correlates, they can be separated. To address this issue we measured SIS using a psychophysical sucrose intensity discrimination task before and after sucrose BE induction. During training sessions 24 rats had to emit differential responses (left or right) according to the taste intensity cue received: low (3 %) or high (18 %). Once subjects learned the task, classification sessions where rats had to classify different sucrose intensities (0, 3, 4.75, 7.5, 11.75 or 18 %) as "low" or "high" were introduced. Response probability to high intensity compartment was obtained and a sigmoid function was fitted to obtain psychophysical SIS. Subsequently, rats were divided into 4 groups (n=6/group) with different access to sweet liquids during 21 d: 1) Intermittent sucrose (2 h, INTsuc), 2) *Ad libitum* sucrose (24 h, ALsuc), 3) Intermittent sucralose (2 h, INTscl), and 4) No sweet access (Ctrl). We found that SIS was not modified by any feeding protocol. Subsequently using a Brief Access Test we evaluated palatability responses evoked by different sucrose intensities. INTsuc displayed higher licking rates for 0 and 3 % intensities, while ALsuc had higher licking rate for all concentrations in comparison to INTscl and Ctrl groups, indicating an increased palatability responses. Licking microstructure was analyzed with a 20 min freely licking test with access to different solutions across days: 1)1-3 d water, 2) 4-8 d sucrose 18%, 3) 9d extinction, 4) 10-13 d reinstatement/sucrose 18%. All groups ingested less sucrose than Ctrl, nevertheless ALsuc had lick bouts almost twice longer than other groups during the first 10 min, while INTsuc during the last 10 min indicating increased palatability responses. INTscl showed a reduced palatability as suggested by shorter bouts than Ctrl during this sessions. During reinstatement we found an increase in palatability during the first 15 min for ALsuc and the last 10 min for INTsuc and INTscl. As well, ALsuc showed higher palatability measured by longer sucrose bouts in comparison with the other groups. Together these data shows that intermittent and *ad libitum* sucrose access did not change the SIS. Nonetheless, it selectively induced a long-term potentiation of sweet palatability responses, leading to pathological overconsumption patterns which is a hallmark in BE disorder.

Title: Normosmic subjective ageusia

Authors: *M. K. ALHAIDAR[1], A. R. HIRSCH[2];
[1]neurology, George Washington Univ. Hosp., Washington, DC; [2]Smell and Taste Treatment and Res. Fndn., Chciago, IL

Abstract: Introduction: Subjective ageusia in the presence of objectively normal gustation, orthonasal olfaction, and retronasal olfaction, has not heretofore been described.
Methods: case report: A 59 year old right handed female, with history of geographic tongue, presented with a 3 year course of sudden onset of burning of her tongue and palate, followed the next day by absent ability to taste. She affirms normal olfaction.
Results: Abnormalities in physical examination: white coating in the anterior and center of the tongue. Café au lait spot, right gluteus, 4x6 cm. Telangiectasia, right forearm and arm. Neurological examination: Cranial nerves: Cranial nerve II: anisocoria OD: 4mm OS: 2mm. Fundoscopy: pale discs OU. Motor exam: drift testing: Mild right pronator drift. Reflexes: 1+ both upper extremities. 3+ bilateral quadriceps femoris. All Chemosensory testing normal with Brief Smell Identification Test: 12. Retronasal Smell Index: 5. Propylthiouracil Disk Test: 10. MRI of brain with and without infusion: normal.
Conclusion: Food induced BMS pain may accelerate swallowing, minimizing transit time in the mouth, reducing gustatory and retronasal stimulation. When the patient used the word taste, she may have been describing other components of food perception. In those who complain of taste loss with normal chemosensory testing, more detailed chemosensory assessment is warranted.

Title: Application of an automated rapid throughput taste measurement system to signal detection theory (SDT) using human subjects.

Authors: *R. K. PALMER, M. K. STEWART;
Opertech Bio, Philadelphia, PA

Abstract: Introduced as an alternative to traditional psychophysics, SDT is a conceptual framework that takes into account the bias inherent in any sensory system as a determinant of stimulus discrimination. Although successfully applied to measurements of responses in a broad variety of sensory modalities, application of SDT to taste measurement has been limited by the low throughput capacity and subjective nature of traditional taste panel methods. We have developed an automated rapid throughput system for the objective measurement of human taste, called TaStation^{TM} . The technology and accompanying methodology is based on presentation of randomly selected tastant solutions from a 96-well plate via an automated pipette mounted on a robotic gantry. Sample volumes are small (200 ul) and are self-administered by the subject upon the appearance of a prompt on a touch-sensitive computer display. Subjects are trained to associate a taste stimulus (representative of the basic tastes of sweet, salty, bitter, sour and water) with specific loci in a visual field on the display. The associations are achieved by rewarding correct touch-responses with virtual poker chips having assigned point value, whereas incorrect responses are penalized by subtraction of points from the tally. Subjects typically complete all 96 trials of taste stimuli in less than 45 minutes. We applied this methodology to an SDT design in which a subject's ability to discriminate between the tastes of 270 and 300 mM sucrose was quantified. In each of 6 consecutive test sessions, a single subject was randomly presented 16 trials each of water, 10 mM citric acid (sour), 0.5 mM quinine (bitter), 100 mM NaCl (salty), 270 mM sucrose and 300 mM sucrose (both sweet). In sessions 1 and 2, no reward or penalty occasioned a response on any trial, and a hit rate (H) of 0.71, false-positive rate (F) of 0.78, d' (a measure of discriminability) of -0.219, and c (decision criterion) of -0.663 were calculated, indicating a "liberal" bias on the part of the subject expressing a tendency to accept a high false positive rate on 300 mM sucrose trials to enhance capture of hits on the 270 mM sucrose trials. Sequentially adding a positive consequence (40-cent poker chip for correct responses) to sessions 3 and 4, and both positive and negative consequences (subtraction of 40 cents) in sessions 5 and 6, resulted in shifts of all parameters, with H=0.6562, F=0.5625, d'=0.245, and c=-0.280. Thus

by manipulating the consequences of responses to taste stimuli in the discrimination task, the bias of the subject was shifted to less liberal and discriminability improved.

Title: Rapid generation of concentration-response functions for taste in human subjects using an automated 96-well platform and interactive algorithms for taste measurement.

Authors: *M. M. STEWART, D. J. LONG, R. K. PALMER;
Opertech Bio, Philadelphia, PA

Abstract: Taste is a chemosensory phenomenon mediated by receptors expressed in highly specialized cells of the tongue. As such, taste responses in principle should be amenable to the methods of pharmacology for quantitative analysis of receptor-mediated processes. Critical to any pharmacologic analysis is the establishment of robust concentration-response functions. Applying the principles of pharmacology to the study of human taste has been impeded by prevalent low-throughput methodologies that rely upon large numbers of subjects subjectively evaluating a few samples at a time. We have developed a rapid throughput technology and methodology for human taste measurement, referred to as TaStation^{TM}, with the capacity for establishing robust concentration-response functions for taste in individual subjects within single 45-minute test sessions. An automated pipette mounted on a robotic gantry withdraws 200 ul of taste stimulus solution from a randomly selected well in a 96-well plate. The pipette then is presented to a subject seated before a touch-sensitive display. Prompts appear on the display that instruct the subject step-by step. When prompted, the subject removes the pipette from the gantry and self-administers the 200 ul of taste stimulus. After tasting, the subject then is prompted to respond by touching the display. Underlying a visual field on the display is a Cartesian grid in which specific sets of coordinates have been designated to be associated with basic taste standards (sweet, sour, bitter, salty, and water). Subjects learn the locations of the target coordinates through trial-and-error and are rewarded for correct responses by the appearance of

virtual poker chips carrying point values. Incorrect responses are penalized by reductions in the point tally. Once trained under this procedure, subjects are presented with novel stimuli (i.e., test articles that are not standards) and on these trials responses made anywhere on the display are rewarded. Using this approach we established robust concentrations-response functions for individual subjects within single test sessions. Nonlinear regression of data from a single test of Subject 1 (representative) yielded taste EC50s of 0.08, 4, 32, and 65 mM for quinine (bitter), citiric acid (sour), sucrose (sweet), and NaCl (salty), respectively. In a test of bitter taste, EC50s for denatonium and caffeine were 132 nM and 19 mM, respectively, were measured for Subject 1. The robust concentration-response functions generated through this technology enable a pharmacologic analysis, and thereby a more rigorous quantification of human taste than previously has been available.

Title: Neural processing of sweet taste in Hispanic young adults: An fMRI study.

Authors: *J. SZAJER[1], A. JACOBSON[2], E. GREEN[3,4], L. HAASE[5], C. MURPHY[1];
[1]Joint Doctoral Program in Clin. Psychology, SDSU/UC San Diego, San Diego, CA; [2]San Diego State Univ., San Diego, CA; [3]Dept. of Veteran's Affairs, VA Palo Alto Hlth. Care Syst., Palo Alto, CA; [4]Dept. of Psychiatry and Behavioral Sci., Stanford Univ. Sch. of Med., Palo Alto, CA; [5]Dept. of Psychiatry, Univ. of California San Diego, San Diego, CA

Abstract: Research on what is known as the “Hispanic Paradox” has revealed that individuals of Hispanic ethnicity have a higher prevalence of and risk for diabetes than Caucasians. Increasing evidence points to biological bases for these differences, as well as lifespan environmental and lifestyle factors (e.g. diet and eating behavior). Notably, brain response to the physiological states of hunger and satiety has been shown to differ as a function of factors related to risk for diabetes, and differences in brain activation have been associated with childhood diabetes in

Hispanic populations. However, there has been insufficient research on the neural correlates of ethnic and cultural differences in the risk for diabetes in adulthood. Research suggests the typical Hispanic diet includes high consumption of high energy food, such as fructose. Taste is a primary determinant of risk factors like food selection. Differences in the neural response to taste stimuli have been associated with risk factors for diabetes such as obesity and poor nutrition. As such, understanding the neural response to sweet taste stimuli in healthy Hispanic adults is an important first step in characterizing the potential neural mechanisms for this behavior. We used fMRI to examine differences in brain activation during the hedonic evaluation of a sweet taste stimulus (sucrose) as a function of ethnicity (Hispanic vs. Non-Hispanic young adults) and hunger state. Taste stimuli were administered orally during two sessions using a GE 3T-750 scanner: in a fasted state (hunger) and after a caloric preload (satiety). Stimuli were rated for pleasantness on a generalized labeled magnitude scale during each scan session. Data were analyzed at the group level controlling for BMI and age, using the AFNI 3d Mixed Effects Meta Analysis (3dMEMA) program. During hunger, Hispanics had significantly less activation than non-Hispanics in regions critical for taste and reward valuation (e.g. frontal operculum, and frontal and orbitofrontal cortices). During satiety, Hispanics had significantly greater activation in voxel clusters including memory (e.g. hippocampus, entorhinal cortex) and emotion (e.g. amygdala). Differences in processing of sweet tastes have important clinical and public health implications, especially considering increased risk of diabetes in Hispanic populations. Future research aimed at better understanding relationships between health risk and brain function in Hispanic adults is warranted to better conceptualize and develop interventions for these populations.

Title: Paradoxical gustatory intensification from traumatic anosmia

Authors: T. LOPES[1], *G. HANSRA[2,1], A. R. HIRSCH[3];
[1]Caribbean Med. Univ., Willemstad-Curacao, Netherlands Antilles; [2]Chicago, IL; [3]Smell & Taste Treatment and Res. Fndn., Chicago, IL

Abstract: Objective: Up to 90% of flavor is due to retronasal smell. Despite this, traumatic anosmia without a reduction in flavor has been reported. Contrastingly, actual flavor enhancement due to orthonasal anosmia has not been reported.
Method: Case Study: A 19-year-old female flipped over a golf cart while driving and sustained a skull fracture with loss of consciousness and intracranial hemorrhage, with anterograde amnesia for 20 minutes and retrograde amnesia for 5 minutes. Shortly thereafter, she noted inability to smell other than for occasional olfactory windows with a whiff of odor. There is no dysosmia, phantosmia, parosmia, or cacosmia. She did admit to flavorful eructation. Despite such loses, not only did she deny any taste loss but actually noted that her sense of taste was exaggerated. Before the trauma her sense of taste was 100% (normal), whereas afterwards, her sense of taste grew to 120% (hypergeusia), such that garlic paste was now too intense and hot sauce was too strong. Her taste acumen remained impeccable such that she was easily able to differentiate foods with mild flavor differences including; types of chocolate, blueberry vs. strawberry yogurt, flavors of almond milk, flavors of rice, and even 312 beer vs. Bud Lite beer. The taste of foods were so magnified that it was "an explosion in [her] mouth-unexpected." This amplified flavor perception has persisted for over 4 months since the trauma. Her preferences have changed in that before she despised alliaceous vegetables and now is partial towards the flavor and seeks them out. Moreover, before she preferred food bland but now prefers them highly seasoned.
Results: Abnormalities on physical examination: Neurological examination: Mental status examination: Digit span: 5 forwards and 3 backwards. Recent recall: 3 of 4 objects in 3 minutes without improvement with reinforcement. Chemosensory: Olfactory: (anosmic). Q-SIT Quick Smell Identification Test: 1 of 3 (anosmic). Olfactometer Identification Test: left nostril 7.00, right nostril 3.00 (anosmic). Brief Smell Identification Test: 7 (abnormal). Snap and Sniff Phenylethanolamine Threshold: left > -2.0, right > -2.0. Alcohol Sniff Test: 0. Retronasal smell: Jelly Bean Difference Test: 2 (abnormal). Gustatory: 6-n-propylthiouracil Disc Test: 10 (normal).
Discussion: Possible mechanisms include; olfactory loss induced disinhibition of gustatory sensation, narcissistic loss with overcompensation and unconscious denial, multisensory input induced illusion, and oral sensory epiphany in the absence of warning smell. The new preference for alliaceous and spicy food suggests compensatory trigeminal and gustatory stimulation.

Title: Role of insulin-1 in conditional taste aversion learning paradigm

Authors: *S. PANGULURI;
Col. of Pharm., Univ. of South Florida, Tampa, FL

Abstract: Conditioned taste aversion (CTA) is an adaptive behavior that benefits survival of animals including human, and is a powerful model to study the neural mechanisms of learning. Accumulating evidence suggests that this learning-dependent modulation of taste preference relies on direct axonal projections from the PBN to the ventral forebrain. We also know that long-term memory formation is a necessary component of CTA learning, which requires protein synthesis and altered gene expression. Of the forebrain areas the role of amygdala (CeA and BLA) in CTA has been studied most for its role in long-term memory formation. There is evidence demonstrating that CTA learning is correlated with altered expression of specific genes like Fos and Jun in forebrain and brainstem nuclei, and, at least for Fos expression in the amygdala, a functional role is implicated. Undoubtedly, the regulation of additional unidentified genes plays a role in the establishment and maintenance of taste preference/aversion memories. Other than the expression pattern of these immediate-early genes, little is known about the regulation of target gene expression induced by CTA. As a first step to address this gap in knowledge, we utilized rat whole genome chips to identify genes in the amygdala whose activity either increased or decreased following CTA learning. Using rigorous filtering of the data set followed by validation and confirmation with qRT-PCR and Western blotting or ELISA, we identified 4 of 10 select genes including adrenergic receptor 2b, insulin-1, oxytocin, and major histocompatibility complex class I-C play a role in CTA learning specifically in amygdala. Finally, behavioral analyses demonstrated that blockade of insulin signaling centrally using a high affinity insulin receptor antagonist disrupted CTA learning. To further understand the exact role of insulin-1 in CTA behavior, we utilized bilateral injections of lentivirus carrying insulin-1 specific shRNA in amygdala (both BLA and CeA) of rats. Control groups were injected with scrambled shRNA lentivirus. One week after lentiviral injection, these rats were subjected to CTA behavior test and the data was analyzed. Based on our data, specific injection of insulin-1 shRNA in amygdala does not disrupts the CTA acquisition in rats, but effects long-term memory formation. Molecular insight of insulin in amygada for CTA learning is therefore warranted to understand its complete mechanism of action.

Title: Innocuous experience enhances aversion learning and affects aversion-related neural activation

Authors: *V. FLORES, D. LEVITAN, T. PARMET, D. B. KATZ;
Brandeis Univ., Waltham, MA

Abstract: In conditioned taste aversion (CTA), an animal learns to avoid a particular taste that has been paired with malaise. Familiarity with future conditioned taste stimuli (CS) is known to influence the strength of aversion learning; the effect of familiarization with innocuous tastes—tastes other than the CS—has received little investigation, however. Our previous work demonstrated that pre-exposure to salty and sour tastes strengthened a later learned aversion towards novel sucrose, and showed that the phenomenon scaled with both the number of tastes in the pre-exposure array and with the number of pre-exposure sessions. The present studies begin an inquiry into the neural underpinnings of this phenomenon, using c-FOS, optogenetics, and (in future work) electrophysiology. The use of c-FOS enabled us to survey many possible relevant brain sites, but inquiry focused on gustatory cortex (GC), which is known to be involved in the integration of experience with taste behavior. Rats that had been pre-exposed to innocuous tastes demonstrated higher levels of c-FOS in GC after exposure to novel sucrose, compared to animals that had been pre-exposed to water alone. Furthermore, optogenetic inhibition of GC during pre-exposure sessions reduced the magnitude of a later CTA to novel sucrose, rendering taste pre-exposed rats identical to rats exposed to water alone. These results suggest that GC plays a controlling role in determining the impact of innocuous experience on learning-related behavior.

Title: Transcription factors to define subsets of taste neurons in the geniculate ganglia of adult mice

Authors: *G. DVORYANCHIKOV[1], D. HERNANDEZ[1], N. CHAUDHARI[1,2];
[1]Physiol. and Biophysics, [2]Program of Neurosci., Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: Sensory neurons included in dorsal root (DRG) and cranial ganglia are highly diverse, functionally and morphologically and concordantly, express various molecular markers. The determinants of this molecular diversity during development and in the adult are transcription factors (TFs) that orchestrate the gene expression program to generate functionally specialized neurons. While the transcriptome of somatosensory ganglia (dorsal root and trigeminal) have been assessed, the ganglia that include taste afferents are less explored. To understand the basis of the diversity of taste afferent neurons, we examined transcription factors expressed in individual neurons of the geniculate ganglion (VIIth nerve) in adult mouse. RNAseq data were obtained from mouse geniculate ganglia and compared to those from trigeminal ganglia. To identify candidate TFs that may determine neuronal diversity, we screened for those expressed at levels ≥ 2-fold higher in geniculate relative to trigeminal ganglia. From this list of TFs we selected 15 to analyze further by RT-PCR, first in 4 pools of 8-10 neurons each. Seven of these TFs were further analyzed by single-cell RT-PCR on 20 taste afferent neurons (labeled with TRITC-dextran via the chorda tympani taste nerve). Of the 7 analyzed, 2 TFs (Skor2 and Zbtb7c) were not detectable in labeled taste neurons. The remaining 5 TFs (Phox2b, Eya1, Eya2, Pbx3, and Tcf4) were found to be expressed in variable numbers of taste neurons. Specifically, Phox2b, previously reported as taste-associated, was detected in 17 of 20 taste neurons. 3 of 20 neurons displayed expression of all 5 of these potential taste-related TFs. Eya2 expression was detected in 8 of 20 (40%) taste neurons. To examine their pattern of expression, we label neurons from the chorda tympani and greater superficial petrosal nerves (which carry afferent fibers to tongue and palate respectively) and use the ganglia for immunofluorescent histochemistry for TFs. We are currently testing TFs identified as above to assess which are expressed in non-overlapping sets of taste neurons and thus may represent distinct functional groupings.

Title: Effect of color on taste thresholds

Authors: *S. NAGAHAMA;
Human care, Teikyo Heisei Univ., Tokyo, Japan

Abstract: Several reports have demonstrated that color can influence a person's ability to distinguish threshold levels of the four basic tastes (sweet, salty, sour and bitter). Maga (1974) reported that red colored water solution did not affect the sensitivity of sweet and sour, but decreased bitter taste sensitivity. Color did not affect salty taste sensitivity significantly. Kostyla and Clydesdale (1978) found that red increased sweetness perception and other color (blue and yellow) had only minor effects on sweetness. Clydesdale (1993) concluded that color had little effect on the perception of saltiness. The author hypothesized that the effect of color on taste threshold is affected by food culture which varies by country and/or generation. This study reported the influence of color solution on recognition thresholds of four basic tastes by untrained Japanese college-age (ranging from 20 to more than 22 years of age) students. Participants were 15 female and 15 male healthy volunteers not complaining of taste disorders. Simultaneously, participants were all non-smokers. In this study, the whole mouth gustatory method was prepared. The series of taste solution presented the four basic tastes, i.e., sweet, salty, sour and bitter, which were prepared using sucrose, common salt, acetate and quinine, respectively. Each taste test was done individually and distilled water was available at all times. Results of the threshold tests showed that red color had the effect of lowering the threshold of sweet and salty taste, while sour and bitter taste sensitivities were not affected. Blue color decreased the thresholds of saltiness and bitter taste. In the case of sweet and sour taste, both of the thresholds were increased by blue color. These results showed that the influence of color on four basic tastes was different from the previous reports.

Title: When matter matters: taste of solids versus liquids

Authors: *S. KANWAR[1], M. R. CHAND[2], A. R. HIRSCH[2];
[1]Neurol., Smell and Taste Treatment and Res. Fndn., Miramar, FL; [2]Smell and Taste Treatment and Res. Fndn., Chicago, IL

Abstract: Objective: Whether in liquid or solid form, the substance remains the same. One would anticipate that variation between the states of matter would not affect taste since they have equivalent concentrations of specified ingredients. It's been noted that in normogeusic individuals, solid sugar tastes less sweet than the same sugar in liquid form. In those with chemosensory disorders, loss of taste of solids with preservation of liquids has not heretofore been described. Methods/Results: **Case 1:** A 60 year old female with eight years of Burning Mouth Syndrome presented with a four month history of being able to taste sweet in liquid form but not in solid or semi-solid. Chemosensory testing: Brief Smell Identification Test (BSIT): 10 (hyposmia). Retronasal Smell Index: 7 (normal). Propylthiouracil disk taste test: 6 (normogeusia). Intensity of 1 gram dextrose, maltodextrin, sucralose (Splenda) applied onto tongue in solid form: 3/10, liquid form: 7/10. **Case 2:** A 60 year old female presented with a one year impaired ability to taste, dysgeusia, cacogeusia and salty phantogeusia. She is unable to taste solid food, but her sense of taste to liquids is normal. Physical Examination: General: Scalloped tongue. Chemosensory testing: Olfaction: BSIT: 11(hyposmia). Quick Smell Identification Test: 2 (hyposmia). Retronasal smell index: 2 (abnormal). Gustation: Propylthiouracil disk taste test: 9 (normogeusia). Discussion: Theories postulated for the effect of taste between solids and liquids are myriad. Spatial summation of taste with liquid dispersion throughout the oral cavity; taste enhancement with colder temperatures, with liquid being cooler than solid; and counter-stimulus of the solid granules inducing pressure sensation through stimulation of the Pacinian corpuscles thus inhibiting taste. Sucralose is often mixed with dextrose and maldextrin as bulking agents from corn, which composes majority of the molecule as a filling agent of splenda. When crystallized, it may cover the sucralose component causing decreased sweet sensation, but when in water, the sugar component is released which is more potent. The T1Rs in taste suggest that sweet and umami taste receptors share a common subunit. With this, there may be a dominance of glutamate (umami) over glucose (sweet) taste in solids, which causes umami taste more than sweet. In liquids, it is reversed and there's a predominance for sweet more than umami. Formal assessment of liquid versus solid taste in those with chemosensory dysfunction is warranted.

Title: Role of innervation in HH signaling in the adult mouse fungiform taste papilla

Authors: A. KUMARI[1], B. L. ALLEN[2], R. M. BRADLEY[1], A. A. DLUGOSZ[3], *C. MISTRETTA[1];
[1]Univ. Michigan Sch. Dent., Ann Arbor, MI; [2]2Department of Cell and Developmental Biology, Med. Sch., [3]Dept. of Dermatology, Med. Sch., Univ. of Michigan, Ann Arbor, MI

Abstract: Inhibition of the Hedgehog (HH) signaling pathway leads to disruption of fungiform papilla (FP) taste organs and loss of taste buds (TB) but innervation to taste organs is retained. However, it is known that cutting the innervation to TB and FP organs also leads to loss of taste buds. To study potential interactions between innervation and HH signaling, we unilaterally severed the combined chorda tympani/lingual nerve (CT/LN) in mice carrying a HH-responsive *Gli1lacZ* allele, and stained for β-Galactosidase activity to identify cells with active HH signaling. We removed a few mm of the nerve where it runs deep in the neck to permanently interrupt the chorda tympani nerve (CT, Cranial Nerve VII) innervation to taste buds and the lingual nerve (LN, Cranial Nerve V) innervation to the FP organs and anterior tongue epithelium. In the contralateral Control side of the tongue the CT/LN nerve was exposed but not cut. In initial studies, after 21 days we measured effects on FP and TB integrity and the location of HH-responding cells, and used immunohistochemistry to identify CT fibers (P2X3 antibody), CT/LN fibers (NF), HH ligand (SHH) and taste bud cells (K8). In FP on the uncut Control side of the tongue, TBs were observed in about 85% of FP, SHH was within TB cells, and HH-responding cells were distributed throughout basal epithelial cells in lateral papilla walls, in the perigemmal epithelial cells around the taste bud, and in stromal cells of the FP. In the tongue half with nerve cut, TBs were undetectable in about 70% of FP; cell remnants of TBs were observed in about 10% of FP; and, typical TB were seen in about 20% of FP. Loss of taste bud cells after nerve cut was associated with loss of TB-restricted SHH and elimination of HH-responding, *lacZ+,* perigemmal cells and basal cells in epithelium of the FP. However, in a majority of FP, HH-

responding cells remained in the FP stroma. Whereas P2X3+ fibers were eliminated in FP with TB loss, some NF+ fibers remained in about 70% of the papillae without TBs and these were in close proximity to the stromal HH-responding cells. In summary, TBs, SHH ligand and HH signaling activity are largely eliminated in the FP epithelium after CT/LN nerve cut. P2X3+ fibers also are eliminated and NF+ fibers are decreased in the FP. Interestingly, the presence of NF+ fibers in the FP stromal core correlates with the presence of HH-responding cells in the stroma that associate with these nerve fibers. We propose that NF+ fibers transport HH ligand into the FP core that can maintain HH signaling in the stroma even in the absence of TB-derived SHH. Supported by NIH NIDCD R01 DC0114428.

Title: Normosmic normogeusic subjective ageusia, why is food tasteless if I can smell and taste?

Authors: *P. KHEIRKHAH[1], A. HIRSCH[2];
[1]Neurosurg., UIC, Chicago, IL; [2]Smell & Taste Treatment and Res. Fndn., Chicago, IL

Abstract: Introduction: Complaints of ageusia with normal taste, normal orthonasal smell, and normal retronasal smell has not heretofore been described. Two such cases are pre- sented.
Method: Case study:
Case 1: A 59 years old female with a lifelong history of geo- graphic tongue. One year prior to presentation, developed a flu and burning in her mouth. The next day she noted total loss of taste without recovery since then. She admits to occasional dysgeusia, but denies flavorful eructation or any smell dysfunction.
Results: Chemosensory testing: Dirhinous Olfactory Testing: Brief Smell Identifi- cation Testing: 12 (normosmia). Retronasal Smell Testing: Retronasal Smell In- dex: 5 (normal). Gustatory Testing: Propylthiouracil Disk Taste Test: 10 (normo- geusia).
Case 2: A 53 year old right handed male, was nasute until falling and striking his head with loss of consciousness, two years prior to presentation. Initially he had no ability to smell at all, but it gradually returned to what he perceives to be 85% of normal. He does admit to flavorful eructation. Concurrent with smell loss there was impaired taste and continues detecting only highly spicy foods. Results: Chemosensory testing: Dirhinous olfactory testing: Brief Smell

Identifica- tion Test: 11 (normosmia). Pocket Smell Test: 3 (normosmia). Alcohol Sniff Test: 17 (normosmia). Olfactometer Smell Identification test: left nostril 18 (normosmia), right nostril 15 (hyposmia). Retronasal Smell Testing: Retronasal Smell Index: 9 (normal). Gustatory Testing: Propylthiouracil Disk Taste Test: 9 (normogeusia). Taste threshold : normogeusia to sodium chloride, sucrose, hy- drochloric acid, urea and phenylthiocarbamide.
Discussion The origin for these patient's complaints is unclear. The possibility of this being a primary psychiatric problem, or chemosensory malingering should be entertained. On the other hand, the primary problem may be in the testing strate- gy. The tests might not have been sensitive enough to detect a mild sensory deficit- presenting with high intensity testing stimuli may register normal, even when a true deficit is present (false negative). Alternatively, they may have had an exceptionally good taste or retronasal smell prior to loss, and after the loss it dropped a little bit, but still within the normal range, but low for their baseline abil- ity. This combined with a personality which may have induced them to be ultra- sensitive to small losses of function, may have been sufficient to cause them to perceive that all their taste is gone. Given the above, detailed chemosensory and psychiatric tests in those who complain of smell or taste loss, in the absence of chemosensory deficits, is warranted.

Title: Temperature dependent dysgeusia: a reverse Goldilocks syndrome

Authors: *A. DUNN[1], A. HIRSCH[2];
[1]Lake Forest Col., Lake Forest, IL; [2]Smell and Taste Treatment and Res. Fndn., Chicago, IL

Abstract: Introduction: Dysgeusia inhibited by extreme hot and cold temperature has not been described. Such a case is presented. **Methods:** Case study: A 60 year old right handed woman was nasute until 7 months prior to presentation when she slipped, striking the back of her head with loss of consciousness. A few days later she noted trouble tasting. She can taste pickles and sweet food but nothing else. She feels her ability to taste is 20% of normal. She also complains of salty dysgeusia, which is temperature dependent, for instance water at room temperature tastes salty but very hot or ice water tastes normal. Similarly, solid semisweet Tollhouse chocolate chips taste salty, but when heated into liquid form, they taste like chocolate. Some foods only obtain flavor when heated, for instance chocolate brownies and tomato soup at room temperature

are without taste, but when heated, the brownies have a normal flavor. **Results:** Chemosensory testing: olfaction: Brief Smell Identification Test: 11 (normosmia). Alcohol Sniff Test: 19 (normosmia). Pocket Smell Test: 2 (hyposmia). Quick Smell Identification Test: 2 (hyposmia). Retronasal smell testing: Retronasal Smell Index: 9 (normal). Gustatory testing: propylthiouracil disc taste test: 9 (normogeusia). Taste threshold: normogeusia to urea, phenylthiocarbamide, sucrose, and hydrochloric acid. Mild hypogeusia to sodium chloride. Taste quadrant testing: impaired citric acid on the palate. Whole mouth weakness to sodium chloride and sucrose. Fungiform papillae count right: 18, left: 22 (normal). CAT scan of the brain: mild to moderate small vessel ischemic changes. **Discussion:** High and low temperatures may stimulate small C-fiber pain discharges, and the pain may act to inhibit the distorted taste. Possibly temperature extremes cause cognitive distraction, leading the patient to focus on the temperature instead of the distorted taste, therefore reducing the perception of taste. Maybe the salty dysgeusia is a minor manifestation of burning mouth syndrome, both representing pathology in the gustatory nerves, and thus, as temperature extremes help burning mouth syndrome, it would help other gustatory nerve dysfunction, i.e. dysgeusia. Since those with dysgeusia are often unable to eat due to the unpleasant taste, and with subsequent loss of weight, one possible approach for this condition would be providing foods at temperature extremes, reducing dysgeusia, hence inducing greater palatability of foods.

Title: Objective chemosensory testing in subjective salty hypergeusia; report of three cases

Authors: *K. KAVEH[1], K. NATASHA[2], A. R. HIRSCH[2];
[1]Smell and Taste Treatment and Res. Foundation,, Chicago, IL; [2]Smell and Taste Treatment and Res. Foundation, Chicago, IL, chicago, IL

Abstract: Introduction Three patients with subjective salty hypergeusia who underwent chemosensory testing are reported. **Methods: Case Studies:** Case 1: Four years prior to presentation, a 49 year old left-handed (familial) woman, suffered a subdural hematoma and intracranial hematoma. One month later, she lost all smell and taste except for salt too intense, at 150% more than normal. **Results**: Chemosensory testing: olfaction: Anosmia on all olfactory

tests including: Quick Smell Identification Test (QSIT), Alcohol Sniff Test (AST), Sniff Magnitude, Olfactometer Butanol Threshold and Identification, Brief Smell Identification Test (BSIT), Suprathreshold Amylacetate Odor Intensity and Amylacetate Hedonics, Sniff-N-Sticks and Retronasal Smell Index (RSI). Gustation: normogeusic to Propylthiouracil Disk and Threshold to sodium chloride, sucrose, hydrochloric acid, urea, and phenylthiocarbamide. Case 2: A 60 year old right-handed woman struck her head with loss of consciousness. A few days later, noted loss of taste, with ability to only taste pickles and sweet, dysgeusia wherein water and most foods taste salty, a constant salty phantogeusia, and salt hypergeusia hypergeusia, where salt tastes 200% more intense than it should. **Results**: Chemosensory testing: olfaction: normosmic to BSIT and AST. Hyposmic to QSIT and Pocket Smell Test. RSI: 2 (abnormal). Gustatory testing: normogeusic to propylthiouracil disk and Threshold to sucrose, hydrochloric acid, urea, and phenylthiocarbamide. Mild hypogeusia to sodium chloride. Case 3: A 60 year old right handed woman presented with eight years of intermittent burning mouth syndrome. Four months prior to presentation, she noted a constant salty taste followed two weeks later by total absence of taste, wherein everything tasted sour, gradually changing to metallic. Salty foods were 120% more salty than normal. **Results**: Chemosensory testing: olfaction: normosmia to AST, Pocket Smell, BSIT and RSI. Gustation normogeusia to Propylthiouracil Disk and Threshold to sodium chloride, hydrochloric acid, urea, and phenylthiocarbamide. Ageusia to sucrose. Other: MRI of brain with and without infusion: right cerebellar hemisphere, small infarction. **Discussion** The common findings in this group were abnormal AST and normal Propylthiouracil Disc Taste Test. Despite this normal taste test, there may be an impaired ability to taste, since this test only assesses the ability to taste bitter. The impaired olfactory ability based on AST may indicate a primary defect in olfaction; smell may act to inhibit intrinsic salt taste discharge. With smell impairment, salt perception would be disinhibited, thus increasing salt perception.

Title: Characterizing receptive fields in awake primate auditory cortex using principled correction of the spike-triggered average

Authors: *J. BIGELOW, R. E. BEITEL, B. J. MALONE;
UCSF, San Francisco, CA

Abstract: Characterizing auditory cortical receptive fields has been the subject of numerous studies, the majority of which have been conducted in anesthetized cats and ferrets. Comparatively little is known about auditory cortical receptive field structure in nonhuman primates. Considering the extensive homologies between human and nonhuman primate auditory cortex, characterizing auditory receptive fields in primates could serve as an important model of auditory cortical processing, with particular relevance for developing neural prostheses. Because anesthesia is known to affect response properties of auditory cortical neurons, studies using awake preparations are especially needed. The current study characterized spectrotemporal receptive fields (STRFs) in primary auditory cortex of two alert squirrel monkeys (*Saimiri sciureus*). Extracellular single- and multi-unit recordings were obtained using 16-channel linear multielectrode arrays (150 μm spacing), with neurophysiological traces sampled at 30 kHz. The spectrotemporal preferences of each unit were probed with a 30-m dynamic moving ripple (DMR) stimulus presented through a free field speaker from a central distance of ~40 cm. A novel 30-s DMR segment was subsequently presented (50 repetitions) to assess the prediction accuracy of the STRF estimates. STRFs were estimated by computing the average DMR spectrogram preceding each spike (spike-triggered average [STA]), at a resolution of 193 frequency bins and 200 time lags (1 ms). Although the STA can theoretically reflect an unbiased estimate of the STRF, we found that a two-step correction procedure nearly doubled prediction accuracy across units, presumably reflecting more accurate STRF estimates. First, a conventional amplitude threshold was used identify regions of the STRF that exceeded chance values obtained from simulated STRFs computed for each unit using circularly shifted spike times to preserve the spike rate and inter-spike interval distribution. Second, a cluster size threshold was used to limit clusters that survived the amplitude threshold to those that exceeded chance cluster size values obtained from simulated STRFs subjected to the same amplitude threshold. The amplitude and cluster size thresholds were optimized for each unit by cross-validation to maximize the correlation between predicted and observed responses to the repeated DMR segment. On average, this procedure resulted in a liberal amplitude threshold but a conservative cluster size threshold. The resulting corrected STRF estimates are used to provide a detailed characterization of spectrotemporal response properties of awake primate auditory cortex.

Title: Noise-robust encoding of frequency modulation in awake primate cortex

Authors: *B. J. MALONE[1], M. HEISER[2], R. BEITEL[1], J. BIGELOW[1], C. SCHREINER[1]; [1]Otolaryngology & Head & Neck Surgery, UCSF Sch. of Med., San Francisco, CA; [2]Dept. of Psychiatry, Child and Adolescent Div., UCLA Semel Inst. for Neurosci. and Behavior, Los Angeles, CA

Abstract: Natural listening environments are often characterized by multiple 'noise' sources that compete with 'signals' of interest. The presence of noise is thought to degrade central representations of competing signals by suppressing responsiveness via shifts in threshold, or obscuring the representation by eliciting responses unrelated to the signal. We tested this assumption by recording multi-unit cortical responses to logarithmic frequency-modulated (FM) sweeps against backgrounds of white noise at signal-to-noise ratios (SNRs) spanning over 20 dB. Awake squirrel monkeys were trained to sit quietly in an acoustically transparent primate chair. Recordings were obtained using 16 channel linear probes while sounds were presented on a free field speaker. FM sweeps were presented at 6 different velocities designed to encompass the range of FM rates typical of vocalizations in this species (e.g., twitter calls). Ascending and descending sweeps were presented for a total of 12 distinct trajectories. One FM sweep was also presented at several sound levels. We evaluated the effects of the SNR condition by comparing the performance of nearest-neighbor Euclidian distance classifiers tasked with decoding and sweep trajectory (i.e., velocity and direction) and sweep level as the noise level was varied. FM sweeps were also presented in isolation for the purposes of comparison. Roughly a third of cortical sites decoded sweep trajectory best for FM sweeps presented in isolation. Another third decoded sweep trajectory as well in presence of moderately unfavorable SNRs (0 to -10 dB) as they did against a silent background. A final third of cortical sites exhibited enhanced decoding performance in the presence of noise. The cortical representation of the FM sweeps consisted largely of sharp peaks in the peristimulus time histogram aligned with the intersection of the

sweep with the site's best frequency. Generally speaking, increasing noise levels and increasingly negative SNRs either reduced or eliminated these peaks, but did not increase baseline firing rates: firing rates during intervals excluding the sweeps but including the noise were essentially constant across SNR conditions. As a result, it was possible to decode information about the SNR condition for identical sweeps only if the analysis interval included the sweeps themselves. Effectively, the SNR context modulated the transmission of information about the sweeps but adaptive mechanisms compensated for global changes in the noise level. These results suggest that signal transmission in the central auditory system is organized to ensure robust information transfer in a wide range of listening contexts.

Title: Locomotion modifies sound perception in mouse primary auditory cortex

Authors: *A. G. GUSEV, M. WEHR;
Psychology, Inst. of Neuroscience, Univ. of Oregon, Eugene, OR

Abstract: We performed cell-attached recordings from 460 neurons throughout the depth of primary auditory cortex in awake, head-restrained mice. We compared baseline firing rates and and evoked responses in two behavioral states of the mouse: quiet sitting and locomotion on a ball. In the majority of neurons, locomotion decreased baseline firing rates, but a substantial population of neurons showed increased baseline firing rates. We measured sound-evoked responses to either white noise or CF tones, delivered in free field. About 30 percent of neurons were initially suppressed by sound, which could be due to binaural effects of the free-field sounds arriving at both ears. Excitatory responses in the remainder of neurons were either monophasic (a sustained increase in firing rate) or biphasic (an initial increase in firing rate, followed by suppression that typically lasted three times longer than the excitatory phase). Locomotion decreased both baseline and evoked firing in the majority of neurons in cortical layers L2 through L5, although a substantial population of neurons showed increased baseline and evoked activity. Suppression during locomotion transformed responses in two ways:

monophasic excitatory responses were converted into biphasic responses, and biphasic responses were converted into monophasic suppression. Comparison of white noise and CF stimulation revealed distinct effects of locomotion on surround suppression, non-monotonic intensity tuning, and off responses.

Title: Neural response differences in the rat primary auditory cortex under anesthesia with ketamine versus the mixture of medetomidine, midazolam and butorphanol

Authors: *H. OSANAI, T. TATENO;
Hokkaido Univ., Sapporo, Hokkaido, Japan

Abstract: Although anesthesia is known to affect central auditory processing, it is unclear the extent to which the choice of anesthetic agents exerts different effects on neural responses to sound stimulation. A mixture of three anesthetics (medetomidine, midazolam and butorphanol) was recently developed as an alternative to ketamine, which has potential addictive effects. However, little is known about the effect of this combination of anesthetics on neural responses. In this study, we compared spontaneous activities, tuning properties, the temporal response properties, and the oscillatory activities of primary auditory cortical (A1) neurons under these two anesthetic conditions, using multi-channel electrophysiology. In addition, we identified the A1 using flavoprotein endogenous imaging before electrophysiology, which takes less than half an hour and thus enables efficient electrophysiological recording. Frequency tuning properties did not show a significant difference. In contrast, neural activities under the combination anesthesia showed decreases in the spontaneous and tone-evoked firing rates in a layer-dependent manner. Moreover, the temporal response patterns were also different between the

anesthetics in a layer-dependent manner. On the other hand, the amplitude of sound-driven oscillations was decreased in high gamma activities (over 120 Hz) across cortical layers under the combination anesthesia, whereas we found no differences in activities including lower frequency components (< 120 Hz), which may reflect differences in the anesthetic mechanisms. Our results provide a fundamental view of how response properties in the primary auditory cortex are affected by the choice of anesthesia.

Title: Response profiles of inferior colliculus neurons in young and old rats

Authors: *E. X. HAN[1,2], A. PARTHASARATHY[3], E. L. BARTLETT[1,2];
[1]Weldon Sch. of Biomed. Engin., [2]Dept. of Biol. Sci., Purdue Univ., West Lafayette, IN; [3]Mass. Eye and Ear, Harvard Med. Sch., Boston, MA

Abstract: The processing of auditory stimuli is affected at different levels of the central auditory pathway by aging. While there are in vivo single-unit studies involving auditory processing across aging in the inferior colliculus (IC), many of them failed to represent or predict the age-related impacts on IC neurons beyond a small number of stimuli dimensions, either due to using simple stimuli measuring one or two aspect, or treating IC neurons as a fundamentally homogenous group with varying spectrotemporal preferences. In this study, we aim to address this issue by analyzing responses towards various spectrotemporal stimuli from individual neurons to establish their “neuronal profiles”. We recorded in vivo single-unit responses from the IC of young and aged F334 rats in response to simple stimuli, such as tones and wide-band or band-passed noise, and more complex sounds, such as random spectrum stimuli. Our study indicates that aging may take different electrophysiological effects on individual IC units. Such effects might be less evident when only a few stimulus dimensions are considered.

Title: Varying frequency in vagus nerve stimulation to optimize plasticity in the rat auditory cortex.

Authors: *E. BUELL[1], M. BORLAND[2], K. LOERWALD[2], M. KILGARD[2];
[1]Univ. of Texas At Dallas, Richardson, TX; [2]Univ. of Texas at Dallas, Richardson, TX

Abstract: Vagus nerve stimulation (VNS) is an FDA-approved treatment option for patients suffering from depression or epilepsy. Repeatedly pairing stimulation of the vagus nerve with a sensory stimulus increases the number of responding cortical neurons. Such changes have been observed in the primary auditory cortex (A1) when pairing a pure tone with VNS, as well as in the primary motor cortex when pairing a movement with VNS (Engineer et al., 2011; Porter et al., 2012). Patients with tinnitus have reported long-lasting relief from VNS treatment paired with tones outside their tinnitus frequency. However, no patient has yet reported having no perception of tinnitus as a result of this treatment. Inverted-U functions have been observed after altering the intensity of stimulation given per treatment session. Specifically, significant cortical changes were observed at 0.4-0.8 mA, but not at 1.2 or 1.6 mA (Borland et al., 2015). This function may exist in other parameters of VNS, as well.
Although it is clear that VNS drives plasticity, optimal parameters under which this treatment is delivered remain undefined. The purpose of this project is to investigate how varying levels of frequency (Hz) of VNS can change the degree of map plasticity, and optimize clinical treatment outcomes. Preliminary data suggest low frequency (7.5 Hz) decreases neuronal selectivity. Preliminary data suggests high frequency stimulation (120 Hz, 15 pulses) reduces neuronal responses to 8-16 kHz tones in the auditory cortex, whereas 30 Hz (standard) has been shown to increase responses in that range (Figure 1). These results indicate levels of stimulation frequency could have a role in efficacy of treatment in the clinical setting.

Title: Brain rhythms reveal how words integrate into phrases

Authors: ***A. TAVANO**[1], S. BLOHM[2], C. KNOOP[2], V. WAGNER[2], M. SCHARINGER[2], N. DING[3], O. GHITZA[4], D. POEPPEL[1,5], W. MENNINGHAUS[2];
[1]Dept. of Neurosci., [2]Dept. of Language and Literature, Max Planck Inst. For Empirical Aesthetics, Frankfurt, Germany; [3]Col. of Biomed. Engin. and Instrumental Sci., Zhejiang Univ., Hangzhou, Zhejiang Province, China; [4]Dept. of Biomed. Engin., Boston Univ., Boston, MA; [5]Dept. of Psychology, New York Univ., New York City, NY

Abstract: Low-frequency brain rhythms can track the main constituents in a linguistic hierarchy: phrases and sentences (Ding et al., 2016). Notably, cortical rhythms were cross-linguistically tested using English and Mandarin Chinese; they were found to reflect structure-building operations. Extending this paradigm to German, we here focus more explicitly on the integration of words into phrases. We hypothesized that neural rhythms tracking hierarchical levels of

phrases and sentences can vary in frequency depending on the size of the respective constituents. Participants listened to monosyllabic words (250 ms duration) continuously delivered to both ears at a constant (isochronous) rate of 4 Hz. The stimulus sequences constituted grammatically correct and meaningful four-word sentences with a two-word noun phrase followed by a two-word verb phrase. Phrase and sentence boundaries were not marked by acoustic cues. Stimuli were organized in blocks of 40 sentences, while electroencephalographic activity was recorded using 32 electrodes. The analysis used a Fast-Fourier transform run for the EEG data from each block. Results replicate the main findings of Ding et al. (2016), highlighting the extraction of phrase- and sentence-level parsing rhythms, at 2 Hz and 1 Hz, respectively, despite the absence of any acoustic cues at the corresponding rates. We then tested sentences with one word in the noun phrase and three words in the verb phrase. In this case, the 2 Hz rhythm was absent but substituted by a 1.33 Hz rhythm, which corresponds to the integration rate across the verb-phrase (three words, 750 ms) and which has no harmonic (multiple integer) relationship to the stimulus rate. As a control, we flipped the size of constituents, with three words in the noun phrase and one word in the verb phrase. Again, the 1.33 Hz rhythm surfaced, suggesting that the human brain tracks the size of phrases within a sentence using temporal integration processes reflected in low-frequency brain activity. These data constitute a next important step towards understanding the role of brain rhythms in on-line tracking of natural spoken language.

Title: Distortion of tonotopic maps in auditory cortex of rats following blast exposure

Authors: ***S. MASRI**[1,2], H. LUO[2], E. PACE[2], J. ZHANG[2], S. BAO[1];
[1]Univ. of Arizona, Tucson, AZ; [2]Otolaryngology, Wayne State Univ., Detroit, MI

Abstract: Blast exposure is often associated with traumatic brain injury (TBI) and central auditory processing disorders. Here we use an established rat model of blast exposure to investigate effects on tonotopic organization in primary auditory cortex (A1). We subjected adult

male Sprague-Dawley rats to a single 10-msec blast shockwave at 14 psi or 194 dB sound pressure level (SPL). Three weeks after exposure, behavioral tests showed that 5 of 7 rats had developed tinnitus. We then mapped A1 in control and blast-exposed rats using established electrophysiological techniques. Control animals showed tonotopically organized cortical frequency maps with all frequencies approximately equally represented. However, animals with blast-induced tinnitus often had expanded cortical representations of a narrow and apparently random frequency band. Consistent with ABR tests, hearing thresholds as measured at cortex were 7 dB higher for animals with blast-induced tinnitus compared to the control animals. Furthermore, cortical tuning properties were significantly broader in blast-exposed rats while cortical response latencies were significantly shorter. These data indicate that blast exposure induces a frequency nonspecific distortion of A1 frequency maps, which may contribute to blast-induced central processing disorders.

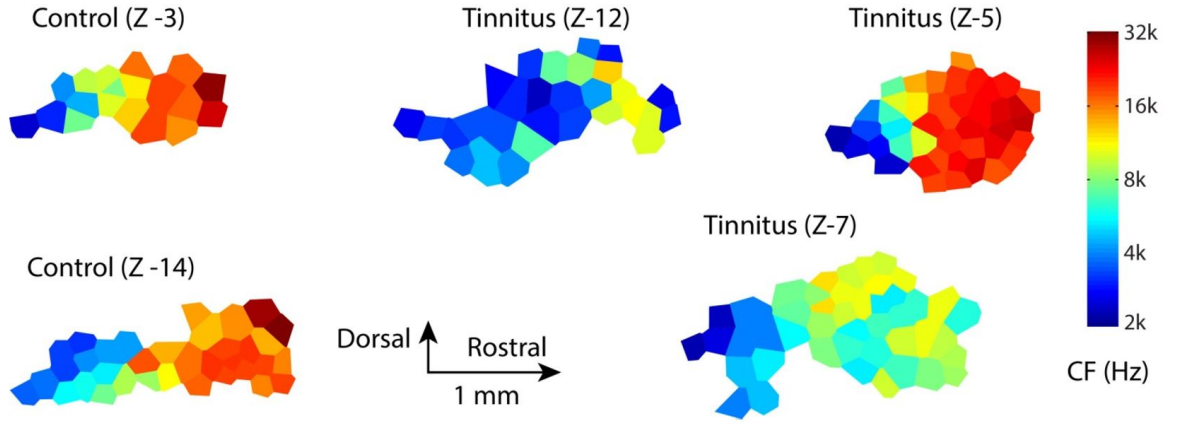

Figure 1. Representative cortical frequency maps showing disrupted cortical map in animals with blast-induced tinnitus. Compared to control maps (Z-3 and Z-14), maps from animals with blast-induced tinnitus often show enlarged representation of a frequency band. Z-12 had enlarged representation of low frequencies (blue colors), Z-7 had enlarged representation of middle frequencies (blue and yellow colors) and Z-5 had enlarged representation of high frequencies (red colors).

Title: Responses to sinusoidal frequency modulation in the guinea pig ventral cochlear nucleus

Authors: *N. PARAOUTY[1], A. STASIAK[2], C. LORENZI[1], I. WINTER[2];
[1]Dept. d'études cognitives-DEC IEC, Ecole Normale Superieure Paris, Paris, France; [2]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Background Many psychophysical studies have investigated the detection of sinusoidal frequency-modulation (SFM) and on the type of sensory information it predominantly relies on: temporal-envelope (ENV) resulting from cochlear filtering, or temporal fine-structure (TFS) cues conveyed by changes in the neural phase-locking pattern over time, or a combination of both. Few neurophysiological studies have addressed this issue and data is still lacking regarding the coding of SFM in the early stages of auditory processing (below inferior colliculus). This work aimed at characterizing the responses of ventral cochlear nucleus (VCN) neurons to SFM tones presented at various modulation depths and sound levels. **Methods** Single-units in normal-hearing anaesthetized pigmented guinea pigs were recorded extracellularly using tungsten-in-glass microelectrodes. Stimuli were 1-second SFM tones played at the unit's best frequency (BF), at modulation rates of 2, 5 and 10 Hz and modulation depths of 2, 4, 8, 16, and 32 % relative to BF. All stimuli were presented at positive and negative polarities and at several sound levels. **Results** VCN responses to SFM varied as a function of sound level, bandwidth and unit type. Shuffled correlogram analyses were carried out in order to assess the relative strengths of ENV and TFS coding for the different unit types in the VCN. For small modulation rates (≤5Hz) and small modulation depths (≤16%), low-CF units showed weak temporal ENV coding but high phase-locking to TFS. In comparison, high-CF units generally followed the stimulus ENV for most conditions. The transition region over which temporal coding changes from being dominated by TFS coding to ENV coding was around 1-2 kHz. **Conclusion** The results provide physiological evidence that SFM is encoded via neural phase-locking to TFS cues for low carrier frequencies and modulation rates, and via neural phase-locking to ENV cues at high carrier frequencies. The results also suggest weaker phase-locking to TFS in guinea pigs compared to other species. Further work will be carried out in order to assess the strengths of these two coding mechanisms in the presence of a hearing deficit.

Title: Thalamocortical circuitry of oscillatory phase reset

Authors: *M. N. O'CONNELL[1], A. BARCZAK[2], T. MCGINNIS[3], D. ROSS[2], P. LAKATOS[2,4];
[1]Nathan Kline Instit, Orangeburg, NY; [2]Nathan Kline Inst., Orangeburg, NY; [3]Nathan KLine Inst., Orangeburg, NY; [4]Dept. of Neurosci. & Physiol., New York Univ. Sch. of Med., New York, NY

Abstract: Our external world is composed of numerous temporally structured rhythmic stimuli, especially in the auditory modality. Several studies have shown that the alignment of internal rhythmic neuronal excitability fluctuations, or neuronal oscillations, to the temporal structure of these stimuli significantly aids in their processing. In fact, an inability to align or entrain neuronal oscillations to the temporal structure of external stimuli in schizophrenia patients has been suggested as a basis for their sensory processing deficits. To be able to align internal to external rhythms, the brain needs a mechanism called phase reset, which is able to modulate the phase of neuronal oscillations. Phase reset is supramodal, and in its purest form - without specific event related responses - occurs in response to non-preferred modality stimuli. It has been speculated that inputs originating in the non-specific, thalamic matrix are responsible for the mechanism of phase reset. In the present study, we directly tested this hypothesis by recording LED flash related responses of neuronal ensembles and single neurons from primary auditory cortex (A1) and the auditory thalamus (MGN) concurrently. Neuroelectric activity was recorded using linear array multielectrodes in awake macaques who were presented with a rhythmic stream of LED flashes. After isolating the activity of single neurons in MGN, we found that less than 20% responded to LED flashes. Individual neurons within this subset reliably responded to the LED across approximately 50% of trials. The onset latencies of these neurons were only slightly delayed compared to responses of LGN neurons, and the majority were located in the dorsal division of MGN. Examination of concurrently recorded A1 laminar CSD response profiles during trials where the visual-responsive MGN neurons fired showed signatures of phase reset and entrainment, accompanied by significant laminar inter-trial coherence (ITC). For the trials when these MGN neurons failed to fire, ITC failed to reach significance in A1 indicating that in these trials ongoing activity was not modulated by visual stimulus related inputs. Lastly, we identified a population of units in cortex that only fired on

trials when “phase reset neurons” of the MGB did, indicating that these are also part of the circuitry that is responsible for phase reset. Our results provide evidence that as previously proposed, phase reset indeed employs a thalamocortical circuitry that involves non-specific, matrix regions of thalamic relay nuclei.

Title: Modulation of acoustic processing in the auditory cortex by frontal cortex synaptic inputs.

Authors: *J. W. MIDDLETON[1], S. M. BROWN[2];
[1]Cell Biol. and Anat., LSU Hlth. Sci. Ctr., New Orleans, LA; [2]Cell Biol. and Anat., Louisiana State Univ. Hlth. Sci. Ctr., New Orleans, LA

Abstract: Anatomical and functional neural circuitry forms the basis for cortical representations of the sensory world. This circuit architecture needs to be both plastic and adaptable to allow for the cognitive flexibility animals need to survive in complex and dynamic sensory environments. In the auditory system, neural responses to tone frequency exhibit plasticity when acoustic stimuli arrive concurrently with synaptic inputs from modulatory brain centers. This results in a functional reorganization of the auditory tonotopy, i.e. the ordered distribution of frequency specific responses across the surface of the auditory cortex. “Top-down” pathways are responsible for attention, extracting contextual information, cross-modal sensory integration and signaling other internal brain states. The prefrontal cortex (PFC) has a role in many of these higher cognitive functions. We are interested in how a particular PFC sub region, the orbitofrontal cortex (OFC) is involved in mediating plastic changes in the auditory cortex. The OFC plays a critical role in evaluating reward outcomes, signaling aversive stimuli and regulating emotional behavior. It has established anatomical connections with the primary auditory cortex (A1) and can modulate auditory cortical responses. In order to understand how the OFC influences functional circuitry and signal processing in the auditory cortex we

performed *in vivo* multielectrode array recordings simultaneously in the auditory cortex and the OFC. We calculated cross correlations of activity in these two areas to quantify functional coupling. Additionally, we optogenetically activated OFC neurons and measured the resultant LFP responses in auditory cortex. We found that the funcitonal properites of inputs from OFC to auditory cortex were dependent on the rostro-caudal position of the auditory cortex recording. The characterization of this pathway is an important first step in understanding the mechanisms underlying OFC dependent modulation of auditory processing.

Title: Information processing by synchronized neuronal ensembles in the primary auditory cortex

Authors: *J. SEE, C. ATENCIO, V. SOHAL, C. SCHREINER;
UCSF, San Francisco, CA

Abstract: The primary auditory cortex (AI) contains interconnected populations of neurons that are responsible for auditory information processing. Most studies of information processing in AI involve either single unit spectrotemporal receptive field (STRF) estimation or paired neuronal correlation analyses, and thus assume that AI neurons filter auditory information either as individual entities or, potentially, as pairs. However, mounting evidence suggests that sensory stimuli are processed by interconnected, co-activated populations of neurons. Therefore, determining how AI encodes information will require an integrated approach that combines receptive field and multi-neuronal ensemble analyses. To assess multi-neuronal information processing in AI, we performed multi-electrode extracellular recordings in rat AI while presenting dynamic, broadband stimuli, which allowed us to construct STRFs. We then used dimensionality reduction techniques to identify distinct groups of AI neurons (neuronal ensembles, or NEs) that reliably fired synchronously in AI. Via multiple models, we verified that neurons in the same NE had higher rates of coincident firing than would be by chance or by having similar stimulus preferences. For each NE, we then identified synchronous spiking events, and used the events to assess spectrotemporal information processing. For neurons that

were members of an NE, the spikes associated with the NE conveyed greater information than the spikes that were not associated with the NE. These findings challenge the classical idea that AI neurons produce a homogeneous set of spikes that may be equally weighted to estimate a single STRF. Instead, spikes of AI neurons may represent different pieces of information, and equally weighting all neuronal spikes to form a single STRF ignores this. Therefore, by taking into account the stimulus preferences associated with each NE, we may gain a more complete evaluation of information processing in A1.

Title: Adaptation in auditory cortex is actively shaped by somatostatin-positive and not parvalbumin-positive interneurons

Authors: *R. G. NATAN[1,2], W. RAO[1], M. N. GEFFEN[1,2];
[1]Dept. of Otorhinolaryngology, [2]Neurosci. Grad. Group, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Adaptation to repeated stimuli is a ubiquitous property of cortical neurons that is thought to enhance the efficiency of sensory coding. In primary auditory cortex, the vast majority of neurons exhibit stimulus specific adaptation, i.e. firing rate attenuation dependent upon stimulus prevalence, which modulates neuronal frequency tuning properties. Such history-dependent adaptation is thought to support sensory-motor behaviors like stimulus habituation, discrimination and deviance detection, yet little is known about the neuronal mechanisms that control how adaptation is generated. In these experiments, we show how frequency tuning in A1

is differentially shaped by two inhibitory interneuron subtypes prior to and following adaptation. During tone pip trains that induce varying levels of adaptation across frequencies, we measured firing rates of putative excitatory pyramidal neurons (PNs), while using optogenetic manipulation to selectively suppress specific populations of interneurons. Prior to adaptation, i.e. during the first tone of each train, suppressing parvalbumin-positive interneurons (PVs) or somatostatin-positive interneurons (SOMs) each lead to increases or decreases in tone evoked responses in different PNs. Following adaptation, i.e. during the last tone of each train, PVs mediated inhibition increased modestly but continued to bi-directionally modulate tone evoked responses similarly to the first tone. In contrast, SOM mediated inhibition after adaptation increased dramatically and modulation became mostly uni-directional. Thus, SOM mediated inhibition appears to track the dynamics of adaptation more closely than that of PVs. In addition, we tested how inhibition and adaptation shape frequency tuning in PNs. First, we found that adaptation leads to a robust divisive suppression across the tuning curve for PNs, with stronger suppression for preferred frequencies. Matching the aforementioned findings, PV mediated inhibition across frequencies did not change during adaptation. In contrast, SOM mediated inhibition increased more strongly for preferred frequencies than off-peak frequencies, matching the pattern the pattern of suppression observed for adaptation. We further explore circuit mechanisms that may underlie this novel phenomenon. This study reveals a previously unknown functional mechanism of SOMs in generating adaptation.

Title: Amplitude modulation coding in awake mice

Authors: *N. HOGLEN[1], E. A. K. PHILLIPS[2], P. LARIMER[3], B. J. MALONE[4], A. R. HASENSTAUB[4];
[2]Neurosci. Grad. Program, Kavli IFN, Ctr. for Integrative Neurosci., [3]Dept. of Neurology, Kavli IFN, Ctr. for Integrative Neurosci., [4]Dept. of Otolaryngology/Head and Neck Surgery, Kavli IFN, Ctr. for Integrative Neurosci., [1]Univ. of California, San Francisco, San Francisco, CA

Abstract: Amplitude modulation is a prominent feature of the vocalizations of many species, including rodents. Sinusoidal Amplitude Modulation (SAM) has been used to define the nature and limits of temporal encoding in central auditory neurons in multiple animal models. The increasing use of mice as a model system for central hearing and the utility of mouse models for circuit dissection using optogenetic tools requires more detailed descriptions of cortical encoding of the temporal dynamics of complex stimuli. To this end, we presented moderate-amplitude, fully-modulated SAM stimuli with modulation frequencies ranging from 2-128 Hz to passive-listening, head-restrained awake mice. Electrophysiological recordings were obtained using 16-channel probes (NeuroNexus) spanning the laminar depth of the cortex. During the experiments the mice were free to move on an air-suspended styrofoam ball. Cortical responses were assessed with respect to both firing rates and response synchronization (Vector Strength) throughout the duration of the stimuli. Simple linear decoders (nearest-neighbor Euclidean-distance classifiers) were also used to classify the modulation frequency associated with individual spike trains to obtain a lower-bound estimate of the mutual information between stimulus envelope features and spiking responses. Multi-unit responses from a sizable fraction of cortical sites exhibited robust response synchronization to stimuli at the low modulation frequencies (< 20 Hz) that dominate animal vocalizations and human speech sounds. Reduced but significant synchronization was occasionally observed at the highest modulation frequency tested (128 Hz) as has been observed in awake nonhuman primate models. These results demonstrate that the temporal precision of cortical responses in awake mice is broadly comparable to that observed in other awake model systems. Further, cortical representation appears sufficiently precise to reward optogenetic experiments aimed at determining how excitatory and inhibitory circuits interact to represent the dynamics of complex signals including mouse vocalizations and human speech.

Title: Forward masking and synaptic inhibition in the auditory cortex of awake mice

Authors: *E. A. PHILLIPS[1,2], C. E. SCHREINER[1], A. R. HASENSTAUB[1];
[1]Kavli IFN and Coleman Mem. Laboratory, Dept. of Otolaryngology, [2]Neurosci. Grad. Program, Univ. of California, San Francisco, San Francisco, CA

Abstract: The precise temporal relationship between stimulus components is critical for the appropriate interpretation of rapidly fluctuating stimuli, such as speech. In line with this, responses to auditory stimuli are often influenced by recent stimulus history. For example, recent sound exposure can suppress both the perception of, and the neural responses to, a subsequent sound, and the magnitude of this suppression depends on both the spectral and temporal distances between the two sounds. This temporal suppression, called forward masking, is present in the auditory system as early as the auditory nerve, but is enhanced within the cortex. Synaptic inhibition has been hypothesized to mediate this enhancement, but the relative contributions of inhibition versus other potential mechanisms (such as intrinsic adaptation or short-term synaptic depression) remain unclear. Additionally, most prior studies of forward masking in the cortex have been performed under anesthesia, in which synaptic inhibition is greatly altered. This issue is further complicated by the engagement of diverse interneuron populations that may influence temporal processing in unique ways.To test if forward masking is qualitatively similar in the awake animal compared to under anesthesia, we recorded single-unit responses from the auditory cortex of awake mice during the forward masking stimulus (a two-tone sequence). First, we found that masking was qualitatively less robust in the auditory cortex of awake mice compared to prior studies conducted in anesthetized mice or in other anesthetized species. Additionally we found that masking strength weakly correlated with several cellular properties, such as onset latency, average response rate, tuning bandwidth, and spike shape. To test how synaptic inhibition contributes to forward masking within the auditory cortex, we optogenetically inactivated either somatostatin-positive (SST+) or parvalbumin-positive (PV+) interneurons during the forward masking stimulus. Inactivating interneurons produced marked changes in the strength and structure of forward masking. Moreover, by comparing trials with matched firing rates to the first tone, we found that these effects were independent of the response to the first tone, in opposition to intrinsic adaptation models of forward masking. We hypothesize that

forward masking is not only inherited from subcortical structures, but that it is transformed within the cortex, in part, by cortical interneurons.

Title: Background EEG activity modulates auditory-evoked response in C57BL/6J mice

Authors: B. H. TRACEY[1], L. SCOTT[2], C. SIOK[2], *D. VOLFSON[2];
[1]Electrical and Computer Engin., Tufts Univ., Medford, MA; [2]Pfizer, Cambridge, MA

Abstract: Using electrophysiological recording techniques, auditory evoked potentials (AEPs) have been used both clinically and pre-clinically to assess sensory processing in disease and disease model populations. In interpreting AEP data, an important question is to what extent AEP response is modulated by the underlying state of the animal at the time of stimulation. In this study we explored this question using AEPs recorded from the frontal cortex of freely moving adult male C57BL/6J mice, using a paired pulse paradigm. We present changes in the AEPs in response to the novel pre-clinical candidate PDE4 inhibitor, ABI-4, which along with the clinically prescribed antipsychotics risperidone and haloperidol, have been shown to dose-dependently enhance sensory gating. To quantify the underlying state, we utilized frequency domain EEG features from pre-stimulus data from vehicle treated animals. The animal's background activity was sorted into one of several states defined using unsupervised clustering. Similarly clustered traces were averaged at each time point, and wavelet-based denoising was applied to suppress high frequency noise. Signal amplitudes at fiducial points were extracted and a linear mixed model with cluster as a covariate was used to analyze the dataset. The results shown that incorporating background activity significantly improves model fit and that cluster and cluster/treatment interactions are statistically significant factors for many endpoints. The analysis demonstrated that background activity modulates AEP response in mouse model and taking this into account may improve interpretation of AEP studies.

Title: Developmental changes in the functional laminar mesoscale organization of primary auditory cortex revealed with multi-scale imaging

Authors: *K. SOLARANA[1], D. WINKOWSKI[2], Z. BOWEN[2], J. LIU[2], N. FRANCIS[2], D. NAGODE[2], P. O. KANOLD[2];

Abstract: Early experience of the world is fundamental in shaping the structural and functional organization of the brain. Sound inputs are particularly relevant for the proper maturation of the primary auditory cortex (A1), which requires exposure to behaviorally relevant acoustic stimuli during the critical period of auditory development. Previous studies have shown that artificially manipulating environmental sounds during early postnatal life results in wide-scale restructuring of topography in adult rodents, yet little is known how fine-scale A1 organization develops during ear opening and throughout the critical period. Here we investigated how the functional responses of A1 neurons and the mesoscale sound frequency representation in A1 changes and matures in different cortical layers throughout early hearing development. We used *in vivo* two-photon calcium imaging and wide-field imaging in one to four-week old Thy1-GCaMP6s mice and measured fluorescent responses of A1 neuronal populations in thalamorecipient layer 4 and supragranular layers 2/3 in response to amplitude-modulated tones. This age range allowed us to examine A1 development from just before ear opening, throughout the critical period, and into adulthood. We measured response changes on an individual neuronal level (response amplitude, frequency selectivity, sound level threshold) and on a population level (best frequency variability across the imaging window, signal and noise correlations), and found that significant changes occur during the critical period that are reflective of specific modifications in feed-forward and intracortical connectivity as the circuit is refining. A greater understanding of the complexity and plasticity of A1 during development will provide insight into the critical relationship between early sensory experience and the maturation of fine-scale cortical organization.

Title: Two types of cortical interneurons differentially modulate behavioral frequency discrimination acuity

Authors: ***J. BLACKWELL**[1], M. AIZENBERG[1], L. MWILAMBWE-TSHILOBO[1], S. JONES[1], R. G. NATAN[1], M. N. GEFFEN[2];
[1]Otorhinolaryngology, [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: The ability to discriminate between tones of different frequencies is fundamentally important for everyday hearing. Primary auditory cortex regulates behaviors that rely on frequency discrimination (Aizenberg and Geffen, 2013), but the underlying neural mechanisms are poorly understood. Frequency tuning of cortical excitatory neurons are thought to be shaped by the interplay of excitatory and inhibitory inputs. In the cortex, the two most common classes of inhibitory interneurons are parvalbumin-positive (PV) interneurons and somatostatin-positive (SOM) interneurons. PVs target the soma and initial axon segment, while SOMs target distal dendrites. Therefore, these two interneuron classes may differentially affect responses of excitatory neurons. We recently found that photo-activation of PVs enhanced tone-evoked responses of excitatory neurons, which was correlated with an improvement in behaviorally measured frequency discrimination acuity (Aizenberg et al., PLoS Biology, 2015). We now find

that photo-activation of SOMs diminished tone-evoked responses in the excitatory neurons, by suppressing tone-evoked responses more strongly than spontaneous activity. Interestingly, photo-activation of SOMs also increased the frequency selectivity of excitatory neurons, but had mixed effects on behaviorally measured frequency discrimination acuity. These findings are consistent with the interpretation that PVs and SOMs carry out differential roles in shaping frequency selectivity in the auditory cortex.

Title: A high-frequency tonotopic reversal in marmoset parabelt auditory cortex

Authors: ***D. GAMBLE**, X. WANG;
Johns Hopkins Univ., Baltimore, MD

Abstract: The current working model of primate auditory cortex comprises the hierarchical arrangement of a series of functionally distinct information processing stages: a primary 'core' region, a secondary 'belt' region, and a tertiary 'parabelt' region. Combined anatomical, physiological, and imaging experiments in monkeys have subdivided core and belt into multiple tonotopic subfields (Kaas & Hackett 2000). Human fMRI investigations have attempted to find homologues of the primate core fields A1 and R by looking for a low-frequency tonotopic reversal near Heschl's gyrus (HG), the histologically-identified site of human primary auditory cortex. While many studies have found such a reversal, a long-standing contradiction exists between results supporting an auditory cortex oriented parallel to HG, and others perpendicular to HG (Baumann, Petkov & Griffiths 2013; Moerel, de Martino & Formisano 2014). Using a single neuron mapping technique in awake and behaving marmosets, we have identified a previously unrecognized high frequency tonotopic reversal in putative parabelt auditory cortex, immediately lateral to the previously known low frequency reversal in lateral belt. Such a spatial arrangement of high and low frequency regions in adjacent fields could conceivably be mistaken for a single field with a tonotopic axis perpendicular to the true cortical configuration. Thus this high frequency region may explain the mutually contradictory patterns of results observed in

human imaging studies. Neurons in this high frequency region exhibit long response latencies, strong selectivity for acoustic parameters, such as bandwidth, intensity, temporal modulation, and spatial location, as well as response modulation by behavioral engagement.

Title: A high-throughput platform for combined optogenetic stimulation and wireless EEG recordings for use with auditory assays in awake-behaving rodents

Authors: *D. J. GRAZIANO[1], A. M. PATINO[2], M. M. SIDOR[2];
[2]Neurosci., [1]Novartis, Cambridge, MA

Abstract: Optogenetics is a powerful tool that that enables the control of neural firing with high spatial and temporal precision. Studies in awake-behaving rodents have provided valuable insight into the neural circuits that underlie normal and disease-related physiological states. There is a growing need for a consolidated platform to study specific circuit perturbations using optogenetics as well as sensory driven perturbations using evoked related potentials, while simultaneously recording the electrophysiological response to these inputs.
Currently available tools, however, are relatively low-throughput in design. Furthermore, the tethered nature of electrophysiological setups makes integrating this technology with optogenetics cumbersome for awake-behaving studies. Here we describe a flexible and versatile platform using a wireless telemetry system for EEG recordings (Data Sciences International) and a custom-made Arduino based auditory delivery system in combination with optogenetic stimulation that permits real-time simultaneous modulation of neural activity and EEG recording in awake-behaving mice. A single optogenetic-EEG recording platform is scalable up to 14 mice. Various TTL triggered optogenetic laser/LED set-ups can be integrated with the EEG recording system, however, we describe an enclosed-laser/LED system comprised of separate but simultaneously controlled lasers, with the ability to individually modulate light intensity output at each fiber end, i.e. at the light-animal interface. Light pulse trains are recorded via an analog-to-digital signal convertor that reliably tracks light pulse trains up to 200Hz in order to time-lock light delivery with EEG activity. Similarly, each auditory assay is time-locked to the EEG signal so that all responses can be temporally correlated. In addition to its high-throughput advantage,

the wireless EEG system is useful for long-term or chronic monitoring of brain activity in awake-behaving mice following optogenetic stimulation.

Title: Functional organisation of the thalamo-cortical auditory system in awake ferrets using fast ultrasound imaging

Authors: ***C. BIMBARD**[1], C. DEMENÉ[2], C. GIRARD[1], S. RADTKE-SCHULLER[1], S. SHAMMA[1], M. TANTER[2], Y. BOUBENEC[1];
[1]Lab. Des Systèmes Perceptifs CNRS UMR 8248, Paris, France; [2]Inst. Langevin, Waves physics for medecine, Inserm U979, Paris, France

Abstract: Large-scale functional imaging techniques are part of a fast growing field of neuroscience aiming at understanding whole brain activity. Functional Ultrasound Imaging (fUS) is a new method monitoring changes in blood flow with a high spatial (~100µm) and temporal (down to the cardiac time scale) resolution, with a typical imaged section is typically 1cm wide and 2cm deep.It is thus an unequalled modality in the landscape of functional imaging, MRI included. We used this technique to study the functional organization of auditory circuit from the inferior colliculus (IC) to the cortex in the awake ferret. Craniotomies were performed above the auditory cortex, yielding a ~15x10mm window over the brain, and subsequentyly sealed with an ultrasound-transparent TPX cover, embedded in dental cement. First, we characterized the tonotopic organization of several areas of the auditory cortex in three dimensions, including deep sulci which are cortical regions typically inaccessible to standard intrinsic and voltage sensitive imaging techniques. Using a linear classifier algorithm, we found that blood flow activity in the capillaries gave access to a precise representation of the information encoded in the auditory cortex. This information was mostly present in medium and deep layers, mirroring previous studies that showed more refined tonotopic organization in granular and infragranular layers. Taking advantage of the penetration depth of fUS, we then describe for the first time the 3D

functional tonotopic organization of the ferret MGB and of the IC, confirming previous anatomical studies. In summary, we show that fUS is a powerful tool to study the fine organization and connections of brain structures with a great temporal precision and high spatial resolution, all in a short amount of time and with no damage to the brain.

Title: Auditory analogues of simple and complex cells: linearity of responses to periodic stimuli

Authors: *P. KUSMIEREK, J. P. RAUSCHECKER;
Neurosci., Georgetown Univ., Washington, DC

Abstract: Recently, S and C neurons were described in macaque auditory cortex based on segregation of “on” and “off” responses in the frequency domain, i.e. in cochlear space (Tian et al 2013). These cell types were proposed to correspond to simple and complex cells of the visual cortex, which are distinguished based on segregation of “on” and “off” responses in retinal space. This suggests a similarity of cortical computational mechanisms across sensory modalities, whereby cortical receptive fields (RFs) are generated from aligned thalamic inputs in their respective sensory epithelium space.
Another way to distinguish simple and complex cells in the visual cortex is by testing the linearity of their responses to sinewave drifting gratings (Skottun et al 1991): the response of simple cells varies linearly with the spatial frequency of the grating (indicated by a high response at the stimulus frequency normalized to DC, F1/F0), while complex cells respond non-linearly (low F1/F0). If auditory cortical neurons show a similar distinction, it would provide further support for the generalized RF model above.

We recorded 189 cells from areas A1 and CM of rhesus auditory cortex. Neurons classified as S based on the difference between "on" and "off" frequency-rate curves, compared to those classified as C, showed smaller distances between "on" vs. "off" best frequency, narrower tuning range and higher frequency selectivity, consistent with Tian et al (2013). In contrast to that study, we found longer response latencies in S cells vs. C cells. However, this was due to a subset of long-latency S cells; in an analysis restricted to latencies <40 ms no difference was found between S and C neurons.
To test linearity of S and C cell responses, we recorded responses of 91 cells to auditory "moving ripple" stimuli, which are equivalent to drifting sinewave gratings. We show that the F1/F0 ratio in auditory S cells is significantly higher than in C cells. This provides new evidence for correspondence between visual simple/complex and auditory S/C neurons. The reported effects were robust against changes in the method of S/C classification, and against restricting the analysis to A1 cells or to cells with confirmed driven responses in both "on" and "off" segments. Tian et al (2013) proposed that S cells might serve as detectors of boundaries between two successive sounds with different spectra, a mechanism that could be important for speech and music processing. However, we did not detect increased firing rate at such boundaries in S cells (n=24). On the other hand, C cells (n=66) decreased their firing rate at boundaries between two different sounds, compared to boundaries between repeated identical stimuli.

Title: Subcortical and cortical color representation and attentional modulation

Authors: *S. HONG[1,2], Q. YU[3], W. SHIM[3,4,5];
[1]Psychology, [2]Ctr. for Complex Systems and Brain Sci., Florida Atlantic Univ., Boca Raton, FL; [3]Psychological and Brain Sci., Dartmouth Col., Hanover, NH; [4]Ctr. for Neurosci. Imaging Res. Inst. for Basic Sci., [5]Dept. of Biomed. Engin., Sungkyunkwan Univ., Suwon, Korea, Republic of

Abstract: Subcortical color processing is mediated by two distinct neural pathways, parvocelluar (L-M) and koniocellular (S-(L+M)). Studies on the non-human primate visual system suggest that the strict distinction between these two chromatic channels results in a limited color representation at the LGN level. Using functional Magnetic Resonance Imaging (fMRI) in conjunction with a forward encoding model (Brouwer & Heeger, 2009), we investigate first,

whether and how cardinal and inter-cardinal colors are represented in the human LGN as well as visual cortices by reconstructing population-level color tuning responses, and second, whether these color representations can be modulated by selective attention. On each block, observers viewed equi-luminant concentric ring patterns, composed of either one of four cardinal colors varying on only one channel or four inter-cardinal colors varying on both channels, and equal-energy-spectrum white, which drifted alternately in expanding and contracting directions. Observers performed either a central RSVP task (attention to fixation condition) or a color discrimination task (attention to color condition), which were alternated between blocks within each experimental run. Observers were instructed to report the target (letter 'J' or 'K') among other letters in the central RSVP task or to detect near-threshold level (measured for individual observers and for each color separately) changes in a color probe presented at a random location in the color discrimination task. We found that attention can modulate the population-level color tuning responses to both cardinal and inter-cardinal colors in the LGN. Our results demonstrate that both cardinal and inter-cardinal colors can be represented at the LGN level and that attentional feedback alters population-level responses to chromatic information in the LGN.

Title: A firing-rate based simulation tool for studying roles of cortical feedback in lateral geniculate nucleus (LGN)

Authors: *M. HOBBI MOBARHAN[1], G. HALNES[4], P. M. CAÑADA[5], T. HAFTING[2], M. FYHN[1], G. T. EINEVOLL[3,4];
[1]Dept. of Biosci., [2]Inst. of Basic Med. Sci., [3]Dept. of Physics, Univ. of Oslo, Oslo, Norway; [4]Norwegian Univ. Life Sci., Aas, Norway; [5]Univ. of Granada, Granada, Spain

Abstract: The corticothalamic feedback from layer 6 in primary visual cortex (V1) to neurons in the lateral geniculate nucleus (LGN) allows cortex to dynamically shape its own input during sensory processing. Despite several experimental and modeling studies, the functional role of the

cortical feedback is still not well understood. Thus a systematic exploration is needed to understand the effects of the feedback on spatiotemporal responses in the LGN under various conditions. These conditions include different visual inputs and brain states. Recent advances in experimental techniques such as optogenetic and pharmacogenetic methods provide data to better constrain models of the thalamocortical circuit. While biophysically detailed LGN circuit models will be required to properly probe effects of neuronal details (Heiberg et al, 2016, PLoS Comp Biol), simulation of large networks with such models is computer intensive. This often prevents extensive testing of how the model output depends on the (typically uncertain) model parameters.
In order to elucidate notable features of visually evoked cortical-feedback effects, we have developed an efficient, firing-rate based simulator of spatiotemporal responses in the early visual system. The simulation tool is based on a previous model (Einevoll & Plesser, 2012, Cogn Neurodyn) which assumes a phase-reversed push-pull arrangement of ON and OFF cortical feedback, as has been seen experimentally. In this model the LGN cells exhibit linear firing properties despite non-linear firing characteristics of the corticothalamic cells. The advantage of the simulator lies in its computational and conceptual ease, allowing for fast and comprehensive exploration of various scenarios for the organization of the cortical feedback.
We find as a first application of the simulation tool, that even with circularly symmetric feedback it is possible to account for experimental findings on feedback effects on the spatial receptive fields of LGN cells (Sillito et al. 2002, Phil Trans R Soc Lond B). Thus even if the LGN circuit receives feedback from cortical cells of all orientation selectivities, the net resulting cortical feedback may still have circular symmetry. In addition to this, we will also present results for how the cortical feedback affects the temporal response properties of LGN cells.

Title: A reassessment of retinogeniculate convergence using optogenetic stimulation

Authors: E. Y. LITVINA[1,2], *C. CHEN[1];
[1]F.M. Kirby Neurobio. Ctr., Children's Hosp, Harvard Med. Sch., Boston, MA; [2]Program in Neurosci., Harvard Med. Sch., Boston, MA

Abstract: The retinogeniculate synapse is classically described as a simple relay between the retina and the primary visual cortex. Electrophysiological measurements have previously estimated that 1-3 retinal ganglion cell (RGC) synapse onto a mouse geniculate relay neuron (Chen & Regehr, 2000; Jaubert-Miazza et al., 2015). However, technical limitations have set these estimates as the lower bound of possible retinogeniculate convergence. Recent advances in connectomics have yielded much larger estimates of the number of connections between RGC axons and postsynaptic relay neurons (Morgan et al, 2016). Just as slice electrophysiology inherently underestimates input number, anatomical reconstruction lacking a functional readout can overestimate the degree of functional convergence, as not all anatomical contacts may be functional. To address the discrepancy between functional and anatomical descriptions of the retinogeniculate circuit, we took advantage of optogenetics in combination with an improved slice preparation protocol that helps to preserve the health of relay neurons in slice. We determined the upper and lower bounds for average retinogeniculate convergence by comparing the number of inputs estimated with conventional electrical versus optical stimulation of RGC afferents. To express ChR2 in a broad RGC population, we crossed Chx10-Cre mice with Ai32 (ChR2(H134R)-EYFP mice). As with electrical stimulation, we placed an optic fiber over the optic tract several hundred microns from dLGN to stimulate RGC axons with a small spot of blue light. Occlusion experiments showed the same single fiber input can be recruited using either blue light or electrical stimulation. We could reliably isolate single retinogeniculate fibers in Chx10-cre x Ai32 animals using this stimulus, yielding a distribution of single fiber amplitudes similar to that obtained with electrical stimulation of the optic tract. The amplitude of maximal currents we obtained by stimulating retinogeniculate synaptic terminals with full-field blue light illumination were almost twice the electrically-driven maximals, suggesting that optic tract stimulation in slice recruits approximately half of the total retinal input current onto relay neurons. Therefore, our new assessment of the number of RGCs that make contacts with a relay neuron falls between previous functional and anatomical estimates. However, using a simple Monte Carlo simulation, we find that the majority of these contacts make weak synapses while only a few of the inputs are strong.

Title: Corticogeniculate feedback enhances temporal precision of LGN neurons in a stream specific manner

Authors: *J. M. HASSE, F. BRIGGS;
Physiol. & Neurobio., Dartmouth Col. Geisel Sch. of Med., Lebanon, NH

Abstract: An important function of the visual system is to filter relevant visual information from the noisy visual environment. The corticogeniculate pathway, which connects primary visual cortex (V1) with the visual thalamus (lateral geniculate nucleus or LGN) in the feedback direction, may play a role in this filtering process. We are investigating the functional role of the corticogeniculate pathway by optogenetically manipulating the activity of corticogeniculate neurons in anesthetized ferrets. First, we inject a modified Rabies virus expressing m-Cherry and channelrhodopsin2 (ChR2) into the LGN such that corticogeniculate neurons are selectively infected. Following surgical virus injection, we perform an in vivo experiment in which we place electrode arrays into retinotopically-aligned regions of the LGN and V1. Our V1 electrode is paired with a fiberoptic cable such that we can record responses of ChR2-expressing corticogeniculate neurons to both visual stimulation and optogenetic stimulation (via blue LED). We record the activity of V1 and LGN neurons in response to drifting sinusoidal gratings and m-sequence stimuli under conditions in which corticogeniculate neurons expressing ChR2 are light-activated. Our data suggest there are multiple morphological subtypes of corticogeniculate neurons that modulate feedforward LGN neurons in a stream specific manner, and that corticogeniculate feedback enhances the temporal precision of LGN neurons. These results support the notion that corticogeniculate feedback increases the salience of information carried by discrete feedforward processing streams. Title: Functional mapping of retinogeniculate inputs on mouse thalamocortical relay neurons

Authors: *J. A. BEATTY, C. L. COX;
Physiol., Michigan State Univ., East Lansing, MI

Abstract: Anatomical evidence indicates that excitatory retinogeniculate terminals preferentially synapse on proximal dendrites of thalamocortical relay neurons. Retinogeniculate terminals can be part of a triadic arrangement consisting of the retinogeniculate axon terminal, the presynaptic dendrite of a local inhibitory interneuron, and the dendrite of the thalamocortical neuron. In this arrangement, excitatory drive from retinogeniculate terminals may activate inhibitory dendrodentritic synapses (F2 terminals) from thalamic interneuron dendrites onto dendrites of thalamocortical relay neurons. These F2 terminals are also thought to preferentially reside proximal on thalamocortical dendrites based on anatomical data, but to date, there has been little functional evidence to corroborate both of these anatomical findings. Here, we use subcellular channelrhodopsin-2 (ChR2)-assisted circuit mapping of the retinal inputs onto thalamocortical relay neurons of the dorsal lateral geniculate nucleus (dLGN) in mice. Briefly, intraocular injections of an adeno-associated viral vector containing ChR2 were made in 8-10 day old mice. Animals were allowed to recover for at least two weeks, to allow transfection of the virus, before brain slice recording were performed. Whole-cell intracellular recordings were made in dLGN thalamocortical relay neurons using a cesium based internal solution with Alexa-594 to aid in visualizing the dendritic morphology. Depolarization of retinogeniculate terminals by ChR2, and subsequent release of glutamate, was elicited with a small diameter (~2.5 μm) laser beam (473 nm) scanned in a grid (11 X 11, 20 μm spacing) centered over the soma. At hyperpolarized holding potentials (-60 mV) mapping resulted in excitatory postsynaptic currents (EPSCs) at proximal locations (<100 μm from soma) that persisted in the presence of tetrodotoxin (TTX) and 4-aminopyridine (4-AP). At holding potentials of 0 mV, EPSCs were replaced by the presence of inhibitory postsynaptic currents (IPSCs) that were shown to be GABAergic, persisted in the presence of TTX and 4-AP, and were more proximally distributed than the EPSCs (<60 μm from soma). These results functionally mapped retinogeniculate inputs on proximal dendrites of thalamocortical relay neurons. In addition, we were able to elicit inhibitory currents, presumably through F2 terminals, via subcellular ChR2-assisted circuit mapping of

retinogeniculate terminals and these inputs display a more proximal distribution on dendrites of the same thalamocortical relay neurons.

Title: Thalamic suppression as revealed in a Hidden Markov Model

Authors: *A. R. CASTI;
Dept. of Mathematics, Fairleigh Dickinson Univ., Teaneck, NJ

Abstract: Visual neurons in the mammalian lateral geniculate nucleus (LGN) reside in an elaborate circuit that includes suppressive input from numerous sources, including local thalamic interneurons and feedback collaterals from the reticular nucleus and primary visual cortex. Although some of the most prominent features of LGN relay cell responses, such as its receptive field, seem to be dominated by feed-forward excitation from retinal ganglion cells (RGC), the importance of thalamic suppression in controlling LGN activity has becoming increasingly clear. There is now strong evidence that a dynamic interplay between excitation and inhibition in the LGN sharpens response precision, primes relay cells for burst spiking, and reduces response redundancy without information loss. While relay cell models that incorporate only retinal input can be quite successful for spatially localized visual stimuli, they usually break down as the stimulus size increases and more of the retinogeniculate and thalamocortical architecture that produces inhibition is engaged.
Detecting the presence of LGN suppression *in vivo* is extremely difficult. For this reason inhibition is often inferred from extracellular spike records using a versatile model like the GLM. In this study, we use an Input-Output Hidden Markov Model (IOHMM) combined with single-cell, “quasi-intracellular” recordings of cat LGN to detect the presence of thalamic suppression and its influence on relay cell activity driven by temporally noisy flashing spots of various sizes. In these recordings, the electrode was placed sufficiently close to an LGN cell body to capture the primary retinal input (S potentials), and often also picked up “interloper” events of unknown origin, which were either fast biphasic or slower monophasic events in the extracellular voltage trace. Of particular interest was whether these interloping events were inhibitory in nature, and whether they could be exploited to improve the predictive power of LGN neuron models. Within the framework of the IOHMM, with S potentials as input and LGN spikes as output, the

hidden variables were interpreted as states of undetected excitation or inhibition. We correlated the hidden state transitions with the recorded "interloper" activity, and found that, for the larger stimulus sizes, interlopers of the fast biphasic type were indeed inhibitory, in that they were associated with hidden states producing a reduced conditional spiking probability in the optimized IOHMM. The results for the monophasic type events were mixed, suggesting in some cases inhibition and in some cases excitation, with more variable degrees of influence on LGN spiking.

Title: Response profiles of interneurons in the ferret vs. cat lateral geniculate nucleus

Authors: *V. SURESH[1], U. M. CIFTCIOGLU[1], K. R. DING[1], F. T. SOMMER[2], J. A. HIRSCH[1];
[1]Biol. Sci., USC, Los Angeles, CA; [2]Redwood Ctr. for Theoretical Neurosci. & Helen Wills Neurosci. Inst., Univ. of California, Berkeley, CA

Abstract: Local inhibitory interneurons in the lateral geniculate nucleus of the thalamus (LGN) influence all retinal signals that relay cells convey to cortex. In cat, receptive fields of most interneurons and relay cells are made of concentrically arranged subregions that have the opposite preference for luminance contrast, On or Off. Furthermore, there is a push-pull pattern of excitation and inhibition within each subregion: e.g. in On subregions bright excites and dark inhibits. A simple circuit might explain this pattern of response; the push is supplied by retinal ganglion cells with the same center sign as the postsynaptic target whereas the pull is fed forward from nearby ganglion cells of the opposite sign, via local interneurons. This scheme is difficult to test however, because in cat, as in most species, On and Off cells are intermingled in the LGN. The main layers of the ferret LGN, however, divide into On and Off leaflets, providing a potential means to gain insight into mechanisms of push-pull.
Previously, using whole-cell recording in vivo, we showed that basic synaptic physiological features of interneurons and relay cells are conserved in ferret and cat. In both species, membrane currents recorded from interneurons were dominated by trains of unitary IPSCs and

those recorded from relay cells by individual EPSCs (Wang et al., Nat. Neurosci., 2011). Also, relay cells in both cat and ferret displayed push-pull responses. Unlike cat, however, ferret interneurons lacked push-pull. For these cells, stimuli of the preferred sign did not evoke a sustained push current (as in cat) but instead elicited a response whose envelope comprised a transient hyperpolarization followed by a slowly developing depolarization that drove spikes. Similarly, stimuli of the non-preferred sign did not evoke a maintained pull but rather induced waveforms whose shape varied across the population. To quantify the variations in response pattern among interneurons in the ferret and across species, we developed a method in which the neural signal is represented as the weighted sum of the convolution of the stimulus (a square function) and a set of filters that include a Gaussian function and its first and second derivatives. The weights estimated for responses from ferret interneurons spanned a wide range of values that partially overlapped the distribution measured for cat. It was nonetheless possible to reconstruct the envelope of the pull in ferret relay cells from a composite of On and Off responses of interneurons. Thus, even as push-pull is preserved in relay cells of ferret and cat, the wiring diagram that generates this pattern of response in the two species may not be wholly identical.

Title: Contrast dependent synchrony in the retinogeniculate circuit

Authors: ***P. C. ALEXANDER**[1,2], H. J. ALITTO[1,2], T. G. FISHER[2], D. L. RATHBUN[3], W. M. USREY[1,2];
[1]Ctr. for Vision Sci., [2]Ctr. for Neurosci., Univ. of California, Davis, Davis, CA; [3]Inst. for Ophthalmic Res., Eberhard Karls Univ., Tübingen, Germany

Abstract: Across the visual hierarchy, neurons at successively higher stages of processing tend to exhibit an increased sensitivity to stimulus contrast. This phenomenon has been observed in the transition between the retina, lateral geniculate nucleus (LGN), primary visual cortex (V1),

and extrastriate areas. Although we lack a mechanistic understanding for how this process occurs, it seems likely that patterns of multi-neuronal activity play a role. Here we test the hypothesis that contrast-dependent changes in synchronous firing between LGN neurons contributes to the increased contrast sensitivity of V1 neurons. To do so, we made extracellular recordings from pairs of neurons in the LGN of anesthetized cats that showed a prominent peak in their cross-correlation function at zero time lag, suggesting shared retinal input. The tendency of cell pairs to spike with tight synchrony (±0.5 ms) in response to drifting sine wave gratings was assessed across multiple contrast levels while controlling for changes in overall firing rate. Our results show that across cell pairs the proportion of synchronous spikes increases with decreasing contrast, suggesting that contrast-dependent correlations between LGN cells may contribute to elevated contrast sensitivity in V1, as synchronous spikes are more effective in evoking cortical responses. Using a network of leaky integrate-and-fire model neurons we explore the ability of different circuit configurations to account for our findings in the LGN and further examine how the observed correlations might impact V1. Model simulations demonstrate that depression at the retinogeniculate synapse is capable of modulating the probability of synchronous firing among LGN relay cells receiving shared retinal input in a contrast-dependent manner. Ongoing simulations are examining possible influences from other cellular and circuit mechanisms including facilitating inhibitory input from geniculate interneurons.

Title: New methods to identify extra-classical receptive fields in macaque lateral geniculate nucleus.

Authors: N. J. KILLIAN[1,2], *J. S. PEZARIS[1,2];
[1]Massachusetts Gen. Hosp., Boston, MA; [2]Harvard Med. Sch., Boston, MA

Abstract: Receptive field mapping techniques for measuring the detailed responses of LGN neurons are built around transfer function estimation techniques using broadband stimuli. Typically such stimuli are constructed to be spatially and temporally white, such as a *m*-sequence, and often presented in either luminance-only or cone-isolating modes. These techniques fundamentally address linear response characteristics alone, and have most often been used in anesthetized, paralyzed animals. We address many of these shortcomings by using an awake behaving macaque preparation and wideband stimuli (RGB noise) with both white and non-white spatiotemporal (1/f-like) characteristics. While the response fields match in fundamental character between the two stimulus conditions, the lower high-spatial frequency energy content of the non-white stimuli produce generally lower signal-to-noise measurements, but allow fitting of non-linear parameters that rely on, for example, local contrast levels. Using additional non-linear post-processing noise-reduction techniques such as same-sign connectivity and annular summation, evidence for extra-classical responses can be identified in many cells.

Title: Brain state-dependent modulation of thalamic visual processing by cortico-thalamic feedback

Authors: *K. REINHOLD[1], M. SCANZIANI[2];
[1]Neurosciences, Harvard Med. Sch., Boston, MA; [2]Univ. of California at San Francisco, San Francisco, CA

Abstract: The behavioral state of an animal impacts the way that sensory stimuli are processed by the brain. The response of thalamic neurons to temporally modulated visual stimuli, for example, depends on the alertness of the animal. In the alert state the response of thalamic neurons in the dorsal lateral geniculate nucleus (dLGN, the principal thalamic target of retinal axons) is strongly modulated by the timing of the visual stimulus, while during non-alert states this temporal modulation is profoundly reduced. The underlying mechanisms are still unclear.

Here we show that cortico-thalamic feedback through cortical layer 6 neurons plays a critical role in the state-dependent modulation of dLGN responses. As alertness to visual stimulation declines, cortico-thalamic feedback suppresses the amplitude of the response of the dLGN to time-varying visual stimulation. Thus, this top-down mechanism interacts with bottom-up sensory processing to change representations in sensory thalamus as a function of behavioral state.

Title: Contrast and temporal dynamics of extraclassical suppression in the lateral geniculate nucleus of the alert macaque monkey

Authors: *D. ARCHER, W. M. USREY;
Univ. of California, Davis, Davis, CA

Abstract: Nonlinear extraclassical suppression is a fundamental receptive-field (RF) property for neurons in the early visual system, including the retina, LGN, and primary visual cortex. The influence of extraclassical suppression is evident when stimuli overlapping and extending beyond the classical RF (CRF) noticeably suppress the CRF driven response. Given the extraclassical surround has been proposed to serve as a means for gain control as well as provide context for stimuli appearing in the CRF, understanding the temporal dynamics of extraclassical suppression is critical for gaining insight into the underlying circuits involved. Although, stimulus contrast has been shown to affect the spatial extent and response latency of CRF responses, our understanding of how contrast affects the temporal profile of extraclassical suppression in the LGN is less established. To determine whether stimulus contrast affects the time course of extraclassical suppression in the LGN, we made single-unit recordings from LGN neurons in the alert, fixating macaque monkey and measured responses to stationary sinusoidal gratings varying in size and contrast centered over the receptive field of the recorded cell. We then compared the temporal profiles of responses evoked from optimal size stimuli to profiles

evoked from large size stimuli over a range of contrasts. Across our sample of cells and consistent with the literature, response onset latencies increased as stimulus contrast decreased. Interestingly, suppression latencies also increased as contrast decreased, but to a much greater extent than for response latency. Suppression latencies also increased as stimulus size decreased, further suggesting that suppression latency depends on suppression strength. Taken together, these results indicate that the additional circuits recruited for extraclassical suppression require greater synaptic drive to engage than those underlying CRF responses.

Title: What features are matched binocularly for stereopsis?

Authors: *I. OHZAWA[1,2], D. KATO[1], M. BABA[3], K. S. SASAKI[1,2];
[1]Osaka Univ., Suita, Osaka, Japan; [2]CiNet, Suita Osaka, Japan; [3]Natl. Inst. for Physiological Sci., Okazaki, Aichi, Japan

Abstract: The key problem of stereoscopic vision is traditionally defined as accurately finding the positional shifts of corresponding object features between left and right images. Here, we demonstrate that the problem must be considered in a four-dimensional parameter space; with respect not only to shifts in space (X, Y), but also spatial frequency (SF) and orientation (OR). The proposed model sums outputs of binocular energy units linearly over the multi-dimensional V1 parameter space (X, Y, SF, OR). Experimentally, extracellular single-unit recordings were made in area 17 of 17 anesthetized and paralyzed adult cats. A binocular SF stimulus consisted of pairs of dichoptic sinewave gratings with various combinations of left-right SFs (SF_L, SF_R) and phases (ph_L, ph_R). Similarly, a binocular OR stimulus consisted of pairs of dichoptic sinewave gratings with various combinations of left-right ORs (OR_L, OR_R) and phases (ph_L, ph_R). Binocular version of reverse correlation analyses were performed in these domains. Both the theoretical analyses of the model and the physiological experiments show that many

binocular neurons achieve sharp binocular tuning properties by pooling the output of multiple neurons with relatively broad tuning. Pooling in the space domain sharpens disparity-selective responses in the SF domain so that the responses to combinations of unmatched left-right SFs are attenuated. Conversely, pooling in the SF domain sharpens disparity selectivity in the space domain, reducing the possibility of false matches. Analogous effects are observed for the OR domain in that the spatial pooling sharpens the binocular tuning in the OR domain. Such neurons become selective to relative orientation disparity. Therefore, pooling in the 4-dimensional space sharpens or tightens the binocular matching requirement constructively along all dimensions, and allows the visual system to refine binocular information into a form more desirable for stereopsis.

Title: Fast contrast adaptation in V1 neurons - neural correlates of fading illusion -

Authors: *K. S. SASAKI[1,2], K. KURIHARA[1], I. OHZAWA[1,2];
[1]Osaka Univ., OSAKA, Japan; [2]CiNet (Center for Information and Neural Networks), Osaka, Japan

Abstract: Vision is a dynamic sense; we move eyes intermittently to see visual objects of interest at the center of gaze. This means that contrast of local visual scene stimulating a portion of retinae can change abruptly just after saccadic eye movements. Thus, neurons in early visual pathway might adapt to these sudden changes in contrast so fast that they can function properly. To the contrary, if retinal images are still for seconds during fixation, dim percepts in periphery fade away gradually and disappear eventually (Troxler fading). Traditionally, this fading is explained by a hypothesis that physical stimulus is cancelled by a negative image generated in the visual pathway, because the negative image is perceived momentarily when the physical stimulus is removed suddenly. Measuring the contrast responses of single neurons, we asked the

following two questions in the striate cortex of anesthetized and paralyzed adult cats. (1) Do these neurons show fast adaptation to change in contrast in the receptive fields? (2) Do these neurons respond to a blank screen in the faded or adapted state as if they actually 'see' the negative image.
We recorded single-unit activity of neurons in area 17 to measure the contrast response function during flashed grating stimuli of various contrasts were presented (7 contrasts in straddle, ±25%, range and pedestal, within 0-50%, range; negative values for phase reversal) in a rapid succession. The orientation and spatial frequency of gratings were fixed at the optimal value of each cell. Recorded spikes were analyzed using a reverse correlation technique.
We found that neurons in area 17 showed a shift of contrast response function during pedestal conditions. This adaptation process appeared to be completed within 500 milliseconds for the majority of our cells. The amount of shift was generally consistent with the arithmetic mean of contrasts in each experimental condition. Furthermore, shifts of contrast response function caused neurons to respond to a blank screen (i.e., 0% contrast stimulus) as if neurons had been stimulated by their preferred stimulus. This result supports the hypothesis that a negative image is generated during visual fading, and it behaves as if it were a real stimulus.

Title: Serotype-specific tropism of adeno-associated viruses in ferret primary visual cortex

Authors: A. DANIELS[1], T. BOUCHER[2], *K. J. NIELSEN[3,1];
[1]Zanvyl Krieger Mind/Brain Inst., Baltimore, MD; [2]Krieger Sch. of Arts and Sci., [3]Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Ferrets constitute an important neuroscience research model for both the auditory and visual system. Increasingly, viral vectors are used in ferrets to transduce neurons with novel transgenes for optogenetic manipulation or calcium imaging. Adeno-associated virus (AAV) has become a popular choice for this purpose, owing to its low pathogenicity and stable long-term transgene expression. A number of different AAV serotypes are commonly available. Studies in other species, in particular rodents, demonstrate differences between serotypes in the cell types infected (tropism) and the transport to other brain regions. The choice of serotype is therefore an important factor in designing experiments. Currently, neither tropism nor transport have been

compared across serotypes in the ferret. Here, we sought to quantify tropism and transport for four different AAV serotypes in ferret primary visual cortex (V1).
Our experiments investigated serotypes AAV1, AAV5, AAV9, and AAV-DJ. All viral constructs contained GCaMP6 under control of the human synapsin promoter (hSyn). Viruses were injected in V1 in either one or both hemispheres, and a terminal experiment was performed 14-21 days later depending on the peak expression time for each serotype. The tissue was then fixed in 4% PFA and sagittally sectioned. Immunohistochemistry was performed using a primary antibody against GFP to detect GCaMP6 expression. In addition, sequential sections were stained against parvalbumin, calretinin or calbindin. To quantify tropism, we analyzed multiple sections containing the injection region in each animal. For each section, a tiled image of the whole injection region was taken using a 510 LSM confocal (Zeiss). We then determined which percentage of GCaMP6-infected cells were inhibitory neurons. To quantify transport, we determined the number of somata in the lateral geniculate nucleus that were infected with GCaMP6. Our preliminary data suggest differences in tropism between serotypes: While all serotypes similarly infected excitatory neurons in layers II/III, AAV-DJ infected a larger subpopulation of inhibitory neurons in these layers than the other serotypes.
These data contribute to a growing body of literature on species-dependent changes in AAV tropism and transport. A better characterization of these differences is key for selecting the correct serotype for an experiment, in particular as viral tropism - in addition to the chosen promotor - may be a critical factor in achieving cell-type specific expression of transgenes.

Title: Retinal input and callosal neuron axons regulate activity-dependent elimination of Chandelier cells at the V1-V2 border before eye opening

Authors: ***B.-S. WANG**, Z. J. HUANG;
Neurosci., Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Proper distribution and wiring of cortical inhibitory interneurons are crucial in regulating the balance of local circuitry and routing of cortical information flow. Although progress has been made in understanding the specification and long-range migration of cortical interneurons, the mechanisms that regulate their density and cortical integration remain unclear. The chandelier cells (ChCs) innervate pyramidal neurons (PyN) at axon initial segment – the spike initiation site, thus the proper distribution of ChCs may play a major role in shaping functional PyN ensembles. After their specification in the late embryonic medial ganglionic eminence, ChCs migrate with stereotyped route and schedule to arrive at designated cortical layers by the end of the first postnatal week. Surprisingly, we found that young ChCs then undergo massive apoptosis throughout the developing cortex between P7 and P14. In particular, the density of ChCs at the V1-V2 border region is reduced by half. The V1-V2 border receives input from callosal neuron (CN) axons of the contralateral visual cortex. By blocking CN growth or activity using Kir2.1 or inhibitory DREADD, we found that contralateral CN activity between P7-14 regulates the survival and density of ChCs at the border region. Further, ectopic CN axon projection induced by monocular enucleation at birth resulted in corresponding ectopic ChC elimination. Importantly, blocking retinal activity by monocular TTX injection between P7-14 had no effect on CN axon projection but reduced ChC pruning at ipsilateral V1-V2 border. Together, these results suggest that the density of ChCs at V1-V2 border is regulated by contralateral CN axons and retinal inputs. CNs receive inputs from the temporal retina that represents the central visual field and contribute to the seamless fusion of the left and right visual field. We hypothesize that activity-dependent elimination of ChCs at V1-V2 border may contribute to the development of a fast bi-lateral signaling pathway between the CNs that correlate their discharges when stimulated by the same orientation stimulus. Current effort is directed toward understanding the role of ChCs in the interhemispheric callosal projection pathway that integrates the cortical representation of the central visual field.

Title: Separating ON and OFF pathway inputs to cortical simple cells reveals receptive fields with ON-dominated asymmetric push-pull.

Authors: *A. GHARAT[1], C. L. BAKER, Jr[2];
[1]Integrated Program in Neurosci., [2]Ophthalmology, McGill Univ., Montreal, QC, Canada

Abstract: Simple cells in the early visual cortex are conventionally thought of as linear Gabor-like spatial filters with an output nonlinearity. Spatial linearity of simple cells has been demonstrated in cat Area 17 receptive fields with intracellular recordings (Martinez et al., 2005). This linearity across the receptive field is thought to arise from a symmetric "push-pull" arrangement of inputs from ON and OFF pathways. However the generality of this finding to a wider sample of neurons, and to other early cortical areas, remains unclear.
We used 32-channel multielectordes (polytrodes and linear arrays) to record extracellular single-unit responses of cat Area 17 & 18 simple cells to natural image sequences. We estimated a two-stage (LNLN) receptive field model of individual simple cells using regularized gradient descent optimization. In this model, first stage filters correspond to receptive fields of ON- and OFF-center lateral geniculate nucleus afferents, while the second stage (weight map) corresponds to the spatial layout of their summation by the cortical neuron. This model enables us to visualize the spatial arrangement of excitatory and inhibitory inputs from ON and OFF subcortical pathways to individual receptive fields.
The estimated receptive field models of most Area 17 simple cells have symmetric push-pull, as demonstrated previously by intracellular recordings. That is, excitatory ON input at a given spatial location in the receptive field is balanced by inhibitory OFF input and vice-versa. Interestingly, a large fraction of simple cells in Area 18 do not have such symmetric push-pull receptive fields. Instead, these cells have strong excitatory as well as inhibitory input from ON pathway inputs, and very weak complementary input from the OFF pathway. Some receptive fields receive input only from the ON pathway.
This novel system identification method demonstrates the presence of ON-dominated asymmetric push-pull receptive fields in early visual cortex. Further, these results challenge the generality of the widely accepted model of simple cells as linear spatial filters.

Title: Targeted optogenetic activation of the parvalbumin inhibitory neuron circuit in cat primary visual cortex sharpens orientation tuning of putative excitatory neurons

Authors: *D. C. LYON, A. T. FOIK, Y. LIU, L. A. ZHANG;
Anat. and Neurobio., Univ. of California Irvine, Irvine, CA

Abstract: Major strides have been made in recent years on realizing how different cortical inhibitory neuron subtypes shape neuronal selectivity. For example, optogenetic studies targeting parvalbumin(PV)-positive inhibitory neurons in primary visual cortex (V1) of transgenic mice demonstrate gain control at low PV activation and sharpening of orientation tuning at higher activation (Atallah et al. 2012 Neuron 73, 159-70; Lee et al. 2012 Nature 488, 379-83). While functional differences in several inhibitory neuron subtypes have now been described in transgenic mouse lines, there is little understanding of similar cell types in higher visual species due to a lack of transgenic models. Here, we used a helper virus containing a *Fugu* PV promoter to target infection of a modified rabies for selective delivery of channelrhodopsin-2 (ChR2) to PV neurons, initially (starter cells), and to the neurons providing direct inputs (connected cells) to these PV starter cells. In this local circuit expressing ChR2 in cat V1, both PV cells and putative excitatory neurons projecting directly onto PV cells can be activated through optical stimulation, which in theory can lead to reduction in firing rate of local non-ChR2 expressing neurons. This was confirmed in preliminary analysis, where we found a 10, 11 and 17% reduction in firing rate for the population of recorded neurons ($n > 110$; $p < 0.01$) to low, moderate and high laser intensities, respectively, compared to no-laser. Nevertheless, ~30% of recorded cells instead showed an increase in firing rate to increasing laser intensity and may correspond to cells expressing ChR2. Also found for the entire population at high laser intensities, orientation tuning widths measured by the half-width at half-height (HWHH) were sharpened by 14% ($p<0.05$). Note that the visual stimulus and laser were shown simultaneously for 500 ms and a 1500 ms inter-stimulus time interval was used to allow recovery from ChR2 activation. The above results were found when stimulating the classical receptive field (CRF). In contrast, when visual stimuli also included the extraclassical surround, there was no change in firing rate or HWHH to increasing laser intensity. Thus, our data suggest that for CRF sized stimuli which elicit the maximum response of a cell, local PV neurons in cat V1 play a role in sharpening orientation tuning by reducing the firing rate. However, for larger stimuli, which generally already lead to sharper HWHH and reduced cell firing through surround suppression (Liu et al. 2015 J Physiol 593.19, 4485-98), PV neuron circuit activation is not a factor.

Title: Synaptic architecture of visual space in ferret visual cortex

Authors: *B. SCHOLL, D. E. WILSON, D. FITZPATRICK;
Max Planck Florida Inst., Jupiter, FL

Abstract: Understanding how single neurons integrate synaptic inputs from myriad sources to generate somatic responses remains a challenge. Despite decades of somatic subthreshold voltage measurements, we still lack a fundamental understanding of the functional properties of individual synaptic inputs and their dendritic integration. Here we address this issue by examining how visual space is represented in the synaptic inputs onto dendrites of neurons in ferret visual cortex. We focused on visual space because retinotopic maps are highly conserved across mammals and mapping spatial receptive fields (RFs) can be accomplished with 1-dimensional noise stimuli. To measure the functional properties of synaptic inputs we used two-photon imaging of cortical cells sparsely labeled with a genetically encoded calcium indicator, allowing the visualization of hundreds of dendritic spines on single neurons. Despite the presence of a retinotopic map in V1, there was no evidence for retinotopic organization in the arrangement of synaptic inputs within the dendritic field. Pooling across the entire population of synaptic responses for individual neurons revealed that synaptic inputs arise from a much wider region of space than the soma; nevertheless, the preferred spatial location of the soma could be predicted from the summed synaptic responses. Individual synaptic inputs were often tuned for regions of space outside the somatic RF and there was considerable diversity in synaptic RF properties. Despite the lack of a clear dendritic retinotopic organization, the arrangement of inputs was not random, and we found that some dendritic branches exhibited clusters of spines with a high degree of similarity in the spatial selectivity of their responses. The summed synaptic input from correlated spines on dendritic branches revealed spatial RFs confined to subregions of the larger summed synaptic RF. In contrast, summed synaptic input from uncorrelated spines spanned much larger areas of the summed synaptic RF. The functional clustering of synaptic inputs responsive to localized regions of visual space suggests that dendritic computations may play an important role in spatial interactions that contribute to cortical neuron RF properties.

Title: Subthreshold spatio-temporal receptive fields in developing ferret visual cortex

Authors: A. ROY, B. MESCHEDE-KRASA, W. ALFORD, *S. D. VAN HOOSER;
Biol., Brandeis Univ., Waltham, MA

Abstract: In visual cortices of cats and ferrets, selective responses to edges with specific orientation (orientation selectivity, OS) develop prior to eye opening, whereas selective responses to oriented edges moving in specific directions (direction selectivity, DS) develop through visual experience following eye opening. Cortical DS is thought to arise from spatially separated detectors projecting on to cortical neurons with varying time delays such that motion inputs only in the preferred direction summate at the cortical neuron to produce robust spiking. This model predicts slanted spatio-temporal receptive field (STRF) for direction-selective V1 neurons, experimentally demonstrated previously. How does this slanted STRF develop following visual experience? According to a Pre-existing bias model, weak but slanted structure of STRFs already exists at eye opening and visual experience merely allows the maturation of these patterned synaptic inputs. Alternatively, according to a flexible plasticity model, visual experience works via an instructive mechanism to develop slanted STRFs from immature thalamo-cortical inputs that are diffusely organized in space and time. To distinguish between these models it is necessary to map the STRFs directly before visual experience. Neurons in developing cortex exhibit relatively low firing rates, and mapping STRFs with extracellular recordings is problematic. Therefore, we carried out in vivo sharp-microelectrode intracellular recordings from V1 of ferrets at young (P30-35) and older (P40-60) ages, and using white noise reverse correlation technique computed the sub- and supra-threshold STRFs of these neurons. While the STRFs from DS cells in older animals showed distinct slanted structure, STRF structures in younger animals were more diverse. Some non-DS neurons in younger animals showed weakly slanted STRFs, but most immature neurons had diffusely structured STRFs. Implications of these immature STRF structures on visual experience-dependent plasticity will be discussed.

Title: Horizontal organization of thalamic inputs in visual cortex

Authors: *A. SIAHKAMARI[1], E. ZABEH[1], J. JIN[2], R. LASHGARI[1], J.-M. ALONSO[2];
[1]Neural Engin. Res. Lab., Inst. For Res. In Fundamental Sci., Tehran, Iran, Islamic Republic of;

Abstract: Thalamocortical afferents are thought to play a major role in the organization of visual cortical maps, however, we still have a poor understanding of how they are horizontally arranged within the cortex. To address this question, we measured horizontal changes in ON and OFF cortical retinotopy within cat visual cortex by using multielectrode arrays (Neuronexus, 32 electrodes horizontally separated by 0.1 mm from each other). We then performed computer simulations to estimate the horizontal pattern of thalamic axons that best reproduced the ON-OFF cortical changes. Thalamic afferents were first given random values of receptive field position/size/polarity, synaptic strength per cortical point and axon-terminal size, while constraining the parameter range with physiological data (e.g. equal number of ON and OFF afferents, matched size of thalamic receptive field center and cortical receptive field subregion, average thalamic receptive field scatter per cortical point: 2.5 receptive field centers). After randomizing the initial values, thalamic axons went through two different stages of pruning. In the first stage (retinotopic pruning), the synaptic weights and axonal branches changed to match the ON-OFF cortical retinotopy. In the second stage (fine pruning), we tested three different approaches: 1) minimize size of axon terminals, 2) minimize number of thalamic inputs, 3) both. At each pruning stage, we performed a weighted sum of the receptive fields from ON and OFF thalamic afferents and compared the sum with the spatial structure of ON and OFF cortical receptive fields (200 afferents combined in 200 separate simulations). Among the three approaches, minimizing axon terminal size provided the best fits to the cortical data (9% of mean unexplained variance vs. 20% and 12%, $p<0.0001$, Wilcoxon tests here and below) and reproduced more closely the unity slope of the correlation between ON/OFF ratios for axon number and synaptic strength found in physiological experiments (0.89 vs. 0.56 and 0.56, $p<0.0001$). The minimization of axon terminal size also made OFF afferents to cover larger horizontal distances than ON afferents (1.17 vs. 1.06 mm at half-amplitude of exponential distribution, $p<0.0001$) while making each of the multiple axon patches more locally restricted for OFF than ON afferents (221 vs. 286 microns at half-amplitude of exponential distribution, $p<0.0001$). These preliminary results demonstrate that changes in ON/OFF cortical retinotopy can be accurately reproduced from linear combinations of thalamocortical inputs and suggest a

possible difference in the local and long-range organization of ON and OFF thalamic afferents in visual cortex.

Title: Cellular and synaptic mechanisms of direction selectivity in visual cortex

Authors: *D. E. WILSON, B. SCHOLL, D. FITZPATRICK;
Functional Architecture & Develop. of Cerebral Cortex, Max Planck Florida Inst. For Neurosci., Jupiter, FL

Abstract: Individual neurons in the primary visual cortex respond selectively to the direction of motion of visual stimuli. In simple cells, previous studies have shown that weak biases in synaptic inputs are amplified by a spike threshold nonlinearity to generate robust direction selectivity. These biases in membrane potential direction selectivity derive from differences in the relative timing of synaptic inputs rather than differentially tuned excitatory and inhibitory conductances. The cellular and synaptic mechanisms of direction selectivity in complex cells have remained largely unexplored. *In vivo* two photon imaging of calcium signals in the dendritic spines of single neurons in ferret visual cortex indicates that direction selective neurons receive excitatory synaptic inputs tuned to both the preferred and null directions, and that direction selectivity cannot be predicted by summing spine inputs and applying a threshold nonlinearity. Despite the prevalence of null-tuned excitatory synaptic inputs, *in vivo* whole-cell patch recordings show that neurons with strong spiking direction selectivity tend to show similarly strong direction selectivity in their subthreshold membrane potential. This highly selective membrane potential tuning may arise from null-direction tuned inhibition in these neurons. Consistent with this notion, we find that the membrane potential variance decreases at the null direction in these neurons, and that this reduction in noise at the null direction is strongly correlated with membrane potential direction selectivity. Finally, hyperpolarizing highly selective neurons strongly reduces their membrane potential direction selectivity. These findings

suggest that inhibitory inputs tuned for the null direction enhance direction selectivity in complex cells.

Title: Modeling individual variations in contrast perception as lateral connections within V1

Authors: ***E. C. MORGAN**, V. R. DE SA;
Cognitive Sci., UC San Diego, La Jolla, CA

Abstract: The FLODOG model (Robinson et al., 2007), based on the ODOG model (Blakeslee & McCourt, 1999), has previously demonstrated that perception of contrast illusions can potentially arise solely from lateral interactions between neurons in the primary visual cortex, but as an abstract model it does not have the ability to represent individual differences in human perception of contrast. We are creating a new model based on FLODOG with more biologically realistic connections based on a model of correlation-based connectivity by Troyer et al (1998). This new model shows increased ability to represent individual differences in perception of contrast illusions as found in previously collected psychophysical data, as well as providing the ability to correlate these differences with individual variations in neural connectivity in V1. Further refinements to this model are ongoing, and we expect to improve its ability to represent contrast perception. **References:** Blakeslee, B and McCourt, M.E. (1999). Title: Color processing in mouse primary visual cortex

Authors: *I. RHIM[1,2], G. COELLO-REYES[1,2,3], I. NAUHAUS[1,2,3];
[1]Dept. of Psychology, [2]Ctr. for Perceptual Systems, [3]Dept. of Neurosci., The Univ. of Texas At Austin, Austin, TX

Abstract: Mice, in common with other mammals, have dichromatic vision. Most mouse cones coexpress opsins that are sensitive to either 'green' (M-opsin) or 'UV' (S-opsin) light., with varying S:M expression ratios along the retina's dorsoventral axis. In addition to the co-expressing cones, there are pure S-cones intermixed throughout the retina. Opponency (i.e. subtraction) between the M- and S-opsins has been observed in ganglion cells, indicating that the mouse may be a useful model for the study of color vision. However, little is known about color vision in the mouse primary visual cortex (V1). Here, we developed a green-UV visual stimulus to study the balance of cone inputs to V1. Two projectors, one emitting green light (540 nm) and one emitting near-UV light (405 nm), were aligned to a rear-projection screen. We used S- and M-opsin sensitivity functions to generate drifting gratings with equated total opsin contrast in multiple directions of the S/M plane. Neural responses were measured with two-photon imaging within identified locations of the visuotopic map. We identified neural responses tuned to unique directions in the S/M plane, which allowed us to estimate the relative input from S and M components. In addition, orientation and spatial frequency of the gratings were varied to examine spatial properties of cells tuned to each directions of color space. Our results show a diverse population of chromatic tuning in V1: neurons are selective for S+M, S-M, S-isolation, and/or M-isolation. Together, we provide evidence for color-tuned responses in mouse V1 and a useful platform for studying chromatic vision in the mammalian brain.

Title: Large visual stimuli induce two distinct gamma oscillations with different tuning properties in the primary visual cortex of macaque monkeys

Authors: *P. RAVISHANKAR[1], M. V. P. S. DINAVAHI[2], V. SHIRHATTI[3], S. RAY[3];
[1]Ctr. For Neurosci., [2]Ctr. for Neurosci., [3]Indian Inst. of Sci., Bangalore, India

Abstract: Gamma rhythm (30-70 Hz) has been associated with high level cognitive functions and known to be elicited in many parts of the brain. Gamma oscillations elicited in the primary visual cortex have been extensively studied but its functionality is poorly understood. Although recent reports have suggested the presence of two gamma oscillations in the hippocampus, only a single gamma rhythm (whose center frequency varies depending on the properties of the visual stimulus) has been observed in the primary visual cortex. We recorded local field potentials (LFP) from chronically implanted microelectrode arrays in the V1 area of two macaque monkeys and found that large visual stimuli that cover both visual hemi-fields induce a slow gamma rhythm between 20-35 Hz in the primary visual cortex of awake monkeys, in addition to the previously reported gamma between 40-70 Hz. More importantly these two rhythms have distinct orientation preferences that are almost orthogonal to each other. The tuning preference for stimulus parameters like contrast, spatial frequency and temporal frequency are also different for both these rhythms. Lack of evidence from previous studies in observing two gamma rhythms can be largely attributed to the use of small stimuli localized around the classical receptive field. Two gamma rhythms with different tuning preferences might together provide a more extensive representation of the external input and better coding or communication mechanisms in the primary visual cortex.

Title: Evidence of nonlinear dynamics in cortical processing of the color VEP

Authors: *V. NUNEZ[1], R. SHAPLEY[2], P. SCHUETTE[1], A. AMIR[1], C. BRITTENHAM[1], A. BUTT[1], N. CHAN[1], S. A. HASSAN[1], P. PEHME[1], C.-S. RIDWAN[1], Y. SONG[1], J. GORDON[1]; [1]Psychology Dept., CUNY Hunter Col., New York, NY; [2]Ctr. for Neural Sci., NYU, New York, NY

Abstract: Recent research has provided support for the notion that the primary visual cortex (V1) is involved in the processing of color form perception through the combined activity of single-opponent and double-opponent cells. While many color researchers subscribe to the view of linear cortical function, receptive field measurements have indicated the possibility of cortical nonlinearities. To investigate the nature of cortical processing for color patterns, we examined human cortical responses to isoluminant color appearance-disappearance checkerboard and full-field patterns as a function of color contrast. The patterns were square-wave modulated from gray to color and back to gray (0.5s on and 1.5s off) and the stimuli used chromatic excitation purities ranging from 0.03 to 0.53. We measured the chromatic visual evoked potential (cVEP) with a 64-channel BioSemi system (but obtained the spatial resolution of a 128-channel system by positioning the 64 electrodes on the back half of the head from Cz using the extended 10-20 system). Cortical topography indicated the cVEPs were highly localized at electrodes near Oz, pointing to V1 cortex as their major source. Responses (30 repeats) were signal-averaged and Fourier-transformed. Remarkably, the cVEP waveform of the checkerboard pattern at Oz showed evidence of two different chromatic mechanisms: one was early, fixed around 100 ms for all excitation purities, whilst the other had a latency that decreased dramatically as excitation purity increased. In full field the N100 was stronger (characteristic of area-responsive, single-opponent cell contributions) and the second mechanism was absent (indicating it had been due to edge-dependent double-opponent cells). Gomes et al (2010) measured the VEP of equiluminant red-green sine-wave gratings as a function of pooled cone contrast; their resulting waveforms did not contain a peak equivalent to the N100 that we had observed, thereby supporting the suggestion that the N100 was due to single-opponent cells. Whilst this mechanism was clearly linear, the double-opponent mechanism was strikingly nonlinear; as was confirmed by Fourier analysis which showed phase advances and large changes in the amplitude spectrum with increasing excitation purity. These data establish the existence of color-contrast-dependent non-linear dynamics in cortical processing.

Title: Red predominance of gamma band power in macaque v1 and v4

Authors: ***Y. LIU**[1,2], J. YIN[1], Z. CHEN[1,2], I. M. ANDOLINA[1], W. WANG[1];
[1]Lab. of Visual Perceptual Mechanisms, Inst. of Neuroscience,CAS, Shanghai, China; [2]Univ. of Chinese Acad. of Sci., Shanghai, China

Abstract: Our visual world is rich in spectral information, and the evolution of separate L / M cone and resultant L—M opponent channels in catarrhine and some platyrrhine primates is indicative that distinguishing "red" from "green" serves a critical purpose. Psychophysical studies in humans, and electrophysiology in both human and non-human primate visual cortices suggests a red dominance in driving neural responses in comparison to other colors. Here we used 16-channel laminar probes to record local field potentials (LFP) and multi-unit activity (MUA) across the cortical depth for full-field isoluminant color stimuli in both V1 and V4. We computed band-limited power from the LFP 0-200ms during stimulation induced by seven isoluminant colors (red, orange, yellow, green, cyan, blue, purple). As the gamma (γ) band is commonly assumed to be related to attention and stimulus awareness in visual cortex, we hypothesized that the red may differentially drive gamma band power during visual perception. Consistent with our hypothesis, we found that red stimulation induces significantly higher power at both the γ-low (30-50Hz) and γ-high bands (50-100Hz) across all laminar depths in both V1 and V4. Even when recording within V4 color domains whose color preference was other than red, or V4 form domains with little color preference, red still drove a higher γ-band power response. The fact that red drives a significantly enhanced γ-band response invariant to color or form domain preferences is consistent with the perceptual preference to red seen across primate species.

Title: Interocular gain control in primate LGN

Authors: *K. DOUGHERTY, M. A. COX, A. MAIER;
Dept. of Psychology, Vanderbilt Univ., Nashville, TN

Abstract: Visual appearance differs rather little when we use one or both eyes despite the drastic difference in sensory input to the visual system. This similarity between monocular and binocular viewing suggests that the brain accounts for the difference in input through a process of interocular gain control. The dorsal lateral geniculate nucleus of the thalamus (LGN) has been identified as a candidate structure for such interocular gain control. The anatomical connectivity of the LGN allows for neurons that receive inputs from one eye to be modulated by neurons that receive inputs from the other eye. However, due to a lack of converging evidence, it remains unclear in how far responses of LGN neurons depend on the views of both eyes. Here we directly test the hypothesis that interocular gain control occurs within the main pathways of the LGN. Towards this aim, we recorded single unit responses from multiple LGN layers simultaneously with a linear multi-contact electrode array in macaques. Animals were trained to fixate while visual stimuli were presented to one or both eyes through a mirror stereoscope. We compared visual responses to varying levels of interocular luminance and contrast differences. For the majority of magnocellular and parvocellular LGN neurons in our sample, visual responses were comparable under monocular and binocular stimulation. However, for a small fraction of LGN neurons the contrast response functions systematically shifted between monocular and binocular conditions. This finding suggests that, while it is possible that interocular gain control begins in the LGN, it seems unlikely that the LGN is the main structure supporting this process in primates.

Title: Effect of stimulus discontinuities and chromatic input on gamma rhythm in primate primary visual cortex

Authors: *V. SHIRHATTI[1], S. RAY[2];
[2]Ctr. for Neurosci., [1]Indian Inst. of Sci., Bengaluru, India

Abstract: Gamma rhythm (~30-80 Hz) has been hypothesized to play an important role in perception and feature binding, which posits that gamma should be generated by a wide range of stimuli. However, while gamma is elicited strongly in local field potential (LFP) signals by stimuli such as bars and sinusoidal gratings, whether natural images also produce salient gamma is contested (Brunet et al (2013), Hermes et al (2014)). To elucidate this we studied the effect on gamma of two important aspects of natural images - stimulus discontinuities and chromatic properties.

Because a natural image contains arbitrary low-level discontinuities in many dimensions (such as luminance or orientation), it is difficult to determine the effect of such discontinuities on Gamma rhythm using natural images alone. We therefore studied the effect of experimentally controlled and parameterized discontinuities (such as a cut or discontinuity in orientation, contrast or phase) in grating stimuli on Gamma rhythm in LFP recorded from the primary visual cortex of two awake rhesus macaques (Macaca Radiata).

We observed that Gamma rhythm was robustly induced by continuous sinusoidal gratings, but was drastically reduced in the presence of even a small discontinuity. This drop was observed for discontinuities of various types, such as luminance, orientation or phase. In a separate set of experiments we found that chromatic input also significantly modulates gamma rhythm in V1 LFP even though the neuronal responses are largely unaffected.

When presented with natural images, as predicted by these results, Gamma rhythm was found to be weak or absent for most images, consistent with the findings of Hermes and colleagues (2014). Overall, our results show that Gamma rhythm is unlikely to play a major role in the processing or binding of natural images. Instead, it could be a resonant phenomenon that depends critically on the excitation-inhibition balance within the local neuronal network and gets disrupted if this balance is compromised due to discontinuities. Additionally, our results report for the first time that chromatic input is also a major determinant of gamma rhythm in LFP in the

primate primary visual cortex.

Title: Neuronal dynamics related to figure-ground modulations in V1 and V4 of the macaque monkey

Authors: *S. VAN STIJN[1], W. H. BARNES[1], W. SINGER[2,3], S. H. LEE[4,3];
[1]Ernst Strüngmann Inst. (ESI) In Cooperation With Max Planck Society, Frankfurt Am Main, Germany; [2]Max Planck Inst. for Brain Res., Frankfurt, Germany; [3]Ernst Strüngmann Inst. (ESI) In Cooperation With Max Planck Society, Frankfurt am Main, Germany; [4]Max Planck Inst. for Empirical Aesthetics, Frankfurt am Main, Germany

Abstract: An ongoing mystery of visual processing is how fragmented local visual information gets bound into a unified global percept. Feedback from higher order areas with larger receptive fields modulates incoming visual information already at the level of primary visual cortex. To further elucidate the mechanisms of figure-ground segregation, the current study investigates the neural dynamics (MUA and LFP) of macaque V1 and V4 in response to two figure-ground stimuli. We use chronically implanted electrode arrays (Graymatter Research) which allow us to sample from a large number of cells simultaneously with adjustable electrodes.
The first stimulus consists of an array of dense coherently rattling random dots. For a certain time period within a trial, a subset of dots confined to a circular area rattles out of sync to the global rattle, but with an equivalent magnitude. This creates the temporary percept of a pop-out disc while keeping local stimulus properties unchanged for the length of the trial.
The second stimulus consists of an array of randomly placed randomly oriented Gabor patches. At one time point in the trial, the Gabor patches are replotted with a subset of the patches forming either an open or a closed apparent figure. At the beginning of each trial, Gabor patches that will become part of the figure, or the background respectively, are placed over the RFs. These Gabor patches are kept unchanged during the trial. Thus, the effect of a global perceptual change can be assessed while the local stimulus features remain constant. To increase attention

to the figure, the monkey must report whether the figure is open or closed.
We observed an increase in spike rates when the RFs were part of the figure but only when there was a strong pop out (rattling disc) or figure directed attention (Gabor figure task). Furthermore, we observed a bifurcation in spike rates for the Gabor task in the first 100ms after the appearance of the figure. Units with RFs on the figure showed a significant increase in spike rate while units with RFs over elements of the background showed a decrease. In addition there was an increase in synchronous firing of the V1 neurons responding to elements of the figure.

Title: The extra integration time window for illusory contour representation in macaque V2 and V4

Authors: ***Z. CHEN**[1,2], J. YIN[1], Y. LIU[1,2], Y. LU[1], X. LI[1], I. M. ANDOLINA[1], W. WANG[1]; [1]Inst. of Neuroscience, CAS, Shanghai, China; [2]Univ. of Chinese Acad. of Sci., Shanghai, China

Abstract: One distinct feature of the primate ventral stream is that neural response latencies monotonically increase accompanying the increasing complexity of encoded physical features and the size of neuronal receptive fields along the hierarchy (Rousselet et al., 2004; Kravitz et al., 2013; Yau, Pasupathy et al. 2013). However, it is less clear for neural representations of visual illusions. Previous studies of neural responses mediating the Kanizsa triangle suggest that this type of illusion is represented in higher visual areas and fedback to early visual cortices (De Weerd et al. 1996; Mendola et al. 1999; Ramsden et al. 2001; Lee & Nguyen 2001; Murray et al. 2002; Halgren et al. 2003; Stanley and Rubin 2003, Cox et al., 2013). Abutting-line illusions represent the simplest illusory contour (IC) whereby aligned local line-ends elicit a global perception of an illusory contour. We hypothesized that this type of IC is mediated through a feed-forward integration of local defining cues, and therefore would show a monotonic relationship along the visual hierarchy. To test this hypothesis, we studied neuronal response latencies for abutting-line IC stimuli of the same spatial scale from V1 to V4 using electrophysiological recording in awake macaque. We found that a longer integration time window is required for the representation of ICs when compared with the representation of real

physical lines or gratings. The representation of ICs takes on average 24ms of extra time than for real contours in V4 (79ms versus 55ms for IC and real contours, respectively). The latencies for real and illusory contours in V4 are significantly longer than in V2, where the extra time taken for the representation of ICs is about 14ms. The average visual response latency of V2 neurons for IC and real contours is about 62 and 48ms, respectively, which agree with re-measurements from the spike responses of V2 neurons from von der Heydt & Peterhans 1989. No neurons recorded in V1 signaled the presence of ICs due to the spatial scale of our stimuli. Thus our findings strongly support that the view that the neuronal representation of abutting-line ICs follows a serial feed-forward integration along the ventral stream, needing extra time for representation when compared with real contours.

Title: Inter-ocular contrast normalization in the amblyopic visual cortex

Authors: ***B. RICHARD**, F. LYGO, D. H. BAKER;
Psychology, The Univ. of York, Heslington, United Kingdom

Abstract: Doubling the input to visual cortex by presenting stimuli to two eyes rather than one has little impact on the magnitude of neural responses (Moradi and Heeger, *JoV,* 9, 1-22). This is well explained by a normalization process whereby each eye contributes equally to the suppression of the other. This type of model can also explain psychophysical binocular vision deficits in individuals with amblyopia when the input from the amblyopic eye is attenuated prior to inter-ocular suppression (Baker et al., *Vis Res*, 48, 1625-1640). Importantly, the model defines the amblyopic binocular deficit as monocular attenuation without any abnormal suppression or structural changes to the binocular combination process. Here we measure neural signals, using both a Steady-State (SSVEPs) and a functional Magnetic Resonance Imaging (fMRI) method, to test the model assumptions in regards to attenuation and inter-ocular suppression in individuals with and without amblyopia. In both studies, stimuli were sinusoidal gratings with a spatial

frequency of 3 cycles/° at five different contrast values (0, 1.5, 6, 24 and 96%). Stimuli flickered (contrast modulation) at a rate of 4Hz and were presented monocularly, binocularly, and dichoptically (stimuli of different contrasts presented to each eye) to observers for trials of 12 seconds. Stimulus viewing conditions were identical in both the SSVEP and fMRI studies. Our control participants showed typical contrast response functions in the monocular viewing conditions, which increased monotonically as a function of stimulus contrast. Under binocular and dichoptic viewing conditions, contrast response functions showed evidence of sub-linear summation, a consequence of inter-ocular suppression. In participants with amblyopia, we observed a reduction in the response of the amblyopic eye, and a rightward shift of contrast response functions under dichoptic conditions. This pattern of results is consistent with monocular attenuation of signals in the amblyopic eye without any modification to inter-ocular suppression. This computational account of amblyopic deficits demonstrates how vision can become functionally monocular without requiring structural changes to binocular combination, or abnormal suppression.

Title: Multiple mechanisms underlying color appearance and color naming

Authors: ***K. EMERY**[1], V. J. VOLBRECHT[3], D. H. PETERZELL[4], M. A. WEBSTER[2]; [1]Dept. of Psychology (0296), [2]Psychology, Univ. of Nevada, Reno, Reno, NV; [3]Psychology, Colorado State Univ., Fort Collins, CO; [4]Psychology, John. F. Kennedy Univ., San Francisco, CA

Abstract: The number and nature of the mechanisms underlying color appearance remain poorly understood. Standard models posit two opponent channels mediating red vs. green or blue vs. yellow sensations. However, a neural basis for this representation has yet to be identified. We took advantage of the large individual differences in color perception to analyze the processes underlying color percepts in color normal observers, using factor analysis to explore the patterns of variability in both hue scaling and hue naming. 30 observers were shown 36 hues of roughly equal saturation spanning steps of 10 deg around the standard cone-opponent space. The stimuli

were shown on a calibrated CRT as 2 deg uniform fields demarcated by black borders from an equiluminant (20 cd/m2) gray background. In the hue scaling task observers judged the component proportions of red, green, blue, or yellow. In the naming task they used unrestricted names or a fixed set of basic color terms to label each hue. A factor analysis of both data sets revealed multiple factors with each largely confined to a narrow range of contiguous hue angles. These were inconsistent with predictions for classical opponent channels varying in their tuning or relative sensitivity, which instead predict broad and bimodal patterns of factor loadings. The observed factors instead reveal that putatively opponent pairs (e.g. red and green) are constrained by independent processes, and moreover that binary hues (e.g. orange) vary independently of their constituent primaries (e.g. red and yellow). Our results suggest that different narrow angles of color space may each be governed by different mechanisms that can vary across observers, and these are manifest even in the standard hue scaling task that requires observers to perceptually decompose each hue into red-green and blue-yellow components. The pattern we observed is consistent with a cortical representation of color mediated by population coding in multiple "higher-order" mechanisms such that different hues reflect qualitatively different perceptual categories rather than metrical variations within a "neural" color space.

Title: Chromatic interaction profile in macaque area V4

Authors: *T. M. SANADA[1,2], H. KOMATSU[1,2];
[1]Natl. Inst. For Physiological Sciences, Div. of Sensory and Cognitive, Aichi, Japan;
[2]SOKENDAI, Okazaki, Aichi, Japan

Abstract: Neurons in area V4 of the macaque monkey plays important roles in color vision. Although color selectivity of V4 neurons has been examined, most studies have measured selectivity to single color stimulus. Objects in natural scene typically have various colors on their

surfaces as well as texture, which provides important cue for our object recognition. Some studies have reported response modulation by surrounding color (Schein and Desimone 1990, Kusunoki et al., 2005), however, combinations of color stimuli were limited in these experiments and it is still unclear how V4 neurons respond to multiple colors presented on the receptive field (RF). In this study, we examined response profile to combinations of colors and tested if the chromatic interaction profile can be predicted by responses to single color stimuli. After identifying RF position/size by hand mapping, color selectivity was measured in conventional way by single color stimulus (16 colors). Then, chromatic interaction profile was measured by presenting color combination stimuli with center and annulus over the RF. Colors of center and annulus were randomly selected from 8 hues that evenly divided an iso-saturation circle in CIE-uv chromaticity diagram. For each neuron, we tested 64 color combinations (8x8 hues). In addition, responses to single color patch (either center only or annulus only) were tested (8 hues each, single patch conditions). We found that about 45% of the V4 neurons tested showed strong modulation of the responses due to color combination. Such response modulation to specific color combination was observed even in neurons that did not show significant color selectivity measured by single color stimulus. The chromatic interaction profile cannot be predicted by linear sum of responses in single patch conditions. Furthermore, in some neurons, such responses to specific color combination disappeared when colors were swapped between the center patch and annulus. This indicates that there is spatial configuration on the chromatic interactions. These results suggest that V4 neurons represent chromatic information in a manner more complex than previously thought. References:1. Title: Green face illusion

Authors: ***M. HASSANTASH**[1], A. AFRAZ[2];
[1]Cognitive science, Inst. For Res. In Fundamental Sciences,Ipm, Tehran, Iran, Islamic Republic of; [2]McGovern Inst. for Brain Res., cambridge, MA

Abstract: We have accidentally discovered a visual illusion; faces (and -seemingly- no other objects) appear greenish under the monochromatic yellow light of a sodium lamp. This is an unusual observation because under monochromatic sodium illumination there exist only one hue, yellow. Thus the greenish appearance of faces cannot be attributed to a retinal origin. We systematically measured the magnitude of this object-based color illusion and its selectivity for faces in comparison to other objects. 6 different objects, 9 Munsell chips, 3 human hands and 3 human faces were presented to the subjects (n=9, normal color vision, age 20-30) in two illumination conditions: sodium and white light. Additionally, to dissociate the effect of the monochromatic light on perceived skin tone from its potential interaction with facial (or hand) features, the whole face/hand, as well as a patch of the face/hand skin (the rest masked by a thick black cover) were presented in both conditions. For both illumination conditions, the test objects were presented in a random sequence and the subjects matched the color of a point on each object using a color-matching paradigm. The color matching display was a computer screen placed inside a black box to avoid contamination of the ambient illumination with the screen light, subjects looked at the screen through a small aperture. We then compared the color matching results with spectral measurements of the tested objects for both illumination conditions. Observed hues and matched hues were significantly correlated for the white light condition ($r>0.68$ $p<0.05$, all subjects) indicating the ability of subjects to perform color matching. This correlation went away when objects were viewed under monochromatic light ($r<0.19$, $p>0.067$). As expected, under the sodium light, the perceived hue for different stimuli was highly similar (CIE x=0.45, STD=0.14, CIE y=0.48, STD=0.12) and all stimuli were matched as different shades of yellow. However, perceived color of faces deviated from other objects under monochromatic yellow light and shifted towards greenish shades (CIE x=0.63, STD=0.11, CIE y=0.59, STD=0.09). This shift happened exclusively for faces and did not occur for other stimuli, it also did not happen for patches of face skin. Chromatic selectivity has been frequently documented throughout the ventral stream, thus shape and color information might be systematically entangled. Our results provide an example of interaction of color perception with shape processing, revealing existence of strong hue-priors for certain object classes (faces in this case).

Title: Comparison of contrast sensitivity in human and non-human primates.

Authors: *W. RIDDER[1], A. KARSOLIA[1], K.-M. ZHANG[2], J. BURKE[2];
[1]SCCO, Marshall B. Ketchum Univ., Fullerton, CA; [2]Allergan, Inc, Irvine, CA

Abstract: **Purpose:** Non-human primates (NHPs) are frequently investigated to understand human diseases of the visual system. A common clinical measurement for many visual diseases is visual acuity. Visual acuity can be measured by employing psychophysical (e.g., the contrast sensitivity function) techniques in NHPs. The purpose of this investigation was to determine the relationship between acuities determined with similar psychophysical techniques in human and NHPs. **Methods:** Ten normal humans and 8 normal NHPs (Macaca fascicularis) took part in this project. The NHPs were placed in a primate chair in a sound isolating chamber. The NHPs were trained to hold and then release a lever when they detected a sine wave grating on the monitor. Threshold was operationally defined as two misses in a row for a descending method of limits (10 spatial frequencies from 0.3 to 20.2 cpd). A similar paradigm was used for the humans except that the descending method of limits was combined with a 2 AFC technique and the spatial frequency range was 0.75 - 18.50 cpd. The contrast sensitivity functions were fit with a double exponential function and acuity was determined by extrapolating the fit to a contrast sensitivity of 1. **Results:** The averaged peak contrast sensitivity, peak spatial frequency, and acuity for the humans were 279.6 ± 37.6 (Mean ± SE), 3.50 ± 0.32 cpd, and 27.3 ± 2.5 cpd and for the NHPs were 112.0 ± 14.0, 4.3 ± 0.45 cpd, and 28.7 ± 3.60 cpd. A two-sample t-test indicated that the peak contrast sensitivities were different ($p < 0.001$). The peak spatial frequencies ($p = 0.13$) and the extrapolated visual acuities ($p = 0.75$) were not different. **Conclusions:** The contrast sensitivity functions for the NHPs had lower peak contrast sensitivities than the humans. The peak spatial frequency and visual acuity extrapolations were the same for the humans and the NHPs. The contrast sensitivity differences and similarities between humans and NHPs need to be considered when using NHPs to study human disease.

Title: Stimulus dependence of gamma oscillations (20 - 70 Hz) in human EEG

Authors: *M. V. P. S. DINAVAHI[1], V. SHIRHATTI[2], P. RAVISHANKAR[1], S. RAY[1];
[1]Ctr. for Neurosci., [2]IISc Mathematics Initiative, Ctr. for Neurosci., Indian Inst. of Sci., Bangalore, India

Abstract: Stimulus characteristics of Cartesian gratings such as spatial frequency, size, contrast, orientation and drift speed have been shown to influence power, centre frequency, and temporal evolution of stimulus-sustained gamma oscillations in local field potentials (LFP) in animals, but how these characteristics influence gamma oscillations recorded in human electroencephalogram (EEG) is not well studied. Here we compared the stimulus dependence of gamma oscillations in EEG recorded from humans versus LFP recorded from the primary visual cortex of monkeys. We found that large Cartesian gratings centred on the fovea generated not one, as reported in previous studies, but two gamma oscillations in human EEG. Specifically, we observed a slower gamma at 20 - 40 Hz along with the traditional band at 40 - 70 Hz. Similar results were observed in monkey LFP recordings as well. The low gamma band was observed in two-thirds of the subjects studied, and about half of the subjects showed at least 1 dB increase in power from the baseline in both the low and the traditional gamma band for the same stimulus set. Also, bipolar reference scheme used in this study for analysis of data revealed strong lateralisation of both the gamma bands in most subjects. The low gamma band showed similar tuning characteristics as the traditional gamma oscillations. In general, both the gamma bands showed a sharp spatial frequency tuning around 2 - 4 CPD (cycles per degree). The power in both the bands increased with increase in size and contrast of the grating. It was maximum for stationary gratings and decreased with increase in the speed of drifting gratings. Similar results were obtained in comparable recordings in the LFP recorded from the monkey. In EEG recordings, both gamma bands showed weak or no tuning to orientation, while tuning was much stronger in monkey LFP recordings with low and traditional gamma bands tuned to different orientations.
Two gamma rhythms can potentially provide better coding or communication mechanisms, more flexible and robust signal for brain machine interfacing applications, and a more comprehensive biomarker for diagnosis of mental disorders such as Alzheimer's disease.

Title: Powerful visual illusion of light/dark perception in human faces

Authors: ***R. BACHY**, J. ALONSO, Q. ZAIDI;
GCVR, SUNY Optometry, New York, NY

Abstract: We present a striking new lightness illusion in face perception. When the grey-level image of a face is half-wave rectified into images above and below the 50^{th} percentile of the luminance histogram, the two images have similar features but non-overlapping grey levels except for the mid-grey. Remarkably, the two faces appear to have widely overlapping ranges of lightness, and we discovered to our surprise that the face with the higher luminance values appears much darker. We quantified this observation in two ways. Images of a face digitally modified to 4 different skin shades from fair to dark, were rectified into high and low luminance versions. Observers who were asked to arrange the 8 faces by perceived skin color from lightest to darkest, ranked every face with the higher luminance as darker than its lower luminance pair. Observers also matched the grey level of a small disk in white noise to the perceived lightness of 8 features of face images in original, high and low versions. The range of matched brightness of the rectified images was shifted and expanded from 50% of the original image to over 90% in some cases. To explain the illusion, a model of time-varying brightness induction was modified for the static case. The model first applies a punctate gain, controlled by local adaptation, to each point in the image, which compresses the luminance range and shifts it lower, simulating photoreceptor responses. Then brightness induction signals from all surrounding points are added for each point. The induction from each surrounding point is calculated as the signed difference between the receptor signals at the two points, gain controlled by the absolute difference between the signals, and weighted by an exponentially decreasing function of the spatial distance. The

parameters controlling the luminance and induction gains, and the space constant of the spatial weighting, were adjusted to fit the data. The model explained the illusion by reproducing the perceived brightness in both high and low luminance images. The luminance-based gain-control reduced the effect of absolute luminance. The induced effect of surrounding points overcame the resulting range contraction, and made perceived lightness largely a function of the surrounding brightness, with the effect of gradual luminance gradients being enhanced by the induction gain. Our illusion also affects the perceived lightness of animal and object surfaces in natural images, thus revealing that neural mechanisms generically expand perceived brightness and enhance the effect of luminance gradients over absolute luminance. Our model shows that local adaptation and surround induction can function as these mechanisms.

Title: Attention and amodal completion affect metacontrast masking.

Authors: *V. S. RAMACHANDRAN[1], M. VAJANAPHANICH[2], C. CHUNHARAS[2,3]; [1]UCSD, La Jolla, CA; [2]UCSD, San Diego, CA; [3]Med., Chulalongkorn University, KCMH, Bangkok, Thailand

Abstract: If a square patch of grating target, 1.5 degree, is flashed for 75 ms followed by flanking gratings (mask) flashed for another 75 ms; the target becomes invisible (metacontrast). We cycled the target-mask pair in a continuous cycle with inter-pair interval being 400 ms. The target remained continuously invisible. The degree of masking was measured by having the subject discriminate the orientation of the target grating. Remarkably, when the subject reached out with his index finger to “touch” the invisible target, the target became instantly visible. The effect could be produced using a tiny photo of a finger superposed on the target even though one wouldn’t ordinarily expect continually visible features to interfere with the masking. The photo by itself or pointing behind the computer screen was not quite as effective suggesting a contribution from proprioception, attention, and/or re-afference. We also noticed that if several target-mask pairs were displayed simultaneously on the screen the single unmasked one “popped out”. Next experiment, we asked whether amodal-completed rectangle could be masked by non-occluded flanking rectangles. We found the masking did occurred compare to the control condition of fragmented target without occluder. This demonstrated the image segmentation

based on implied occlusion occurred prior to metacontrast masking. Taken collectively, our experiments demonstrate a striking modulation of metacontrast masking by visual attention, segmentation and proprioception.

Title: Monkeys see snakes like humans do: A comparative analysis of internal noise and efficiency in contour integration

Authors: *A. ZHANG[1], P. KHAYAT[1,2], H. AKHAVEIN[1], A. BALDWIN[1], R. HESS[1], R. FARIVAR-MOHSENI[1];
[1]Ophthalmology, McGill Univ. Hlth. Ctr., Montreal, QC, Canada; [2]Sch. of Optometry, Univ. of Montreal, Montreal, QC, Canada

Abstract: The visual system's ability to detect contours, even in the presence of discontinuities, is essential for interpreting everyday scenes. Previous studies have shown that both humans and monkeys are equally proficient on tasks where they are required to detect a contour embedded in a noisy background. However, it is not clear whether the underlying neural process is similar between species. We designed a novel task that allows us to determine the efficiency and level of internal noise governing contour perception. Internal noise reflects the quality of the visual information received by the brain while efficiency is how well the brain uses that information. Through these measures, we compared how contours are internally represented and processed between species. In our task, contours were presented with external noise added by adjusting the orientation of Gabor elements such that there was no longer good continuation between the elements. On each trial, contours had different degrees of curvatures or degrees of noise. Three macaques were trained to saccade to the contour with better continuation in a two-alternate forced choice task. Psychometric performance as a function of curvature was obtained for each noise level, showing that detection threshold increases with increasing external noise. The thresholds for each condition and subject were then fitted with a Linear Amplifier Model that calculates internal noise and performance efficiency as a function of external noise. At

decreasing external noise, thresholds are increasingly determined by internal noise, so the limit of the fitted function allows us to determine levels of internal noise alone. Macaque data was then compared to human subjects on an analogous task. The results show that contour integration efficiency and internal noise is similar in monkeys and humans. Our findings are indicative that not only do monkeys perform equally well on a contour detection task, contours are internally represented and processed in a similar manner. This evidence suggests that humans and monkeys have a common framework for contour perception and therefore may share an underlying neuronal mechanism for visual integration.

Title: Which side of the face is more sensitive to enfacement illusion?

Authors: *E. GÜLBETEKIN;
Dept. of Psychology, Akdeniz Univ., Antalya, Turkey

Abstract: “The experience of observing oneself reflected in the mirror involves the integration of motor, proprioceptive, tactile and visual cues, as every touch on one’s face is mirrored by a compatible visual event” (Tajadura-Jiménez, Lorusso and Tsakiris, 2013). A mirror-like effect can be induced by another face during the‘‘enfacement’’ illusion paradigm. Research on enfacement illusion indicated that this experience affects one’s self face perception. The aim of the experiment is to find out which side of the face is more sensitive for enfacement illusion.
Method
Subjects: Twenty eight male undergraduate students (M = 21.28years, SD = ±1.82) participated the study.
Stimuli: A video of a male model was recorded while his face was stroked with a cotton bud (Fig1, Fig2).

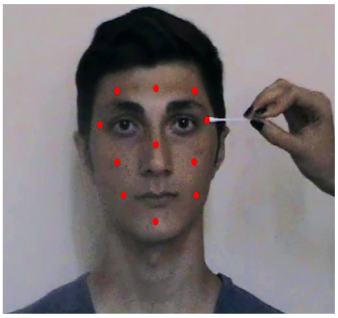

Figure1. 11 points were touched in both the synchronous and asynchronous sessions.

Figure 2. The right side and the left side of the face around cheeck were touched linearly for three times in both the synchronous and asynchronous sessions.

1. While the other person's face was touched I seemed to feel the touch on my own face.
2. It seemed that the touch I felt on my face was caused by the cotton swab touching the other person's face.
3. It seemed that the other person's face was mine.
4. It seemed that the other person's face was part of my body.
5. It seemed that the other person's face belonged to me.
6. I seemed to see my face reflected in a mirror rather than the other person's face.
7. It seemed that the shape of the other person's face began to resemble mine.
8. It seemed that the skin color of the other face began to resemble mine.
9. It seemed that the features of the other person's face began to resemble mine.
10. It seemed that the other person's face would move if I moved.

Strongly Diagree						Strongly Agree
-3	-2	-1	0	1	2	3

Procedure

The participants were asked to watch the video clips from a viewing distance of 150 cm. A synchronous and asynchronous sessions were applied. While watching the video, participants were touched on their face at the same time and the same locations with the video in the synchronous sesions. However, there was a delay between the strokes on the two faces in the asynchronous sessions. After watching the video clips, 10 enfacement questions were asked to the subjects. An additional question was asked to asses on which side of the face a stronger stimulation was sensed while the viewing of the video clips. The order of stimulation type and side were counterbalanced between subjects.

Results

Mean responses for each of the 10 questions were calculated. Wilcoxon signed-rank tests were conducted. The subjects gave higher ratings of agreement to 7 of the 10 illusion questions items after synchronous relative to asynchronous sessions, showing that synchronous stimulation could successfully induce the illusion. Chi-square test indicated that there was a significant difference among face side for enfacement effect X^2 (2, 28) = 17.64, p =.001. The results indicated that the subjects experienced stronger enfacement effect when the right side of the face was stimulated.

Title: Repulsion of perceived visual motion direction as an emergent property of deciding to unify or segregate sources

Authors: *A. I. MESO[1,2,3], K. HARUHANA[3], G. S. MASSON[2], J. L. GARDNER[4];
[1]Fac. of Sci. and Technol., Bournemouth Univ., Poole, United Kingdom; [2]Inst. de Neurosciences de la Timone, CNRS/Aix-Marseille Univ., Marseille, France; [3]Riken Brain Sci. Inst., Wakoshi-Saitama, Japan; [4]Dept. of Psychology, Stanford Univ., Stanford, CA

Abstract: To understand dynamic scenes, humans must infer which motion signals should be unified, that is, labelled as coming from the same object, and which should be segregated into signals from different objects. In the face of ambiguities, this underlying computational task of unclassified separation (separating mixed signals with unknown labels) is not trivial and solutions may engender perceptual consequences. We studied the case of motion transparency: simultaneous perception of two directions within the same region in space; and motion repulsion, the phenomenon in which perceived separation between transparent directions is wider than physical separation. In a psychophysical task, six participants made direction comparisons of components of two large random dot stimuli. We varied dot appearance and measured small changes in repulsion size. Judgements were made on controlled simultaneous presentations of two stimuli in the left and right visual field. Cardinal and oblique motion directions were deliberately excluded to avoid known reference attraction biases. Precision of single direction estimates of 0.5-3° were measured across individuals, consistent with a fine-grain sensory representation of individual components. Under transparent presentation, repulsion values of between 4-8 degrees were measured, consistently stronger at 30 than at 60 degrees of separation. Ambiguity in local direction introduced by appearance changes resulted in stronger repulsion. The pattern of shifts in repulsion suggests that the probabilistic component neural representations were consistently pushed away from the average during transparency perception. Incorporating experiment insights, the underlying separation task was modelled using a hierarchical two step Bayesian formulation. In the first step, an initial estimate was made to determine whether a motion signal comes from a unified source or whether there are two segregated sources based on the spread of direction signals. In the second step, this number of source estimates acts as a prior which for two sources inhibits the average direction and shifts the posterior distribution for the

two directions of motion away from each other, thus resulting in motion repulsion. We suggest that determining whether to unify or segregate motion signals could explain motion repulsion effects and that this is just one example of a consequence of such a computation that may appear in other neural processing contexts.

Title: Solid field of visibility: first model and test

Authors: *S. GEPSHTEIN[1], G. LYNN[2], A. MCDOWELL[3];
[1]The Salk Inst. VCL-A, La Jolla, CA; [2]Sch. of the Arts and Architecture, Univ. of California at Los Angeles, Los Angeles, CA; [3]USC, Los Angeles, CA

Abstract: Visual systems are unequally sensitive to different features of the world. One characteristic of the unequal sensitivity is the contrast sensitivity function (CSF) commonly measured with periodic stimuli, such as luminance gratings, viewed over a fixed distance. For a fixed viewing distance, the CSF describes how different amounts of luminance contrast are required to make the stimulus just visible for different spatial frequencies of luminance modulation in the stimulus. When the spatial frequency is fixed but the viewing distance is varied, a similar profile of contrast sensitivity is expected as a function of viewing distance. Using this method, we predict the range of viewing distances over which the stimulus is visible in any direction. A complex optical environment that contains multiple patterns can be described in terms of multiple corresponding solid regions of visibility that may overlap or nest in one another. This structure is usefully summarized as a 'solid field of visibility' in which the value of visibility varies smoothly across location. This description constitutes a sensory counterpart of the light field, which is a radiometric description of the amount of light flowing in every direction through every point in space. We derived a simplified model of the solid field of visibility using an established characterization of human spatiotemporal CSF (Kelly, 1979). We tested the model using large-scale robotics at the UCLA Architectural Robotics Laboratory. A large screen and a projector were mounted on the end arms of two computer-controlled industrial

robots, capable of moving synchronously along linear tracks. An integrated custom-built suite of hardware and software coordinated the positions of robots and presented visual stimuli on the screen. Observers were seated between the tracks and performed the tasks of detection and direction discrimination by means of a wireless computer mouse. First, we confirmed that visibility of static stimuli was confined to the solid spatial regions predicted by the model. Second, the boundaries of visibility were tested for stimuli projected on moving screens. Visibility was found to change across location as predicted by the model, sometimes changing from zero to full visibility over a distance of half a meter, indicating a sharp boundary of the solid field of visibility. Such abrupt spatial transitions of visibility have immediate applications in design of immersive environments: fully virtual and mixed. Knowing the solid field of visibility of an environment allows one to selectively enlarge or diminish the solid regions of visibility for specific parts of the environment and thus control user engagement.

Title: Modeling orientation preference in the apical and basal trees of L2/3 V1 neurons

Authors: A. PAPOUTSI[1], J. PARK[2], S. M. SMIRNAKIS[3], *P. POIRAZI[1];
[1]IMBB-FORTH, Heraklion, Crete, Greece; [2]Baylor Col. of Med., Houston, TX; [3]Harvard Med. Sch., Boston, MA

Abstract: Pyramidal neurons receive inputs in two anatomically and functional distinct domains, the apical and the basal tree. Inputs to the basal tree, due to their proximity to the soma, greatly influence neuronal output, whereas the more remote apical tree has less potential to influence somatic activity. How these inputs co-operate to form the functional output of the neurons is currently unknown. In this work we focused on how inputs to the apical and basal trees shape orientation tuning in L2/3 V1 neurons. In particular, we investigated how dendritic integration of orientation tuned inputs to the apical versus basal trees allows for the emergence of stable neuronal orientation preference. Towards this goal a model L2/3 V1 pyramidal neuron was implemented in the NEURON simulation environment. The passive and active properties of the model neuron were extensively validated against experimental data. Synaptic properties, number

and distribution were also constrained according to available data. Using this model neuron we investigated a) the differences in the mean orientation preferences of the two trees and b) the distribution of orientation preferences to individual synapses that allow for the emergence of orientation tuning. In addition, we further identified how apical versus basal dendritic tree ablation would affect neuronal tuning in the different conditions implemented. Model results provide insights regarding the 'tolerance' to different input properties at the apical and basal tree in order to achieve stable orientation preference.

Title: Cortical mechanisms of stereopsis vision investigated using naturalistic stimuli and magnetoencephalography

Authors: ***Y. CHEN**[1], A. DEHMOOBADSHARIFABADI[1], E. BOCK[2], S. BAILLET[2], R. FARIVAR-MOHSENI[1];
[1]Ophthalmology Vision Res. Unit, The Res. Inst. of the McGill Univ. Hlth. Ctr., Montreal, QC, Canada; [2]Montreal Neurolog. Institute, McGill Univ., Montreal, QC, Canada

Abstract: Binocular disparity enhances human visual perception in natural scenes. Previous fMRI studies (Hasson, et al, 2004) have shown that natural viewing of a movie induces inter-subject correlation (ISC) of cortical responses, which has been suggested to increase when stereoscopic depth is added to the movie (Gaebler, et al., 2014). We raise two inter-related questions using an MEG approach in the presence of depth information in the movie stimulus: what is the frequency profile of ISC, and how disparity does addition of disparity affect ISC? 27 subjects were recruited to watch two clips from the movie 'Under the Sea' in both 2-D and 3-D version with central fixation. Eye blinks and cardiac activities were removed by signal-space projection in brainstorm (Tadel F, et al, 2011). Screen noise components were removed using independent component analysis. Brain sources were estimated by minimum norm methods. Hilbert transformation for the brain source response was performed in 6 difference bands: delta (2-4Hz), theta (5-7Hz), alpha (8-12Hz), beta (15-29Hz), low gamma (30-59Hz), and high gamma (60-90Hz). The transformed data were then low-pass filtered to 4Hz to emphasize the low

oscillation pattern for the high frequency amplitude. Comparing 3-D movie viewing condition with 2-D movie viewing condition, we observed greater ISC in the ventral visual areas (fusiform and inferior temporal) in the low gamma band in the left hemisphere. Thus our results support the claim that addition of binocular disparity enhances some aspects of ISC, but that these aspects are highly constrained to late-stage visual areas and to the high frequency range of cortical activity. An additional analysis of the relation between oscillatory activity and depth vs. luminance contrast will be presented.

Title: Color signal processing in the larval zebrafish brain

Authors: ***D. A. GUGGIANA-NILO**, F. ENGERT;
Harvard Univ., Cambridge, MA

Abstract: Light in the ultraviolet region is invisible to humans, but is ubiquitous in nature as it is one of the components of sunlight. This range of the electromagnetic spectrum is of particular importance to organisms in contact with it, given its higher energy per photon and concomitant potential to generate cellular damage and trigger mutations in DNA. The ability to detect these low wavelengths is present in a variety of organisms, ranging from mammals to insects. One of such organisms is the larval zebrafish (Danio rerio). This small teleost possesses 4 types of cone photoreceptors that can detect wavelengths from the red to the UV and are active as early as 4 days post fertilization (dpf). Additionally, this organism is a newly encumbered model for a variety of fields in biology such as development, pharmacology and neuroscience. This is due to a combination of well-described genetics, rich behavioral and physiological repertoire and optical transparency. In the past we have shown that larvae avoid UV light in an intensity dependent manner and that UV light is able to overcome phototactic behavior in freely swimming animals. In the current work we monitored the neural responses elicited by UV light in a tethered animal preparation. For this we relied on a custom built 2 photon microscope to

capture calcium spike signals from RGC terminals and the Optic Tectum of the animal, and we correlated these responses with the behavioral output of the larva during stimulation.

Title: Figure-ground discrimination by a population of V4 cells.

Authors: *K. SAKAI[1], M. HASUIKE[2], D. MINOWA[2], Y. YAMANE[3], H. TAMURA[3]; [2]Comp. Sci., [1]Univ. Tsukuba, Tsukuba, Japan; [3]Frontier Biosci., Osaka Univ., Suita, Japan

Abstract: Figure-ground (FG) segregation, a process to separate an object from background in a visual scene, is a crucial step toward object recognition in the visual cortex. Physiological studies on monkeys have reported that V4 cells appear to be sensitive to FG organization [Nat. Neurosci. 5, 1332-1338, 2002; Neuron, 75, 143-156, 2012] although their selectivity to FG in natural images has not been clarified. We investigated whether the intermediate-level visual areas represent information capable of determining FG in natural image patches. We recorded multiple single unit activities from V4 of two analgesized and immobilized macaque monkeys (Macaca fuscata) using 32 channel array electrodes. Eight hundred forty patches that were sampled from natural images with the constrains of diversity [Front. Psych., Article 1685, 2015] were presented for ten times. For a half of the patches, the objects that were therein were filled with black and white. The recordings included the responses from 1725 cells with their classical receptive field (CRF) center located within the patches.
First, we analyzed whether the responses of single cells in monkey V4 depend on FG organization of stimuli with respect to their CRF center. A two-way ANOVA with the factors of FG and contrast at the CRF center showed that 20% (351/1725) of cells showed the significance to FG ($p<0.05$), 30% to contrast, and 12% to the interaction. The mean FG-discrimination rate of the FG-significant cells was 51% that was barely above the chance. These results indicate that a part of cells in monkey V4 show the responses that depend on FG at their CRF center. However, these single cells are hardly capable of discriminating FG correctly for the natural image and

filled patches.
Second, we investigated computationally whether an integration of the responses of multiple cells enables the correct discrimination of FG for the stimulus patches. We used support vector machine (SVM) as an ideal machine for the integration of the responses of multiple cells. If the machine was capable of segregating correct FG from the cellular responses, it indicates that the responses of the cells included the sufficient information for judging FG. Our simulations showed that the responses of fifty V4 cells were capable of achieving 66% correct in the FG discrimination of the natural image and filled patches, suggesting the distributed population representation of FG in the intermediate-level visual area.

Title: Population coding model of color in visual cortex

Authors: T. WACHTLER[1,3], ***C. KELLNER**[1,2,3];
[2]Grad. Sch. of Systemic Neurosciences, [1]Ludwig-Maximilians-Universität München, Planegg-Martinsried, Germany; [3]Bernstein Ctr. for Computat. Neurosci., Munich, Germany

Abstract: Color information in the retino-cortical pathways is encoded by cone-opponency. The link of these physiological signals to perception is still unclear. Neither do the cone-opponent signals correspond to perceptually pure hues, nor is the color space defined by these signals perceptually uniform. Various properties of color perception, such as color discrimination and color induction, indicate a non-uniformity of the cone-opponent color space that corresponds to an expansion along the oblique blue-yellow axis. Here we present a model for the cortical encoding of color based on a population code that accounts for this perceptual non-uniformity. The model assumes that stimulus hue is encoded by a population of neurons with bell-shaped color tuning and color preferences distributed in color space. The model further assumes modulatory interactions between neurons with similar preferences, which results in the

prediction of chromatic induction for stimuli in chromatic surrounds. Tuning parameters of the model neurons were adjusted by fitting the predicted induction strengths to empirically determined color shifts for different chromatic surrounds. Fitting was constrained by the assumption of an expansion of color space along a single, adjustable axis. The resulting orientation in color space of the expansion axis fell close to the perceptual blue-yellow line. Compressing the empirical induction data along the expansion axis, i.e., compensating for the predicted non-uniformity of color space, reduced the variability between the induction curves. Small residual differences, which depended on stimulus size, remained for some directions in color space, suggesting an additional direct effect of the center-surround opponency of midget cells. The resulting population code was non-uniform, according to the color space non-uniformity, with tuning widths varying by ±6% around an average width of 44 degrees. The results indicate that a population code for color that incorporates the non-uniformity of cone-opponent color space can account for color induction effects observed in humans.

Abstract: Most of the current methods used to assess differences of chromatic equiluminance rely on human perceptual reports or on optokinetic responses to moving colored stimuli (e.g. Cavanagh et al. 1984; Chaudhuri and Albright, 1990). However, all these approaches require some minimum amount of training and cooperation from the participants. Here we report a novel Pupil Frequency Tagging method (PFTM), where oscillatory changes in relative stimuli brightness over time are mirrored by pupil constrictions and dilatations.
PFTM was apply to 10 human participants during 5 sessions of 6 minutes. We computed the spectral density of the pupil response and analyzed signal amplitude at the tagging frequency. As predicted, our results showed that the luminance-induced pupil oscillations are reduced at

equiluminance.
These results suggest that the amplitudes of pupil responses at the tagging frequency closely follow the variation of luminance and therefore provide access to the coding of stimulus luminance without any participant training. PFTM gives us a new opportunity to study chromatic luminance not only in cooperative adult human subjects but also in very young infants, or animals with minimal constraints on training, movement artifacts and length of the recordings sessions.

Title: OptokineSys: an automated method of quantifying visual function, even in people who cannot follow commands

Authors: ***J. HILL**[1,2,3], M. SUNER[1,2], J. B. CARMEL[1,2,3], G. T. PRUSKY[1,2,3];
[1]Burke Med. Res. Inst., White Plains, NY; [2]Blythedale Children's Hosp., Valhalla, NY; [3]Weill Cornell Med., New York, NY

Abstract: Brain injury may lead to cerebral visual impairment (CVI), a leading cause of disability in children. Diagnosing CVI is difficult, as brain injury often also leads to cognitive impairments that preclude traditional vision assessment methods. To address this, we developed an automated system to measure vision based on the smooth tracking of moving visual stimuli. Our system, called OptokineSys, moves visual stimuli smoothly across a large computer screen while an eye-tracker measures gaze position. Our algorithm determines in real time whether the eyes smoothly follow stimulus movement. It rewards smooth tracking by playing music of the subject's or caregiver's choice, to motivate continued engagement with the task. The algorithm tolerates reverse saccades, catch-up saccades and changes of direction, but interruptions longer than these will cause the system to pause the music. Smooth tracking in the correct direction and approximately correct speed is evidence that the subject can see the stimulus. An adaptive procedure uses this evidence to alter contrast and spatial frequency and determine a threshold of

visuomotor function. Our use of OptokineSys as a vision assessment tool is based on the principle that, given intact smooth pursuit, these tracking thresholds reflect the subjects' spatial vision.
We used OptokineSys to vary the contrast of a band-limited visual noise stimulus, to measure contrast thresholds as a function of spatial frequency. We also adapted spatial frequency at a fixed contrast level, to obtain spatial frequency thresholds as a single acuity measure. In healthy adult subjects, we found:(1) that the system worked robustly and without needing per-subject calibration; (2) that the resulting contrast sensitivity functions had an inverted-U shape, as expected of a true measure of spatial vision; (3) that contrast sensitivity measures were highly repeatable within and across subjects; (4) that spatial-frequency thresholds were well correlated with eye-chart acuity (LogMAR). In children with brain injury, we found (5) that OptokineSys engages children even when they are unable to follow verbal instructions, and (6) that it provides objective information about visual function, including repeatable spatial-frequency thresholds, even in children who cannot communicate and hence cannot otherwise be measured.
We conclude that our system is a promising tool for assessing spatial vision, even for people who cannot follow commands. Efficient, objective measurement of visual thresholds in people with brain injury should enable future studies to determine incidence, natural history, and treatment of CVI.

Title: Advancing models of shape representation for mid-level vision

Authors: *D. V. POPOVKINA, W. BAIR, A. PASUPATHY;
Biol. Structure, Univ. of Washington, Seattle, WA

Abstract: Visual area V4 is a critical part of the neural pathway underlying object recognition in primates. Our goal is to develop models that explain V4 responses to visual stimuli and thereby elucidate the computations supporting mid-level form processing in the visual cortex.
The current best-performing models of form representation in V4 (e.g. Cadieu *et al*., 2007) emphasize oriented features at the object boundary while disregarding surface attributes such as boundary phase information. Specifically, these contour-template models make the clear prediction that simple, filled 2D shape stimuli should evoke responses very similar to those evoked by only the outlines of the same shapes. However, past experiments in V4 have not explicitly tested the effect of surface fill on shape-selective responses.
We recorded responses from 43 single, well-isolated V4 units in awake, fixating macaques using a large battery of simple shapes (Pasupathy & Connor, 2001; 2002) that were presented either in filled or outline form. Surprisingly, we found that only 8/43 neurons (19%) maintained tuning for filled and outline shapes that was consistent with the predictions of the contour-template model. 19/43 neurons (44%) exhibited strong and selective responses only to filled shapes and 6/43 neurons (14%) only to outline shapes; tuning was poor or absent for the other category of stimuli. The remaining ~23% of neurons responded well to both stimulus types but responses were poorly correlated between types.
To improve the contour-template model to capture these physiological observations, we first verified that differences in spatial frequency content between filled and outline stimuli alone were insufficient to predict response differences. Next, we focused on the early stages of the model hierarchy and tested two ways to retain previously discarded boundary phase information. We allowed early inputs to be phase-sensitive rather than combining phases; alternatively, we added unoriented units to the early phase-pooled inputs. Both approaches explained the data better than the original model for most neurons, with greater improvement for those neurons that responded best to one or the other class of stimuli. Thus, our modifications allowed the model to distinguish filled and outline stimuli without disturbing the form-selectivity architecture.
Together, our results suggest that boundary orientation and surface information are both maintained until at least the mid-level visual representation. This finding supports the idea that in addition to their role in shape processing, V4 neurons can participate in scene segmentation tasks requiring information about object surface.

Title: Behavioral and neural correlates of the effect of context-dependent lightness on threshold and suprathreshold contrast perception

Authors: *H. BOYACI[1,2], Z. PAMIR[1];
[1]Bilkent Univ., Ankara, Turkey; [2]Giessen Univ., Giessen, Germany

Abstract: Contrast is an important feature for visual performance on many tasks such as object identification, speed or motion detection (Kilpeläinen, Nurminen, & Donner, 2011). Perceived contrast of a pattern depends on the luminance of its background. On the other hand, context often causes a large perceived difference between equiluminant regions (e.g. simultaneous brightness contrast). Thus, characterizing different effects of luminance- and context-dependent lightness on contrast is critical. In this study, we investigate how context-dependent lightness affects contrast judgement using a variant of Adelson's checkerboard illusion stimulus (Adelson, 1995), and psychophysical and fMRI methods. Two series of behavioral experiments were conducted. First, we measured perceived contrast of rectified gratings with incremental and decremental suprathreshold gratings superimposed on equiluminant backgrounds which appeared different in lightness (context-dependent lightness). Participants adjusted the contrast of an external matching grating to match that of the test grating for different levels of frequency, luminance and contrast. Results showed that perceived contrast of gratings superimposed on the perceptually lighter background was higher than those superimposed on the darker background (N=6). However, this pattern was present only for incremental, not for decremental contrast. Second, we measured the contrast detection threshold using an adaptive two alternative forced-choice (2-IFC) procedure. The detection threshold was lower for the gratings superimposed on equiluminant but perceptually brighter target regions (N=6). Thus, we found that not only appearance judgment but also contrast detection threshold is affected by context-dependent lightness. These findings indicate that context-dependent lightness of the target region, not only its luminance, influences the perceived contrast of gratings both at threshold and suprathreshold levels. Next, in an fMRI study we investigated neuronal correlates of this perceptual effect (N=9). Using the same contextual stimulus, we superimposed flickering gratings on equiluminant patches that appeared different in lightness. We found that, parallel to the behavioral results, the BOLD signal in V1 was greater when the grating was superimposed on the perceived-lighter patch. Our findings unveil the significant effect of context-dependent

lightness on contrast perception, thereby provide evidence that contrast perception does not depend only on the contrast of the image formed on the retina, and that higher level context-dependent factors also play a role.

Title: Scotopic fixation eye movements dependence on eye position: separate visual modes?

Authors: *O. SPIVAK[1], P. THIER[2], S. BARASH[3];
[1]IMPRS For Cognitive and Systems Neurosci., Tuebingen, Germany; [2]Cognitive Neurol., Hertie Inst. for Cinical Brain Res., Tuebingen, Germany; [3]Dept. of Neurobio., Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Last year we presented evidence that, in scotopic conditions, fixation eye movements differ from those in photopic conditions. Scotopic fixations comprise larger but less frequent saccades than photopic fixations. In mesopic fixations, scotopic-like and photopic-like fixation movements are combined, with their relative frequencies contingent on the ambient light intensity. Fixations made with dark background are marked by a shift of gaze direction: the eyes seem to be directed above the target, so that the target's image may fall off the fovea. These results indicate that fixation eye movements reflect different retinal focus regions. In photopic vision, frequent small fixation saccades keep the target's image on the fovea. The larger scotopic fixation saccades might reflect the larger rod-dense region in superior retina, most sensitive in scotopic conditions. The upshift reflects the use of the superior retina instead of the fovea. These observations might solve the paradox, of why there are saccades and visual fixations in the dark, even though the foveal cone receptors are inactive. The tentative solution is that these are indeed the superior retina rods that are activated by the target's image, not the foveal cones. Here we analyze the dependence of the upshift and of the fixation movement parameters on the position fixated. Preliminary analysis shows that the upshift is largest while the eyes fixate positions on the bottom of the screen, and smaller if the fixated target is placed higher. We will present analysis of this dependency on eye position. We have collected data from several monkeys. Most of the data contains visual fixation intervals, each lasting ~2s, with the target appearing in 24 locations, arranged on 3 concentric circles of radii 5, 10, and 15 degrees. Blocks with dark background are run either directly after blocks with bright background (no dark adaptation), or

with 45 min in the dark in between (dark adaptation). There are also blocks with intermediate background intensities, allowing studying mesopic vision. The spectrum of experimental conditions is broad enough to allow us to fully characterize the effect of eye position on the fixation movement parameters, including the upshift.If an up-down asymmetry is indeed revealed by this analysis, what does it reflect? Our tentative hypothesis is that fixation upwards and fixation downwards reflect separate modes of vision. Fixation downwards is used for manipulated objects, as in photopic vision. Hence vision during downward fixations is more concerned with details than during upward fixations.

Title: GABAergic dysfunction in the olivary-cerebellar-brainstem network causes eye oscillations and body tremor

Authors: E. PRETEGIANI[1], F. ROSINI[2], R. ROCCHI[2], F. GINANNESCHI[2], A. RUFA[2], *L. M. OPTICAN[1];

Abstract: Eye and body oscillations are shared features of several neurological diseases. The pathophysiology of ocular oscillations may be simpler to explain, which then might suggest why other motor systems oscillate. Opsoclonus and flutter are ocular oscillations consisting of continuous, involuntary, conjugate saccades without intersaccadic intervals. Two main hypotheses have been proposed for their pathomechanism: reduction of glycinergic inhibition generating oscillations in the positive feedback loop between saccadic brainstem burst neurons, and disinhibition of cerebellar fastigial nuclei inducing unwanted saccades through excitatory projections to the burst neurons. However, both theories remain controversial because they were neither confirmed by clinical findings nor simulated by models. We propose that ocular and body oscillations might be generated by a GABAergic failure in a complicated circuit involving the

cerebellum (vermis and fastigial nuclei), the inferior olives and the brain stem saccade pre-motor neurons (excitatory and inhibitory burst neurons, and omnipause neurons). The GABA dysfunction of the olivary-cerebellar-brainstem network leads to transitory fastigial deficiency, causing saccadic hypermetria and macrosaccadic oscillations. Associated impairment of omnipause neurons eliminates intersaccadic intervals, producing saccadic oscillations. Fastigial deficiency also causes olivary hyperactivity, creating an instability that induces eye and limb tremor. The olivary-cerebellar dysfunction may also explain combined forms of ocular and somatic tremor. For example, involvement of different parts of the IO could explain the difference in oscillation frequency between eye (firing rate of neurons in dorsal cap of Kooy > 30 Hz) and limb (firing rate of neurons in principal olive, 4-8 Hz). The simulations reproduce the findings of eye movement recordings in patients with opsoclonus/flutter, including a novel spindle-shaped asymmetric saccadic oscillation associated with ocular and body tremor.

Title: Bilateral fastigial control of the horizontal amplitude of saccades: evidence from studying oblique and vertical saccades after unilateral inactivation

Authors: *J. J. QUINET, L. GOFFART;
Inst. De Neurosciences De La Timone, CNRS, Marseille, France

Abstract: The caudal fastigial nuclei (cFN) are supposed to adjust the horizontal amplitude of saccades by their anatomical projections to the excitatory and inhibitory burst neurons located in the left and right pontine and medullary reticular formation (RF). Unilateral inactivation of cFN with muscimol alters the horizontal component of fixational and regular saccades, made with or

without a concurrent movement of the head: its amplitude is increased for all ipsilesional saccades and reduced for all contralesional saccades, whereas vertical saccades are deviated horizontally toward the inactivated side (ipsipulsion) with a magnitude that increases with saccade duration.
We studied in 3 head restrained monkeys how this inactivation alters the coupling between the horizontal and vertical components during oblique saccades by 1) comparing the effects on horizontal saccades with the effects on the horizontal component of oblique saccades, 2) examining whether the changes in the horizontal component of oblique saccades are associated with changes in the vertical component and 3) further testing vertical saccades. The results show that when a vertical component is added to the horizontal one, the magnitude of the horizontal hypermetria of ipsilesional saccades is consistently increased. While their duration is increased during oblique saccades, changes appear in the dynamics of the vertical component. For contralesional oblique saccades, more pronounced hypometria of the horizontal component were observed but rarely associated with concomitant changes in the vertical component. Under particular testing conditions, we were able to make observations which suggest that the burst emitted by saccade-related neurons in the opposite (intact) cFN also participate in the ipsipulsion and the horizontal hypermetria that alter the trajectory of vertical and oblique saccades.
In conclusion, after unilateral cFN inactivation, the hypermetria that affects the horizontal component of ipsilesional saccades is not due to an absent “brake”. It is the consequence of a reduced influence from inhibitory burst neurons located in the medullary RF contralateral to the inactivated cFN, together with an enhanced (and unopposed) influence from excitatory burst neurons in ipsilateral pontine RF as a result from bursting activity in the opposite (not inactivated) cFN. These results are more consistent with a “bilateral” rather than “biphasic” (accelerate-decelerate) fastigial control of saccades. The firing of saccade related neurons in both cFN regulates the dynamic equilibrium between the inhibitory and excitatory burst input to the agonist motoneurons in the abducens nucleus.

Title: Neuronal diversity in macaque frontal eye field

Authors: *K. LOWE, W. ZINKE, J. D. COSMAN, J. D. SCHALL;
Vanderbilt Univ., Nashville, TN

Abstract: Morphological and connectional anatomy demonstrate the diversity of neuron types in the cerebral cortex. Some of this anatomical diversity relates to biophysical measurements; it has been proposed that excitatory pyramidal cells and inhibitory interneurons could be distinguished based on spike width and spiking statistics. To improve our understanding of cortical function, we are characterizing neuronal diversity with *in vivo* measurements of neurons recorded from frontal eye field (FEF) in macaque monkeys performing memory guided saccades. We applied a set of multivariate classification procedures to identify groups of neurons according to either their biophysical features or response modulation related to stimulus presentation, maintenance, and saccade initiation. A hierarchical cluster analysis based on the spike waveform identified multiple groups that were further subdivided based on spiking statistics (mean firing rate, Fano factor). A separate hierarchical cluster analysis based on response modulations yielded multiple groups of functionally similar neurons. Notably, results demonstrate that the traditional three neuron categories in FEF - visual, visuomovement, and movement-related neurons - underestimate the diversity of functional categories of FEF neurons. We further found that the two independent classification schemes produced overlapping groups; that is, we found a relationship between putative anatomical neuron types and functional neuron types. Supplemented by information about the location of neurons in the cortical neuropil, this approach will be used to identify and provide experimental access to different neuron types and their connections at the mesoscale circuit level, alongside their link to behavior. This will elucidate the link between cognitive outputs and their anatomical implementation, providing a theoretical framework for further circuit-level investigations.

Title: Parallel processing for the generation of saccades to simultaneously moving centrifugal targets

Authors: *L. GOFFART;
CNRS, Marseille, France

Abstract: The simultaneous presentation of two static targets in the visual field leads to a saccade which lands on a location situated along a line that connects the two targets. The landing position depends upon the relative salience of the targets. The more salient the target, the stronger its influence on the landing position. A similar process happens during saccades made in response to two sequentially presented targets. Saccades with the shortest latencies land on the location of the first target whereas saccades with longer latencies land closer to the second target location. Obviously, the visuomotor brain does not switch abruptly between two targets; the transition is gradual and made continuously. The spatiotemporal properties of this target selection process were explored further by testing in two monkeys, the saccades made in response to two centrifugal targets moving rapidly and simultaneously in different directions. After the fixation of a central target for a variable interval, two conditions were possible. During the single-target condition, one target moved toward the periphery along the cardinal (horizontal or vertical) or oblique axes. During the double-target condition, the central target was replaced by two identical targets moving away from the center toward the periphery with a constant speed. One target moved along an oblique axis while the other target moved along one of the cardinal axes. The speed of the target moving along the oblique axis was maintained constant (30 deg/s) whereas the speed of the target moving along the cardinal was varied (from 15 to 60 deg/s). The monkeys were free to track anyone of the targets and were rewarded on every trial. The examination of saccades made in response to targets moving in the same visual quadrant show different scatterings of landing positions between the testing conditions. During the double-target condition, the landing positions were scattered in the region of the visual field which is situated between the paths of the targets. Although their distributions were biased toward the slower target, the orientation of the scatters depended upon the speed of the two targets: the landing positions were scattered between lines of isochronous target locations. Thus, in response to two centrifugal targets, the monkeys do not select one of the two targets for its foveation. The first saccade is made toward an intermediate location, a location which corresponds to the average of two commands weighted by their speed (or the duration of retinal exposure). The scattering of endpoints between lines of target isochrony and some curved saccades indicate parallel and continuous visuomotor flows until the saccade is completed.

Title: Discrimination of saccade latencies.

Authors: *V. VENCATO[1,2], L. MADELAIN[1], L. MADELAIN[2];
[1]Lab. SCALab UMR CNRS 9193, Univ. Lille 3, Villeneuve d'Ascq Cedex, France; [2]Inst. de Neurosciences de la Timone, Marseille, France

Abstract: Saccadic eye movements are widely used to investigate underlying decision processes and numerous quantitative models have been proposed to account for changes in saccade reaction time (SRT) distributions, often in conjunction with neurophysiological data. Although they are typically short - often ranging from 100 to 400 ms - and conventionally regarded as a consequence of the duration of decision-making process, previous findings showed that reinforcement contingencies modulates SRT distributions (Madelain et al. 2007) which raises the possibility of a voluntary control of SRTs. Because some perception must be necessary for any voluntary response we ask how precisely one can perceive such short reaction time.
We first collected baseline SRTs in four subjects tracking a stepping visual target. For each subject we computed four SRT classes using the four quartiles of the individual baseline SRT distributions (individual example of SRTs class intervals: 80-182ms; 183-212ms; 213-237ms; 238-400ms). Subjects were then trained to discriminate their SRTs: after each saccade they had to classify the saccade latency in a 4AFC task and then received a feedback indicating the correct answer.
Results indicate that, after intensive training, subjects could overall classify their SRT with up to 42% of correct responses, well above chance level (25%). Moreover, data showed that for each of the four latency classes the probabilities of correct responses were systematically higher ($p<0.01$) than for the incorrect ones.
Because these results could depend on volitional control of SRT rather than on an actual perception, the SRT's distributions were manipulated using the overlap paradigm.
Previous research shown that applying a temporal overlap between the fixation point disappearance and the target appearance, the saccadic eye movement latencies increase. Taking advantage of this effect, we used overlap's intervals of 0, 20, 40, 60, 80, 100, 120 and 140 milliseconds in the stepping visual target task, in the 4AFC task described above. In accordance to our previous study, one subject was able to classify his SRTs with up to 51% of correct responses well above chance level.

Altogether these results are the first to indicate that human subjects are able to discriminate their own saccade latencies, albeit imperfectly. The precision and extent of this ability remains to be further probed.

Title: Adjustments in the Purkinje cell simple spike discharge parallels changes in saccade metrics warranting movement precision despite diminished vigor

Authors: *A. MARKANDAY, Z.-P. SUN, P. THIER;
Dept. of Cognitive Neurol., Hertie Inst. For Clin. Brain Res., Tuebingen, Germany

Abstract: The physical properties of our bodies are not constant. Rather they change continuously as a consequence of using them. For instance muscle action inevitably results in muscular fatigue leading to a decline of movement vigor. However, movement vigor may as well result from a decrease of interest in the movement goals. Despite these changes, we are able to maintain a reliable level of precision of our movements by exploiting compensatory mechanisms, the roots of which lie in the cerebellum. This has been established by studying saccadic eye movements of cerebellar patients. Both healthy subjects and patients exhibit a use dependent decrease of saccade velocity. However, only healthy subjects show a compensatory upregulation of duration, preventing a consecutive decline of saccade amplitudes (Golla et al., E. J. Neurosci., 2008). We wondered if changes in saccade duration compensating the declining vigor of eye movements of healthy subjects are reflected in the firing of Purkinje cell simple spikes (PC-SS), the vehicle used by cerebellar cortex to influence extra-cerebellar information streams. This is why we tested two rhesus monkeys on a fatigue inducing repetitive eye movement task, requiring accurate constant amplitude saccades to a fixed peripheral target location at very short inter-saccade intervals. As expected, eye velocity declined over the course of the experiment by 15-20 %. Nevertheless, the required endpoint accuracy was warranted by a fully compensatory upregulation of saccade duration. We recorded the saccade related responses of 60 oculomotor vermal PC-SS and calculated their collective instantaneous firing rate. The behavioral changes were clearly paralleled by changes in the resulting population burst whose amplitude decreased, while the overall duration increased. We also recorded PC-SS (n=60) from 3 rhesus monkeys on a gain decrease adaptation task, in which saccade amplitude is reduced in

response to a consistent intra-saccadic shift of the saccade target back in the direction of the starting position. In accordance with previous findings (Golla et al., see above), the saccade gain reduction could at least partially be explained by a reduction of saccade peak velocity, not compensated by an increase of saccade duration. Again, the changes of the PC-SS population signal paralleled the behavioral changes. These findings clearly indicate that the duration adjustments warranting movement precision despite changes in vigor can be led back to corresponding adjustments of cerebellar control signals. Moreover, they support the notion that gain decrease adaptation is at least to some extent uncompensated fatigue.

Title: Correlation between pupil size and self-timed saccade latency in non-human primates

Authors: ***T. W. SUZUKI**[1], J. KUNIMATSU[1,2], M. TANAKA[1];
[1]Hokkaido Univ. Sch. of Med., Sapporo, Japan; [2]NEI, NIH, Bethesda, MD

Abstract: Our daily experience of passage of time is strongly influenced by internal states, such as arousal, attention and mood. To investigate the underlying mechanism, we recorded pupil diameter, which has a close link with internal factors and neuromodulatory signaling, in monkeys performing the oculomotor version of the time production task. In this task, a visual cue was presented briefly (0.1 s) during fixation. The animals (n = 3) reported the passage of 1 s by making a self-initiated memory-guided saccade to the cue location to obtain a liquid reward. Pupil diameter was measured using the infrared eye tracking system. When we divided the trials into equally-numbered 10 groups according to the pupil diameter measured during the 500-ms before the cue onset, self-timed saccade latency negatively correlated with the pupil size (r_s = –0.90, $p < 10^{-3}$). This correlation cannot be explained solely by facilitation of saccades because no significant correlation was found for visually-triggered saccades (p = 0.33). When the amount of reward was alternated every 10 trials, pupil size and saccade latency altered in the opposite directions, showing a significant negative correlation (r_s = –0.38 ± 0.23, n = 12, $p < 10^{-3}$). Furthermore, sessions with greater modulation of pupil size exhibited larger latency modulation (r_s = –0.80, n = 12, $p < 10^{-2}$). Finally, when animals were trained to produce two different

intervals (short or long) depending on color of the fixation point, we again found a negative correlation between the pupil size and saccade latency within each condition. To assess correlation across short/long conditions, the data for each condition were divided into three groups according to saccade latency, and then the longest latency group in the short condition (S3) and the shortest group in the long condition (L1) were compared. We found that pupil was larger for L1 than S3 (paired *t*-test, $n = 10$, $p < 10^{-2}$), while saccade latency was longer for L1 than S3 ($p < 0.05$). Thus, although trial-by-trial variation of pupil size accounted for the variation of self-timed saccade latency, the pupil size did not correlate with actual saccade timing in different conditions. These results suggest that the pupil-linked brain state, which parallels the level of noradrenergic neuronal activity (Joshi et al., 2016), may regulate the trial-by-trial variability of subjective passage of time.

Title: The value of simultaneous EOG and EEG recording for measurement of saccade-related brain activity

Authors: ***Y. JIA**, C. W. TYLER;
The Smith-Kettlewell Eye Res. Inst., San Francisco, CA

Abstract: Introduction. Both to elucidate the cortical mechanism involved in the control of eye movements, and because eye movements cause a large amount of artifacts during electroencephalographic (EEG) recording, it is important to investigate the effects of eye movements on the study of brain activities. The aim of this project is to examine both EEG and electrooculography (EOG) signals during eye movements.
Method. The eye movement target consisted of stimulus squares appearing in one of 25 positions (a 5-by-5 array subtending 20 degrees in each side). Each stimulus was presented for 1.5 seconds, in random order. The participant was asked to saccade onto the presented stimulus and maintain fixation until the next stimulus appeared. EEG and EOG were measured simultaneously with a 128-channel EGI electrode net at a 500 Hz sampling rate. The resulting EEG signals were analyzed using principal component analysis (PCA) separately for saccades around each cardinal

direction (left, up, right, down).
Results. The analysis showed a primary EOG component with a saccade-like waveform measured with anti-symmetry across the facial electrodes for leftward and rightward movements and symmetry for upward and downward movements. These primary components scaled in amplitude and direction with the saccade extent from 5 to 28 degrees. A whole-scalp component with a single negative 50 milliseconds peak at the time of the saccade was found for all directions of eye movement, interpretable as representing the neural substrate for saccadic suppression. A component with an occipital focus peaking about 100 milliseconds after the saccade was interpretable as the cortical response to the fovea landing on the target stimulus. Components with an occipital focus peaking about 100 milliseconds before the saccade were also identifiable, interpretable as the cortical activity generating the saccade signal.
Conclusion. The results show that EOG signals allow accurate analysis of the amplitude and directions of the saccades with a temporal resolution of 500 Hz, which make the EOG from the electrode net a convenient means of measuring eye movements. The findings suggest that the technique allows the measurement of brain responses responsible for, and elicited by, saccadic eye movements.

Title: What saccadic behavior can tell us on how we use haptic feedback in collision tasks

Authors: *F. SALMEN[1,2], F. CREVECOEUR[1,2], J.-L. THONNARD[2,3], P. LEFÈVRE[1,2]; [1]ICTEAM, Univ. catholique de Louvain, Louvain-la-Neuve, Belgium; [2]Inst. of Neurosci. (IoNS), Univ. catholique de Louvain, Brussels, Belgium; [3]Physical and Rehabil. Med. Dept., Cliniques Universitaires Saint-Luc, Brussels, Belgium

Abstract: Humans and animals rely on internal representation of the trajectories of moving stimuli, allowing predictive tracking despite transient target disappearance. In collision tasks mainly visual and haptic input influences those predictions. Saccadic eye movements based on the internal models reveal how the different sensorial inputs are integrated.
We studied predictive eye movements in a semi-static (fixed hand, moving target) collision task. Participants interacted with a robotic device (KINARM, BKIN Technologies, Kingston), which applies a force (i.e. haptic feedback of the collision) to the participant's hand. Visual targets were projected on a virtual reality display. Eye movements were recorded with an Eyelink camera (SR Research Ltd., Ottawa, Ontario, Canada).
The participants (N=14) were instructed to perform visual tracking of round-shaped targets of different sizes before and after a collision with a bar representing the hand position. We assumed constant mass density, such that for a given velocity, a higher impact force was experienced for objects greater in size. The target was blanked for a constant period of 800ms immediately after the collision to induce/provoke predictive eye movement. Two different object sizes and velocities resulted in four different impact forces and four different post-collision velocities due to simulated energy loss during the collision. The different conditions corresponded to a factorial design in which visual cues about target size and haptic feedback were provided or not. We then investigated saccadic behavior during target occlusion to address participants' strategies on how to integrate haptic and/or visual feedback.
Our results show that participants adjusted their gaze correctly to different target velocities after the collision in all conditions. Providing only haptic feedback, we found a weaker spatial modulation (≈ 70%) of first saccades regarding to target position after occlusion (linear regressions, $p<0.005$), whereas the spatial modulation after later saccades were similar for all conditions. Also first saccade latencies were significantly longer (KS test, $D>0.15$, $p<0.005$) when only haptic feedback was provided compared to visual and/or combined feedback.
These results show that predictive tracking of the target is adjusted in conditions in which haptic feedback is available in addition to internal predictions from visual information. The increase in saccade latency associated with haptic feedback, and the reduced compensation of the first saccade sheds light on the time course of integration of haptic feedback in the internal estimate of the target location.

Title: Sequential hemifield gating of 8-15 hz behavioral performance oscillations after microsaccades generation

Authors: *J. BELLET[1,2], Z. M. HAFED[1];
[1]Ctr. for Integrative Neurosci., Tuebingen, Germany; [2]Intl. Max Planck Grad. Sch. of Behavioral and Neural Sci., Tuebingen, Germany

Abstract: Many visual neuroscience experiments impose gaze fixation to rule out potential influences of eye movements on neural and behavioral results. However, even during periods of attempted gaze fixation, our eyes are in constant motion. Among the types of fixational eye movements that are known to occur are microsaccades, which are tiny saccades (typically < 1° of visual angle) occurring 1-3 times per second. Even though visual processing has already been shown to be modulated close to the time of microsaccades (e.g. Chen et al., Curr. Biol., 2015), it is not clear how microsaccade generation might influence longer-term fluctuations in brain activity and behavior. Here we show that visual processing is significantly affected, and in a hemifield-specific manner, even several hundreds of milliseconds after a microsaccade had occurred. We conducted two psychophysical experiments aiming at testing reaction time (RT) and contrast sensitivity for visual targets presented at different times after microsaccades. In the first experiment, 10 human subjects were instructed to fixate a dot in the middle of a screen. After a random period, the fixation dot disappeared and, simultaneously, a target appeared 5 deg to the right or left of fixation. We investigated whether the relative time and direction of the microsaccade preceding target appearance could influence saccadic RT to the target. Mean RT varied in a rhythmic fashion depending on when the stimulus was presented relative to a preceding microsaccade. Surprisingly, the performance oscillations were sequentially pulsed across hemifields: the first 400 ms following a microsaccade revealed strong oscillations in RT (~15 Hz), but only in the hemifield towards which the microsaccade was directed to; the next 400 ms presented similar (albeit lower-frequency) oscillations (~8 Hz), but this time in the opposite hemifield. Thus, there was sequential hemifield activation of behavioral oscillations that were phase-locked to microsaccade generation. In a second experiment involving 14 subjects, we tested contrast sensitivity long after microsaccades. Subjects fixated a dot in the middle of the screen. At a random time, a faint stimulus was presented 5 deg to the right or left of fixation. Subject performance to detect the stimulus was increased in the hemifield towards which the last microsaccade was directed to, but only during the period in which the ~15 Hz pulse of RT modulations occurred in the first experiment. Taken together, our results suggest that microsaccades have prolonged effects on behavior, and that across-hemisphere phase-resetting of brain activity by microsaccades proceeds in a pulsed, sequential manner.

Title: Classification of COMT Val^{158}Met genotype by oculomotor behavior

Authors: *J. BILLINO, J. HENNIG, K. GEGENFURTNER;
Justus-Liebig-Universität Gießen, Giessen, Germany

Abstract: The neural circuits involved in oculomotor control are extremely well described; however, neuromodulation of eye movements is still hardly understood. Dopamine in particular has been discussed as a functionally significant neurotransmitter because of pronounced oculomotor deficits observed in patients with psychiatric or neurological diseases for which dysfunctions of dopaminergic neurotransmission are considered as the major pathologic mechanism. The crucial question that has remained to be answered is whether dopaminergic modulation of eye movements can also be seen in healthy human observers. A non-invasive way to investigate behavioural effects of dopamine in humans is provided by functional genetic polymorphisms. The COMT Val^{158}Met polymorphism represents probably the best documented dopaminergic polymorphism and its functional mechanism is well-established. Genotype modulates activity of catechol-O-methyltransferase (COMT), an enzyme that plays a major role in dopamine catabolism in prefrontal cortex. The enzyme is supposed to be less active in carriers of the Met-allele who in turn show higher prefrontal dopamine levels. We investigated the functional association between COMT genotype and the performance in two eye movement tasks known to involve substantial top-down control. We measured anticipatory smooth pursuit as well as memory guided saccades in 111 healthy subjects (93 females, age M=23.7, SD=5.1) and determined their individual COMT genotypes (ValVal n=24, ValMet n=55, MetMet n=32). For both tasks we found significant functional associations. Anticipatory pursuit response was most pronounced in individuals with genotypes putatively associated with higher prefrontal dopamine levels, i.e. carriers of the Met allele (anticipatory eye position: $F(2, 107) = 12.25$, $p < .001$, $\eta^2 = .19$). In contrast, higher dopamine levels were detrimentally associated with saccadic accuracy in memory guides saccades ($F(2, 103) = 5.63$, $p = .005$, $\eta^2 = .10$). Most importantly, by using a simple discriminate analysis we were able to segregate Val homozygotes and Met homozygotes successfully with an accuracy of 88% based on performance in both eye movement tasks. This result highlights the importance of selecting the proper combination of paradigms. Each single task explained rather little variance, but combined they got close to perfection. Our approach

emphasizes the value of systematic variability and individual differences for uncovering functional processes that would elude investigation otherwise.

Title: Compound effects of transcranial magnetic stimulation on the oculomotor system

Authors: ***I. G. CAMERON**[1], A. CRETU[2,4], F. STRUIK[2], I. TONI[2,3,5];
[1]Donders Inst. For Brain, Cognition and Behav., Nijmegen, Netherlands; [2]Ctr. for Cognitive Neuroimaging, [3]Ctr. for Cognition, Donders Inst. for Brain, Cognition and Behav., Nijmegen, Netherlands; [4]Dept. of Hlth. Sci. and Technol., ETH Zurich, Zurich, Switzerland; [5]Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: Transcranial magnetic stimulation (TMS) is used extensively to focally perturb function in a brain region in order to infer that region's causal contribution. This approach largely ignores the fact that TMS can influence distal nodes in a network, possibly triggering compensatory responses in those nodes. Here we use a well-defined circuit, the cortical oculomotor system, to qualify distal network-level changes triggered by a focal TMS intervention. This study tested 24 participants across 4 sessions. The first session used fMRI to localize cortical oculomotor regions in each participant, and guide the stereotactic administration of TMS in sessions 2-4. Across the four sessions, participants performed pro- and anti-saccades to visual stimuli along the horizontal meridian, while their gaze was monitored at 500 Hz. Sessions 2-4 used TMS interventions according to this rationale: first, inhibitory continuous theta-burst stimulation (cTBS) was applied (40 s) to the dorsolateral prefrontal cortex (DLPFC), frontal eye fields (FEF), or a control region (primary somatosensory cortex, S1), in the right hemisphere. Second, while the oculomotor network was still perturbed (50 min post-cTBS), single TMS pulses were applied to the right parietal eye fields (PEF) at variable times during task performance. Because FEF and PEF have complementary functions related to visuo-motor behavior, in particular during the performance of anti-saccades, we hypothesized cTBS to FEF would impair visuo-motor effects of anti-saccade behavior, and single-pulses to PEF might compound this effect. However, if the oculomotor network compensates for FEF inhibition following cTBS, then single-pulses to PEF following cTBS on FEF might lead to smaller deficits than single-pulses to PEF following cTBS on the control region (S1). Furthermore, we

hypothesized that cTBS to DLPFC would impair executive control aspects of anti-saccades, but not drive a compensatory effect in PEF.
Contralesional anti-saccades had reduced amplitude, with invariant reaction times and error rates, following cTBS over FEF or DLPFC (as compared to cTBS over S1). After cTBS over S1, single-pulses over PEF also reduced anti-saccade amplitudes. Preliminary data suggests that combining cTBS over FEF and single-pulses over PEF led to a larger reduction in contralesional anti-saccade amplitudes than when that combination involved S1 cTBS and PEF single-pulses.

Title: Dopamine modulates sensorimotor transformation in the optic tectum

Authors: *J. PÉREZ-FERNANDEZ[1], A. KARDAMAKIS[2], B. ROBERTSON[2], S. GRILLNER[2];
[1]Karolinska Inst., Stockholm, Sweden; [2]Karolionska Institutet, Stockholm, Sweden

Abstract: The optic tectum (superior colliculus in mammals) shows well conserved features through vertebrate evolution, and controls gaze movements through excitatory output neurons projecting to the brainstem. In all vertebrates the optic tectum integrates different sensory modalities (which are species dependent), and when two stimuli from different senses coincide in space and time a response enhancement occurs increasing event detection reliability. In lamprey, visual and electrosensory information is integrated at the level of single output cells of the deep layer, where direct excitatory inputs are combined to reinforce the motor command. Sensory inputs also evoke strong inhibition following the excitatory input, which arises in the superficial layer interneurons and continually resets the output cells allowing for spatial and temporal

stimuli discrimination. This sensorimotor transformation is also modulated by dopamine from the nucleus of the posterior tuberculum, the homologous region of the mammalian substantia nigra pars compacta (SNc). The dopaminergic system was already well developed at the dawn of vertebrate evolution, and the basal ganglia in general, and the SNc connectivity in particular, are very similar from lamprey to mammals. One striking feature is that the SNc in lamprey, as in mammals, sends direct dopaminergic projections to motor command centers, including the diencephalic and mesencephalic motor regions and the output layer of the optic tectum. Here, we explore how dopamine modulates motor responses in the optic tectum. D1 and D2 receptor expressing cells are two different subpopulations, and dopamine has a differential modulation of their excitability, enhancing the excitability of D1 expressing cells, and decreasing the excitability of those expressing the D2 receptor. This differential modulation affects their responsiveness to the multisensory inputs regulating their motor responses. We have developed a novel preparation keeping the eyes with the brain and rostral segments of the spinal cord, allowing us to apply different visual paradigms coupled to electrophysiological recordings. Local injections of dopamine agonists in the optic tectum have a strong effect in tectal motor responses, including eye movements, but also escape and orienting movements, as reflected in ventral root activity. Our results show that dopamine performs a complex modulation in the optic tectum and, given the high degree of conservation of the basal ganglia and the presence of direct dopaminergic projections from the SNc to the superior colliculus in rats, this previously unexplored mechanism is likely to be present also in mammals.

Title: Effect of maintaining neck flexion on reaction time of memory-guided saccade: An investigation using transcranial magnetic stimulation to the frontal oculomotor field

Authors: *K. KUNITA[1], K. FUJIWARA[2];
[1]Fac. of Sports & Human, Sapporo Intl. Univ., Sapporo, Japan; [2]Dept. of Sports and Hlth., Kanazawa Gakuin Univ., Kanazawa, Japan

Abstract: We applied transcranial magnetic stimulation (TMS) to the frontal oculomotor field, and investigated the effect of maintaining neck flexion on reaction time of memory-guided

saccade. The subjects were 10 healthy young adults. The experimental protocols were approved by our institutional ethics committee. All subjects provided written informed consent after receiving an explanation of the experimental protocols. The motor area of the first dorsal interosseous muscle (FDI) was determined as the site at which a motor evoked potential was elicited by TMS. The position of the frontal eye field in the frontal oculomotor field has been reported at 2 cm anterior or 2-4 cm anterior / 2-4 cm lateral to the motor area of the FDI. Based on a location 2 cm anterior to the motor area of the FDI, the TMS coil was positioned at various points in the anterior-posterior and left-right directions. We determined in advance the position of the frontal oculomotor field at which TMS induced prolongation of the reaction time of the memory-guided saccade. After identifying the frontal oculomotor field, the reaction time was measured with the chin resting on a stand (chin-on condition) and with voluntary maintenance of neck flexion (chin-off condition) at 80 % maximal neck flexion angle, with and without TMS. TMS timing producing the longest prolongation of the reaction time was first roughly identified for 10 ms intervals from 0 to 180 ms after the start signal of the saccade (lights-out of central fixation point). Thereafter, TMS timing was set finely at 2 ms intervals from −20 to +20 ms of the 10 ms interval producing the longest prolongation. The reaction time without TMS was significantly shorter (25.6 ms) for the chin-off condition (231.6 ± 44.6 ms) than the chin-on condition (256.6 ± 45.9 ms). TMS timing producing maximal prolongation of the reaction time was significantly earlier (23.3 ms) for the chin-off condition (102.6 ± 16.8 ms) than the chin-on condition (125.8 ± 13.6 ms). The ratio of the forward shift in TMS timing relative to the shortening of reaction time was 93.2 %. We indicated that information processing time in the neural pathway of the memory-guided saccade before the frontal oculomotor field shortened with maintaining neck flexion.

Title: Choice bias after lateral intraparietal (LIP) area inactivation predominantly reflects a decision rather than an attention deficit

Authors: *V. N. CHRISTOPOULOS[1], I. KAGAN[3], R. A. ANDERSEN[2];
[1]Div. of Biol., [2]Caltech, Pasadena, CA; [3]German Primate Ctr. (DPZ), Göttingen, Germany

Abstract: The posterior parietal cortex (PPC) has been traditionally associated with spatial perception, awareness, and attention; i.e., largely sensory attributes. However, a growing body of evidence indicates that it is also involved in a wider range of brain functions, such as decision-making. In large part this evidence is based on reversible pharmacological inactivation of specific PPC regions. For instance, recent studies showed that the unilateral inactivation of the lateral intraparietal (LIP) area - i.e., the area of PPC which is involved in saccades - leads to a reduction of contralesional choices in oculomotor decisions. Although these findings suggest that LIP is involved in saccade choices, an equally plausible interpretation is that the choice bias reflects deficits in spatial attention rather than in decision-making. To address this concern, we need to determine whether the choice bias after LIP inactivation is effector-specific. We reversibly inactivated part of LIP by locally injecting the GABA-A agonist muscimol, while two monkeys performed memory-guided saccade and reach movements either to a single target (instructed trials) or selected between two targets presented simultaneously in both hemifields (free-choice trials). Reaches were performed using a 2D joystick positioned between the legs of the animals. Eye-fixation was required during the reach trials. Consistent with previous studies, LIP inactivation led to a strong reduction of contralesional choices, but mostly for saccades. On the other hand, the inactivation did not cause any appreciable change in reach choices. No effects found on the reach/saccade movements to single targets presented in either hemifield. The decision bias cannot be driven by attention, since the temporary “lesion” affected predominantly saccade choices. These results extend our previous findings from the inactivation of the parietal reach region (PRR) on internally-guided decisions. In particular, we showed that the PRR inactivation led to a reduction of contralesional choices but only for reaches. On the other hand, saccade choices were not affected by PRR inactivation. This double dissociation provides direct evidence that LIP and PRR are nodes in networks for making saccade and reach decisions, respectively.

Title: Graph theoretical analysis of functional network changes during recovery of saccade selection bias following stroke in nonhuman primates

Authors: *R. ADAM[1], K. JOHNSTON[1], R. HUTCHISON[2], S. EVERLING[1];
[1]The Univ. of Western Ontario, London, ON, Canada; [2]Harvard Univ., Cambridge, MA

Abstract: Spatial extinction is an attention deficit commonly seen following unilateral stroke in humans and nonhuman primates. It is characterized by impaired detection of a contralesional stimulus when two stimuli are presented simultaneously in both the ipsilesional and contralesional hemifield. This results in a disabling ipsilesional saccade selection bias that often recovers over time. Here, we used graph theory to identify changes in complex network properties during recovery of the saccade selection bias following a right frontal stroke. We created a nonhuman primate model of ischemic stroke using macaque monkeys by injecting endothelin-1, a potent vasoconstrictor, in the right dorsolateral prefrontal cortex and frontal eye field. Saccade selection bias was measured using a free-choice task in which macaque monkeys were presented with two stimuli, one in each hemifield, either simultaneously or at varying stimulus onset asynchronies. Following stroke, the animals exhibited both a profound ipsilesional saccade selection bias and increased contralesional saccadic reaction times that gradually recovered over time. We used resting-state functional MRI (rs-fMRI) at 7T to obtain the blood oxygen level-dependent (BOLD) signal time series at pre-stroke and week 1, 4, 8, and 16 post-stroke. Graph metrics were calculated using the Brain Connectivity Toolbox and compared within-subjects across all rs-fMRI sessions. At week 1 post-stroke, there was decreased mean global efficiency and small-worldness (decreased clustering, increased mean shortest path length). By week 8-16 post-stroke, when the saccade selection bias had recovered, mean global efficiency and small-worldness had increased. At the time of full recovery at the nodal level, right premotor, supplementary motor, TPO, MST, and extrastriate cortex showed decreased betweenness, degree, and local efficiency; whereas right MT and LIP and left premotor, TPO, and extrastriate cortex showed increased betweenness, degree, and local efficiency. Our preliminary findings suggest a pattern of global and local network changes following unilateral stroke that may underlie recovery of the saccade selection bias.

Title: Evolution of a reference frame along a brain pathway: persistently hybrid coordinates of auditory signals in Frontal Eye Fields implicate the Superior Colliculus in computing eye-centered sound location

Authors: *V. C. CARUSO[1], D. S. PAGES[2], M. A. SOMMER[2], J. M. GROH[2];
[1]Ctr. For Cognitive Neurosci., [2]Duke Univ., Durham, NC

Abstract: Cues for determining visual and auditory locations differ. The optics of the eye provide for eye-centered visual signals. Sound location is inferred from cues that depend on the sound's position with respect to the head and ears. The computations necessary to integrate these different cues are a central problem in multisensory and sensorimotor integration. Previous work has shown that auditory signals are transformed into eye-centered coordinates for integration with vision. This process begins at least as early as the inferior colliculus (Groh et al. 2001) and may in fact begin with eye position-dependent displacements of the eardrum (Gruters et al. SfN 2015). The transformation is "completed" by the time the saccade-related bursts of superior colliculus (SC) neurons are generated: these bursts specify sound location in eye-centered coordinates (Lee & Groh 2012). Yet, to date, these are the only known pre-dominantly eye-centered auditory signals in the brain; all other known signals reflect hybrid head- and eye-centered information (IC, A1, LIP). The SC may compute the eye-centered signal in time or it may receive this signal from an as yet unknown source. Since the frontal eye fields (FEF) plays a similar role to the SC in saccade generation, and projects to the SC, we sought to evaluate the reference frame of auditory signals in the FEF in comparison to the SC. Previous work by Russo and Bruce (1994) had established that the FEF's auditory signals vary with eye position, but had not fully determined the reference frame. Information about FEF's auditory code and its evolution in time can resolve whether the computation of eye-centered sound location is broadly present in saccade-programming areas or unique to the SC (and maybe its afferents). We tested the activity of 324 FEF neurons while 2 head-restrained monkeys performed saccades to the locations of sounds from different fixation positions. We dissociated target-related and saccade-related activity in time by delaying the saccade go-cue relatively to target onset. We found that auditory signals were prevalent in the FEF, occurring in as many as 76% of FEF neurons. At sound onset and throughout the saccade preparation, sound location was encoded in hybrid head- and eye-centered coordinates. Only during the saccade burst we observed a modest shift towards eye-centered coordinates (roughly 60% of neurons remained hybrid, while the eye-centered neurons increased from 15% during the sensory period to 30% during the motor period). Overall, the results in the FEF contrast considerably with the results from the SC, and implicate the SC as the main player in the final computation of eye-centered auditory target location.

Title: Adult cat injured motoneurons recover a normal firing pattern and synaptic inputs after VEGF administration

Authors: P. M. CALVO, A. M. PASTOR, *R. M. DE LA CRUZ;
Dept. de Fisiología, Univ. de Sevilla, Facultad de Biología, Sevilla, Spain

Abstract: Vascular endothelial growth factor (VEGF) was initially characterized by its activity on blood vessels. However, recent evidences indicate that this factor can also act directly on neurons, exerting a neuroprotective role particularly on damaged motoneurons. Nonetheless, to date, there is no available information regarding the functional state in which those motoneurons that has been rescued by VEGF remains, which is of extreme relevance to assess the therapeutical potentiality of this factor. We pursued this objective by recording in the chronic alert cat preparation the discharge activity of axotomized abducens motoneurons (which innervate the extraocular lateral rectus muscle) following VEGF administration. Abducens motoneurons encode eye position and eye velocity during spontaneous and vestibularly-induced eye movements. Axotomy produced severe changes in the firing of these cells that affect all the components of their discharge, with a general reduction in firing activity and a loss of eye-related signals. VEGF was administered peripherally (from the orbit after removing the lateral rectus muscle and cutting the VI nerve) through a home-made devise that allowed to introduce the distal end of the cut VI nerve on a camera through which the factor was delivered (0.2 μg/kg on alternated days). During the axotomy period only vehicle was administered to the sectioned nerve. The administration of VEGF restored completely the tonic-phasic discharge of axotomized motoneurons during different types of eye movements, so that all eye movement parameters in VEGF-treated motoneurons were similar to control and differed significantly from axotomy. Since injured motoneurons re-established a normal discharge activity after VEGF treatment, we were interested in correlate this finding with the synaptic inputs received by these motoneurons in the three conditions (control, axotomy and axotomy plus VEGF). For this purpose we carried out double immunofluorescence at the microscopy confocal level. Motoneurons were identified as choline acetyltransferase (ChAT)-positive. Synaptic boutons

were labeled by synaptophysin and astrocytic profiles by glial fibrillary acidic protein (GFAP). Our results showed that, as compared to control, axotomy was characterized by a significant loss of synaptic boutons in association with a prominent astrocytic reaction, both returning to normal values after VEGF treatment. Therefore, the present findings show, for the first time, that VEGF is a potent physiological neurotrophic and synaptotrophic factor for motoneurons which reinforces the therapeutical potential of VEGF for diseased or injured motoneurons.

Abstract: Acute injection of subanesthetic dose of ketamine in non-human primates is an effective model for creating schizophrenia-like symptoms, such as deficits in working memory. We trained three rhesus monkeys to perform a rule-based working memory task involving pro- and anti-saccades, and recorded both spiking activity and local field potentials from the dorsolateral prefrontal cortex both before and after ketamine injection. Previously we reported that ketamine injection negatively impacted the maintenance and the application of the correct task rule, possibly via a reduction in the signal-to-noise ratio in both single unit and ensemble activities. Comparing to spiking activities, neural oscillations are more easily monitored and better studied in humans, providing an opportunity to test the mechanistic validity of animal models. In healthy humans, the strength of gamma band oscillation is modulated by working memory processes. In patients with schizophrenia, either abnormal enhancement or reduction in gamma band activity depending on the working memory load was correlated with impaired performance (Haenschel et al., 2009). Meanwhile, low frequency oscillations are often attenuated in patients. Studies in rodent models generally reported an enhanced gamma power following treatment with NMDA channel blockade. To quantify the oscillatory activity

specifically associated with working memory, we subtracted the amplitude of gamma activity during inter-trial intervals from the gamma power measured during the delay periods. We found enhanced delay-related low gamma power (30 to 60Hz) accompanied by reduced power in the beta band (13 to 30Hz) during the delay period preceding correct responses following ketamine treatment. To understand how ketamine affects the rule information encoded in oscillatory activity, we calculated the task selectivity, defined as the difference between oscillatory amplitudes associated with the two rules, divided by the sum of these amplitudes across both rules. In two of the three animals, task selectivity was significantly reduced in both beta and low gamma frequency ranges following ketamine injection. These results support an important role of prefrontal oscillatory activities in information processing in working memory.

Title: Investigating the contribution of M1 in Eye-Hand coordination using TMS

Authors: ***J. MATHEW**, A. EUSEBIO, F. DANION;
Medicine-Neuroscience, Aix Marseille Univ. - PACE, Marseille Cedex 05, France

Abstract: Previous literature has shown that the ability to track a moving target with the eye is substantially improved when the target is self-moved as compared to when it is moved by an external agent. To account for this result, it has been proposed that the oculomotor system has access to an estimate of the current hand position by means of a forward model that receives the arm efferent copy. However, direct neurophysiological evidence is needed to support this scheme. The goal of the current study was to explore whether eye motion could possibly be altered by TMS over the hand area of the primary motor cortex (M1) during eye-hand coordination. Practically subjects were asked to track with their eyes a visual target whose horizontal motion was driven by their grip force. When TMS was applied over M1 hand area, involuntary grip force pulse led to transient target jumps. We reasoned that if the output of M1 is

used by the oculomotor system to keep track of the target, TMS on top of disturbing grip force, should also disrupt eye motion. For comparison purposes, the effect of TMS was also monitored when applied while tracking an externally-moved target. In agreement with earlier observations, the current results showed that eye tracking performance is improved when the target is self-moved as compared to when being externally-moved. More importantly, our data suggest that eye motion is poorly influenced by TMS over M1. Indeed when the target was externally-moved, TMS did not disrupt eye motion. Furthermore during Eye-Hand coordination TMS induced an increase in eye-tracking error, but a very similar observation was noticed when using SHAM mimicking the visual effect of TMS on target motion. Overall the results of this TMS study suggest that the output of M1 has limited contribution to eye tracking performance during Eye-Hand coordination.

Title: Parameters of the presaccadic EEG potentials in the experimental scheme with distracters

Authors: ***V. MOISEEVA**[1,2], M. SLAVUTSKAYA[2], V. SHULGOVSKIY[2], N. FONSOVA[2]; [1]HSE, Moskva, Russian Federation; [2]Lomonosov MSU, Moscow, Russian Federation

Abstract: For successful goal-directed behaviour, it's crucial to attend relevant stimuli in the visual field while ignoring distractor elements. The oculomotor system is a good model for the study of this competition between different elements. The goal of this research was to analyse spatial-temporal parameters of saccades and presaccadic EEG-potentials at the simultaneous presentation of the target and distracting stimuli to the leading and unleading eye. The complex of the positive and negative potentials was revealed in the saccade latent period. Latency of all components was shorter upon presentation of stimuli to the left, unleading eye, that may indicate the earlier saccade preparation. At the same time LP saccades were longer in this conditions ($p<0.05$). The results show that early potentials N1 and P1 were higher in amplitude and dominated in the controlateral parietal-occipital areas. It can be reflection of visual sensory

processing. The amplitude of the later negative potential N2 at the stimulation of the right eye increased in the case when target stimulus was at the same location than at the previous realisation. It's possible that N2 component is connected with processes of preliminary extracting of motor program from memory together with attention processes. N2 amplitude was higher when the distance between target and distracting stimuli was 15 degrees in comparison with the minimal distance 5 degrees. It's corresponded with LP data. The findings show an active role of attention and decision-making processes in saccade programing.

Title: Simultaneous analysis of local field potential and spikes to understand the visuo-motor transformation in monkey frontal eye field

Authors: ***N. SENDHILNATHAN**[1,2], D. BASU[2], A. MURTHY[2];
[1]Columbia Univ. Dept. of Neurosci., New York, NY; [2]Ctr. for Neurosci., Indian Inst. of Sci., Bangalore, India

Abstract: The Frontal Eye Field (FEF) is one of several nodes in the oculomotor system that helps transforms a visual input into a saccadic motor commnad. In this study, Local Field Potentials (LFP) collected from the FEF, along with simultaneously recorded spike data, were used to characterize visuomotor cells of the FEF and study their contribution to the visuomotor transformation computation. We used a memory guided saccade to temporally dissociate the visual epoch from the saccadic epoch and study the processes that link them in time. A comparison of the LFP and spike signals during the visual epoch revealed that LFPs typically preceded the spikes and were more broadly tuned suggesting that the LFPs may reflect input into the FEF. In contrast, we observed that the spikes generated during the saccade epoch preceded the LFP signal suggesting that saccade related activity is generated de novo in FEF. Using the frequency domain information of the LFP, we observed that the gamma band activity increased in power only during the memory epoch. Nevertheless, gamma activity was spatially tuned and predicted the subsequent saccadic reaction time of the animal. These evidences suggest that LFP

signals, particularly in the gamma band, may represent a neural correlate of the visuomotor transformation process that is local to FEF. Taken together these results together make a valuable addition to the mechanism and the process of visuomotor transformation in FEF.

Title: Oculomotor plant dynamics during quick and slow phase movements in alert rhesus monkeys.

Authors: *K. SCHULTZ[1], J. M. MILLER[2], P. D. GAMLIN[1,2];
[1]Univ. of Alabama at Birmingham, Birmingham, AL; [2]Eidactics, San Francisco, CA

Abstract: An oculomotor plant model valid for a broad range of velocities is essential for resolving the transformation from ocular motorneuron (OMN) activity through extraocular muscle (EOM) force to eye position. A simple linear model is generally applied to the relationship between OMN firing and eye position, but fails to predict eye movement profiles and can even lead to paradoxical behavior (Miller et al. 2011). While OMN activity during eye movements is well known and highly stereotyped, the dynamics of EOM and orbital tissues are still being explored. Most models of the plant are derived from Robinson's (1964) model, which includes a series of viscoelastic Voigt elements with different time constants. Apart from nonlinearities related to stimulation frequency (Anderson et al. 2009) and passive muscle forces (Quaia 2009, 2010), Voigt elements in series continue to be used, despite the fact that muscle force is seldom actually measured, and when it is, the muscles are disinserted and/or the animal is sedated. By using muscle force transducers (MFTs) that do not restrict natural eye movements, we sought to address these weaknesses, as well as another - the restricted range of eye movement velocities used to develop plant models based on EOM force and eye position. MFTs were implanted on the horizontal recti of Rhesus monkeys trained to fixate targets. Forces were recorded during both saccades and horizontal pursuit movements at various frequencies, while eye position was recording using scleral search coils. Model parameters were determined in

Matlab (Simulink). The force profiles during pursuit movements were very similar to the eye position profiles. A simple model using one Voigt element was able to closely predict eye position, whereas multiple Voigt elements with multiple time constants were required to predict saccadic behavior. However, estimating parameters from only saccadic movements led to time constants and compliance values able to predict only quick phases; pursuit movements were poorly modeled, both in general profile and smaller oscillations. Likewise, parameters estimated from pursuit movements failed for saccadic movements. To fit a model for both pursuit and saccadic movements requires that parameters be estimated from both types of movement. This suggests that a wide range of eye movement types is necessary to correctly estimate general model parameters.

Title: Action selection after motor adaptation.

Authors: ***L. TEUNISSEN**, F. MAIJ, L. P. J. SELEN, W. P. MEDENDORP;
Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: Theories about motor decision-making suggest that actions are selected to achieve a (more) rewarding bodily state while minimizing the cost of performing those actions. To estimate the required cost of different potential actions, information of body and world dynamics derived from a continuously adapting forward model might be essential (Cos et al. 2014; see Pélisson et al. 2010 and Shadmehr et al. 2010 for reviews of saccadic and reach adaptation respectively). Therefore, we hypothesize that adaptation of the forward model biases the selection of actions towards the action with the relatively lower cost after adaptation. We investigated this hypothesis for both saccades and reaching movements by asking participants to either make free choice saccades or reaches to one of two (equally rewarding) targets, placed at

equal distance from the fixation location. We varied the targets' stimulus onset asynchrony (SOA) to psychometrically determine the SOA at which both targets were chosen equally often as a quantitative measure of target preference. Next, we performed saccadic adaptation or we modified the visuomotor gain for reach adaptation for one of the two targets and again determined the preferred target psychometrically. The adaptation was thus used to visually have similar amplitudes before the decision was made but to induce different eventual movement amplitudes in the post-adaptation free choice stage of the experiment. Preliminary results suggest a shift in target preference after adaptation, suggesting that visuomotor adaptation affects the process of action selection. Further experiments are currently performed and analyzed to see how changes in the forward model are reflected in action preferences for both eye and arm movements. **References:** Cos, I., Duque, J., & Cisek, P. Title: A shared mechanism for control of vigor in saccades, reaching, and head movements

Authors: *T. REPPERT[1], A. RAMAMOORTHY[1], O. KOMOGORTSEV[2], R. SHADMEHR[1]; [1]Johns Hopkins Univ., Baltimore, MD; [2]Texas State Univ., San Marcos, TX

Abstract: Some people consistently move faster than others. For example, some individuals move their eyes with high speed, while others make saccades of the same amplitude with lower speed. These inter-individual differences are reproducible across days and months of recordings. Do individuals that move their eyes with high speed also move other body parts rapidly? When vigor of one movement increases, does it coincide with increased vigor of other kinds of movements? Let us define vigor as the relationship between peak speed and amplitude of

movements for one individual with respect to the mean relationship for the population. For example, a subject has high saccade vigor if their speed-amplitude curve lies above the population mean. We asked subjects (n=286) to complete two sessions during which they made reflexive saccades to targets presented on a computer screen. The target positions were spaced randomly between +/-15 deg horizontally, and +/-9 deg vertically. We found a wide range of saccade vigor across the population. Importantly, subjects who exhibited high vigor for horizontal saccades also exhibited high vigor for vertical saccades. We then asked whether vigor is conserved across movement modalities. We recorded simultaneous eye, head, and reaching movements in subjects (n=25) as they completed a natural pointing task. Subjects were presented with visual targets, and then reached and touched that target. The movement included motion of the eye, head, and arm, with amplitudes ranging from 5-50 deg in 11 subjects, and 30-50 deg in 14 subjects. We found that vigor of head movements and reaching movements were strongly correlated: individuals who exhibited fast reaching movements also exhibited fast head movements. However vigor of saccades was only weakly related to that of head movements and reaching. During the task, each subject exhibited natural variability in their vigor. Given a subject's average vigor of movements for each modality, we studied within-subject changes in vigor about this mean. We found that within a subject, trial-to-trial changes in vigor of saccades were correlated with changes in vigor of both head movements and reaching movements. Specifically, vigor of all three movement modalities increased abruptly following a set break, and then decreased exponentially within-set. Therefore, our results suggest two ideas: 1) movement vigor may be a trait, conserved across head and reaching movements; 2) within-subject change in vigor of one type of movement (saccades) is a predictor of change in vigor of other types of movements (head and arm).

Title: The gap effect on performance in the minimally delayed oculomotor response (MDOR) task

Authors: *P. C. KNOX[1], F. D. A. WOLOHAN[2], E. HEMING DE-ALLIE[1];
[1]Univ. Liverpool, Liverpool, United Kingdom; [2]Psychology, Edge Hill Univ., Liverpool, United Kingdom

Abstract: The antisaccade (AS) task, often used to investigate inhibitory control, involves other aspects of processing (eg attention, working memory). The MDOR task, in which participants inhibit saccades to target onsets and instead saccade to target offsets, generates an error rate (saccades to onsets) and a modulation in saccade latency (Wolohan & Knox, 2014, Exp Brain Res 232:3949). AS error rates are higher in gap AS tasks. Are MDOR error rates similarly affected by gaps and overlaps? In experiment 1, 20 healthy adult participants completed blocks of gap or synchronous MDOR tasks. After a randomised fixation time (1-1.5s), the fixation target was extinguished and a saccade target appeared 5^{o} to either left/right for either 200ms or 1000ms (both randomised) either immediately (synchronous task) or after a gap of 200ms. Participants were instructed to maintain fixation centrally and saccade to the target position on target offset. Eye movements were recorded using an infrared eye tracker; latency and amplitude of primary saccades was measured. Saccades occurring <80ms post target offset, directed at the target, were classed as errors. In experiment 2, 10 participants completed overlap (central fixation target remained throughout the trial) and synchronous tasks. The presence of a gap had no influence on saccade latency to offsets (gap vs synchronous tasks: $F_{1,19}=1.6$; $p=0.2$) or error rate ($F_{1,19}=0.26$; $p=0.6$); display time affected both (latency: $F_{1,19}=70$; error rate: $F_{1,19}=43$; both $p<0.0001$; Figure). In experiment 2, the same display time modulation was observed, there was no difference between overlap and synchronous latency, but error rates were lower in overlap tasks ($F_{1,9}=5$; $p=0.053$). For all trial types, most errors were inhibition failures (ie saccades to onsets). The lack of a gap effect on error rate or latency reflects the lack of competition (present in AS tasks) between the reflexive and the voluntary responses. The reduction of error rates in the overlap task may indicate facilitated inhibition, and a potential dissociation between processes determining latency and error rates.

Research to Prevent Blindness

Title: Neural mechanisms associated with normal and pathological vergence.

Authors: *M. M. WALTON[1], M. J. MUSTARI[2];
[1]WanPRC, [2]Univ. of Washington, Seattle, WA

Abstract: Convergence insufficiency is a common disorder, characterized by impaired vergence eye movements and difficulty with close work, such as reading. Clinically, convergence insufficiency is often detected as an exophoria that is greater at near than at far. Because there is no animal model for this disorder, little is known about the neurological abnormalities that may underlie these symptoms. We have conducted preliminary studies in two monkeys, one with normal convergence and one with a naturally occurring impairment of disparity vergence (CI1). The normal animal easily converged on a scene placed at 10 cm distant (>15° of convergence). However, our impaired animal was only able to achieve 12° of convergence on the near scene for a few seconds at a time, despite extensive training. This vergence response did not decrease when one eye was patched. Disparity vergence was tested using a Risley prism placed in front of one eye while the animal fixated a red laser spot surrounded by a random gray-and-white checkerboard pattern at a distance of 57cm. The animal showed an unstable convergence response (maximum 6°) that increased with prism correction, up to 12 prism diopters (PD). By comparison, the normal monkey (N1) was able to achieve stable, appropriate convergence up to 26 PD. Single unit recording data were collected from 10 near response cells and 8 far response cells in the supraoculomotor area (SOA) while monkey CI1 fixated red plus-shaped LEDs at 12 different distances, in five different directions. After three minutes of recording, neurons were then tested while the animal fixated the visual scene at near (10 cm). Vergence rate-position curves were plotted for all neurons. Although the firing rates were clearly related to vergence angle the mean absolute value of the slope was substantially lower than we observed for a sample of 17 SOA neurons recorded from monkey N1 (Monkey CI1 = 2.78; Monkey N1 = 5.53). In addition, instantaneous firing rates for monkey CI1 were often highly variable, even when the vergence angle was not changing. This was not the case for our normal monkey N1. Our preliminary data suggest that impaired disparity vergence may be associated with aberrant tuning in near response cells.

Title: Individual differences in the speed of oculomotor processing

Authors: *B. PARSONS, C. GAMBACORTA, I. LIU, R. B. IVRY;
UC Berkeley, Berkeley, CA

Abstract: Eye movement behavior differs widely between individuals, but is relatively consistent and stable within subjects across a variety of viewing tasks. To investigate the factors underlying these idiosyncratic patterns in visual scanning, twenty subjects were tested on a battery of experimental tasks covering two broad psychological constructs, motor initiation and attentional orienting. We used a novel task, alternating voluntary saccades (AVS), to assess the speed of sequential oculomotor movements with minimal demands on processing related to perception or decision-making. In the AVS, participants made a series of saccades between two targets at a rapid rate, with the primary dependent variable being fixation duration (between successive saccades). Participants completed a series of other tasks used to study eye movements and/or attention. These included a delayed saccade task, fixation stability while maintaining gaze on a small fixation marker, visual search, and the attentional blink task. Mean fixation duration in the AVS was strongly correlated with delayed saccade reaction time, variance in fixation stability, and fixation duration during visual search. In contrast, AVS fixation duration was not correlated with the size of the attentional blink (cost to detect the second of two targets at a short inter-target interval relative to a long inter-target interval), or with accuracy in detecting the first target. The results confirm the existence of stable individual eye movement measures and indicate that the underlying constraint may be associated with individual differences in the speed of motor implementation, rather than attentional factors (i.e., time to shift attention). Whether the motor implementation variability between individuals is related to processes associated with fixation release or saccade initiation remains an open question. This emphasis on motoric constraints in gaze behavior stands in contrast to dominant eye movement control models, which stress exogenous factors and the rate of evidence accumulation.

Title: EEG denoising and decoding of smooth pursuit eye movements by using Extra-Dipole Method

Authors: *K.-I. MORISHIGE[1,2], M.-A. SATO[2], M. KAWATO[3];
[1]Toyama Prefectural Univ., Toyama, Japan; [2]ATR Neural Information Analysis Labs., Kyoto, Japan; [3]ATR Brain Information Communication Res. Lab. Group, Kyoto, Japan

Abstract: Eye movements may produce electrical changes that is measured as eye artifacts with EEG data at scalp electrodes. This artifact can be orders of magnitude larger than the signal from the brain, thus making cortical current estimation extremely difficult. In order to remove the eye artifacts, we used Extra-Dipole Method, which is based on hierarchical Bayesian method and simultaneously estimates the cortical and extra-brain source currents while placing dipoles not only on cortical surfaces but also on extra-brain sources. We varied the values for prior information for cortical surface and the eye current source dipoles, and their optimal values for estimation were systematically explored. For this two criteria were deemed necessary. First, the prior and posterior current variances should be the same. Second, the spatial patterns of fMRI activities and estimated current power should be highly correlated. In our previous studies we applied this method to MEG data. Here it is applied to EEG data. EEG is more difficult than MEG because the scalp electrical potential is the combination of different electric conductivities in various shells. The three-shell boundary element method (BEM) model derived from the MRI data set was employed. We calculated the current intensities from the estimated mean cortical currents during tasks. The current intensities were increased in the cortical regions of the lateral occipital temporal cortex (LOTC), the intraparietal cortex (IPC), the precentral cortex (PreCC), and the medial superior frontal cortex (MSFC). These areas are related to the saccadic and smooth pursuit eye movements. By introducing proper prior information, our approach can reasonably remove the effect of artifacts from contaminated EEG signals. To confirm the performance of our denoising method, we reconstructed the target velocities from the estimated cortical currents using a sparse linear regression (SLiR) method. First, the dataset was divided into to ten subsets. For each subset, the optimal sparseness parameter for linear regression model was determined by using an inner 10-fold nested cross-validation. Given this parameter, a regression model was trained using nine of the ten datasets and performance was evaluated on the remaining set. Test datasets for a typical subject demonstrated a good performance (Pearson correlation coefficients: 0.94; determination coefficient: 0.88), and weight values were mainly distributed on the cortical regions that related to the smooth pursuit eye movements. These results indicated that our method isolate cortical activities and eye artifacts from contaminated EEG data by using the Extra-Dipole Method.

Title: Are vestibular contributions to online reach execution processed by an internal model of the limb?

Authors: *C. MARTIN, D. LUCIEN, P. LAPIERRE, A. M. GREEN;
Neurosciences, Univ. De Montreal, Montreal, QC, Canada

Abstract: To reach accurately, estimates of body motion are required to compensate for spatial displacement of the limb relative to a reach goal as well as for additional forces imposed on it during body motion. Vestibular signals are important contributors to such estimates. However, the mechanisms by which they contribute to reaching remain poorly understood. Recently, we used galvanic vestibular stimulation (GVS) to selectively activate the vestibular sensors during reaching for different head-re-body orientations and showed that vestibular signals contributing to online reach execution have been appropriately transformed from a head- to a body-centered reference frame (Moreau-Debord et al., J Neurophysiol, 2014). The goal of the current study was to explore whether such transformed vestibular signals are processed by an internal model of limb biomechanics. To address this question, we used GVS to simulate body rotation as human subjects reached in different horizontal plane directions. Model simulations were used to predict how trajectories would be perturbed if subjects used vestibular signals to compensate either 1) purely kinematically for the expected spatial displacement of the arm or 2) both kinematically and dynamically, taking into account the additional forces that would be imposed on the arm by the simulated rotation and its biomechanical properties. If vestibular signals contribute to purely kinematic compensations then GVS is predicted to elicit deviations perpendicular to the desired trajectory that are symmetric for reaches to the left and to the right of body midline. In contrast, if vestibular contributions take into account limb dynamics then when reaching with the right arm, leftward reaches should elicit larger deviations than reaches to the right. To test these predictions, 12 subjects made 20 cm reaching movements while seated with their head inclined forward and their right arm supported in the horizontal plane by a robotic exoskeleton (KINARM, BKIN). Reaches were made in darkness to remembered targets in three directions (straight forward, 60^{o} to the left, 60^{o} to the right). GVS of unpredictable polarity (3 mA pulse) was applied during reaching in 17% of trials chosen pseudo-randomly. Average perpendicular trajectory deviations for forward and leftward reaches were similar in amplitude and significantly

larger than those for rightward reaches, consistent with the predictions for a compensatory mechanism that takes into account both reach kinematics and dynamics. The results suggest that the mechanisms by which vestibular signals contribute to on-line reach execution indeed take into account the biomechanical properties of the limb.

Title: Functional tuning of rubromotoneuronal cells in the forelimb movement in a macaque monkey

Authors: *T. OYA[1], T. TAKEI[2], K. SEKI[1];
[1]Dept. of Neurophysiol., Natl. Ctr. of Neurol. and Psychiatry, Kodaira, Japan; [2]Ctr. for Neurosci. Studies, Queens Univ., Kingston, ON, Canada

Abstract: Rubromotoneuronal (RM) cells consist of the descending tract that has a monosynaptic contact with spinal motoneurons. As the contribution of RM cells to generating electromyographic (EMG) activity remain elusive, we sought functional significance of RM cells on the basis of analysis of spatiotemporal profiles of its neuronal activity, i.e., synaptic linkages (SL) with muscles (post synaptic effects: PSEs) and functional linkage (FL): a broad temporal correlations with muscles (cross-correlations) in a behaving monkey, as studied in premotor (PreM) neurons in the spinal cord (Takei & Seki 2013). RM cells were identified based on PSEs using spike-triggered averaging; we recorded the single-unit activities from magnocellular part of red nucleus neurons concurrently with EMG activities from the 26 forelimbs muscles while a macaque monkey performed a sequence of whole-limb movements (reach-to-grasp of an object, precision grip, and self-feeding).
The identified 88 RM cells were characterized with divergent SLs with forelimb muscle with a

preference on forearm extensors and the muscles spanning proximal joints, and discharge of bursts in timings where a variety of muscles were recruited.
These RM cells were further subject to cross-correlation analysis with the same 26 muscles with a time windows ranging between 1s before and after the neuronal activity. A pair with a significant cross correlation validated with Monte Carlo simulation was defined as having a FL. We compiled pairs with SLs and FLs among 2288 (88 (RM cells) x 26 (muscles)) pairs and examined their overlap in population.
Out of whole pairs, FL pairs had a greater proportion (784/2288) than that of SL population (327/2288), with positive correlations being predominant (positive:negative = 652:132 out of 784), as contrasted with relatively even proportions of SLs (excitatory:inhibitory = 168:159 out of 327). It is notable that a large number of incongruities between SLs and FLs were found; overlapped pairs (SL∧FL) were counted as 153, whereas the number FL-exclusive pairs (!SL∧FL) was 673 and the number of SL-exclusive pairs (SL∧!FL) was 216, indicating 41.6% of SL pairs were overlapped with FL pairs. Further, out of 153 overlapped pairs, congruent pairs (i.e., positive FL/excitatory SL or negative FL /inhibitory SL pairs) were counted as 76. The disparity of SLs and FLs in RM cells was markedly contrasted with coherent SLs and FLs in spinal PreM interneurons (ca. 80% overlap), suggesting a different functional role of RM neurons than spinal synergistic control.

Title: Temporal dynamics of interaction between efference copy and sensory feedback in the primary somatosensory cortex

Authors: ***T. UMEDA**[1], Y. NISHIHARA[2,3,4], M. SUZUKI[2,3,4], Y. YAMANISHI[2], T. ISA[2,3], Y. NISHIMURA[2,3];

[1]NCNP, Kodaira-Shi, Japan; [2]NIPS, Okazaki, Japan; [3]Kyoto Univ., Kyoto, Japan; [4]SOKENDAI, Hayama, Japan

Abstract: The brain deal with anticipation of the sensory consequences during stereo-typed voluntary movement. Primary motor cortex (MI) is thought to be source of this anticipations by generating an internal copy of motor output that alerts somatosensory cortex (SI) to change their response to peripheral afferent input, termed efference copy. However, there is no clear evidence how the interaction of inputs from MI and peripheral afferent generates activity of the SI. In this study, we calculated activity of the SI from activity of the MI and peripheral afferents using a decoding algorithm to clarify signal processing in the SI. We simultaneously recorded electrocorticogram (ECoG) signals from cortical areas including the SI and MI, activity of population of dorsal root ganglion (DRG) neurons which conveys activity of peripheral afferents, electromyography of 11 muscles and kinematics of forelimb joints of two monkeys in voluntary reaching and grasping movements. During voluntary reaching-and-grasping task in awake, high gamma activation in the MI and SI preceded movement onset, discharge of DRG assemble and muscle activities. High gamma activity of the SI after movement onset could be predicted from activity of the DRG neuronal ensemble, but not just prior to movement onset. This results implies SI activity contains not only the information from peripheral afferent inputs but also from other source. Activity of the SI in prior to movement onset could be predicted by including high gamma activity of the MI in addition to DRG neurons into the decoding model. Furthermore, prediction of SI activity from activity of the MI and DRG neurons is more accurate than those from activity of premotor cortex and DRG neurons. The results suggest that the SI receives efference copy which represents sensory information in anticipation of upcoming movement from the MI before the actual feedback signal from the periphery. Thus, efference copy from the MI can affect processing of the following feedback signal in the SI.

Title: Distinct temporal evolution for visuomotor feedback of the hand and target

Authors: *D. W. FRANKLIN;
Tech. Univ. of Munich, Muenchen, Germany

Abstract: Visual feedback of the hand and target guides goal-directed reaching movements. However, the magnitude of visuomotor responses to visual shifts of hand location are not consistent throughout the movement, but evolve temporally, peaking in the middle and falling as the hand nears the target (Dimitriou et al., 2013). Recently we showed that the two visual feedback systems of hand and target motion elicit partially independent responses that are integrated in later stages of the sensorimotor system (Franklin et al., 2016), thereby suggesting that the evolution of feedback could differ in these two systems. Here we examined to what degree the temporal evolution of the visuomotor feedback gain of the target differs from the visuomotor feedback gain of the hand. Participants performed reaching movements to a target while grasping a robotic manipulandum. Visual feedback of both the hand position (cursor) and target position was provided in the plane of movement using a virtual reality setup. On random trials (probe trials), the cursor or target was momentarily laterally displaced visually before returning to the actual hand or target position. On all probe trials the hand trajectory was constrained by a mechanical channel in order to measure the resulting feedback force. The perturbations occurred at thirteen different times prior to movement initiation, during movement, or after movement completion. The involuntary force responses to both target and cursor shifts exhibited a strong temporal evolution, and were not present before or after the movement. Consistent differences in the temporal pattern of hand and target responses further demonstrate independent control of visual feedback systems for hand and target motion.

Title: Gravitational effects on proprioceptive sensitivity

Authors: *J. D. KLEIN[1,2,3], B. WHITSELL[4,1], M. PATEL[1,5], P. ARTEMIADIS[4,1], C. A. BUNEO[6,1];
[1]ASU, Tempe, AZ; [2]Interdisciplinary Grad. Abstract: Proprioception is the sense of body position, movement, force and effort. Loss of proprioception can affect planning and control of limb and body movements, negatively impacting activities of daily living and quality of life. Assessments employing planar robots have shown that proprioceptive sensitivity is dependent upon the location of the limb within a horizontal plane (Wilson et al, 2010). Little is known however about proprioceptive sensitivity in the vertical plane. Previous studies have suggested that proprioception plays a key role in anticipating arm configuration dependent effects of gravity (Proske & Gandevia, 2005) suggesting that proprioceptive sensitivity could differ for arm displacements performed with and against the direction of the gravitational vector. To test this hypothesis we developed a novel experimental paradigm employing a 7-DoF anthropomorphic robot arm (LWR4+, KUKA Inc.), which enables reliable testing of arm proprioception along arbitrary paths in 3d space, including vertical motion.A participant's right arm was coupled to a trough held by the robot that stabilized the wrist and forearm, allowing for changes in configuration only at the elbow and shoulder. Sensitivity to imposed displacements of the endpoint of the arm were evaluated using a "same-different" task, where participant's hands were moved 1-4cm away from a recently visited reference position. The proportion of trials where subjects responded "different" when the stimuli were different ("hit rate"), and where they responded "different" when the stimuli were the same, ("false alarm rate"), were used to calculate d', a measure of sensitivity derived from signal detection theory. Data were obtained from 20 subjects, 5 in the upward direction and 16 in the downward direction (one subject was tested in both directions). In both directions sensitivity (d') increased monotonically as the distance from the reference location increased. Sensitivity was generally more variable across subjects for the downward direction and beyond 1 cm median sensitivity was also reduced for the downward direction with respect to the upward direction. A Mann-Whitney U test comparing sensitivity between the upward and downward directions at each displacement distance revealed that sensitivity was significantly different for the 2 cm displacement but not for other distances ($p<0.05$). These data suggest that the ability to estimate the position and velocity of the limb via proprioception might be enhanced for movements performed against gravity, which has important implications for understanding the multisensory planning and control of reaching movements performed in 3d space.

Title: Multisynaptic projections from the basal nucleus of the amygdala to the ventral premotor cortex in macaque monkeys

Authors: *H. ISHIDA[1], K.-I. INOUE[2], M. TAKADA[2], E. HOSHI[1];
[1]Frontal Lobe Function Project, Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan; [2]Systems Neurosci. Section, Primate Res. Institute, Kyoto Univ., Aichi, Japan

Abstract: The forelimb region of the ventral premotor cortex (PMv) plays a central roll in reaching, grasping, and eating food. In such feeding behavior, it is crucial to evaluate a target to reach for. The amygdala has been implicated in this process. Amygdalar neurons code the visual-gustatory valence of food. Dysfunctions of the amygdala induce a compulsion to reach, grasp, and bring to mouth food, regardless of its value. These facts suggest that PMv uses a valence signal about the target derived from the amygdala for planning and executing feeding behavior. Since no direct connectivity between the amygdala and PMv has been reported, the structural basis of their interaction still remains elusive.
In order to identify possible multisynaptic projections from the amygdala to PMv in macaque monkeys, we employed retrograde transneuronal labeling with rabies virus (CVS-11). The survival time was set to allow the second-order neuron labeling across one synapse. Histological analysis of the distribution pattern of amygdalar neuron labeling after rabies injections into PMv revealed that PMv receives disynaptic inputs primarily from the basal nucleus; mostly (67.2% of the total labeled neurons in the amygdala) from the intermediate subdivision, less frequently (13.4%) from the
magnocellular and parvicellular subdivisions, and rarely (1.5%) from the accessory basal nucleus. It was also found that PMv receives additional disynaptic inputs from the central nucleus (10.5%), the dorsal portion of the lateral nucleus (5.9%) and other nuclei (1.5%).
The present results provide the first evidence for the anatomical linkage from the amygdala to PMv. The following structures may mediate the disynaptic projections from the amygdala to the forelimb region of PMv: (1) the medial cortical areas including the presupplementary motor area and cingulate motor areas; (2) the lateral cortical areas including the precentral opercular cortex

and posterior insular cortex; and (3) the cholinergic cell group 4 (Ch4) in the basal forebrain. The PMv could receive the valence signals about target objects derived from the amygdala via these pathways. Dysfunctions of the pathways might underlie Klüver-Bucy syndrome in which animals behave as if they were ignorant about the value of target objects.

Title: Effects of the vertical-horizontal illusion on visual perceptions and manual estimations

Authors: S. YAN[1], *J. M. HONDZINSKI[2];
[1]Kinesiology, Louisiana State Univ., Baton Rouge, LA; [2]Kinesiology, Sch. of Kinesiology; Louisiana State Univ., Baton Rouge, LA

Abstract: Visual illusions often provide important clues for understanding perceptual mechanisms associated with sight, which can influence motor output. This illusion refers to the overestimation of the vertical segment when compared to a bisected horizontal segment of the same length. The bisected segment (horizontal) looks shorter than the bisecting segment (vertical). Similarly, the vertical segment also appears to be longer than the horizontal segment when the horizontal segment is not bisected. With discrepancies in the literature we chose to determine if perceptions and manual estimations of healthy young adults were influenced by the vertical-horizontal illusion of varied bisected segments. In the perceptual task, subjects were presented with the inverted "T" (T), modified inverted "T" (MT), or "L" configurations with horizontal and vertical segments equal in length or with 10-15% longer vertical segments, or with 10-15% longer horizontal segments. After viewing a figure, subjects reported which segment in the figure looked longer or if the segments looked equal. In the motor task, subjects were presented with vertically or horizontally oriented reference segments with a very long perpendicular segment attached. Subjects were instructed to touch the figure at the intersection of these two segments, then again at a distance on the long segment so that the length from first touch to second touch matched the length of the reference segment. Perceptual accuracy varied to a large extent across subjects. However, subjects were mostly affected by inverted "T" figures in the perceptual task. Illusory configurations with longer horizontal segments or identical segment lengths had the strongest illusory effects. In the motor task, subject's manual estimations of vertical segment lengths were larger than the estimations of horizontal lengths to

suggest vertical-horizontal illusory effects on manual estimations. These data offer insights to the vertical-horizontal illusion effects on perception and action and suggest that varying the bisection of the illusion is strongest when it occurs centrally.

Title: Modulation of muscle synergy activation during arm movements in patients with hemiparesis

Authors: *T. KAWASE[1], A. NISHIMURA[2], A. NISHIMOTO[2], F. LIU[2], Y. KIM[1], H. KAMBARA[1], N. YOSHIMURA[1], Y. KOIKE[1];

Abstract: Previous studies have suggested that damage to central nervous system may alter muscle synergies, coordinated activities of multiple muscles that organize modules for motor control. To investigate the alternation following the damage will facilitate more effective design of neurorehabilitation technologies. Most of the studies have focused on muscle synergies of the patients recruited during simple tasks, such as isometric force generation or reaching movements, and contributed significant insight into the research field. However, few studies have investigated muscle synergies of the patients related to complex movements in daily activities. In this study, we investigated how the muscle synergies were modulated during a peg transfer task in patients with hemiparesis toward the realization of effective neurorehabilitation systems covering complex movements.
Seven patients with hemiparesis (Fugl-Meyer upper arm score 19-58) picked a peg on 3×3 grid points on a board and placed it out of the board sequentially by using their affected arms. Six able-bodied subjects also performed the same task. We estimated a set of muscle synergies for each subject by applying nonnegative matrix factorization to electromyographic signals measured during the task, and classified the synergies into 14 classes by using a hierarchical

clustering method. For each class of the synergies, we calculated mean activation coefficients of the synergies during a movement corresponding to each peg position in the patients and the able-bodied subjects.
We found 10 of 14 classes of the synergies were activated during the movements in both of the patients and the able-bodied subjects. The activation coefficients in 4 classes were well explained by coordinates of the peg positions in both the groups (linear regression model, $R^2 > 0.7$), but in 3 classes, different coefficients of the coordinates were derived in the two groups (cosine similarity of the coefficients < 0.7). One of the classes showed almost opposite effect of the coordinates in the two groups (cosine similarity of the coefficients < −0.9).
These results suggested the patients modulated activation levels of the muscle synergies according to the peg position, but the manner of the modulation was differed from the able-bodied subjects. The results may be useful for development of new neurorehabilitation technologies.

Title: Thalamocortical mechanisms controlling motor timing in behaving primates

Authors: ***A. NASHEF**, O. COHEN, Y. PRUT;
Med. neurobiology, Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: The timing of actions is considered to be dictated by cerebellar output that is relayed to the motor cortex via the motor thalamus. This hypothesis is consistent with the finding that cerebellar patients exhibit poorly timed and uncoordinated actions. We investigated the mechanisms by which the cerebellar-thalamo-cortical (CTC) system dictates temporal properties of motor cortical activity and the events that emerge when information flow through this pathway is temporarily interrupted.
Monkeys were trained to perform a 2-D reaching task that required tight control of motor timing.

A cortical chamber was implanted above the motor cortex and stimulating electrodes were chronically implanted in the ipsilateral superior cerebellar peduncle (SCP). Neural activity was recorded from primary motor (M1, n=252) and premotor areas (PM, n=131).
Single pulse SCP stimuli efficiently recruited neurons in both M1 and PM (77% and 68% respectively) producing an early excitation followed by a prolonged inhibition. Cortical response in M1 occurred earlier than in premotor cortex (2.9 vs. 3.6 ms, $p < 0.01$) and had a shorter duration, whereas the subsequent inhibition was significantly longer (34.6 vs. 26.5 ms, $p < 0.01$).
Persistent high frequency SCP stimulation (HFS) led to a significant increase in reaction time (RT; -144ms vs. -189.3ms in control; $p<0.005$) and movement time (MT; 447.2ms vs. 369.6ms in control; $p<0.001$). In addition, the path travelled from center position to the peripheral target became more variable and generally longer (3.8cm vs. 3.5cm in control; $p<0.001$). Finally, these changes were more prominent for targets that required a coordinated elbow-shoulder movement.
These behavioral changes were accompanied by changes in neural activity. We computed the preferred direction (PD) of single cortical cells and their phasic-tonic index (PTI) which measured their tendency to fire in a tonic vs. phasic manner. Single cortical cells maintained their PD during HFS trials but their PTI decreased significantly ($p < 0.005$), consistent with a shift from a phasic to tonic response pattern.
These results suggest that the CTC evokes an extensive excitatory-inhibitory motor cortical volley that is temporally organized across M1 and PM areas.
Interfering with the flow of information in this pathway produces motor deficits similar to those found in cerebellar ataxia. The neural correlate of these behavioral changes is the loss of phasic firing at movement onset. It is thus suggested that CTC system controls the timing and coordination of voluntary movements by shaping the response pattern of single cortical cells independently of their spatial properties.

Title: Task-dependent vestibular feedback corrections in reaching

Authors: *J. KEYSER, L. P. J. SELEN, W. P. MEDENDORP;
Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: When reaching for an object during self-motion, our motor system should appropriately integrate vestibular signals to compensate for the intervening motion and its induced inertial forces. We asked whether the brain processes these vestibular signals automatically with the aim to preserve hand trajectory in space or more flexibly, correcting trajectories only in task-relevant spatial dimensions.
Using a robotic manipulandum, we tested subjects (n=24) making reaches to either a narrow (2 cm) or a wide (60 cm) target in front of them. Subjects reached to the target without instruction on where to hit it. In 20% of reaches, subjects received galvanic vestibular stimulation (GVS) and shutter glasses prevented visual feedback. In GVS trials, the current was proportional to hand speed, but clipped at 3 mA, with either positive polarity (cathode left) or negative polarity (cathode right).
We found that the same vestibular stimulation led to smaller trajectory corrections for the wide target compared to the narrow target. We interpret this reduced compensation as a task-dependent modulation of vestibular feedback responses, tuned to minimally interfere with the task-irrelevant dimension of the reach (Todorov and Jordan, 2002). These flexible vestibular feedback corrections mimic the sophistication seen in feedback responses to mechanical (Pruszynski et al., 2008) or visual (Knill et al., 2011) perturbations of limb position.

Title: Effect of handedness on unilateral and bilateral reaching movements under the influence of the mirror illusion

Authors: *K. YAMANAKA;
Showa Women's Univ., Tokyo, Japan

Abstract: The mirror illusion can be used to induce systematic errors for reaching movements made with the unseen hand behind the mirror. However, it remains unclear whether the reaching errors induced by the mirror illusion differ depending on 1) movement of the contralateral hand seen in the mirror (unilateral or bilateral reaching) and 2) participant's handedness (right-hander or left-hander). The aim of this study is to investigate the performance of the unilateral and bilateral reaching under the influence of the mirror illusion in right- and left-handed individuals. Six right-handed and six left-handed female volunteers conducted reaching tasks under the influence of the mirror illusion. Participant initially placed one hand in front of, and the other hand behind, a mirror placed vertically in the mid-sagittal plane on the table. She asked to move the hand seen in the mirror to the directions toward or away from the mirror, or not to move it. After 10 s of exposure to the mirror reflection, participant reached to unseen target situated 15 cm forward with their unseen hand behind the mirror (unilateral reaching) or both hands simultaneously (bilateral reaching). We record the reaching trajectories and endpoint errors made with the tip of index finger of the unseen hand using by VICON motion capturing system. As a result, regardless of whether the mirror faced to right or left side, reaching errors in horizontal direction were larger in the bilateral reaching than in the unilateral reaching. These results suggest that participants can detect their visual-proprioceptive conflicts in unilateral reaching condition more easily, while they remain insensitive to the conflict in the bilateral reaching condition. Next, when the mirror faced to the right side, unseen left-hand reaching errors in anteroposterior direction were larger in the right-handers than in the left-handers. In contrast, when the mirror faced to the left side, there was no difference in unseen right-hand reaching errors between right- and left-handers. These results suggest that right-handers are difficult to control their non-dominant left hand under the influence of the mirror illusion while left-handers can control their non-dominant right hand even under the influence of the mirror illusion.

Title: Sensorimotor transformation during reaching investigated with transcranial magnetic stimulation and biomechanical simulations

Authors: *R. L. HARDESTY, JR[1,2], E. OLESH[2], B. POLLARD[2], P. H. ELLAWAY[3], V. GRITSENKO[2];
[1]Neurosci., [2]West Virginia Univ., Morgantown, WV; [3]Imperial Col. London, London, United Kingdom

Abstract: Coordinated movement of the multi-segmental musculoskeletal system requires the nervous system to employ or compensate for diverse dynamic properties. This is achieved by multisensory integration and internal predictive circuits shaped by experience. While the importance of this information has been extensively documented, the specific roles of forward motor planning and sensory feedback to the formation of motor commands is not entirely understood.
We investigated the role of cortical input to the formation of motor commands during reaching by healthy young human subjects. The subjects pointed to virtual targets placed in locations that created distinct dynamic characteristics, such that the movement was largely passive (#1), interaction torques were resistive with increasing gravitational load (#2), and interaction torques were assistive with decreasing gravitational load (#3). A wearable headset (Oculus Rift) and the WorldViz (Vizard) system was used to create the virtual environment and provide visual feedback of performance. At randomized time periods during the reaching movement, the primary motor cortex was noninvasively stimulated using transcranial magnetic stimulation. During movement electromyography (EMG, MotionLab Systems) of 12 muscles of the arm and kinematics (PhaseSpace) were recorded. Kinematics was used to calculate joint torques and simulate sensory feedback. Motor evoked potentials (MEPs) were integrated and normalized to background EMG activity measured in non-TMS control trials. Sensory feedback was simulated using published models and an OpenSim model of the human arm to estimate muscle lengths. The data was analyzed with hierarchal clustering of multiple correlations to derive quantitative representations of imbedded relationships between motion biomechanics and neural signals. Preliminary results suggest that corticospinal signals measured with MEPs have strong relationships with task-specific dynamic biomechanical variables, while simulated sensory

signals have strong relationships with kinematic biomechanical variables. This suggests that sensorimotor transformation includes task-specific changes of the modality of sensory feedback signals into a dynamic domain.

Applied Physiol., Georgia Inst. of Technol., Atlanta, GA

Abstract: Reach and grasp is one of the most fundamental tasks performed by humans. When sensory feedback from a limb is lost due to disease or amputation, compensatory processes such as increased reliance on vision are thought to be used to ameliorate the deficit. These compensatory processes may come at the cost of increased cognitive load as well as inefficiencies in execution of motor tasks, both of which may contribute to the high rate of abandonment of upper extremity prostheses. To date, no formal studies have been conducted to demonstrate the impact of increased visual reliance in prosthesis users. The purpose of this study was to assess the neural and kinematic differences in a reach and grasp task between intact subjects and intact subjects using an upper extremity prosthesis simulator when vision is occluded. Subjects were divided into four groups; (1) intact using vision, (2) intact with occluded vision, (3) fictively amputated using vision, and (4) fictively amputated with occluded vision. EEG and kinematic data were gathered while the subjects performed a repetitive reach and grasp task. EEG differences in neural behavior as measured by task-related potential, as well as differences in kinematics as measured by harmonicity and smoothness of movement were compared between the four groups with intact/fictive amputation and vision/occluded vision as factors. The results of this study can help drive improvements in rehabilitative and therapeutic practices based on the effect of vision in conjunction with a prosthetic device.

Title: Gaze-dependent coding of proprioceptive reach targets is influenced by effector movement and availability of online information

Authors: *S. MUELLER[1], K. FIEHLER[2];
[1]Justus-Liebig Univ. Giessen, Giessen, Germany; [2]Justus-Liebig-University Giessen, Giessen, Germany

Abstract: In previous research, we demonstrated that the spatial coding of proprioceptive reach targets depends on the presence of an effector movement (Mueller & Fiehler, 2014, 2016). In these studies, participants were asked to reach (in total darkness) with their right hand to the location in space where they had felt a touch on a fingertip of their left hand. In the moved condition, they had to actively move their left hand forward to the target location followed by a touch on one of their fingertips, and then had to move their hand back to the start before reaching to the remembered location of the felt touch in space. In the stationary condition, the left hand was kept at the target location throughout the trial. Thus, the stationary condition did not contain a movement of the target effector; however, online proprioceptive information about the target location was available that was absent in the moved condition. Evidence for gaze-dependent coding reflected by reach errors opposite to gaze direction was obtained in the moved but not in the stationary condition.
In the present experiment, we were interested in whether the observed switch from gaze-independent to gaze-dependent coding is due to the effector movement or due to the availability of online proprioceptive information about the target during reaching. We asked participants to reach to a proprioceptive-tactile target while gaze was varied relative to the target's location. In addition to the moved and the stationary condition, we conducted a moved-online condition in which participants performed the same movement with their target hand as in the moved condition but instead of reaching to the remembered proprioceptive target location, they reached to the current location of their fingertip that had been touched.
We examined whether reach errors varied as a function of gaze relative to target between the three conditions. Indeed, we found a significant interaction showing gaze-dependent reach errors in the moved and moved-online conditions but not in the stationary condition. However, the gaze effects in the moved-online condition were less pronounced than in the moved condition

suggesting that both, the effector movement and the availability of proprioceptive online information about the target location influence the contribution of gaze-dependent coding in proprioceptive reaching.

Title: Differential sensory control of the reach and the grasp in 12-month-old human infants: Increased visual guidance of the reach relative to the grasp in a skilled reach-to-eat task

Authors: *J. M. KARL, A. WILSON;
Thompson Rivers Univ., Kamloops, BC, Canada

Abstract: The ability to reach out and grasp an object is generally believed to develop under visual control and to be mature by about 12 months of age. An alternate view, however, is that the Reach and the Grasp are separate movements, mediated by separate neural pathways that initially develop under haptic control with vision acquiring subsequent control later in development. A hypothesis that has emerged from this latter view is that the Reach and the Grasp come under visual control at different developmental rates. Specifically, it is proposed that visual control of the Reach may developmentally precede visual control of the Grasp. To test this hypothesis we filmed 12-month-old infants and healthy adults as they reached, grasped, and ate ring-shaped pieces of cereal. Adults were separated into a Vision condition (V) and a No Vision condition (NV) whereas infants always had Vision. The participants' movements were video recorded from bottom-up, face-on, and reach-side views and offline frame-by-frame video analysis was used to analyze two measures of Reach accuracy (Maximum Height of the Index Knuckle and Variability of the Reach Trajectory) and two measures of Grasp accuracy (Index-Thumb Aperture at First Contact with the Cereal and Time from First Contact to Final Grasp), with increased accuracy on each of these measures reflecting a greater influence of visual input on movement execution. Preliminary results suggest that the accuracy of the Reach of 12-month-old infants is more similar to that of sighted adults, whereas the accuracy of the Grasp is more similar to that of unsighted adults. These results lend support to the idea that the Reach and the Grasp follow different developmental trajectories such that visual guidance of the Reach is more prominent than visual guidance of the Grasp by 12 months of age.

Title: Former unilateral amputees exhibit bilateral differences in the control of reach to grasp actions

Authors: ***D. MATTOS**[1], N. BAUNE[1], B. PHILIP[1], K. VALYEAR[2], C. KAUFMAN[3], S. FREY[1];
[1]Occup. Therapy, Washington Univ. Sch. of Med., Saint Louis, MO; [2]Psychology Dept., Univ. of Bangor, Bangor, United Kingdom; [3]Christine M. Kleinert Inst., Louisville, KY

Abstract: Upper limb amputation is associated with reorganization of the somatosensory system, where changes are detected in the cerebral hemispheres contra- and ipsi-lateral to the trauma. Some of these changes persist even years after the reversal of amputation through hand replantation or transplantation. We used high spatiotemporal-resolution motion analysis to test the hypothesis that, as a result of limitations in somatosensation, these individuals are heavily dependent on visual feedback of the limb to coordinate reach-to-grasp actions. This study included six control subjects, two hand replants, and one hand transplant recipient (the latter evaluated longitudinally). All were right-handed and, with the exception of one of the replants, had their left hand affected. Subjects grasped cubes of three different sizes, with (light) and without (dark) vision of the hand. Importantly, objects were luminescent and thus always visible. We measured: the peak (PGA) and timing (tPGA) of the grip aperture (measured between index finger and thumb), and the peak (PTV) and timing (tPTV) of the transport velocity of the hand. The values for the right and left hands of the patients were compared to the 95% CI for the mean of the control group, matched by hand dominance. *Controls*. The PGA and tPGA scaled with the object size in both vision conditions. The PGA was smaller in the dark, with a larger decrease in the left than in the right hand. The PTV was ~15% larger for the dominant right [51.77 ± (SD) 3.28 cm/s, CI: 48.33 - 55.21] vs. the left hand (45.12 ± 2.30 cm/s, 42.71 - 47.54), and ~10% larger in the dark (50.75 ± 4.36 cm/s, 46.17 - 55.33) than in the light (46.15 ± 3.29 cm/s, 42.69 - 49.60). *Patients.* As with controls, PGA scaled with object size and was also smaller in the dark. However, when the smaller objects were grasped with the affected hand, patients did not scale the PGA to the same extent as the controls. The PTV was higher than the 95% CI of controls

with the *affected* and *unaffected* limb and for both vision conditions. In contrast to controls, in the affected hand, the values of PTV of all patients were similar in the light and dark. For the unaffected hands of the two replants, the PTV was higher in the dark vs. light, while in the transplant, the PTV was similar in both conditions. Although our hypothesis was not supported, we observed unexpected differences in performance with the unaffected limb in all three patients. While further work is needed, we speculate that these changes in the sensorimotor control of the healthy limb may be attributable to documented bilateral reorganizational changes within sensory and/or motor cortex following unilateral deafferentation.

Title: Intracortical microstimulation maps of motor, somatosensory, and posterior parietal cortex in macaque monkeys

Authors: *M. K. BALDWIN[1], D. F. COOKE[2], A. B. GOLDRING[3], L. KRUBITZER[1]; [1]Ctr. for Neurosci., Univ. of California Davis, Davis, CA; [2]Ctr. for Neurosci., Unviersity of California Davis, Davis, CA; [3]Ctr. for Neurosci., Univ. of California, Davis, CA

Abstract: Long-train intracortical microstimulation (ICMS) has been used in a number of primates and recently tree shrews to reveal movement maps in both motor and posterior parietal cortex; however, the full extent, location, and number of those maps, and the characteristics of the movements elicited using ICMS have not been fully explored in macaque monkeys. In the current study, long-train ICMS was used to reveal the organization of movement maps within a large portion of the primary motor cortex as well as the parietal lobe. Our results revealed roughly topographic motor maps throughout primary motor (M1), as well as areas 1, 2, 5, and 7. Movements involving the forelimb, and specifically movements of digits were represented over the largest area of cortex, especially within posterior parietal cortex. Further, movements usually involved multiple digits or forelimb joints and resembled natural hand movement typical of

macaques, including precision grips and full hand grasps. Representations of similar grasp movements were observed in areas 1, 2, 5L, and 7b. Taken together we find that much of motor and parietal cortex contains representations of ethologically relevant hand movements. Further, movements can be evoked from a larger extent of parietal cortex than was previously believed.

Title: Neural correlates of perceiving audiovisual consequences of voluntary movements

Authors: *B. ARIKAN[1], B. VAN KEMENADE[2], K. PODRANSKI[2], O. STEINSTRÄTER[2], B. STRAUBE[2], T. KIRCHER[2];

Abstract: Theories of motor-control suggest an internal forward model where an efference copy signal is used to predict the consequences of voluntary movements. This mechanism leads to an attenuation of the sensory input mainly to save resources for the processing of unexpected stimuli. Sensory attenuation has been observed for auditory, somatosensory and visual modalities both on a behavioral and neural level, however no research has been done yet on the common experience where a self-generated movement leads to multiple sensory consequences. We aimed to investigate neural mechanisms involved in the prediction of voluntary movements leading to unimodal vs bimodal sensory consequences. In addition, we aimed to manipulate the influence of predictability on attenuation by assessing the processing of temporal discrepancies in the movement-consequence relationship. Participants performed hand movements gripping the handle of a custom-made device inside the scanner while seeing an online movie of their hand as they moved. We systematically introduced temporal delays to the recorded movie, and asked participants to judge whether there was a delay between their hand and the online movie. In order to account for the influence of efference copy, we introduced a passive condition where the handle was moved automatically. Half of the trials involved an auditory tone coupled to the

movement onset, corresponding to bimodal sensory feedback condition. Preliminary imaging analyses showed reduced activation in areas linked to somatosensory, visual and auditory processing in the active compared to the passive condition, suggesting suppressed activity for the sensory consequences of voluntary movements, both for unimodal and bimodal consequences. This is in line with the behavioral finding showing better delay detection the passive condition. These preliminary results support the hypothesis that efference copy-related predictive mechanisms contribute to BOLD suppression in auditory, visual and somatosensory cortices. Further analyses are planned to assess the influence of subjective experience of delay detection, and the contribution of multisensory feedback in this process.

Title: Ultrasound imaging of upper limb muscle velocity during passive movements and involuntary reflex responses

Authors: ***E. MCKENNA**, N. AKHLAGHI, P. OTTO, M. HARRIS-LOVE, W. M. JOINER, S. SIKDAR;
George Mason Univ., Fairfax, VA

Abstract: Ultrasound imaging can be used to visualize and quantify the mechanical deformations (contraction and relaxation velocity) of different muscle compartments in deep tissue. The sensing of muscle activation through mechanical rather than electrical changes may provide complementary insight into changing muscle properties during movement that are not readily observed with standard surface electromyography (EMG) sensors. Specifically, it is difficult to characterize passive movements using EMG, but these movements can be distinguished with ultrasound imaging. There is also a clinical need to separate these passive motions from involuntary muscle activation in certain disease states such as spasticity where

there is an abnormal velocity-dependent resistance to passive stretch. We tested the ability to distinguish these respective motions in unimpaired healthy subjects by examining the changes in mechanical and electrical activity during passive arm reaching movements and subsequent involuntary stretch reflex responses. Using a robotic manipulandum, subjects made passive 10 cm horizontal planar movements with the right arm at 8 different movement durations (200, 250, 300, 350 400, 600, 800, and 1000 ms). We tested two directions of motion: passive flexion of the triceps moving the limb away from the body (90^o) and passive flexion of the biceps moving the limb towards the body (270^o). We made simultaneous measurements of the biceps and triceps muscle velocity, surface EMG, subject applied force and manipulandum joint velocity, and made several observations based on these data. First, there was good correlation between ultrasound based muscle velocity and joint velocity measures for purely passive movements, with minimal EMG activity and force. Second, as the movement speed increased ($\leq$ 400 ms duration) we observed involuntary stretch reflexes which were confirmed using surface EMG and force measures. Additionally, the stretch reflex response was readily observed in the ultrasound data and the measured muscle velocity showed higher variability, which was modulated by motion speed. This quantification and discrimination of passive and involuntary muscle activation patterns through mechanical deformations could potential help differentiate healthy muscle mechanical properties from abnormal states, such as the activation disorders that result from spasticity.

Title: Muscle spindle discharges from lower leg muscles during active ankle movements in humans

Authors: *E. JAROCKA, B. B. EDIN;
Umea Univ., Umea, Sweden

Abstract: We have developed a novel paradigm that for the first time allows stable recordings from unitary human muscle spindle afferents from all lower leg muscles actuating the ankle joint

during active, unconstrained movements of the foot within most of its physiological range. The recordings were obtained from the sciatic nerve ca 5 cm proximal to the popliteal crease with the participants lying prone with the left knee flexed and the lower leg in a vertical position.
The foot was attached to a custom-made contraption which provided a stable position of the lower leg but allowed unconstrained movements in the ankle joint. We recorded force/torque and the 3D position of the ankle joint and surface EMG from the eight accessible lower leg muscles. Muscle length changes for all ankle joint muscles but plantaris were calculated from the joint angles using OpenSim.
The participants controlled the position of a cursor on a video screen by dorsal/plantar flexion and inversion/eversion of the ankle joint. During microneurography they performed a target-chasing task in which they moved the cursor into a displayed target as quickly as possible. As soon as the target had been reached, the trial was over and a new target appeared.
We have recorded from >40 muscle spindle afferents (ca 75% Ia) originating from almost all 12 muscles of interest during >9,400 target-to-target movements. The movement range was about ±20 deg in dorsal/plantar flexion and inversion/eversion corresponding to about ±5 % muscle length changes. The target hit rate varied between 30-60/min and for most afferents >75 movements were recorded.
All afferents responded to passive elongation as has been described repeatedly in the past. During active movements, however, no muscle spindle afferent showed a simple relationship between its discharge and the kinematics of its parent muscle. Nevertheless, during the target-chasing task, the vast majority of spindle afferents encoded muscle stretch velocity whereas only a handful encoded muscle length albeit poorly. In a subset of afferents, recordings during the task were obtained also with loading in the dorsal/plantar direction but it affected discharge rates only marginally. The preliminary analyses indicate that the spindle discharges did not depend on the direction of the ankle joint movement, e.g., with similar muscle stretch during dorsal flexion combined with inversion or eversion, the spindle discharges from the gastrocnemius seemed indistinguishable.
In conclusion, muscle spindle responses during active ankle joint movements cannot be extrapolated from their responses during passive movements.

Title: Using robotics to assess sense of effort in the upper extremity

Authors: L. LOGAN[1], J. SEMRAU[1], S. H. SCOTT[3], *S. P. DUKELOW[2];
[2]Clin. Neurosciences, [1]Univ. of Calgary, Calgary, AB, Canada; [3]Queen's Univ., Kingston, ON, Canada

Abstract: Sense of effort, a component of proprioception, is our perception of the amount of effort required to execute actions (e.g., knowing how hard to squeeze a fruit to determine its ripeness). Given its importance in performing activities of daily living, we developed a robotic task to assess sense of effort. We aimed to investigate sense of effort in the upper limb for 1) different levels of effort and 2) different limb positions in healthy subjects. We hypothesized that subjects would accurately match the effort required to resist a force in one arm with their opposite arm. Further, we hypothesized that they would perform best with their arms in the same position. In the task, a robot applied a submaximal torque (2/3/4Nm) at the elbow. Individuals were asked to match the effort of this torque with the opposite elbow. Their reference arm remained in a constant position (30°/shoulder and 90°/elbow), while their matching arm was tested at a 30° at the shoulder and 75/90/105° at the elbow (0° is full extension). We performed preliminary testing in five healthy individuals in both flexion and extension.
The mean difference between torques in both arms (matched minus reference) across all trials was -0.21±1.03 Nm. The middle torque, 3Nm, was matched most accurately (2.77±0.87Nm). Subjects overestimated loads of lower magnitude (2Nm: 2.33±0.84Nm) and underestimated loads of higher magnitude (4Nm: 3.27±1.10Nm). Subjects also performed better in the more proximal workspace. To quantify this, we computed the ratio of the reference torque matched (matched torque/reference torque). In the 90° position, this ratio was 0.97±0.35 when matching elbow flexors and 0.95±0.29 for extensors. In the 105° position, it was 0.95±0.39 (flexors) and 0.99±0.31 (extensors). Subjects were less accurate in the more distal position (75°). Subjects' matches exceeded the reference torque when matching in flexion (1.15±0.46) and fell below the reference for extension (0.80±0.30).
In conclusion, our preliminary results show that individuals matched elbow torques with reasonable accuracy, but demonstrated variability in performance. Perceived sense of effort was most accurate in positions closer to the body and at the 3Nm torque level. Thus, similar to position sense, sense of effort may be more accurate in the proximal workspace. This work provides a baseline for future studies, and provides an important first step towards the development of a robotic tool to detect deficits in sense of effort in individuals with stroke and brain injury.

Title: Explorative motor learning is decision-making with motor noise

Authors: *X. CHEN, J. GALEA;
Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom

Abstract: The ability of humans to learn a new motor task through behavioural exploration has received considerable recent attention (Dam et al., 2013; Wu et al, 2014). This learning has been characterised as reinforcement learning in which participants use a reward prediction error to learn actions that optimise future reward. One interesting question raised by these studies concerns the contribution of exploration and motor noise to motor learning (Therrien et al., 2015). Our current work shows that explorative motor learning can be conceptualised as a decision making process adapted to motor noise.
We investigated participants' learning performance in a motor reaching task and a decision-making analogue. The tasks were isomorphic with the exception that the motor task was subject to motor noise, whereas the decision making task was not. Specifically, in the motor task, participants had to discover the shapes of 24 hidden trajectories, each of which was characterised by two parameters: direction and curvature. Participants had 25 reaching attempts to find the optimal trajectory, but the only feedback they received was a monetary score that reflected the proximity of their attempt to the target. Importantly, we also took an independent measurement of each participant's motor noise. In the decision-making task, participants had to discover a hidden target cell within a grid that reflected the direction and curvature parameters. Although the feedback function was identical as that used in the motor task, participants did not make a reaching movement but simply selected a cell (thus removing the influence of motor noise).
First, we modelled the decision making task by formulating the learning problem as a Partially Observable Markov Decision Process. The optimal control strategy derived, which governs model behaviour, was a consequence of maximising the cumulative reward. The model was able to explain 91±6% of participants' decision-making behaviour. Next, we applied this model (with the same estimated parameters) to the motor task by adding each participant's motor noise. In other words, we defined the learning observed in the motor task as a decision making process with motor noise. In 80% of the participants (remaining 20% did not perform the motor task correctly) this model was able to explain 79±11% of participant's behaviour during the motor learning task.

This indicates that explorative motor learning could be cast within the same broad theoretical framework used to describe decision-making, such as loss aversion and a propensity to be modulated by levels of dopamine and serotonin in the brain.

Title: Rapid visuomotor corrections in reaching are modulated by gaze position

Authors: *A. J. DE BROUWER, T. JARVIS, J. P. GALLIVAN, J. R. FLANAGAN; Queen's Univ., Kingston, ON, Canada

Abstract: Goal-directed movements are guided by continuous visual feedback about the hands and the target object. This visual feedback supports rapid, automatic corrections to perturbations in hand and/or target position. Here, we examine how the system corrects for lateral visual perturbations in the position of the cursor representing the hand during unimanual and bimanual reaching. Two narrow or two wide targets were always presented and participants were required to fixate one or the other target. We replicated the finding that corrective forces are stronger for narrow than for wide targets, consistent with the framework of optimal feedback control. We found that corrections were stronger during unimanual reaches compared to bimanual reaches. This suggests that there may be limited resources for the processing of visuomotor errors, such that greater resources can be called upon when only one hand is reaching and, as a consequence, the location at which a perturbation could occur is certain. We also found that corrections were stronger when the perturbed hand was directed towards the fixated target compared to the non-fixated target and that the effect of target width on correction strength was stronger when the perturbed hand was directed towards the fixated target. These results suggest that fixating reach targets may confer an advantage in terms of visuomotor error processing.

Title: Objects vs. hand: the effect of knuckle misconceptions on localization task distortions

Authors: *A. SAULTON, H. BÜLTHOFF, S. DE LA ROSA;
Max Planck Inst. For Biol. Cybernetics, Tuebingen, Germany

Abstract: Stored representations of body size and shape as derived from somatosensation are considered to be critical components of perception and action. Recent research has shown the presence of large hand distortions in proprioceptive localization tasks consisting of an overestimation of hand width and an underestimation of finger length. Those results were interpreted as reflecting specific somatosensory perceptual distortion bound to a body model underlying position sense. One important prerequisite to this interpretation is that measured localization task distortions actually stem from body representation. In this study, we re-examine hand distortions underlying positon sense and investigate whether these distortions are body specific or due to non-perceptual factors, e.g. conceptual knowledge. Participants made localization judgments regarding the spatial position of various landmarks on occluded items including their own hand. Our results show that larger hand distortions in localization tasks are likely to be induced by participants' incorrect conceptual knowledge about hand landmarks rather than proprioceptive or somatosensory influences. Moreover, we show that once we account for such incorrect conceptual knowledge, hand distortions in localization tasks are statistically similar to those of other objects. These results suggest that localization task distortions are not specific to the hand and call for caution when interpreting localization task distortions in terms of body specific effects.

Title: Facilitation of short latency responses in human arm muscles by stimuli targeting the reticular formation

Authors: *I. S. GLOVER, S. N. BAKER;
Inst. of Neurosci., Newcastle Upon Tyne, United Kingdom

Abstract: Background: Previous studies have demonstrated that visual stimuli can elicit arm muscle activity at latencies of 75-100ms, with these rapid visual reactions (RVRs) being time-locked to target appearance rather than movement onset (Pruszynski et al., 2010). To investigate the hypothesis that RVRs are mediated by the reticulospinal tract (RST), we combined the RVR-eliciting task with stimuli thought to target the reticular formation: median nerve stimulation, vestibular stimulation and startle. **Methods:** Intramuscular and surface electrode recordings were made from the deltoid and pectoralis major of 16 subjects performing a reaching task in which they were required to make fast movements toward targets appearing within a virtual reality set up. Median nerve stimulation was applied at twice motor threshold at -200, -100, -50, 0, 50 ms relative to target appearance (n=8). In separate experiments, subjects received vestibular stimulation (4mA, 20ms) or startle noises at -150, -100, -75, -50, 0 ms relative to target appearance (n=8). **Results:** Median nerve stimulation, vestibular stimulation and startle all increased the magnitude of RVRs up to 3-fold; this facilitation was significant across all tested stimulus latencies and was observed with both intramuscular and surface recordings. The RVRs showed spatial tuning and were largest in trials with the fastest reaction times. **Discussion:** The short latency of RVRs and their facilitation with stimuli targeting the reticular formation suggest that the RST may contribute to the generation of rapid movements toward visual stimuli.

Title: Absolute haptic cues mediate pantomime-grasping only when egocentric visual cues are delayed

Authors: *S. DAVARPANAH JAZI[1], J. CHAN[1], M. HEATH[1,2];
[1]Kinesiology, [2]Grad. Program in Neurosci., Univ. of Western Ontario, London, ON, Canada

Abstract: Pantomime-grasping entails a movement with dissociated stimulus-response relations and/or responses towards physically removed target objects. Unlike *naturalistic* grasps that are mediated via a target's absolute visual properties and specified in egocentric reference frames, relative and allocentric visual cues support pantomime-grasping. Notably, however, our group recently demonstrated that providing haptic feedback (i.e., of a physically removed target) following a pantomime-grasp supports an absolute visuo-haptic calibration. In the current study we examined specific sensory and spatial requirements necessary to support a visuo-haptic calibration during pantomime-grasping. To that end, in a series of experiments participants pantomime-grasped differently-sized target objects while receiving haptic feedback (i.e., through physical touch) following response completion. Notably, the target's spatial location as well as online limb and target vision were manipulated. Results showed that an absolute visuo-haptic calibration process is limited to situations wherein a spatially-overlapping pantomime-grasp is performed following a visually-based memory delay. In accounting for our results we have drawn upon the maximum likelihood estimator model's (MLE) tenet that multisensory cues integrate in an optimal fashion with processing weighted towards the more reliable sense. As such, we propose that the decay of visual cues renders an increased weighting and salience of haptic signals and thus, supports an absolute visuo-haptic calibration.

Title: Motor adaptation to experimentally extended bills in pigeons.

Authors: *H. MATSUI[1], E.-I. IZAWA[2];
[1]Grad. Sch. of Human Relations, Keio Univ., Shinagawa-ku, Japan; [2]Psychology, Keio Univ., Minato-ku, Tokyo, Japan

Abstract: Feeding behavior in primates consists of two motor components such as arm-reaching to a target food and hand-grasping it, which are visually controlled. Analogously, pecking in birds is composed of neck-reaching and bill-grasping. However, pigeons are known to close their eyes during pecking, suggesting no visual control. Previous studies revealed that pigeons show a brief pause at a close distance to a target, called as fixation, before initiating pecking, suggesting a feedforward control: during fixation, the timing of bill-grasping is predicted based on the perceived distance to the target to generate an appropriate motor command and the command is executed without visual control during pecking. However, it remains unknown what learning mechanisms operate to integrate between the visually perceived distance and the motor control of the timing of bill-grasping. In this study, we hypothesized that the learning is driven by the error between the predicted timing of grasping and the actual timing of physical contact with the target as a somatosensory feedback signal in pecking of pigeons. We examined whether pigeons could adapt their pecking behavior to experimentally extended pseudo-bills. The extended pseudo-bill required pigeons to adjust the timing of bill-grasping since the distance to contact with the target is shorten for the extended bill length. In this study, pigeons' pecking foods (i.e., hempseeds) on a platform was high-speed video-recorded and compared kinematic profiles between before and after pseudo-bill attachment and also after its removal. If pigeons can adapt pecking to the extended bills, the motor adjustment to the bill extension is expected to remain even after its removal. After introducing 10 sessions of 2-43 feeding trials with bill extension, we found that the timing of bill-grasping was temporally advanced in all the 3 pigeons. As expected, the advanced timing of bill-grasping remained even after the bill-extension removal. This bill-grasping adjustment did not occur on the first day of the pseudo-bill attachment, suggesting the lack of visual contribution to the pecking adaptation. These results suggest that pecking in pigeons is controlled by a feedforward system involving an error-based learning mechanism with a somatososory feedback signal.

Title: “Change of mind” (COM) of reach direction from one target to another during reach is more frequent and corrects for more initial target choice errors in speed than precision regimes.

Authors: *S. DUROCHER, J. BEAULAC, L. AIT-ALI, J. F. KALASKA;
Neurosciences, Univ. De Montreal, Montreal, QC, Canada

Abstract: Ten subjects did a "Choose-and-Go" (CG) task in which they decided if a checkerboard-like Decision Cue (DC) had more Blue or Yellow squares and then reached to the one of two targets whose color (B,Y) matched the DC’s dominant color. In each trial, they viewed 1 of 120 DCs with a wide range of total and relative numbers of B&Y squares, from 30/0-100/0 B or Y (strong color bias, evidence for only one target) to 30/30-100/100 B & Y squares (i.e., zero color bias, equal evidence for both targets). Subjects were told to be either precise about their target choices at the cost of longer response times (RTs; Precision regime, P), or fast at the cost of more choice errors (Speed regime, S) in 260-trial blocks on different days. Each subject performed 6000-7000 trials of the CG task in each of the P and S regimes over several daily sessions. In the P regime (Durocher & Kalaska SfN 2015) RTs became progressively longer and error choices increased as DC color bias decreased. Subjects’ RTs were mainly determined by the difference in the number of Y&B squares in the DCs rather than the total numbers of Y&B squares supporting each target. We report here that subjects’ RTs were systematically shorter for all DCs in the S regime, especially for DCs with low color biases (mean RTs for all DCs: P 910±30ms; S 509±23ms). However, overall target-choice success rates decreased only modestly from P to S regimes (mean: P 79.5±1.8%; S 77.3±0.7%). In most trials, subjects began to reach to the correct target, more often overall in the P regime (mean: P 5053±215; S 4843±248), and less often as DC color bias decreased in both regimes. Also, subjects usually reached directly to one target, more often in the P regime (mean: P 95.9±2.3%; S 87.1±5.3%), with similar success rates across regimes (mean: P 80.1±2.1%; S 78.3±1.4%). In other trials, subjects started toward one target but then reversed direction to the other (“change of mind”; COM). COMs were more frequent in the S regime (mean: P 4.1±2.3%; S 12.9±5.2%). COM frequency increased as DC color bias decreased in both regimes, and occurred for all color biases in the S regime but mainly at low biases in the P regime. COMs corrected wrong initial target choices with similar overall frequency in both regimes (mean: P 65.9±6.8%; S

70.7±7.1%), and showed nearly identical increases in the rate of correction for wrong initial choices as DC color bias increased. These findings show that success rates of COM trials are similar in P and S regimes and lower than in non-COM trials. Initial target choices are less accurate in the S regime of the CG task, but COMs correct more reaches with wrong initial choices in the S than the P regime, resulting in nearly similar overall task success rates.

Title: Interaction torque control deficits in patients with stroke

Authors: ***A. SETHI**[1], S. RAJ[2], N. DOUNSKAIA[3];
[1]Occup. Therapy, Univ. of Pittsburgh, Pittsburgh, PA; [2]Bioengineering, Univ. of PIttsburgh, Pittsburgh, PA; [3]Arizona State Univ., Phenix, AZ

Abstract: Introduction: Among the 795,000 individuals who sustain a stroke annually in the United States, 85% exhibit impairments in function of one (or affected) upper extremity (UE), which limits their ability to perform daily tasks such as eating. Current treatments have limited effectiveness, possibly because these treatments may not improve control and coordination of joint motions required to produce efficient UE movements. Movements of healthy adults are characterized by effective incorporation in joint control of interaction torque (IT) caused by mechanical interactions among limb segments during their motion. Research suggests that the skillful use of IT for movement production relies on sophisticated feedforward and feedback mechanisms implemented through activity of multiple brain areas. It is therefore can be hypothesized that stroke disrupts the ability to exploit IT for movement production, thus causing dyscoordinated UE movements. Here, we tested this hypothesis with the use of a kinetic analysis applied to shoulder, elbow, and wrist motions during reaching for a can of soda.
Methods: Five individuals with mild impairments after stroke and six age-matched healthy controls participated in the study. The task was to reach and grasp a soda can. Controls reached with their dominant arm, while patients used their affected arm. At the beginning of each trial, the arm rested on the knee in the neutral position. The can was placed on a table in front of the subject in the parasagittal plane of the shoulder of the used arm. The can position ensured motion

of the entire arm in the parasagittal plane. Arm movements were recorded with a VICON motion capture system. Net torque (NT), muscle torque (MT), GT, and IT were calculated at the shoulder, elbow, and wrist. At each joint, NT=IT+GT+MT. We computed the percentage contribution of IT to NT for each joint in both the acceleration (acc) and deceleration (dec) phases of the hand motion.
Results: In both the acceleration and deceleration phases, the percentage contributions at the shoulder {[Acc ($U = 2$; $p = .01$); Dec ($U = 0 = 2$; $p = .004$) and elbow [Acc ($U = 0$, $p = .004$); Dec ($U = 0$, $p = .004$)]} were significantly higher in healthy controls than patients with stroke. However, the percentage contribution was not significantly different at the wrist between both groups ($U = 14$, $p = .93$).
Conclusion: Though stroke patients were able to complete the task, a lower IT contribution suggests inefficient movement control at the shoulder and elbow joints as compared to healthy controls. This finding supports the hypothesis that stroke disrupts the ability to effectively use IT for joint rotations during UE movements.

Title: Predictability and effort in complex object control

Authors: ***P. MAURICE**[1], F. YE[2], C. J. HASSON[3], D. STERNAD[4];
[1]Biol., [2]Electrical and Computer Engin., [3]Physical Therapy, [4]Biology, Electrical and Computer Engineering, Physics, Northeastern Univ., Boston, MA

Abstract: Manipulation of complex objects or tool use is ubiquitous in everyday life and has given humans an evolutionary advantage. Yet, there has been little research on interaction with dynamic objects, and control principles for such actions remain elusive. To gain insight into the

control of complex motor skills, such as carrying a cup of coffee, the present study examines the strategies that humans choose when manipulating an object with nonlinear internal dynamics. The under-actuated system renders the temporal evolution complex and even chaotic, hence unpredictable. Humans then have to continuously correct and adapt their behavior, which is physically and cognitively tiring. Extending previous research, we hypothesize that humans develop strategies that make the hand-object interactions predictable to avoid excessive sensorimotor processing, even if such strategies require higher interaction forces. To test this hypothesis, a simplified version of moving a cup of coffee back and forth between two targets was implemented in a virtual environment, using a cart-and-pendulum model to mimic coffee sloshing in a cup. Analysis of the mathematical model reveals that the amplitude, frequency and relative cart/pendulum phase strongly influence the force profile and the predictability of the hand-object interaction required to perform the motion. Importantly, optimal predictability did not coincide with low force profiles. Two experiments were conducted in which subjects rhythmically manipulated a robotic manipulandum to displace the virtual cup (cart) containing a rolling ball (pendulum). In Experiment 1, subjects (n=8) were paced at the pendulum resonance frequency, but were free to choose the amplitude of the motion. In Experiment 2, subjects (n=9) were free to choose the frequency of the oscillations, whereas the amplitude was imposed. Results of Experiment 1 showed that oscillation amplitude increased with practice, leading to more predictable object dynamics, while there was no significant change in effort. In Experiment 2, two different strategies appeared, respectively with high and low frequency oscillations, likely the resonance modes of the coupled hand-cup system. Both strategies corresponded to a highly predictable behavior, and again, not to low force profiles. These results show that in complex object manipulation, humans do not prioritize mechanical efficiency, but rather seek strategies where interactions are predictable. This conclusion contradicts common expectations from studies on unrestrained movements and manipulation of simple rigid objects, and highlight that different principles rule the manipulation of complex objects.

Title: The role of the vestibular system in eye-hand coordination

Authors: *L. OOSTWOUD WIJDENES[1], J. MASSELINK[2,1], W. P. MEDENDORP[1];
[1]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ. Nijmegen, Nijmegen, Netherlands; [2]Inst. of Psychology, Univ. of Muenster, Münster, Germany

Abstract: The world offers many potential targets to direct our eye- or hand movements towards. If the body and the world are stationary, which of these potential targets is selected depends on the expected reward associated with the targets and on the cost of moving to the targets. Experiments that disentangled the response preference for eye and hand movement showed that when the eye and hand move to the same target in a coordinated fashion, target selection resembles the preference of hand-only target selection (Horstmann and Hoffmann, 2005). Thus in stationary environments, hand target selection guides the eye movement.
In every day life we often select targets while our body is moving. Body motion is registered by our visual, proprioceptive and vestibular sensors. Recent results from our lab show that vestibular information about body acceleration affects target selection for eye and hand movements. For eye movements, we found a preference for targets that are in the direction of body acceleration. However, for hand movements, data suggests that at the moment of reach execution there is a preference for targets that are in the direction opposite to body acceleration. Thus it seems that the vestibular effect on eye movements is diametrically opposite to the effect on hand movements. Here we ask how combined eye- and hand movements are coordinated under passive full-body translation.
Participants are seated in a vestibular sled that moves them in a sinusoidal fashion along the inter-aural axis. After central fixation of the eye and hand, they are presented with two targets, 10 degrees of visual angle to the left and right of central fixation. The targets are presented at different phases of the sled motion. By dynamically updating the difference in onset time between the two targets, we measure response preference for the eye only, hand only, and a combined condition with eye and hand movements.
Experiments are currently underway and the results analysed according to following hypotheses. If response preferences in the combined effectors condition resemble the preferences in the eye only condition, this suggests that the eye is leading the hand. Vice versa, if response preferences resemble the hand only condition, as is observed in the stationary situation, this suggests that the hand is leading the eye. A third possibility is that at the critical peak acceleration phases, opposing targets are selected for eye and hand movements. This would suggest that the vestibular effect on target selection is response effector specific, even when the two effectors move at the same time. Possibly, cost and reward are optimized for eye and hand separately.

Title: Speed and accuracy in reaching during full-body reaching tasks

Authors: *S. T. LEITKAM, M. E. APPLEGATE, A. HOYNACKE, J. S. THOMAS;
Ohio Univ., Athens, OH

Abstract: Fitts' Law states for a reaching target, the maximum speed and accuracy at which the target can be reached is governed by the size and distance of the target from the end-effector. Few have investigated if these relationships hold true in full-body reaches requiring movement of the trunk and head. Accordingly, 20 healthy participants performed full body reaches to virtual cylindrical targets at four target locations that necessitated lumbar excursions of 0°, 15°, 30°, 60°, with three indices of difficulty (ID=3, 5, 7). For each target location, the size of the cylinder was adjusted to maintain ID according to Fitts' Law. The targets appeared in random order oriented to face the participants who were instructed to reach the targets as quickly and accurately as possible. Participants reached to each target location and ID combination five times.

Movement accuracy was analyzed by comparing the position of the end-effector at the time of the first peak anterior excursion with the position of the center of the target. The distance between the two points was separated into three measures with respect to the target: overshoot error (through the plane of the target), vertical/anterior error ("up" axis in the target plane), and lateral error (horizontal axis). Movement time (MT) was the time between first movement of the hand and first peak excursion after the target appeared. The error measures and MT were analyzed using a mixed-model MANOVA with ID and target location as within subject factors and sex as the between subjects factor.

There was no main of effect of ID on any of the error measures. There were main effects of target location on overshoot error ($p<0.05$) and vertical/anterior error ($p<0.05$). Overshoot error decreased as target height decreased, indicating less movement past the target for trials that required large lumbar excursions. Vertical/anterior error increased in the direction of the participant as target height decreased, indicating that for trials that required large lumbar excursions, participants did not reach out as far for the target. Main effects for MT were found for both ID ($p<0.05$) and target location ($p<0.05$). The movement times were greater for larger ID and for lower targets.

While MT increased as ID increased (consistent with Fitts' Law), MT increased and accuracy decreased as a function of target location when controlling for ID (inconsistent with Fitts' Law). This indicates there are neural or motor control factors influencing full-body reaching tasks that

are not present in other systems that are well-defined by Fitts' Law. Maintaining balance or changing visual frame of reference may override the classic speed-accuracy tradeoff.

Title: Challenging rat motor skills: development of a two-choice forelimb task

Authors: *A. C. MOSBERGER[1], O. LAMBERCY[2], N. HEIRI[1], N. BJELOPOLJAK[1], R. GASSERT[2], M. E. SCHWAB[1];
[1]Brain Res. Institute, Univ. of Zurich, D-HEST ETH Zurich, Zurich, Switzerland; [2]Dept. of Hlth. Sci. and Technol., Rehabil. Engin. Laboratory, ETH Zurich, Zurich, Switzerland

Abstract: Many rodent studies of action selection use two-choice tasks requiring the animal to perform a specific motor response in one of two different locations within a behavioral setup (e.g., left vs. right nose-poke, left vs. right lever press, left vs. right runway). In these tasks, the kinematics of the movements themselves are similar or identical for both responses, and the choice is about WHERE to respond. Here, we aim to investigate the choice of HOW to respond in a given context. More precisely, we study the selection of different skilled actions directed toward the same object. Our paradigm models the interaction with specific objects using upper limb movements in rodents. To achieve this, we have developed a novel task requiring the selection of one of two skilled forelimb movements using a three-degree-of-freedom robotic manipulandum (Vigaru et al. 2013, Lambercy et al. 2015). We train the rats to perform different skilled forelimb motor tasks while recording the precise position of the manipulandum during the forelimb interaction. Animals learn to perform two skilled forelimb movements, i.e. rotation and pulling of the manipulandum, associated with different auditory, visual, and object-based cues;

and go through different stages of training to achieve high success rates in both tasks. Subsequently, animals are asked to respond to the specific cues with either rotation or pulling movements in sessions where both trials are presented in an intermixed design. The detailed kinematic recordings of the interaction with the manipulandum allow us to detect and separate wrongly executed but correctly intended movements vs. wrongly intended but correctly executed movements. This analysis gives a new and unique perspective on rodent skilled action selection. We are currently investigating the impact of different cue modalities on the animals' choice behavior. Furthermore, we are performing extracellular electrophysiological recordings in the dorsolateral striatum to identify neuronal signatures of choice and movement execution.

Title: Spatially selective graded modulation of neural motor planning activity suggests biased competition between task rules in action selection

Authors: *L. SURIYA-ARUNROJ[1], A. GAIL[1,2,3];
[1]German Primate Ctr., Göttingen, Germany; [2]Bernstein Ctr. for Computat. Neurosci., Göttingen, Germany; [3]Georg August Univ., Göttingen, Germany

Abstract: Prior to choice, neurons in dorsal premotor cortex (PMd) and parietal reach region (PRR) can simultaneously encode two alternative spatial locations when monkeys have equal

preference for reaching towards them. Such dual spatial encoding occurs even when competing spatial transformation rules determine the two potential reach goals relative to the position of single spatially incongruent visual cue, suggesting co-encoding of competing potential motor goals. Here, we test if and how PMd and PRR neurons encode two potential reach goals when monkeys showed graded preferences for the two motor goals. Particularly, we ask if the spatial profile of neural modulation is compatible with known models of biased competition.
Two rhesus monkeys had to determine the correct reach goal from two instructive cues. A pre-cue consisted of two differently colored triangles which appeared at one of the four cardinal directions from the center (e.g. top) and which pointed to two opposite directions (clockwise and counterclockwise). The pre-cue indicated the two possible goals at 90 deg CW/CCW from the pre-cue. Triangle sizes could differ and represented rule validity. A delayed rule cue indicated the valid rule if its color matched one of the pre-cue triangles, or, indicated that both options were rewarded with equal probability (free-choice) if it was white.
Results show that graded planability of movements due to the pre-cue induced a graded bias in subsequent free-choice behavior, despite balanced expected values at the time of commitment. The spatial selectivity of PMd and PRR neurons during motor planning was modulated according to the subsequent choice bias, showing bimodal neural spatial selectivity in unbiased trials, increasing neural responses with increasing preference of the animal for the preferred direction of the neuron, decreasing responses for the opposite-to-preferred direction and no bias-dependency for neurons with preferred direction orthogonal to the potential reach directions. Existing biased-competition models with center-surround inhibition at the level of spatial encoding seem not sufficient to explain the observed spatial pattern of bias-induced response modulations. Thus, based on our previous dynamic neural field model (Klaes et al. 2012), we propose that biased competition in rule-guided action selection is implemented via a strong competition between pools of neurons which encode the conjunction of a spatial cue and a learned transformation rule, as they exist in visuomotor association areas. Particularly, we postulate the competition between neurons which share the same spatial preference but which have different rule preference.

Title: Interception of virtual dynamic objects in atypical gravitational accelerations

Authors: *B. J. CHANG, K. M. STUBBS, D. J. QUINLAN, J. C. CULHAM;
Brain and Mind Inst., Western Univ., London, ON, Canada

Abstract: In many sports, we often intercept dynamic objects with various aerodynamic properties and acceleration vectors. Due to non-gravitational forces such as Magnus forces and air resistance in sports like baseball and ultimate frisbee, these objects often have a downward acceleration vector that differs from Earth's native acceleration ($g = 9.81 m/s^2$). How we compensate for these accelerations and intercept these objects remains unknown. That said, we know that expert groups such as jugglers can attend to and intercept multiple objects at different accelerations. In this study, we examine how untrained individuals intercept dynamic virtual objects at different accelerations. We used a back-projected setup allowing participants to directly interact with a large screen. Optotrak (NDI, Waterloo, Canada) infrared emitting diodes (IREDs) were used to calibrate the projected image to real space as well as to track the hand movements. We tested 3 accelerations at a regular and inverted set up in six conditions (-1.5, -1.0, -0.5, 0.5, 1, and 1.5 g). In each condition, participants observed a virtual circle follow a parabolic trajectory velocity at different accelerations. Participants were instructed to intercept the object with their index finger within an allotted space. Preliminary results showed that across all accelerations, inverted (negative) accelerations elicited both slower reaction times as well as an initiation of movement later in the objects trajectory compared to non-inverted (positive) acceleration conditions. These results suggest that additional cognitive processing is required for accelerations which are not often observed in our natural environment. Furthermore, higher gravitational accelerations generally elicited quicker reaction times in both the inverted and non-inverted conditions. In the inverted condition, participants initiated their movement later in the trajectory with greater acceleration. However, this trend was not observed in the non-inverted condition. We are currently expanding this research to include jugglers as an expert group.

Title: Strength vs precision: What does the mouse automated reach task assess?

Authors: *A. BECKER[1], D. BETZ[2], M. P. GOLDBERG[1];
[1]Neurol. and Neurotherapeutics, UT Southwestern Med. Ctr., Dallas, TX; [2]Univ. of Texas at Dallas, Dallas, TX

Abstract: Rodent models of stroke recovery have often failed to translate into useful treatment. Research translation might be improved by developing behavioral tests in rodents that address functionally similar impairments to those of humans. We recently developed a behavioral assessment of functional stroke recovery in mice called the automated reach task. This task requires the use of distal forelimb musculature, the precision of which often suffers in the context of human ischemic stroke. We have previously demonstrated that focal photothrombotic cortical stroke of the forelimb motor area of mice produces a deficit in performance of this task that can be automatically quantified and lasts much longer than in many typical mouse behavioral assays, mirroring the chronic human condition. We asked a further question: is the deficit caused by a loss of precision in distal muscle control, as is the case in the human condition, or to loss of strength alone? To answer this question, we modified the task by lowering strength requirements while leaving precision requirements high and analyzed post-stroke performance of mice in the modified task. We find evidence that reach task performance is sensitive to loss of precision.

Title: Recalibration, heuristics, and learning de novo: On the multiple processes of sensorimotor learning and the role of the medial temporal lobe

Authors: *S. D. MCDOUGLE, N. B. TURK-BROWNE, J. A. TAYLOR;
Princeton Univ., Princeton, NJ

Abstract: It has been over 50 years since seminal work with patient HM (Milner, 1962) led to the codification of explicit and implicit memory systems. Although this work and many other studies have revealed surprising learning of novel sensorimotor tasks (e.g., mirror drawing, rotary pursuit) after medial temporal lobe damage, a detailed examination of how such patients learn — and also why they can display subtle impairments — has been lacking. Recent work has revealed that multiple learning processes contribute to sensorimotor adaptation, including cerebellar-based recalibration (Shadmehr et al., 2010), use-dependent plasticity (Diedrichsen et al., 2010; Verstynen & Sabes, 2011), cognitive strategies/heuristics (Taylor et al., 2014), and the apparent *de novo* learning of entirely new control policies (Telgen et al., 2014). Two seemingly similar sensorimotor tasks — visuomotor rotations and mirror reversals — involve surprisingly different mixtures of these learning processes. Rotation tasks rely on both slow, cerebellar-dependent recalibration (Tseng et al., 2007) and a fast, explicit process that provides rapid, flexible "good enough" solutions to the task, such as "re-aiming" (McDougle et al., 2015). In contrast, mirror reversal is thought to induce the creation of an entirely new control policy from scratch, since recalibration would only amplify the error (Telgen et al., 2014). Here, in healthy controls, we confirm this dissociation, showing that performance in rotation tasks is aided by iterative error-based recalibration, whereas mirror reversal must rely on learning a novel control policy. Importantly, both tasks engage explicit learning, but the latter requires outside coaching for subjects to utilize the appropriate strategy. Furthermore, we replicate the findings from HM in a patient with complete bilateral hippocampal loss, LSJ. Her learning in mirror reversal tasks is comparable to naive age-matched controls, suggesting a preserved ability to learn a new control policy over the course of several days. Controls who are instructed about the nature of the mirror reversal show rapid explicit learning, whereas LSJ is unaided by such instruction. Consistent with this failure of explicit learning, her performance in rotation tasks is slower than controls, reflecting the operation of only an iterative calibration process. These findings confirm the presence of multiple learning processes in sensorimotor tasks and illustrate a more nuanced, process-oriented role for the medial temporal lobe in motor learning.

Title: Exploring structure-specific knowledge in a visuomotor adaptation task

Authors: *K. BOND, J. A. TAYLOR;
Princeton Univ., Princeton, NJ

Abstract: Structural learning is a meta-learning phenomenon evidenced by an accelerated learning rate for novel tasks sharing the same structure as the training task. Exposure to pseudorandomly varying visuomotor perturbations of a fixed structure facilitates the rate at which novel, yet isostructural, perturbations are learned (Braun et al., 2009). Previous investigations suggest that this effect is driven by the implicit extraction of invariant task features, thereby reducing the dimensionality of the hypothesis space (Genewein et al., 2015). However, we have shown that participants can actively counter rotations with explicit strategies, demonstrating explicit structural knowledge of the perturbation (Bond and Taylor 2015). We sought to determine whether participants truly extract task structure (i.e., rotational structure) or use simple heuristics to solve perturbations.

We exposed separate groups of participants to pseudorandom perturbations drawn from either a rotational structure or a complex structure (consisting of a combined rotation, scaling, and shear perturbation) prior to exposing them to a 'consistent' rotation at the end of training (test phase). To probe explicit knowledge of the task conditions, participants were instructed to report their intended aiming direction via a touchscreen monitor prior to reaching.

In contrast to previous results, we found that the rotation and random groups countered the consistent rotation in the test phase equally well ($p = 0.2$). Furthermore, for the rotation group, performance was not attributable to an implicit internal model ($p = 0.07$), but rather explicit aiming strategy ($p < .001$). We examined reported aiming locations in the exposure phase and found that participants in the rotational structure group aimed in what appeared to be a rotation-appropriate way. Indeed, aiming error slowly improved over time. The random structure group failed to show these benefits, suggesting that a relatively simple structure is needed for effective aiming strategies to develop. Despite these differences, aiming strategies in both groups shared some structural similarities. This may reflect either a general heuristic or a higher-order task structure, such as the distribution of training targets.

Given these results, it's likely that there are multiple sources of meta-learning in a visuomotor adaptation task. We suggest that one of these sources may be able to extract structural information from exposure to a variable perturbation sequence and refine aiming strategy, and that another may be more consistent with a generalized aiming heuristic.

Title: Assessing explicit strategies (or knowledge?) in force field adaptation experiments

Authors: *J. A. TAYLOR, S. D. MCDOUGLE;
Psychology, Princeton Univ., Princeton, NJ

Abstract: It has been assumed that learning in sensorimotor adaptation tasks is largely implicit, involving the recalibration of an internal model. However, a growing body of research has shown that explicit aiming strategies contribute substantially to learning, at least in the subdomain of visuomotor rotation tasks (for review, see McDougle et al., 2016). Furthermore, the time course of explicit and implicit learning resemble, respectively, the oft-cited "fast" and "slow" processes first outlined in force field adaptation tasks (Smith et al., 2006; McDougle et al., 2015). While there are clues that explicit learning plays a role in force field adaptation, demonstrating this has proven difficult because the metric usually used as a proxy for strategy use (e.g., aiming direction) is not in the same dimension as the actual learning metric (e.g., lateral force; McDougle et al., 2015). Here, we rectified this mismatch by introducing a technique designed to quantify explicit strategies in force field adaptation tasks. Participants learned to first counter viscous force fields with their right hand in a perturbation rebound paradigm, which introduces a force field in one direction for a long period before reversing direction for a shorter period. During a subset of learning trials, participants performed movements with their left hand in an "error-clamp," which constrains lateral movements of the limb. To assay explicit knowledge of the force field, one group of participants were instructed to use their left hand to mimic what they were doing to counter the forces with their right hand (Instruction group). A control group (No-Instruction) also moved their left hand in the error clamp, but were not instructed about what they should do beyond simply moving to the target. Critically, for the Instruction group we found that various metrics (e.g., max force, adaptation index, etc.) of the left hand closely matched those of the right hand. In the No-Instruction group this was not the case, suggesting that our results were not due to implicit transfer. Consistent with our predictions, the time course of the left hand forces resembled the time course of the fast/explicit process, rapidly ramping up to counter the initial force field, then quickly countering the opposing force field, and, finally, showing a complete lack of implicit rebound in a subsequent error clamp block. These data suggest that even in complex sensorimotor adaptation tasks, explicit strategies may play a surprisingly central role.

Title: Measuring implicit adaptation to task-irrelevant clamped visual feedback

Authors: ***J. R. MOREHEAD**, M. A. SMITH;
Sch. of Engin. and Applied Sci., Harvard Univ., Cambridge, MA

Abstract: Humans display a remarkable capacity for acquiring and modifying motor skills. When there are changes in the environment that alter the movement outcome relative to the command, a type of motor learning termed sensorimotor adaptation occurs. This adaptation retunes the mapping between desired movements and motor commands so that a given command will again achieve its desired outcome.

This is thought to be driven by an error between the predicted sensory feedback and the actual feedback. However, this learning is typically studied in the context of a behavioral task where the perturbation affects both errors between predicted sensory feedback and the actual feedback and errors in task performance. This makes it difficult to differentiate between adaptive responses to these two types of errors.

Here we set out to study visuomotor adaptation in the absence of task performance errors by exposing participants to a visual motion stimulus that matched the radial extent of their hand but was otherwise clamped to a fixed heading angle and offset from the target. We made this feedback task-irrelevant by informing participants of how the motion was manipulated and asking them to ignore it while moving their unseen hand to the target on each trial.

Previous work with this manipulation (Morehead et al., 2014) showed saturation of the initial rate of adaptation for clamp offsets greater than 7.5°, resulting in invariance of aftereffect size at 12°. The present experiments addressed two key limitations of the previous data set: we had a smaller visual feedback delay (25ms vs. 90ms), and many more trials (240 cycles of 8 targets vs 30 cycles) to ensure adaptation indeed reached asymptote. First, we found similar adaptation between clamp offsets of 7.5° or 30°, consistent with previous work. However, the low-latency setup resulted in an initial adaptation function that was 40% greater than the high latency data, and continued to climb over 70 cycles to an asymptote 100% higher than previously observed (25°).

We performed an additional experiment to explore whether further learning is possible after the initial asymptote. After an exposure block of 190 target cycles with 7.5° clamped feedback, we either expanded the clamp size to 22.5° or reversed it to -7.5° for an additional 240 cycles. The expanded clamp group showed no change in performance, while the reversal group showed a ~40° change in the direction of reaches relative to the target. These results rule out several reasons for learning to asymptote, such as a habituation to the clamped feedback. We plan to further study other potential mechanisms, such as an angular limit for implicit adaptation or equilibrium between learning and forgetting.

Title: Motor memories are confined to distinct channels with differing stability across time and experience

Authors: *A. E. BRENNAN, M. A. SMITH;
Harvard Univ., Cambridge, MA

Abstract: The fundamental goal of motor practice is generally to form long term stable memories. Indeed, when we practice a sport or a musical instrument, we train not to perform better during the practice session itself, but to improve the practiced skill set for the future. However, the link between short term learning that happens during a practice session and long term retention of that learning is not well understood.
Here, we study that link by dissecting adaptation from training into three distinct components, then examining their retention over 24h. First, we estimate temporally labile (TL) learning as the adaptation that decays during a 60s time delay; the remaining adaptation is temporally stable (TS). Sing et al (ACMC 2009) found that TL and TS adaptation correspond to the fast and slow learning processes, respectively, as identified by Smith et al (2006). Second, we dissect TS adaptation into a decay susceptible (DS) component that decays with the experience of consecutive error clamp (EC) trials that eliminate lateral errors, and a decay resistant (DR) component that does not.
We trained participants for 200 force field trials, isolated DR adaptation by erasing both TL

(using 60s) and DS adaptation (using 500 EC trials), then examined retention after 24h. We expected this measurement to reveal DR retention in the absence of the other two components, but a multiple linear regression of individual differences in 24h retention onto TL, DS, and DR adaptation revealed contributions from both DS and DR adaptation. DS adaptation was 17% recovered after 24h despite being erased after training; DR adaptation was 73% retained.
We next examined whether 24h retention is susceptible to decay with EC exposure. In particular, consolidation could cause the recovered DS adaptation to become resistant to decay; conversely, DR adaptation might become susceptible to decay after retrieval via a process called reconsolidation (Walker et al, 2003). We found that the 24h memory was indeed susceptible to decay. Moreover we found an intriguing double dissociation whereby day 2 decay was specifically predicted by day 1 DS adaptation, whereas the day 2 memory that survived decay was specifically predicted by day 1 DR adaptation. That is, DS adaptation remained susceptible to decay on day 2 while DR adaptation remained resistant to decay.
Thus we find distinct channels of motor memory formation that vary in stability across time and experience, with little evidence of memories changing channels - that memories in a fragile channel can move to a more stable channel in line with a consolidation process or that memories in a stable channel can move to a more fragile channel in line with a reconsolidation process.

Title: Implicit learning compensates for low-fidelity explicit strategy

Authors: *Y. R. MIYAMOTO[1], S. WANG[2], M. SMITH[1];
[1]Harvard Univ., Cambridge, MA; [2]Harbin Inst. of Technol., Harbin, Heilongjiang Province, China

Abstract: Recent studies investigating the contribution of an explicit strategy alongside implicit learning during visuomotor adaptation (e.g. Mazzoni & Krakauer 2006, Taylor et al 2014) have found that implicit adaptation and explicit strategy both contribute to improved task performance, and it has generally been assumed that implicit and explicit responses are both beneficial. Here we investigate the fidelity of implicit and explicit responses by training

participants on an aim-report visuomotor rotation task that tracks explicit strategy and implicit learning throughout the course of training. We coupled this task with a novel sum-of-sines perturbation sequence that continually varies the amount of visuomotor rotation from trial-to-trial, allowing us to parse implicit and explicit responses into discrete frequency-based components that are appropriate vs inappropriate for the task. We found that implicit adaptation and strategy both show large task-appropriate and task-inappropriate components. Task-appropriate strategy and implicit responses followed each other closely, with a strong positive correlation for both subject-averaged and individual data (r_{avg} = +0.86; r_{indv} = +0.47, $p < 0.001$). In contrast, task-inappropriate strategy and implicit responses mirrored one another, thus largely cancelling each other (r_{avg} = -0.71; r_{indv} = -0.36, $p < 0.001$). Consequently, the combined learning response displays only a small inappropriate component (with a variance less than 10-fold smaller than for inappropriate strategy or implicit responses). This suggests that either (a) implicit responses actively compensate for inappropriate strategy, or (b) strategy actively compensates for inappropriate implicit responses. If one response actively compensated for the other from one trial to the next, the compensatory response would systematically lag the compensated one. We thus performed a Granger causality based lag analysis that revealed that implicit responses inappropriate to the task systematically lag behind the corresponding strategy responses ($p<0.01$), indicating that implicit adaptation systematically compensates for inappropriate strategic performance, rather than the reverse. Furthermore, individuals with higher levels of strategy exhibited systematically higher levels of performance error ($r = 0.42$, $p = 0.02$), suggesting that increased reliance on strategy learning reduces the effectiveness of the overall adaptive response. These results reveal the higher fidelity of implicit learning mechanisms and suggest benefits for training procedures that rely on implicit mechanisms over explicit cognitive strategies.

Title: Intentional and automatic motor rhythm control in human and monkey

Authors: *S. MIYACHI;
Primate Res. Institute, Kyoto Univ., Inuyama, Japan

Abstract: Rhythm is a fundamental factor of the voluntary movement. We can synchronize movements with external rhythms. On the other hand, we often find ourselves moving to some rhythm without intention. To elucidate the characteristics of the intentional and automatic control of motor rhythm, effects of isochronous cue rhythm on the reaction time (RT) in the repetitive button press tasks were examined in the human and monkey. In the first experiment, 18 human subjects were tested in two tasks. In both tasks, subjects responded to the repeatedly presented audio-visual cues by pressing a button. In the "rhythmic" task, the cue was presented 5 times/trial with a constant interonset interval (IOI, 900 ms). The subjects well synchronized the button presses with the cue onsets; RT was < 150 ms for 93% of the 2nd-5th presses. In the "random" task, the cue was presented 11 times/trial. Three IOIs (900/600/1200, 900/600/1500, or 900/1200/1500 ms) were pseudo-randomly mixed in each block of trials. The subjects were encouraged to respond as quick as possible. In some trials, the cue was presented rhythmically with 900-ms IOI for 3-5 times (2-4 IOIs). Such unexpected cue rhythm shortened the RT: 196, 188, 188, and 185 ms after the 1st-4th consecutive 900-ms IOIs (median, $p < 0.01$, Friedman test). Moreover, if a longer IOI (1200 or 1500 ms) was preceded by the repetition of 900-ms IOI, the response was delayed ($p < 0.05$). The delay would reflect the suppression of the unwanted rhythmic movement. The response after 600-ms IOI was not delayed by the preceding repetition of 900-ms IOI; attention to the cue may be independent of the motor rhythm.
In the next experiments, a monkey (*macaca fuscata*) was trained on the rhythmic and random tasks. In both tasks, the cue was presented 7 times/trial. In the rhythmic task, the IOI was 800 ms. Liquid reward was given if the button was pressed within +/-260 ms from the cue onset. The amount of reward was maximized at RT = 0. The median RT for the 1st press was 198 ms, which was hastened progressively to the minimum of -56 ms at the 4th press, then gradually delayed to -16 ms at the 7th press. In the random task, IOIs of 800, 1200, 1600 ms were pseudo-randomly mixed. Each response before 300 ms from the cue onset was rewarded. The reward was maximized if RT = 0, but presses before the cue onset was not rewarded. RT after 800-ms IOI was progressively shortened if the same IOI was repeated 2-4 times ($p < 0.01$). The RT after a 1200-ms IOI was prolonged if preceded by repeating 800-ms IOIs ($p < 0.01$). The present data suggest that monkeys can synchronize movement with isochronous rhythm, and that motor rhythm can be induced by external rhythm even if it was not intended.

Title: Kinematically similar basketball free throws have surprisingly different muscle contraction velocity profiles

Authors: *D. A. HAGEN[1], S. CAJA[1], S. CHAKRAVARTHI[2], F. J. VALERO-CUEVAS[1,3]; [1]Dept. of Biomed. Engin., [2]Dept. of Electrical Engin., [3]Div. of Biokinesiology & Physical Therapy, USC, Los Angeles, CA

Abstract: The pursuit of the perfect basketball shot relies heavily on practice, with only those capable of consistently accurate throws becoming professional athletes. Why is it then that practice or mimicry do not suffice to accomplish a professional level of accuracy? Recent work re-emphasizes that the neural control of limb movements is in fact overdetermined: the rotations of a few joints determine the length changes in all muscles [1]. As pointed out by Sherrington (*Exp. Physiol.* 1913), movement trajectories can be disrupted if even one muscle undergoing eccentric contraction fails to silence its stretch reflex appropriately. Thus throws requiring higher eccentric velocities likely require more accurate and time-critical alpha-gamma control, and are thus more prone to disruption and therefore variability. Also, higher concentric velocities reduce muscle power output. Therefore, we investigated whether kinematically similar throws can exhibit large differences in eccentric and concentric muscle fiber contraction velocities. Using a planar kinematic model of a generalized jump shot with 18 muscle, 10,000 trajectories were calculated for each of the three joint angles. Normalized muscle velocities were calculated using posture-specific moment arms and optimal fiber lengths. Assuming muscles do not go slack, each trajectory was associated with obligatory muscle fiber velocities. We then classified the relative robustness of each trajectory by the sum of squares of maximum eccentric and concentric velocities, *Fig. 1 (Bottom Right),* with throws exhibiting lower velocities likely being more robust. Within the wide range of successful shots there are multiple cases where kinematically similar throws have surprisingly different muscle velocity profiles. This may explain why a "good looking" shot may, in fact, be fundamentally different from a "good" shot. Future work will explore the interplay between these kinematic constraints and the timing and coordination of alpha-gamma co-activation. 1. Title: Characterization of hand motor deficits in a marmoset 6-OHDA model of Parkinson's disease

Authors: ***J. H. SATO**[1,2], B. B. GARCIA[3], M. F. P. ARAUJO[3], H. P. G. SIMPLICIO[3,4];
[1]Mestrado em Neuroengenharia, Juliana Harumi Sato, Macaiba, Brazil; [2]Intl. Inst. for Neurosci. Edmond and Lily Safra, [3]Edmond and Lily Safra Intl. Inst. of Neurosci., Santos Dumont Inst., Macaiba, Brazil; [4]State Univ. of Rio Grande do Norte, Mossoró, Brazil

Abstract: Characterization of motor deficits in animal models of Parkinson's disease (PD) is important for the descriptive accuracy of the impairments observed in PD research. Most studies focus on describing the postural and locomotion parameters observed on the PD animal models. This work describes the use of forelimbs by 2 male marmosets during a reaching task, comparing performance before and after 6-hydroxydopamine (6-OHDA) lesion in the right hemisphere. All procedures were previously approved by the institution's Ethic Commitee for Animal Use (protocol 03/2015). The animals were first trained to reach and grasp marshmallows before induction of PD. During the experimental sessions, they were placed inside a transparent acrylic box (45x45x45cm) and were monitored by two cameras, positioned at the top and at the front of the box. The front wall of the box had 9 holes that gave access to 18 marshmallow pieces (3 for each hole) strategically positioned to evaluate forelimb use and reaching movements. For each animal, 5 sessions before and 5 sessions after 6-OHDA lesion were used to describe the forelimb impairments after the lesion. There was a significant decrease in contralateral motor performance. Specifically, the number of marshmallows captured with the left hand decreased 75.5%. In addition, there was a 165% increase in the number of marshmallows captures with the right hand. An overall reduction in motor performance was also observed, with 19% reduction in the number of marshmallows captured. This study provides a more detailed approach on the motor performance of the forelimbs, in a marmoset model of PD, and provides subsidy for future research that may describe and compare the motor performance of the arms of their DP animal models.

Title: Visual stimulus-locked responses on upper limb muscle are modulated by the upcoming reach trajectory

Authors: *C. GU, J. A. PRUSZYNSKI, P. L. GRIBBLE, B. D. CORNEIL;
Univ. of Western Ontario, London, ON, Canada

Abstract: Recent studies have reported that visually guided reaches are preceded by a wave of very short-latency electromyographic (EMG) activity in upper limb muscles that is time-locked to the visual stimulus rather than movement onset (Pruszynski et al. *EJN* 2010; Wood et al. *EJN* 2015). Such stimulus-locked responses (SLRs) evolve within ~100 ms, providing a unique opportunity to quantify the earliest phase of a sensory-to-motor transformation. Despite the reflexive-like nature of the SLR, it is endowed with a surprising degree of sophistication. For example, the SLR is represented in an arm-centric reference frame that encodes visual stimulus location relative to the limb rather than to the eye, attesting to a rapid integration of visual and proprioceptive signals. Here, we test whether the SLR reflects only the final position of the limb at the end of the reach (i.e. a goal-based response) or whether it is also modulated by the trajectory of the limb over the entire movement (i.e. a path-based response).

18 healthy people performed horizontal reaches with their right arm to either a leftward (45° counter-clockwise from straight away) or a rightward (45° clockwise from straight away) visual stimulus. We recorded surface EMG activity from the clavicular head of the right pectoralis major muscle. To dissociate goal- versus path-based responses, we introduced visual obstacles that participants were told to avoid. In one condition the obstacle did not impede straight reach trajectories, whereas in another condition the obstacle was positioned so that a curved movement was required to get to the final reach target. In the 14 participants exhibiting an SLR, the magnitude of the SLR differed for straight versus curved trajectories to the same final visual target.

Consequently, even though the SLR evolves at very short stimulus-locked latencies, it also conveys path-based information relating to the planned reach trajectory. This result shows that the earliest wave of muscle recruitment, which we quantify through the SLR, is a surprisingly rich signal that conveys many aspects of the upcoming movement.

Title: Are common motor modules activated in static and dynamic motor tasks in the human arm?

Authors: *K. D. WILGER, J. ROH;
Kinesiology, Temple Univ., Philadelphia, PA

Abstract: Our previous studies suggest that activation of a small number of motor modules (a fixed pattern of activation of a group of muscles) underlies isometric (static) force generation. Interestingly, isometric force strengthening has been shown to improve dynamic strength comparable to dynamic training. The finding supports a hypothesis that motor modules are fundamental to both static and dynamic tasks and are an avenue of strength transfer. This study tested the hypothesis by examining modular organization identified in isometric force generation task and dynamic reaching in the human upper extremity. Three neurologically intact adults performed target matches repeatedly in 16 directions equally spaced on the circumference of a circle in the horizontal plane by generating isometric force and by reaching with a manipulandum of a robotic device, respectively. Surface EMG data were recorded from eight key upper arm muscles, preprocessed, and concatenated across trials. A non-negative matrix factorization algorithm identified motor modules and their activation coefficients from the EMG of each motor task. Spatial tuning curves of the averaged motor module activations were examined in two dimensional force and displacement space. Subjects typically expressed four and five modules in the isometric force match and reaching tasks, respectively. During isometric force matches, four motor modules consisted of elbow flexor, elbow extensor, shoulder adduction/flexion, and shoulder abduction/extension patterns. In static force match and reaching, three out of the four modules were common and had similar activation tuning directions: elbow extensor, shoulder adduction/flexion, and shoulder abduction/extension modules. The muscle weights of the static elbow flexor pattern appeared as being split into two modules in the reaching task, resulting in two reaching-specific modules consisting of single activation of the brachioradialis and biceps. The spatial tuning curve of the biceps module in reaching showed no directional tuning to any reaching target, suggesting the activation of the module for compensation for gravity. These findings support that the central nervous system modulates the activation of common and task-specific motor modules to accomplish static force generation and dynamic motor tasks in the human arm.

Title: Motor planning flexibly optimizes performance under uncertainty about task goals

Authors: *A. L. WONG, A. M. HAITH;
Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: In an environment full of potential goals, how does the brain determine a single movement to execute? Existing theories posit that when faced with competing potential goals, the motor system prepares a response for each individual goal by generating several distinct movement plans in parallel (Cisek 2007; Erlhagen and Schoner 2002; Stewart et al. 2013). Such theories are founded on the observation that presenting two competing goals often results in a movement that appears to be the average of the responses to the two targets. These intermediate movements are taken as evidence of unintentional interference between the competing plans. In contrast, normative theories suggest that rather than being accidental, intermediate movements are actually deliberately generated to improve task performance (Hudson et al. 2007; Haith et al. 2015). That is, an intermediate movement allows for additional time to process the stimulus by delaying commitment to a specific goal until later in the movement.

According to this interpretation, moving quickly should hinder this strategy because it limits the time available to resolve goal uncertainty and adjust the movement online. To test this hypothesis, we varied the required speed with which participants moved to the target goal under a go-before-you-know paradigm (Chapman et al 2010), which has been shown to reliably encourage the generation of intermediate movements. We found that the motor system generates intermediate movements only when they lead to improved performance, in support of the normative hypothesis. Interestingly, we also observed speed-modulated biases on unambiguous reaches when there was only a single target goal, suggesting that the occurrence of use-dependent biases might also be explained using the same normative framework.

In summary, our findings thus refute the hypothesis of parallel planning and instead suggest that the motor system forms only a single, flexible plan that is optimized to respond in the face of uncertain goals.

Title: Mass decreases movement speed during arm reaching

Authors: *G. BRUENING[1], M. O'BRIEN[1,2], A. AHMED[1], R. SHADMEHR[2];
[1]Integrative Physiol., Univ. of Colorado Boulder, Boulder, CO; [2]Dept. of Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: A decision-making framework suggests that the goal of movement is to maximize utility, represented as the sum of the rewards obtained during movement minus the costs of the movement itself (i.e. effort) [1]. A critical prediction of this hypothesis is that movement characteristics, such as speed, are influenced by rewards obtained from movement as well as the effort required to complete it. Movement speed should increase towards more rewarding targets and decrease when movements require greater effort. Previous research has shown that humans move faster towards more rewarding targets. Here, we asked whether preferred reach speed is also modulated by movement effort. Seated subjects (N = 26) made horizontal reaching movements while grasping a robotic handle. We increased movement effort by adding mass to the handle. Subjects performed reaching movements from a central starting circle to one of four targets displayed on the perimeter of a 10cm invisible circle, centered at the starting circle. The targets appeared at 45o, 135o, 225o, and 315o in pseudorandom order. They were instructed to reach to the target at a self-selected velocity. Each subject performed reaches under four mass conditions (0, 3, 5, and 8 lbs) in blocks of 200 trials, in randomized order. Eight subjects performed an out-and-stop movement. The remaining 18 subjects performed an out-and-back movement without any visual feedback of the cursor to prevent corrective movements. Importantly, subjects were not penalized for accuracy. Results were compared to the predictions of optimal movement duration given a utility in which effort is represented as metabolic cost and increases linearly with mass. With increasing mass, subjects increased both movement duration and reaction time ($p<<0.01$). We also observed that the faster an individual preferred to reach, the less sensitive their reach speed was to increasing mass, a finding that is in line with model predictions ($p<<0.01$). Our results demonstrate that increased effort slows both reaching movements and reaction time, and this can be explained using a framework in which movement utility is represented as the temporally discounted sum of the reward to be obtained minus the effort of the movement itself.

Title: Effect of the side of the brain lesion on arm reaching movements in upright position of stroke individuals

Authors: *R. B. GARBUS[1], A. G. NARDINI[2], S. R. ALOUCHE[2], S. M. S. F. FREITAS[2]; [1]Univ. Cidade De São Paulo, Santos, Brazil; [2]Univ. Cidade De São Paulo, São Paulo, Brazil

Abstract: Individuals with mild post-stroke hemiparesis present several motor impairments that can negatively affect the performance of arm reaching during upright standing. However, it is unclear whether the side of brain lesion affects differently the reaching performance. Therefore, the aim of the present study was to investigate the effect of the side of the damaged hemisphere on the arm reaching during standing. Nineteen individuals with mild post-stroke hemiparesis divided in two groups (nine on the right and ten on the left side) stood in upright position and performed reaching movements with their arm ipsilateral to the brain lesion. Reaches were performed towards a target shown in a monitor placed at a distance of 105% of the upper limb's length and the targets were presented in one of three heights (a center target placed at the eye level or 10 cm upper or 10 cm lower to the center target). Each participant performed 60 trials in 3 blocks of 20 trials. Target location was the same within each block and changed among blocks. The order of target location was randomized across participants. Participants were instructed to reach and touch the center of the target displayed on the monitor as fast as possible after the auditory beep. Time elapsed from the auditory sound until participants' movement initiation (time of movement onset), time spent to complete the task (movement time) and the accuracy measured by the variable errors were computed and compared among target heights and between groups. The results showed an effect of the side of the brain lesion only on the time of movement onset. Individuals with right hemisphere damage took more time to initiate their movements

compared to the left stroke individuals. The height effect was observed on the movement time and variable error. The movement time increased with the target height. On the other hand, greater variable error was observed for the center target (i.e. placed on the eye level). Overall, the results suggest that the effects of the side of lesion are more evident on the movement planning. The performance of the arm reaching movement during upright standing was not dependent on which hemisphere was damaged.

Title: On action intent: behavioural correlates of reach-to-grasp actions

Authors: *J. W. FLINDALL, C. L. R. GONZALEZ;
Kinesiology, Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Long-train electrical stimulation of the motor and pre-motor cortex has been shown to produce functional movements in anesthetised macaques. Location-specific stimulation may produce either multi-limb defensive or locomotory movements, or context-specific single-limb movements, such as grasp-to-inspect or grasp-to-eat actions. Such grasping movements are always tied to a precise end-goal, regardless of initial limb position. In addition, single-neuron recording studies have shown distinct populations of neurons in the macaque inferior parietal lobule (IPL) that respond uniquely to task-specific grasping actions. These studies show that "grasp-to-eat" and "grasp-to-place" neurons in the IPL selectively fire when their preferred action is performed. This selectivity is maintained irrespective of arm kinematics, end-goal location, target identity, or grip-type. Together, these studies suggest that the macaque motor cortex is organized around the production of functional, goal-oriented movements, rather than the activation of specific muscles. But what about humans? In a series of behavioural studies, we provide evidence that the hand-to-mouth (or "grasp-to-eat") action is not only kinematically distinct from grasp-to-place actions, but that it is left-hemisphere lateralized. In Study 1 we show that smaller maximum grip apertures (MGAs) are produced when grasping to eat cereal items than when grasping to place the same items into a container near the mouth, and that this

difference is lateralized to the right hand. In Studies 2 and 3 we show that this right hand lateralization is not an effect of practice; first, by demonstrating that the lateralization is preserved in left-handers, and second by showing an unexpected pattern of development in children. Studies 4 and 5 tested the specificity of the effect with regards to consumption; they show that the grasped item need not be eaten, nor need it even be edible, provided the action's goal is to bring the target to the mouth. Studies 6 and 7 show that the kinematic asymmetries cannot be attributed to planned mouth movement, nor can they be explained by the (arguably) increased specificity of placement required by the mouth. Altogether, our research suggests that the human motor cortex is also organized around the production of goal-specific actions, and that the hand-to-mouth movement, which almost certainly evolved for the purpose of self-feeding, is lateralized to the left-hemisphere. This hemispheric specialization may have served as the foundation for other lateralized functions such as praxis and speech, as well as the driving force behind species-wide right-hand dominance in humans.

Title: Gravity is used to minimize neural effort for joint coordination during arm movements

Authors: *N. DOUNSKAIA, W. WANG;
Arizona State Univ., Phoenix, AZ

Abstract: How control for gravity is organized during arm movements remains under debate. We tested three alternative interpretations suggested by previous research: (1) that muscular control includes two components, tonic which compensates for gravity and phasic which produces the movement; (2) that there is a tendency to exploit gravity to reduce muscle effort; and (3) that there is a tendency to use a trailing pattern of joint control during which either the shoulder or elbow is rotated actively and the other joint rotates predominantly passively, and to exploit gravity for control of the passively rotated joint. A free-stroke drawing task was performed that required production of center-out strokes within a circle while selecting stroke directions randomly. The circle was positioned in the horizontal, sagittal, and frontal plane. The arm joints freely rotated in space. In each plane, the distribution of the strokes across directions was non-uniform. Directional histograms were built and their peaks were used to identify preferred movement directions. The directional preferences were especially pronounced in the

two vertical planes. The upward directions were most preferred. To test the three interpretations, we used a kinetic analysis that determined the role of gravitational torque in production of movement in the preferred directions. The results supported the third interpretation and provided evidence against the first and second interpretation. The trailing pattern has been associated with reduced neural effort for joint coordination, and therefore, we conclude that the major tendency with respect to gravity is to exploit it for simplification of joint coordination.

Title: Age-related increases in reaction time: slower preparation or sluggish initiation?

Authors: *R. M. HARDWICK[1], M. COSTELLO[2], K. M. ZACKOWSKI[2], A. M. HAITH[3];
[1]Dept. of Neurol., [2]Kennedy Krieger Inst., [3]Neurol., Johns Hopkins Univ., Baltimore, MD

Abstract: Healthy aging is associated with slower reaction times. While corticospinal conduction velocities decrease marginally with aging, these changes are too small to account for changes in voluntary reaction times, suggesting this slowness is primarily a result of age-related changes in behavior (e.g. being more cautious to ensure the correct response) and/or the brain (e.g. decreased myelination). In a recent study (Haith et al., 2015) we have shown that while the reaction times of younger adults are typically within the range of 200-220ms, they can in fact prepare and execute accurate responses in ~130ms, suggesting they introduce a seemingly unnecessary delay of 80-100ms prior to reacting. Here we examined whether the slower reaction times seen in healthy older individuals are due to a slowing of their ability to prepare movements (e.g. due to reduced speed of information processing), or an increase in the delay between when their movements are prepared and initiated (e.g. due to being more cautious), or a combination of both.

In a visually guided planar reaching task, we measured reaction times and assessed the time actually required for accurate movement preparation in older and younger adults. To measure reaction times, participants were instructed to react as soon as possible to the appearance of a visual target. To assess required preparation time, we tested participants' ability to move accurately at lower-than-normal reaction times through a timed-response paradigm. Participants

made reaching movements at a fixed time during each trial (moving synchronously with the last of four equally spaced tones). Varying the time of target presentation in relation to movement onset allowed us to determine the minimum time required for accurate movement preparation. A preliminary comparison was conducted between a group of healthy older (n=8, mean age=73) and younger (n=8, mean age=27) adults. In line with previous studies, we found that reaction times were longer for the healthy older group. Behavior under timed-response conditions revealed that this age-related increase was attributable to slower movement preparation while the delay between the time required to prepare movements and when they were initiated was remarkably similar across age groups (~90ms). These results indicate that the slower reaction times of healthy older adults are not simply due to an increased hesitancy to respond, but may instead be attributable to a declining ability to rapidly process target location and prepare movements accordingly, potentially due to age related changes in brain structure (e.g. reduced white matter integrity) or function (e.g. compensatory brain activity).

Title: Distinct and common processes underlie impaired motor execution and inhibition following stroke

Authors: *A. HARRISON, C. PERRY, T. SINGH, A. ROSS, S. FRITZ, J. FRIDRIKSSON, T. HERTER;
Univ. of South Carolina, Columbia, SC

Abstract: Many motor skills involve executing movements in response to task-relevant stimuli (motor execution) and inhibiting movements in response to non-relevant stimuli (motor inhibition). Stroke survivors commonly show impaired motor execution, but the extent to which stroke survivors exhibit impaired motor inhibition remains unclear. Here we examine extent to which stroke survivors exhibit impaired motor inhibition and whether motor execution and inhibition are mediated by distinct or common perceptual, cognitive and motor processes. METHODS: We studied 31 stroke survivors and 67 controls who used an upper-limb robotic

device to perform a motor execution/inhibition task, Object Hit and Avoid (OHA). Subjects used virtual paddles to hit away target objects (2 geometric shapes, n=200) and avoid hitting distractor objects (4 different geometric shapes, n=100) that moved towards them in the horizontal plane. Hand and eye kinematics were collected and used to compute measures of *Motor Execution* (percent of targets hit), *Motor Inhibition* (percent of distractors avoided), *Limb Movement Control* (hand speed bias), *Visual Search Efficacy* (percent of objects pursued with the eyes), *Eye-Hand Coordination* (distance between the eyes and hand at the time of target contact), *Visual Recognition Speed* (mean distractor pursuit time), and *Motor Planning Speed* (mean difference between target and distractor pursuit times) RESULTS: Compared to controls, many stroke survivors exhibited impairments of both *Motor Execution* and *Motor Inhibition*. However, these impairments did not exhibit a strong relationship with each other ($r = 0.22$, $p = 0.06$). Both *Motor Execution* and *Motor Inhibition* were correlated with *Eye-Hand Coordination* ($r = 0.62$, $p = 0.0001$; $r = 0.33$, $p = 0.366$) and *Visual Recognition Speed* ($r = -0.55$, $p < 0.0001$; $r = -0.58$, $p < 0.0001$). *Motor Execution* was also uniquely correlated with *Visual Search Efficacy* ($r = 0.75$, $r < 0.0001$) and *Limb Movement Control* ($r = -0.34$, $p < 0.0001$). In contrast, *Motor Inhibition* was uniquely correlated with *Motor Planning Speed* ($r = 0.68$, $p < 0.0001$). CONCLUSION: These results show that motor inhibition is a common impairment following stroke and a combination of distinct and common brain processes contribute to motor execution and inhibition.

Title: The striatum encodes the full kinematic details of reaching movements

Authors: *E. A. YTTRI[1], B. PANIGRAHI[2], K. A. MARTIN[2], J. T. DUDMAN[2];
[1]Neurobio., Janelia - HHMI, Ashburn, VA; [2]Janelia Res. Campus, Ashburn, VA

Abstract: To accomplish a successful action, it is important to select not only what movements to perform, but also when, how fast, and how far to perform those movements. The generation of motor plans requires the coordination of several brain areas. The dorsal striatum, the major input nucleus of the basal ganglia, receives input from several cortical areas, including the motor cortex. Motor cortex is a dynamical system that may represent several possible actions while the basal ganglia is thought to act as a gate on action itself. It is possible that downstream structures

such as the basal ganglia might likewise have regular dynamics associated with movement execution, but this have been missed due to previous technique limitations and that stimulation of the two projection pathways of the basal ganglia induce robust starting or stopping of behavior, respectively. However, we recently demonstrated that selective stimulation of either pathway was sufficient to bidirectionally change a specific parameter, the velocity, of a reach, while leaving other movement parameters unaltered. Additionally, rather than being active at only the initiation and termination of an action, the striatum is active throughout an action, with individual neurons reliably responding at the same phase of movement.
To determine in what aspects of action planning the striatum is involved, we trained mice to perform a goal-directed reaching task while we recorded from populations of striatal neurons. We explored the possibility that striatal ensembles function as dynamical systems using GPFA on these population data. We discovered that the striatum encodes not only start and stop of a reach, but also other control parameters such as velocity, amplitude and direction – a profoundly greater level of detail than previously thought.
If striatal dynamics are causally involved, as our prior experiments have shown, we hypothesize that neuronal activity will lead the representative behavior. Alternatively, a reflexive response or corollary read out of movement would occur concurrently or after the behavior is performed. Utilizing a simple decoder, we were able to predict the full path and velocity of a individual reaching movement over 100 milliseconds before it is performed. Furthermore, stimulation just prior to a reach can alter the current reach. These findings suggest that the basal ganglia is actively involved in driving the kinematics of movements. These results demonstrate that neuronal representations of movement in the basal ganglia are not merely to start or stop movement, but are detailed blueprints for precisely how and when to act.

Title: Impedance modulation as a strategy to control force and movement during object manipulation

Authors: *S. D. KENNEDY[1], N. HOGAN[3], A. B. SCHWARTZ[2];
[1]Bioengineering, [2]Neurobio., Univ. of Pittsburgh, Pittsburgh, PA; [3]Mechanical Engin., MIT, Boston, MA

Abstract: Object manipulation necessitates simultaneous control of force and movement. However, the relation between force and movement changes in a way that is specific to the object and the way it is acted upon. The ability to perform manipulation tasks in the face of such changes suggests that flexible and adaptable control of both force and movement takes place in parallel. We studied this control in a task in which five human subjects pulled on a handle that was held stationary until a specified force threshold was reached. The handle was then suddenly released to move along a track and the subjects were required to stop the handle in various target position zones. Targets were spaced at different distances from the release position and we released the handle at different force thresholds. Our main finding was that the subjects varied their arm impedance for different combinations of target distance and force threshold. For the same target distance, arm impedance increased with the force threshold; for the same force threshold, arm impedance increased as the target distance decreased. Surface electromyograms were used to calculate the co-activation of antagonist muscles at the shoulder, wrist, and elbow. Co-activation, combined with arm configuration, was found to be consistently related to arm impedance. This simple task shows that force, movement, and arm impedance can be controlled independently and lays the groundwork for investigating impedance modulation as a strategy for object manipulation.

Title: Options coding in the movement system

Authors: *J. I. GLASER[1,2], M. G. PERICH[1], P. N. LAWLOR[1], P. RAMKUMAR[1], D. K. WOOD[1], M. A. SEGRAVES[1], L. E. MILLER[1], K. P. KORDING[1];
[1]Northwestern Univ., Chicago, IL; [2]Rehabil. Inst. of Chicago, Chicago, IL

Abstract: In general, the state of our body restricts our movement options. When our arm is fully stretched out it can only be moved towards our body, and if our eyes are fully rotated left, we can only move them rightward. The visuomotor system could use this prior knowledge to reduce the range of potential movements during movement selection. We thus studied the encoding of a distribution of potential arm and eye movement options using extracellular recordings from several different areas of monkey cortex. We found strong signatures of options coding in dorsal premotor cortex (PMd) during arm movements (reaching) and in the frontal eye field (FEF) during eye movements (saccades). In both areas, early planning activity averaged across movements represented the distribution of upcoming movements, while late planning activity represented the selected movement. Moreover, by decoding simultaneously recorded neurons in PMd, we showed that the neural population represented upcoming movement options for single reaches. Our results suggest that option representations may be a ubiquitous component of motor planning.

Title: A micro-LED implant for long-term optogenetic stimulation of the rat spinal cord

Authors: *S. E. MONDELLO[1,2,6,3], M. D. SUNSHINE[1,6], A. E. FISCHEDICK[1], P. J. HORNER[2,3], C. T. MORITZ[1,4,6,5];

Abstract: Optogenetic stimulation permits activation of specific neuron populations without the need to penetrate the brain or spinal cord. While many implantable devices have been developed for optogenetic stimulation of the brain, few have been created that allow for long-term stimulation of the spinal cord in freely moving animals. Rats are an ideal animal model for testing therapeutics to treat disorders of the spinal cord such as chronic pain or spinal cord injury. They are capable of learning numerous tasks that allow for comprehensive assessments of their responses to treatment. Further, they are more genetically similar to humans, potentially accelerating translation. Working with rats, however, requires overcoming obstacles not present in mice. One of the greatest obstacles is the lack of a publicly available optogenetic transgenic rat. This results in the necessity to inject optogenetic viruses into the regions of interest, which in turn leads to less efficient optogenetic activation and requires higher light intensities to elicit a response. In the current study, we developed a high-powered LED implant that permits long-term optogenetic stimulation of freely moving rats. Prior to implantation, terminal *in vivo* heat tests confirmed the safety of the implant at 4Hz frequency using ≤ 5ms pulse widths at light intensities up to 215 mW. Some rats received a hemi-contusion at cervical segment C4, followed by an injection of an optogenetic virus (either AAV1-Camkiiα-Chr2-mcherry, or AAV6-hsyn-Chr2(H134)-eYFP) at ipsilateral cervical segment C6. Following an addition of an 8 week transfection period, rats were then implanted with a high-powered 473 nm surface LED directly over the viral injection site. Some rats underwent similar procedures, but without an injury or an initial viral transfection period. Light-intensity thresholds for eliciting movement were tested weekly for 8 weeks. In some animals, the implant was stimulated for 4.5hrs, 5 days/week to simulate therapeutic treatment. For 2 out of 4 transfected rats, thresholds slowly increased over the course of 8 weeks, while thresholds remained relatively constant for the other two animals. All implants succeeded in evoking optically activated forelimb movements for at least 6-8 weeks following implantation. In combination, these findings indicate that this implant could be used for long-term studies using optogenetics as a therapeutic or restorative technology, or to answer fundamental science questions across a longitudinal timeframe.

Title: Stimulation strategies to convey sensory information directly to the cortex via intracortical microstimulation (ICMS)

Authors: *D. A. BJANES[1,2,5], A. L. FAIRHALL[3,2,5], C. T. MORITZ[3,4,2,5];
[1]Electrical Engin., [2]Inst. for Neuroengineering (UWIN), [3]Physiol. & Biophysics, [4]Rehabil. Med., Univ. of Washington, Seattle, WA; [5]Ctr. for Sensorimotor Neural Engin. (CSNE), Seattle, WA

Abstract: Users of current brain-computer interface (BCI) technology must rely on visual feedback of cursor or robotic arm movement. The inherently long delays of visual processing likely contribute to relatively slow and unnatural control of BCIs. Despite increasing numbers of electrode sites and ever growing complexity of control algorithms, BCI technology has yet to achieve rapid and dexterous control comparable to an intact human arm and hand. We believe the lack of tactile perception and proprioceptive input imposes a fundamental limit on speed and accuracy of BCI controlled prostheses or reanimated limbs. By restoring this comparatively low-latency pathway directly to the brain via intracortical microstimulation (ICMS), BCI performance may be improved. To enable artificial sensory feedback, we are exploring sensitivity to several stimulation strategies in order to identify a high resolution space in which to provide feedback. We have developed a novel center-out task for rodents, including automated increments in difficulty to achieve autonomous training. We then use ICMS to present patterns of artificial stimulation directly to the sensorimotor cortex to enable animals to complete the task. Prior to stimulation, neural populations surrounding stimulation electrodes are categorized as responsive to sensory inputs, correlated with features of the behavioral task or as unrelated sites. We can then present stimulation both to correlated populations and unrelated sites and compare learning performance in each case. Stimulation encodes joystick position relative to a target as a proportional feedback signal, rather than simply a cue for a particular target. After determining the just noticeable difference of various stimulation patterns, we present graded stimulation via one or multiple cortical electrodes. By comparing the ability of animals to solve a forelimb spatial exploration task, we can measure comprehension of the encoded stimulation pattern at physiologically correlated and uncorrelated locations in the cortex. Our goal is to

determine an optimal strategy for providing a high resolution sensory feedback directly to the cortex. Using such ICMS strategies, we hope to restore low-latency sensory feedback and improve BCI control. This may enable participants with spinal cord injury and stroke to improve control of their prosthetic or reanimated limb when using a BCI, and also advance our understanding of natural sensory coding in the brain.

Title: Identification of stage transitions of imagined hand movements with electrocorticography

Authors: *J. WU[1,2], L. BASHFORD[6,7], J. A. CRONIN[2,1], D. J. CALDWELL[2,1], N. R. WILSON[1,2], D. SARMA[1,1], B. W. BRUNTON[3], R. P. N. RAO[4,1], J. G. London, London, United Kingdom; [7]Bernstein Ctr., Univ. of Freiburg, Freiburg, Germany

Abstract: Electrocorticography (ECoG) is a promising technique for direct brain control of dexterous upper-body robotic prostheses. However, the underlying stages and stage transitions in ECoG signals during imagined movement remain unclear. Improved understanding of the dynamics of imagined motor movement, and their similarity to movement planning behavior, is required for more rapid development of brain-computer interfaces (BCIs) for the volitional control of assistive prosthetics. We investigated several spatial-time-frequency models of ECoG signals during imagined and overt hand grasping behavior recorded in epileptic patients from clinical platinum subdural ECoG grids (10mm spacing). We matched dimensionally-reduced ECoG "movement staging" features, derived from principal component projections of wavelet transformed recordings during overt hand movement, with corresponding ECoG features in imaginary movement using dynamic time warp (DTW). Our decoding was tested in three patients implanted with 8×8 lateral temporal-parietal clinical grids during a dynamic movement

task with imagined hand movements mimicking a software robotic hand. Decoding with two principal movement axes (power grasp-open palm and pinch-hook) in this closed-loop imagined movement BCI achieved identification of the type of continuous movement with regularized discriminant analysis at an accuracy of 45%, with an above-chance performance in predicting stage transitions within a movement type. These results suggest the presence of stage-linked ECoG features of imaginary movement, and spatiotemporally localized stage transitions during imagined hand movements.

Abstract: A major research challenge in the area of brain computer interface is the creation of a recording platform that combines high signal quality and spatial resolution with minimal tissue damage and chronic stability. Historically, implantable recording devices have been divided into two main categories, penetrating and surface electrode arrays. Penetrating devices typically have a greater signal quality and spatial resolution as compared to surface electrodes, while surface electrodes are minimally invasive and produce a less severe immune response. Previously recording of single action potentials have been limited to the more invasive penetrating electrodes, however new technologies have recently been reported that can record neuronal spikes from a subdural μECoG array. With these new technologies, surface μECoG arrays have greatly improved recording capabilities and spatial resolution, while maintaining their minimally invasive state and superior chronic stability. We have quantified the in-vitro biocompatibility of the devices and the in-vivo tissue response to glassy-carbon surface μECoG electrodes during chronic implantation, both during passive recording and active stimulation. Tissue response was minimal under recording electrodes, likely due to the inert nature of the carbon electrode and location on the brain surface, with no severe immune response observed. Additionally, we show that thin-film μECoG arrays implanted subdurally in rat models are stable over chronic implantation timescales. Further, we introduce the concept of a combined surface and penetrating device - integrated within a single flexible substrate - to validate the ability to record single unit action potential using a non-penetrating electrode and to compare the quality of the signals at different depths above and within the cortex. By fabricating a device with both surface and penetrating electrodes that cover the same cortical regions, we are better able to characterize the signals recorded simultaneous at different depths. Additionally, by combining the signals recorded by the surface and penetrating sites, we may be able to produce a 3D recording map of the area of interest. To realize this potential, we fabricated a flexible microelectrode array, composed of both cortical and penetrating glassy carbon electrodes. We are currently optimizing the method of insertion of the flexible penetrating probe and validating the device with *in vitro* electrochemical tests and *in vivo* characterization. If successful, the ability to record stable single unit action potentials from the brain surface will enable long-term clinical applications of brain computer interfaces.

Title: Unsupervised decoding of long-term, naturalistic human neural recordings with automated video and audio

Authors: *X. WANG[1], A. FARHADI[1], J. G. OJEMANN[2], B. W. BRUNTON[3], R. P. N. RAO[1]; [1]Computer Sci. and Engin., [2]Neurolog. Surgery, [3]Biol., Univ. of Washington, Seattle, WA

Abstract: There have been many successes in using experimental ECoG (Electrocorticography) and EEG (Electroencephalography) studies to decode brain activity; however, natural data has been rarely analyzed. Signals collected from humans "in the wild" are affected by a noisy environment and modulated by a complex range of behaviors. The goal of home Brain-Computer Interface (BCI) use and long-term neural monitoring will need to be robust to these factors. As well, with the great advancements in machine learning and computer vision in recent years, recordings of multiple modalities can provide information about a patient's behavior without the need of strict experimental protocols. In this project, we collected thousands of hours of simultaneous video (including a depth channel), audio and neurophysiological data from patients undergoing clinical long term monitoring for more than 10 ECoG patients. Previously, we were able to automatically cluster behaviorally relevant categories as well as functionally map the brain from the ECoG signals without any supervision nor manual labelling with the aid of computer vision techniques on video. In our current work, preliminary results show that the latest state-of-the art techniques based on deep learning can detect human poses accurately from the video. Our results show the brain mapping and decoding results from the ECoG signals using the automated pose detection from video. Our techniques overall show the suitability of natural data combined with fully automated video and audio analyses in brain activity decoding and prediction.

Title: Error-related potentials for co-adaptive cortical brain-computer interfaces.

Authors: ***N. R. WILSON**[1], D. SARMA[1], J. D. WANDER[1], J. G. OJEMANN[2], R. P. N. RAO[3]; [1]Bioengineering, [2]Neurosurg., [3]Computer Sci. & Engin., Univ. of Washington, Seattle, WA

Abstract: When one's intended action does not match with what has occurred, an error-related potential (ErrP) may occur in various frequency bands in the encephalogram. These potentials may be used to promote unsupervised reinforcement learning in brain-computer interfaces (BCIs), promoting co-adaptation between the user and the decoder. Previous work has shown ErrPs occurring in the frontal and motor cortices with overt movement, in both the high gamma (70-100 Hz) and delta (0-4 Hz) frequency bands. However, ErrPs across different areas in BCI control tasks have yet to be thoroughly examined using electrocorticography (ECoG). We investigated changes in cortical signals during a one-dimensional center-out BCI task, recorded

with clinical subdural cortical electrode grids in epilepsy patients. We presented five subjects with a BCI task in which they controlled the velocity of a cursor to hit a target located above or below the center starting point. The subjects controlled the cursor by modulating their high gamma (70-100 Hz) activity in the electrode most strongly associated with hand or tongue motor imagery. We extracted high gamma and delta (0-4Hz) band amplitude for all trials, and epoched instances where the BCI incorrectly decoded subject intention. For each frequency band and for all 64 channels, we then compared the amplitudes of the ErrP epochs to the correctly decoded epochs. Clinical grid placement varied per subject, so we organized individual channels by location, in order to investigate regional variation in ErrP. We then performed cross-subject analysis to investigate commonality in ErrPs across subjects. Preliminary results suggest that potentials associated with decoder error are different and distinguishable from those associated with correct performance in cortical BCI tasks, and may share common features across subjects (Figure 1).

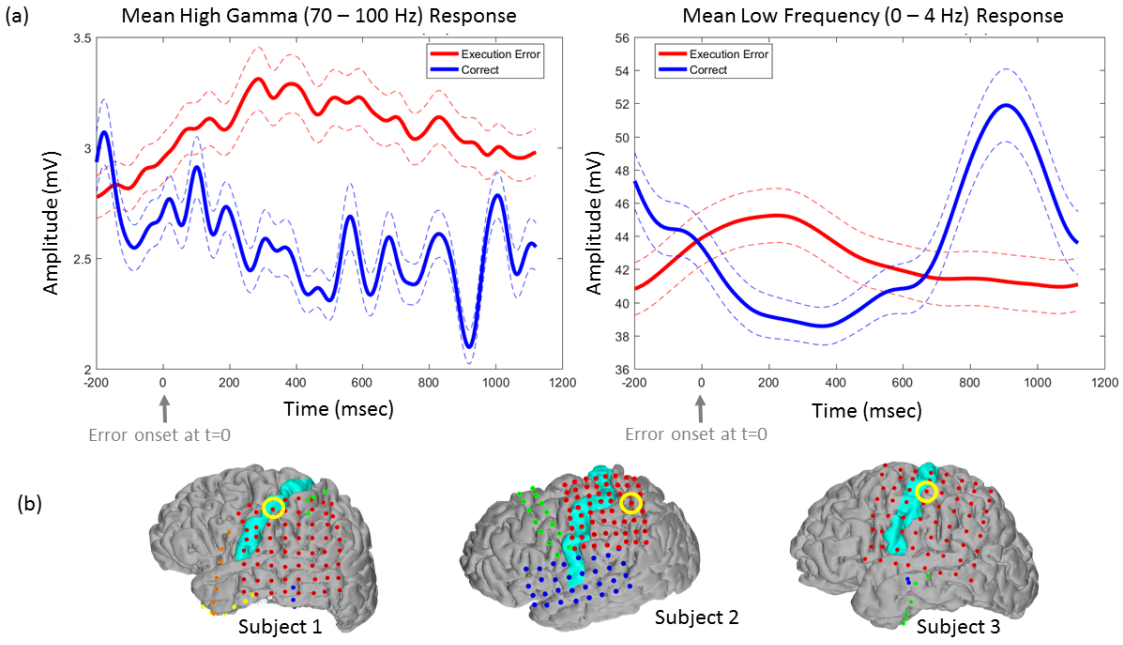

Figure 1. Error-related potentials in M1. (a) The mean responses across the entire primary motor cortex (M1) for both correct and decoder error epochs. (b) Three subjects had left hemisphere M1 coverage. The pre-central gyrus is highlighted in blue and the electrode used for BCI control is circled in yellow.

Title: Somatosensory feedback via direct cortical electrical stimulation in humans

Authors: *J. A. CRONIN[1,5], J. WU[1,5], D. J. CALDWELL[1,5], K. L. COLLINS[2,5], D. SARMA[1,5], R. P. N. RAO[3,5], J. G. OJEMANN[2,5], J. D. OLSON[4,5];

Abstract: Objective: Somatosensory feedback is essential for efficient and precise motor output. Cortical stimulation through electrocorticographic (ECoG) electrodes is a potential method for providing such feedback. Previous research has demonstrated that subjects can distinguish between ECoG stimulation of different frequencies or amplitudes; however, little is understood about how human subjects perceive these novel sensations.
Methods: Subjects were hospitalized for clinical monitoring of epilepsy with implanted ECoG grids. We used Tucker-Davis Technologies hardware to deliver constant-current stimulation using trains of 200 μs biphasic square pulses. We determined the perceptual threshold for stimulation by incrementally increasing the current amplitude, and examined response times and stimulation waveform parameters. For task-specific sensory feedback, subjects wore a 22 degree-of-freedom dataglove to measure their hand position. Subjects opened and closed their hand while they received state feedback via ECoG stimulation. Three states were encoded: 1) hand too open, no stimulation; 2) within the target position, low intensity stimulation; and, 3) too closed, higher intensity stimulation.
Results: Subjects perceived the stimulation on their hands as an abstract sensation, sometimes

described as vibration and/or pressure. Perceptual thresholds were in the range of 1.5 to 2.25 mA. One subject was able to achieve accuracies and R^2 values considerably greater than chance level, with performance dropping during a catch trial (Figure 1).

Conclusions: These results suggest that subjects can react to cortical sensory stimulation and use it as feedback to modulate motor behavior.

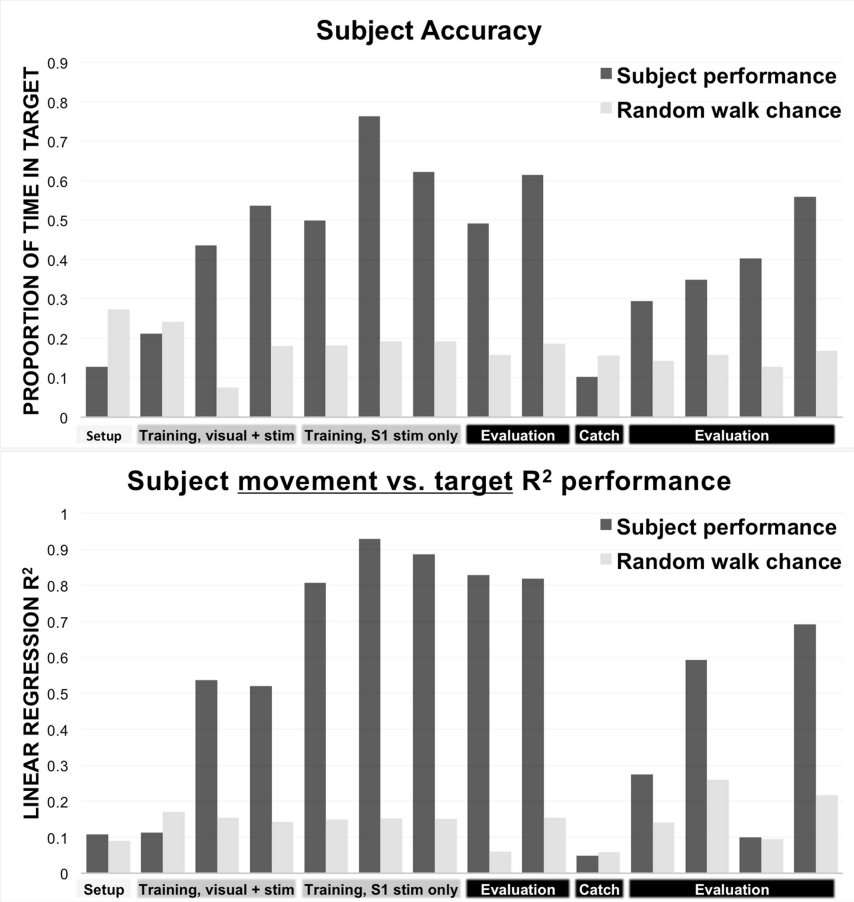

Figure 1. Subject performance in sensory feedback task. Accuracy (top panel) was calculated as *(samples inside target range)/(total samples)*. R^2 values (bottom panel) compare the subject's hand path to the ideal target path. Chance levels were determined by averaging performance on 1,000 simulated random walks. Catch trial used the same stimulation amplitude regardless of the state.

Abstract: While the anatomy of respiratory circuits within the spinal cord is well described, little is known about the ability to activate these circuits using intraspinal microstimulation (ISMS). In this study we quantified how ISMS activates the three primary respiratory muscles in spinally intact rodents. Female Long Evans rats were anesthetized with ketamine/xylazine and the spinal cord was exposed unilaterally from the second cervical (C2) through the first thoracic (T1) segment. Bipolar electromyography (EMG) electrodes were placed ipsilateral to the stimulated spinal cord in the diaphragm (DIA), intercostals (ICs), and sternocleidomastoid (SCM) muscles. An epoxy-coated tungsten electrode (impedance = 300-500 kOhm) was advanced ventrally along 20 tracks each beginning at the dorsal surface and ending at a final depth ranging from 1800-2400 μm, the 20 tracks were arranged in 2 columns 0.5mm and 1mm from midline. Single biphasic stimuli were delivered at amplitudes from 10-90 μA at each location within the spinal cord. To quantify the interaction of ongoing respiratory rhythms with ISMS, stimulation was delivered during each phase of respiration based on integrated, rectified diaphragm EMG. A total of 10 stimulation pulses at each amplitude were delivered in each phase, with the order of delivery randomized. ISMS evoked respiratory muscle activity at many spinal sites that were outside of the locations of the motor neuron pools for the respective muscles based on retrograde tracing with wheat germ agglutinin (WGA). Intraspinal stimulation delivered during expiration produced lower amplitude muscle contractions compared to stimulation during inspiration. Furthermore, the location of muscle excitation during out of phase stimulation was more centralized to the motor pools. Taken together, these results suggest that ISMS activates a network of spinal interneurons related to respiration, and collaborates with

phase-dependent respiratory networks. The ability of ISMS to interact with residual spinal networks controlling respiratory muscle activity will be critical for improving ventilatory function following spinal cord injury.

Title: A wireless bidirectional brain machine interface

Authors: *Y. OZTURK[1], Y. SU[1], K. S. MOON[2], S. PERLMUTTER[3], S. ZANOS[3], E. FETZ[3]; [1]Electrical and Computer Engin., [2]Mechanical Engin., San Diego State Univ., San Diego, CA; [3]Univ. of Washington, Seattle, WA

Abstract: Brain machine interfaces (BMI) provide a communication link between the brain and physical devices by offering an alternative path, bypassing physiological pathways that are no longer intact. An implantable BMI provides better signal quality for a broad range of neural activities and allows delivery of activity-dependent electrical stimulation. Wireless bidirectional interfacing with implanted electrodes is an important step towards increasing the clinical potential of BMIs.
We designed a small form factor, wireless bidirectional BMI (BBMI) system. The core component of the open-architecture BBMI system is a communication system on a chip (SoC) with an embedded processor responsible for wireless data transmission, data acquisition, and controlling delivery of stimulation. The sense electronic module provides 32 input channels with a gain of 45.67dB. The stimulation module provides 4 output channels supporting unipolar 20V stimulus with
programmable frequency and pulse duration. A novel ultrasonic wireless power delivery mechanism developed for efficient delivery of power into a deeply implanted system. The current consumption of the system is in the range of 18.47mA to 19.96mA when the device was in normal operation status. Bench tests were conducted by replaying a set of pre-recorded

intracortical signals recorded from an animal model using a research-grade recording system. The stimulation module was
validated by using a scope to monitor the output stimulus amplitude and frequency. In vivo tests of the system were performed on an awake monkey, with an intracortical array implanted in the primary motor cortex. Local field potentials (LFP) were recorded wirelessly at a sampling rate of 1 KHz. Single-pulse stimuli (biphasic, 0.2ms each phase, 40 uA) were delivered wirelessly through one of the intracortical electrodes at a constant rate of 0.6Hz. Stimulus-triggered signal averaging revealed a stimulus-elicited increase of power in high frequency LFP components at neighboring cortical sites at Gamma (30-60Hz) and high-gamma (60-100 Hz) ranges. The changes in the LFP spectrum might reflect a change in the behavioral state following by the stimulation such as arousal. A wireless BBMI module is being integrated to Neurochip-3 to acquire and deliver EMG signals as an implantable sensor and a spinal stimulation module for delivering stimulation to spinal
cord under the control of Neurochip-3.

Abstract: Objective: Neuromodulation through activity-dependent cortical electrical stimulation may improve neurorehabilitation outcomes by enhancing synaptic plasticity. Cortico-cortical evoked potentials (CCEPs) are a way to assess stimulation-induced changes in plasticity. Inspired by results from nonhuman primate studies, we studied beta-oscillation triggered cortical stimulation in humans.
Methods: Humans with epilepsy were implanted with electrocorticographic (ECoG) grids for clinical monitoring. The band-passed signal (12-20 Hz) at an electrode in somatosensory cortex triggered stimulation across a separate electrode pair. During periods of heightened oscillations, bipolar, biphasic conditioning pulses were delivered at 0°, 90°, 180°, 270° phases. Test pulses outside of conditioning were used to analyze conditioning effects on CCEPs using z-scored CCEP magnitudes. Resting state analyses were performed on 8 minutes of resting state data before and after stimulation.
Results: ANOVA revealed a dose-dependent enhancement of CCEPs. Within subject analysis revealed no clear phase dependence of stimulation and no consistent change in resting state rhythms as assessed by phase locking value in beta. Increased numbers of conditioning pulses delivered during beta-bursts resulted in greater enhancement of CCEPs relative to baseline. In general, the largest CCEPs and greatest enhancement were seen in the beta-recording channel, though effects were also seen on adjacent channels.
Conclusions: Beta-activity triggered cortical electrical stimulation in human subjects demonstrated enhancement of cortico-cortical evoked potentials, which are a marker of short-term plasticity.
Figure representing dose-dependent enhancement of CCEP magnitude. This example is at an electrode adjacent to the beta triggering electrode. No clear phase dependence is seen. Null indicates no conditioning stimuli delivered. The numbers in the legend indicate the number of conditioning stimuli delivered. Playback represents stimuli delivered irrespective of beta.

Title: Closed-loop neural interfacing strategies for the bladder

Authors: *T. J. RICHNER[1,2,3,6], B. J. MAHONEY[4,6], S. D. BOYER[2,6], V. RANGANATHAN[4,6], M. D. SUNSHINE[2,6], G. MOORE[5,6], R. SOLINSKY[2], G. D. HORWITZ[1,3], P. O. ANIKEEVA[7,6], J. R. SMITH[4,5,3,6], J. W. FAWCETT[8], C. T. MORITZ[2,1,3,6]; [1]Physiol. and Biophysics, [2]Rehabil. Med., [3]UW Inst. for Neuroengineering (UWIN), [4]Electrical Engin., [5]Computer Sci. and Engin., Univ. of Washington, Seattle, WA; [6]Ctr. for Sensorimotor Neural Engin. (CNSE), Seattle, WA; [7]Materials Sci. and Engin., MIT, Cambridge, MA; [8]Dept. of Clin. Neurosciences, Cambridge Univ., Cambridge, United Kingdom

Abstract: Neurogenic bladder, both overactive and underactive, has many causes including spinal cord injury, multiple sclerosis, stroke, spina bifida, and Parkinson's disease. Common to these causes is the loss of closed-loop control over the autonomic nervous system by the CNS. Closed-loop control is a feature of homeostasis and requires repetitive measurement, comparison to a set point, and fast actuation. The slow kinetics and lack of measurement by pharmaceuticals means that drugs are generally open-loop. Moreover, systemic drugs often have side effects caused, in part, by a lack of specificity. Encouragingly, the innervation of the bladder often remains intact despite injury or disease. In principle, a system that could record, stimulate, and block the neural activity of an innervated organ could reinstate closed-loop control and thereby restore homeostatic function.

We are developing a closed-loop bladder neuroprosthesis in the rat animal model. Our system features a neural interface and wireless record/stimulate control device. The neuroanatomy of the bladder offers five peripheral targets for interfacing (proximal to distal): the L6-S1 nerve trunk, the preganglionic pelvic nerve, the major pelvic ganglion (MPG), the postganglionic pelvic nerve, and the nerve endings on the bladder muscle. The proximal structures are large enough to cuff or insert probes, while the most distal structures are far too small. We are therefore investigating electrical interfaces in the proximal structures and optogenetics in the distal structures. Proximal structures are potentially less specific when stimulated, so we measured bladder pressure, colon pressure, and pelvic floor EMG while electrically stimulating each structure with a concentric electrical probe. We are also testing viral optogenetic delivery in the bladder muscle and directly to the MPG. We expect that a combination of electrical and optogenetic methods will be required to sufficiently control bladder pressure while avoiding off target effects in the nearby organs. In parallel, we built an implantable wireless device capable of recording electroneurography signals, applying current pulses, and driving LEDs. Our initial tests found that we could power the in vivo device inductively (300 mW for 60 seconds) without significantly heating the surrounding tissue. This charging period was able to power the device for several minutes, depending on LED parameters. Discovery both the principles of selective activation of visceral nerves, as well as implanted device development will lead to applications for bioelectronics medicines in the bladder and other organ systems.

Title: Cortical network changes in individuals learning a bimanual task in coordination with an electrocorticographic brain-computer interface.

Authors: *D. SARMA[1], J. WU[2], J. G. OJEMANN[3], R. P. N. RAO[4];
[2]Bioengineering, [3]Neurolog. Surgery, [4]Computer Sci. and Engin., [1]Univ. of Washington, Seattle, WA

Abstract: Introduction: There are large populations of patients that retain some residual natural motor function and who, even with degradation, could benefit from modulation through BCIs. An important question in evaluating the applicability of BCIs to real world bimanual natural movement is: can subjects use BCIs simultaneously coordinated with overt motor activity? Understanding the learning process and how the neural signal adapts during coordination, could be significant in development of BCIs.
Methods: 7 subjects with intractable epilepsy were implanted with electrocorticographic (ECoG) grids for clinical monitoring prior to surgery. g.USBamp biosignal amplifiers (g.Tec) were used to acquire neural signals from the ECoG electrodes. Subjects were trained to interact with a 2-D center-out cursor task in which y-velocity was driven by the modulation of high-gamma (70-200Hz band) activity in a single electrode over right motor cortex related to left-hand motor imagery and x-position was controlled by keyboard presses from the right hand. Eight targets, equidistant from center were radially distributed and randomly presented for 6 seconds at a time. Targets along xy-diagonals required coordinated control of right (overt) and left (imagined) hand behaviors.
Results: In preliminary analysis, one subject, with lifelong hemiparesis, achieved accurate and precise control despite confounding neural activation from ipsilateral motor activity (Figure 1). As user-control improves, high-gamma activation patterns consolidate over time as per target y-axis modulation requirements (y+/y-), countering the significant HG activations related to the right hand motor activity (x+/x-). HG activation across cortical areas also changes in relation to strength of modulation in the control channel.
Conclusion: Subjects' ability to modulate and adapt their HG signal despite confounding

ipsilateral interference underscores the utility of BCI-training even with damaged cortical areas. These results provide steps towards adapting BCIs for dexterous coordinated bimanual control.

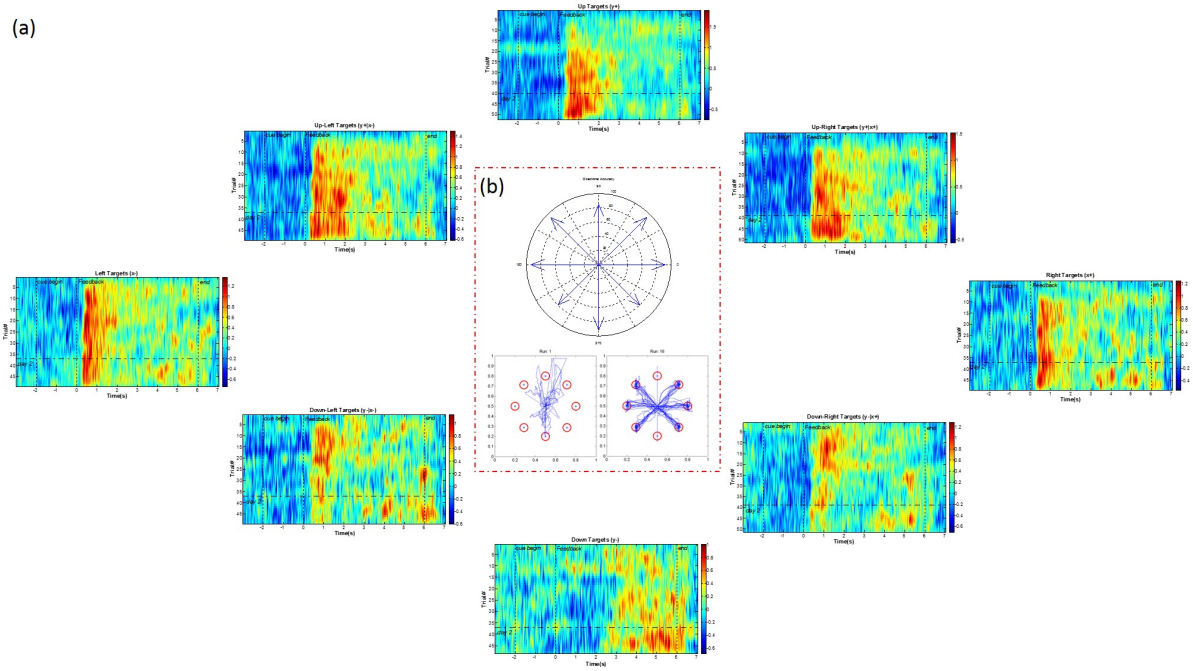

Figure 1 - Trial by Trial HG activation at BCI Control Channel. Recordings were common-average re-referenced over the whole grid. Channel data was band pass filtered for the high-gamma (HG) range (70-200 Hz) using a fourth-order Butterworth filter. A time variant estimate of the HG-band power was calculated from the square of the magnitude of the Hilbert Transform. Data was then log normalized and further z-normalized with respect to the rest (behaviorally quiescent) periods. The HG activation for each trial, concatenated top to bottom, is plotted as an image for each target (in relative spatial orientation). (a) Subject initially had extremely poor performance with left-hand motor imagery. As subject improves, HG activation is seen to increase over the trials, but only in relation to the feedback cue, indicating purposeful modulation. HG suppression or reduction is seen to increase over the trials as control improves for downwards imagery control. For the x+/x- only targets along the horizontal, the right hand key presses result in a HG activation starting from the feedback cue, continuing as right-hand behavior is re-triggered to fight the gravity element along the x-axis. For the up diagonal targets, as control improves, HG activation increases, though activation due to key presses persists. This ipsilateral HG Activation is similar over the trials for the down diagonal targets as well. As control improves, HG activation decreases, though activation due to key presses persists. However, this decrease mirrors the HG decrease for the Down targets and is inverse of the activation pattern for Up Diagonals. (b) Center-inset: the average Directional Accuracy is shown for all targets, plotted radially. In addition, traces of the real cursor behavior are plotted from the first and last runs the subject performed, showing the difference in trajectories between final and initial control.

Title: Controlling false positives on a BCI implant for communication

Authors: *M. P. BRANCO[1], Z. V. FREUDENBURG[1], E. G. M. PELS[1], E. J. AARNOUTSE[1], S. LEINDERS[1], M. A. VAN DEN BOOM[1], T. DENISON[2], M. J. VANSTEENSEL[1], N. F. RAMSEY[1];
[1]Brain Ctr. Rudolf Magnus, Univ. Med. Ctr. Utrecht, Utrecht, Netherlands; [2]Medtronic Neuromodulation, Minneapolis, MN

Abstract: Electrocorticography-based Brain-Computer Interfaces (BCI) are an emergent technology that enables paralyzed patients to restore or replace motor function. Up until now, most BCI systems report classification accuracies ranging from 75 to 90%. However, when aiming for spelling with an implant, 90% accuracy is not good enough. Recently, a fully implantable BCI communication system (Utrecht NeuroProsthesis, UNP) was implemented, which translates neuronal activity elicited upon hand attempted movements into a binary control signal for selection of characters in spelling software.
The UNP system was implanted in a locked-in patient who suffers from late stage Amyotrophic Lateral Sclerosis, with a four-electrode strip covering hand sensorimotor cortex. The best bipolar pair was chosen based on the best R^2 response to a motor localizer task, where the patient alternated between trials of attempted movement and rest.
A standard Cursor Pong task (in BCI2000) was used to estimate the optimal signal processing parameters for a one-dimensional continuous control signal. Across several months the average Pong performance using high-frequency broadband power (65-95 Hz) was 90.73±6.42 % (N=70 runs), which is significantly above chance (50%, $p<0.01$). However, the same set of parameters used for the Pong task showed an unexpected large number of false positives (FP) during a spelling task where a power value exceeding a set threshold was translated to a binary active state, which was converted to an item selection (click). There were on average 2.26 FP/min (N=20 7-letter words), yielding a FP rate of approximately 30% and a true positive (TP) rate of 88%. To reduce the FPs, while preserving the TPs, a number of strategies were applied: 1) the signal threshold for determining binary active state was adjusted; 2) a smoothing filter was added to reduce the rate of spurious active states; 3) an additional narrowband power channel (beta, 20±2.5 Hz) was added to the control signal with an unitary negative weight; 4) and, finally, the number of consecutive active states required to generate a click was increased.
Results indicate that changes in the threshold reduce both TPs and FPs. By smoothing the data TPs were preserved while the rate of FPs declined slightly. The addition of the beta signal showed a clear improvement from previous strategies. Finally, increasing number of active states required for a click improved performance, but did so at the expense of increased patient effort. A compromise was reached where effort was acceptable while performance was improved, resulting in a score of 1.14 FP/min (N=13, 5-letter words, resulting FP-rate of 16%), while keeping TP rate at 88%.

Title: Autonomous communication at home by a person suffering from Locked In Syndrome achieved with a completely implanted permanent Brain-Computer Interface system

Authors: ***N. F. RAMSEY**[1], M. J. VANSTEENSEL[2], E. PELS[2], S. LEINDERS[2], M. P. BRANCO[2], M. A. VAN DEN BOOM[2], T. DENISON[3], E. J. AARNOUTSE[2];
[2]Neurol. and Neurosurg., [1]Brain Ctr. Rudolf Magnus, Univ. of Utrecht, Utrecht, Netherlands; [3]Neuromodulation, Medtronic, Minneapolis, MN

Abstract: People with Locked In Syndrome are not able to communicate at their free will. They can interact by means of very basic channels such as eye blinks to indicate yes or no to closed questions and as such depend heavily on their caregivers. We here report on the first Brain-Computer Interface system that is fully implanted (sensors, amplifiers, signal processing and transdermal wireless transmission) (Investigational Activa PC+S and Nexus System by Medtronic) and enables the user to generate binary signals with which dedicated ‘switch’

software such as a speller can be used autonomously without expert assistance.
A 58 year old women in late stage of Amyotrophic Lateral Sclerosis underwent surgery for placement of several 4-electrode strips under the dura. The exact location of electrodes was based on the combination of a 3T fMRI scan for attempted right-hand movement with the typical location of the hand knob on motor cortex. Strips were positioned through accurately planned burrholes, under the dura. Strips were connected to the device which allowed for bipolar signal acquisition within strips.
After surgery there were no visible signs of the implant, meeting the wish of the patient. During 2 meetings per week (6 months per may 2016), the team visited the patient at her home for testing the system with 4 types of tasks, each designed to address specific features of the bipolar brain signal generated by attempting to make one or more hand movements (fingertapping). Tasks were: the widely used Pong task (general BCI control), a cueing task with short and long 'active states' where the patient was required to regulate the duration of activation (timing properties), an item selection task with scanning software (reliability of decoding), and spelling to test the BCI system for real-life use.
The patient regarded participation as highly motivating due to continuous improvement of performance, in part due to her training but mostly due to development, implementation and optimization of multiple filters for transformation of raw brain signals to a control signal. With deteriorating residual communication capability (minimal speech, eye tracking) she expects to rely on the system for communication in the near future and has started to use the speller autonomously at home without the presence of the research team.
These results indicate feasibility of offering Locked In patients a new means of communication. Mass production of the device, currently a commercially manufactured investigational device, is expected to make the system affordable for a wide range of candidates, and surgery is expected to be straightforward and efficient (4 hours in OR, 3 days of admission to the ward)

Title: Demonstration of minimal invasive surgery for an invisible, permanent Brain-Computer Interface

Authors: *E. J. AARNOUTSE[1], M. J. VAN STEENSEL[1], E. G. M. PELS[1], T. DENISON[2], B. H. VERWEIJ[1], P. GOSSELAAR[1], P. C. VAN RIJEN[1], N. F. RAMSEY[1];
[1]Brain Ctr. Rudolf Magnus, Utrecht, Netherlands; [2]Medtronic Neuromodulation, Minneapolis, MN

Abstract: Increasingly, researchers and users appreciate that an implanted Brain-Computer Interface (BCI) for communication has merits over a non-invasive BCI, such as EEG or NIRS, even when the control signal would be equally reliable. Users of a BCI for communication, e.g. Locked-in patients, benefit from a permanent solution to use at home, with minimal requirements of expertise and time of caretakers. At the same time users feel very strong about esthetics, so a BCI device ideally is invisible (Nijboer et al, 2014). An implanted BCI fits both requirements, but the prerequisite of acceptance of implanting a BCI under the skull is a minimal invasive approach. We have demonstrated that it is feasible to implant a BCI which is permanent, invisible and easy to use.
A 58-year-old female late stage ALS patient, on invasive mechanical ventilation, participated in our study. Functional MRI was used to localize the exact location of the regions with highest activity in a motor task (fingertapping) and working memory task (mental calculation). The peak t-values within the predefined areas of interest were identified ("hotspots") and electrode strip (four electrodes) positions were chosen to cover the hotspots maximally. During electrode implant surgery a question mark incision was made to lift part of the scalp from the skull. Five 1 cm burr holes were made guided by the intraoperative neuronavigation system using the 3D cortical surface renderings with the hotspots and planned locations of the burr holes superimposed. Electrode strips were guided subdurally between two burr holes and fixated. We also implanted two spare electrode strips near the hotspots. Subsequently, leads were tunneled to the thorax and extended with temporary leads that externalized through the abdominal skin. After electrode implant surgery, the subject repeated the localizer tasks to select the strips with highest correlation of the bipolar ECoG signal in the gamma frequency range with the task. In a second surgery we attached two electrode strips to an Activa PC+S neurostimulator (Medtronic) with sensing capabilities, implanted subcutaneously in the thorax.
CT images aligned with the fMRI t-value map show positioning of electrodes within 2 mm over the hotspots. During electrode selection ECoG measured between bipolar electrode pairs was highly correlated with the task (r2=0.93). Correlation analysis between t-values and the gamma signal from bipolar electrodes measured with the Activa PC+S showed a high correlation (r2=0.85).
In conclusion, this is a first demonstration that minimal invasive surgery can be used to implant an invisible, wireless, permanent BCI to be used at home by a user for communication.

Title: ECoG control signal optimization for use of a communication BCI implant in a person with Locked-In Syndrome

Authors: *Z. V. FREUDENBURG[1], M. P. BRANCO[2], E. J. AARNOUTSE[3], S. LEINDERS[2], M. A. VAN DEN BOOM[2], T. DENISON[4], M. J. VANSTEENSEL[2], N. F. Rudolf Magnus, Utrecht, Netherlands; [4]Medtronic Neuromodulation, Minneapolis, MN; [5]Univ. Med. Ctr. Utrecht, Brain Ctr. Rudolf Magnus, Utrecht, Netherlands

Abstract: For continuous real-life use of a BCI implant the standards of performance are much higher than those needed for proof on concept in a controlled lab setting. Optimal neural control signals in real-life use can differ significantly from those established for short experiments in the lab given the requirement for reliable and robust decoding for daily use. In this context it is important to characterize the timing and duration of single intentional brain events used to drive the BCI, and find the optimal signal features.
The Utrecht Neural Prosthesis (UNP) is a fully implanted communication BCI based on bi-polar ECoG signals recorded from the primary motor cortex (Investigational Activa PC+S and Nexus System, Medtronic). A subject in late-stage ALS using the UNP generated a large number of cued short intentional neural events with 3-5s intervals by attempting single hand movements in a task repeated over many sessions across days and weeks at the home.
In this context we investigate the characteristics on the impulse response of several often used electrophysiological bandlimited control signal features (mu (6-12Hz), beta1 (13-16Hz), beta3, (21-30Hz) and high frequency broadband HFB (37-90Hz) neural activity [1]) to single generated

neural events. We then evaluated reliability of the responses for these deliberate events for each bandwidth separately and for combinations thereof.
As expected, the lower frequencies displayed a strong and highly significant drop in power following the cue, whereas the HFB significantly increased in power. The lower frequencies also displayed a distinct rebound response with power significantly exceeding baseline levels. Timing of the bandwidth responses differed between bands, with mu, beta 1 and beta 3 starting to decline immediately after the cue, versus HFB increasing at approximately 0.8 s after the cue. All signal features returned to baseline at approximately 2.6-2.8 s after the cue. The low frequency rebound peaked at about 4 s after the cue. A combination of the features, notably beta3 and HFB, increased significance of the response and improved the reliability of detecting the response against baseline. The rebound contributed to a rapid termination of the combined response, thereby improving control in BCI application such as a spelling device
Our results demonstrate the advantage of combining the beta3 band, associated with task related attention, with the HFB, associated with increased neural activity, to improve the detectability of the neural impulse response. Combined features proved to contribute to a more reliable BCI control signal

Title: A flexible modular neural recording and stimulation system for both surface and penetrating electrodes

Authors: *R. LILJEMALM, T. STIEGLITZ;
Univ. of Freiburg, Freiburg, Germany

Abstract: As the technology for miniaturization of bioelectronics is making progress, the interest for high density electrode recordings in the neural systems increase. A modular system

that can easily be expanded to the desired number of electrodes would be beneficial with that in mind. A high density electrode implant would also increase the possibility to choose specific electrodes, e.g. in the proximity of the desired neural target, or active sites instead of silent. Furthermore, a system that uses surface electrodes, but at the same time allows the use of penetrating probes would make it highly adaptable to the need of the researcher, for studying cortical activity in the brain. In our group we have developed several structures based on the polymer polyimide, which is a flexible, stable and biocompatible polymer, therefore excellent for neural probes, especially for chronic applications with high demands on reliability. We present a modular polyimide based implant for cortical surface recordings of neural activity. Furthermore, the implant design offers the possibility to also use penetrating probes for in-tissue recordings.

Title: Multi-channel neural logger for recording neural activity in free behavior non-human primates.

Authors: *F. DE CARVALHO, W. XU, A. JACKSON;
Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: Advances in chronic electrode arrays allow action potentials to be recorded from multiple neurons in freely behaving animals. However, long-term continuous recording in non-human primates remains a challenge since wireless systems typically have a limited communication range and battery lifetime. Therefore, to obtain continuous recordings from large numbers of neurons during free behaviour and sleep we have developed a custom battery-powered neural data logger. The device uses an off-the-shelf microcontroller (STM32F415) and two INTAN amplifiers to record 8 channels at 20 kHz (for spikes) and 32 channels at 1000 Hz (for local field potentials) with 16 bit resolution. Data is stored to 64 GB flash memory (µSD card) and subsequently transferred to a computer for off-line analysis. Two 3.6V, 1800mAh Li-Ion batteries (Ultralife UBP001) allow continuous recording for up to 28hrs. Neural activity was recorded over a 24-hour period from the primary motor cortex of freely behaving macaque monkeys. During the night, the local field potential revealed cyclic transitions between slow-

wave sleep (high delta power) and REM sleep (low delta power). The firing rates of most neurons were elevated during REM periods. During slow-wave sleep, the neural spiking was strongly phase-locked to low-frequency local field potentials. We have successfully recorded local field potentials and stable spike activity from multiple neurons continuously over 24 hour periods. Initial analyses reveal the known architecture of brain activity during sleep. This technology will enable studies of network dynamics across multiple behavioural states and the mechanisms of memory consolidation.

Title: Implanted brain-computer interface signal stability over time

Authors: *E. G. M. PELS[1], E. J. AARNOUTSE[1], S. LEINDERS[1], Z. V. FREUDENBURG[1], M. P. BRANCO[1], M. A. VAN DEN BOOM[1], T. DENISON[2], M. J. VANSTEENSEL[1], N. F. RAMSEY[1];
[1]Brain Ctr. Rudolf Magnus, Univ. Med. Ctr. Utrecht, Utrecht, Netherlands; [2]Medtronic Neuromodulation, Minneapolis, MN

Abstract: In recent years implanted Brain-Computer Interfaces (BCI) gained more interest. Relying on implanted electrodes these systems carry the advantage of brain signals gathered at the source. Successes in this field have been reported in controlling robotic arms, intended for severe paralysis or arm amputation. For people who have lost most or all ability to communicate, a BCI implant for communication would meet the most important of their needs. The Utrecht NeuroProsthesis (UNP) is designed to restore communication by means of item selection in spelling software, and is completely implanted. Here we report on the stability of signals obtained from the first person implanted with the UNP.
The UNP consists of two four-electrode ECoG-strips connected to an implanted amplifier/transmitter (AT-device; Investigational Activa PC+S and Nexus System, Medtronic). The strip reported here is placed over the left hand sensorimotor cortex. The AT-device amplifies the signal and sends it wirelessly to a computer outside the body. Adapted BCI2000 software is used to analyze and process the signal further.

For this study, a partially locked-in patient (58-year-old female) who suffers from late stage Amyotrophic Lateral Sclerosis (ALS) was implanted with the device. The best performing bipolar electrode pair within the strip was selected based on the correlation of the signal (high frequency band power, 65-95 Hz) with task conditions (expressed as R^2) in a localizer task. For this, the patient alternated attempted movements with rest periods.
At home, weekly repetitions of the localizer tasks, measured in time-domain, enabled us to track R^2 over time, as an indication of signal stability. Additionally, the patient learned to control her brain signal using a one-dimensional continuous cursor control task ('Pong'; measured in the energy saving power-domain), where she had to hit a target at either the top or the bottom of a screen.
The results of the localizer task show a slight increase in R^2 over time (0.88 to 0.93 in 6 months for the bipolar used), and stable baseline power in the gamma band (0.486 ± 0.063 a.u.) indicating that the implanted electrodes are durable and information transfer is preserved. The results from the Pong, however, show a fluctuation in the baseline gamma-band power of 5.7%. The cause of this variation is uncertain but possibilities include temperature, level of fatigue and circadian rhythm. Calibration during each session, nonetheless, solved this issue and the average performance over 6 months with sensorimotor control was $90.73 \pm 6.42\%$, which is significantly above chance (50%, $p<0.001$).

Title: OMNI: A distributed and modular device for wireless neural recording and closed-loop neuromodulation

Authors: *G. ALEXANDROV[1], S. R. SANTACRUZ[2,1], A. MOIN[1], A. J. ZHOU[1], F. BURGHARDT[1], B. C. JOHNSON[3], E. ALON[1], J. RABAEY[1], J. M. CARMENA[2,1], R. MULLER[1,3];
[1]Dept. of Electrical Engin. and Computer Sci., [2]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [3]Cortera Neurotechnologies, Berkeley, CA

Abstract: Technology for chronic neural recordings in humans is limited and tends to be constrained by elements such as low channel counts, minimal flexibility in signal acquisition specifications, and wired connections. Recordings in nonhuman primate (NHP) subjects also typically rely on wired connections, restricting the ability to record during natural behavior. To resolve these impediments, we have developed OMNI, a wireless and autonomous neurotechnology for continuous high-throughput streaming of neural data. The OMNI device features reconfigurable stimulation units that can be dynamically assigned to any electrode, as well as components to support closed-loop neuromodulation and behavioral state classification, eclipsing current commercial implantable technology.
The OMNI device has been deployed in one NHP subject for continuous cortical and subcortical recording during free, natural behavior, as well as closed-loop microstimulation. Neural data was synchronized to behavioral events (wake/sleep transitions) using the accelerometer and gyroscope incorporated in the technology. The OMNI device was utilized in this pilot study to determine sleep states, stimulate target sites with implanted microelectrodes at certain detected time points, and simultaneously record local field potential (LFP) activity in corticostriatal circuitry. LFP signal fidelity was preserved in the streamed data compared to data acquired in a standard cabled electrophysiology equipment. Features of the LFP signal were used to determine the closed-loop stimulation protocol for administration of constant-current biphasic pulses. The realization of this pilot NHP study attests to the comprehensive functionality of the OMNI device.

Title: A real-time sense-and-stimulate intracranial system detects and slows impending movements

Authors: *B. D. MOORE, IV[1], A. R. ARON[2], N. TANDON[1];
[1]Neurosurg., Univ. of Texas McGovern Med. Sch., Houston, TX; [2]Psychology, UCSD, San Diego, CA

Abstract: A major goal of recent work in human neural prosthetics is to deliver stimulation to neural circuits in a manner time locked to ongoing activity. It is well known that voluntary movements are preceded by motor planning related activity in the supplementary motor area (SMA). This lag between neural activity and observable behavior provides a test bed for the development of a decoding system that can then be used to control an external device. Here we tested a method that aimed to detect impending activity in the SMA and then deliver direct cortical stimulation to influence behavior on the same trial.
We focused on electrodes placed in the SMA in a cohort of 4 patients undergoing invasive surgery for treatment of refractory epilepsy. First, the patients performed a task that involved a series of bilateral finger movements. On each trial a cue instructed them to move their fingers in a coordinated sequence. Electrocorticographic (ECoG) signals recorded from electrodes in the SMA were analyzed for pre-movement gamma frequency power increases. We then configured a closed loop control system to detect and quantify gamma power changes in real time. When gamma power exceeded a pre-defined threshold, a transient electrical stimulus was delivered to SMA electrodes. Control and stimulation trials were randomly interleaved such that both patient and experimenter were double-blinded to trial type. The dependent measure was the reaction time measured when the contralateral hand first pressed a button. In a separate experiment carried out in each patient, stimulation was delivered chronometrically, based only on the anticipated time of movement initiation and independent of the detection of pre-movement activity.
Subsequent analysis of the ECoG signal showed that in three of the four patients, the system successfully detected pre-movement gamma activity in the SMA. In these three patients, stimulation based on the detection of this activity resulted in significant slowing of behavior in stimulated versus control conditions (mean for three subjects: 100 ± 19 ms, all < 0.05). Similarly, chronometric stimulation also resulted in significantly delayed behavioral responses (mean for three subjects: 289 ± 25 ms, all < 0.001). The timing of chronometric stimulation was much closer to movement execution, possibly accounting for the larger effect. At the current time, not much is known about when and how to perform real time modulation of endogenous brain activity to alter behavior. Our results show that, within a trial, impending movement can be detected and used to trigger direct current stimulation of SMA to influence ongoing motor behavior safely and in a manner imperceptible to the subject.

Title: Wireless implantable multichannel myoelectric system with infrared data transmission

Authors: *D. R. MERRILL, S. HIATT, B. CROFTS, C. SMITH, K. S. GUILLORY, D. MCDONNALL;
Ripple, Salt Lake City, UT

Abstract: Modern hand and arm prostheses provide multiple degrees of freedom (DoF) of motion, yet their use is severely limited by the biological control interface. Current prostheses are controlled by EMG signals recorded from surface electrodes on the residual limb. These recordings are a composite of signals from several muscles and typically do not provide enough independent sources for simultaneous multi-DoF control. Additionally, the surface recording sites are unreliable. These impediments limit transradial prostheses to two DoF with sequential control. Ripple has developed an implantable system which simultaneously records 32 channels of myoelectric data from multiple residual muscles, and transmits these data to an external transceiver placed in the prosthetic socket. Our objective is to provide simultaneous multi-degree of freedom prosthesis control, ultimately providing an intuitive control experience. This approach supports a high number of independent control signals and provides access to EMG from deep muscles that cannot be accessed with surface electrodes. The system comprises a hermetic implanted module from which nine EMG leads emerge. Eight of the leads contain four electrode sites each for 32 total recording channels. A ninth lead provides the reference electrode. The implant receives power inductively from an external transceiver and sends digitized EMG data to the external transceiver via infrared light. By using a single subcutaneous module for telemetry from which several leads emerge, power coupling efficiency remains high. We have demonstrated high data rate transmission using infrared light in chronically implanted canine. Devices were implanted in deltoideous and the long and lateral heads of triceps. Recorded EMG demonstrate very low noise and clearly indicate antagonistic activity of the gait muscles. We have completed initial safety and performance testing. These efforts demonstrate the ability to amplify and transmit muscle signals and confirm safety and performance requirements. This approach has the potential to provide simultaneous multi-degree of freedom prosthesis control, especially if used with advanced hand and arm prostheses, targeted muscle reinnervation patients, and recently developed pattern recognition algorithms.

Title: Development of cortically-controlled muscle stimulation to restore treadmill locomotion and overground navigation in spinal cord injured rats

Authors: *A. A. KINKHABWALA, M. K. JANTZ, J. A. GALLEGO, T. A. VERNON, M. C. TRESCH, L. E. MILLER;
Physiol., Northwestern Univ., Chicago, IL

Abstract: We have shown previously that FES (functional electrical stimulation) driven by neural activity in the motor cortex can be used to reestablish the ability to grasp and move objects. That work, in monkeys, used only temporary paralysis induced by peripheral nerve block. In order to move this technology closer to clinical application we have begun developing similar methods to restore locomotion to rats with spinal cord injury (SCI).
We are developing techniques to predict muscle activity during locomotion from cortical activity and to restore functional hindlimb movements with FES. We are using a Plexon MAP system to record neural activity from 32 channel microwire arrays implanted 1.4-1.6 mm below the cortical surface in the hindlimb motor cortex, and examining the modulation of neurons beginning several days after surgery. Neural activity is recorded while rats run on a treadmill (Columbus Instruments) or along a custom built hallway. Hindlimb kinematics are measured with a Vicon system along with cortical activity with the rats running either on a level or inclined treadmill, or moving freely along the hallway. Obstacles added to either of these arenas require the rats to plan and execute more complex, cortically-dependent movements. We extract functional parameters from the recorded kinematics to characterize the locomotion and then relate these parameters to the simultaneously recorded cortical activity. Preliminary results show a good modulation of single and multiunit cortical activity to the kinematics of the ongoing locomotor cycle. Our goal is to characterize the information content of the cortical activity under different

locomotor conditions and evaluate its adequacy to serve as an FES control signal.
In parallel, we are using a real-time controllable 16 channel stimulator from Ripple to deliver FES to multiple hindlimb muscles. We monitor the kinematics of evoked movements to evaluate the efficacy of the FES. We have begun by using EMG signals recorded during locomotion from intact rats to specify the FES patterns. In initial experiments, we have been able to produce basic flexion/extension cycles similar to those observed during locomotion. Our goal is to optimize muscle stimulation in order to produce appropriate locomotion movements and ground reaction forces while minimizing fatigue.
Ultimately, we will use the estimates of motor intent obtained from cortical recordings to specify the FES control signals in animals with spinal cord injury, enabling restoration of voluntary locomotion and potentially facilitating functional rehabilitation.

Title: Body-wearable platform for un-tethered, closed-loop stimulation and recording for BCI and neuroprosthetic research with hundreds of electrodes

Authors: *S. HIATT, T. POULSON, E. BARCIKOWSKI, R. ROUNDY, S. BARRUS, C. SMITH, A. WILDER, K. S. GUILLORY, D. MERRILL, D. MCDONNALL;
Ripple, Salt Lake City, UT

Abstract: Human neuroprosthetic research has demonstrated potential major improvement in the quality of life for patients with severe neural impairments. This work has primarily been confined to short laboratory-based sessions due to the size and lack of integration of the instruments required and the computational burden of these applications. Advances in this field require new systems that enable experimental designs focused on real-life unscripted patient activities.
Ripple has been developing the core technologies necessary to facilitate un-tethered ambulatory studies with hundreds of bio-potential recording channels combined with researcher-specified on-board processing algorithms and control of hundreds of independent stimulation channels.

We have developed a wearable neural interface system from these core technology components that meets the size, weight, and performance required for on-subject portability. The device has an internal battery to facilitate short-duration un-tethered subject movement, and with options to attach additional batteries to facilitate longer term portable use. An internal hard drive is included for logging of full bandwidth data and algorithm performance metrics. Wireless interfaces (WiFi and Bluetooth) provide experimenters real-time access to data and control of tunable processing parameters.
This work is being completed in compliance with IEC 60601-1 and portions of IEC60601-2 that are applicable to the instrument, with FDA QSR Title 21, Part 820, ISO 13485, and ISO 14971 and we anticipate a version of the device to be cleared for human use in the US and Europe.

Title: A neuromodulation integrated circuit for high-channel count, bidirectional, and minimally invasive neural interface.

Authors: *S. JUNG[1], T. L. HANSON[2], E. ALON[1], J. RABAEY[1];
[1]Electrical Engin. and Computer Sci., Univ. of California, Berkeley, Berkeley, CA; [2]Univ. of California, San Francisco, San Francisco, CA

Abstract: With a desire to better understand the brain, there have been continuous efforts to develop neural interfaces that support 1) fine (microsecond, micrometer) and broad (year, centimeter) coverage, 2) simultaneous bidirectional communication (recording and stimulation), and 3) minimally invasive hardware. We present a building block toward such a system: a low-power, low-area, high-channel count neuromodulation integrated circuit (IC) for both recording and stimulation. These ICs are controlled via a field programmable gate array that communicates with them via an efficient time-multiplexed serial protocol. The FPGA in turn is linked to a PC for analysis and closed-loop experiments via full-duplex gigabit Ethernet. This tightly integrated system realizes the microelectronics part of a thousand-channel bidirectional neural interface. As a key module in the designed interface system, the IC has state-of-the-art features: energy-efficient programmable 64 recording channels (<3uW/channel); programmable stimulators (variable shape, amplitude, pulse width, and pulse rate); and programmable compression filters for action potential extraction. These tight integration works make the IC an ultra-low power (200uW on average) low-area (4.78mm^2) signal processing hardware. By wire-bonding this IC on a small printed circuit board along with directly bonded fine-pitch electrodes, we are on track to realize a fully miniaturized implant device. All the integrated elements are anticipated to yield improved safety, longevity, robustness, and lower infection risk.

Abstract: Brain Machine Interfaces (BMIs) have demonstrated great potential for generating prosthetic control signals. However, current BMIs still require transcutaneous leads connecting indwelling electrodes to recording devices outside of the body. Several fully implantable, wireless systems have been designed to improve clinical viability, but are limited by high signal bandwidth requirements. The Networked Neuroprosthesis (NNP) developed at Case Western Reserve University is a system of implantable modules that can perform combinations of neural stimulation and recording for controlling grasp and other motor functions. The existing capabilities are not sufficient for intracortical recording; however, the architecture was designed to accept new modules with added functionality. As an extension to the NNP, we have designed a custom module to record neural data from a 96-channel Utah array and generate command signals for grasping using low power circuitry and spiking band techniques as seen in Stark and Abeles (2007). A six layer printed circuit board was designed to be compatible with the existing NNP hardware and software. The module is designed to fit the dimensions of a 1x4 cm flexible PCB. The electronics consist of off the shelf components: primarily, three 32-channel Intan bioamplifiers and a 32-bit Atmel microcontroller (MCU). The bioamplifiers can record from 96 channels in total with 16-bit ADC resolution. The MCU serves as the data processor and central controller, configuring amplifier settings and communicating with existing NNP modules. Testing was performed by exercising the amplifiers, using simulated neural data from a Blackrock Neural Signal Simulator. The required amplifier power was reduced by extracting the signal power in the 300-1kHz frequency band and using a sampling frequency of 2kSps for each channel. Amplifying and digitizing 96 active channels used only 14.8mW. Decoding performance was investigated using neural data previously recorded during motor and sensory experiments and resampled at 2kSps to validate the spiking band technique used to lower power requirements in our device architecture. Using linear discriminant analysis, we performed a 1of 3 classification to predict either finger flexion (97.6% correct) or finger stimulation (97.9% correct). This suggests that extracting signal power within this band is effective for decoding while saving significant power. The device is currently undergoing preliminary bench top testing to optimize settings and reduce power consumption. This low power neural recording module along with the existing NNP represents a path towards a fully implantable cortical BMI system.

Title: Time-dependent bilateral cortical plasticity parallels locomotor recovery after unilateral spinal cord injury in rats

Authors: *A. R. BROWN[1,2], M. MARTINEZ[1,2];
[1]Dept. de Neurosciences, Univ. de Montréal, Montreal, QC, Canada; [2]Ctr. de recherche de l'Hôpital du Sacré-Coeur de Montréal, Montréal, QC, Canada

Abstract: After an incomplete spinal cord injury (iSCI), supraspinal structures, which initiate movement, and spinal circuits, which generate them, remain partially connected through residual descending pathways. In this scenario we and others have shown that, even after extensive iSCI that disrupts all sensorimotor tracts on one side (hemisection at thoracic level), animals recover locomotion spontaneously. The contributing neural structures and neuroplastic mechanisms supporting locomotor recovery are poorly understood. By using a combination of intracortical microstimulation (ICMS) and behavioural techniques, we evaluated the cortical mechanisms of hindlimb locomotor recovery for 12 weeks after a spinal hemisection at T8 in rats. In intact rats, the location and size of the hindlimb representation within the motor cortex (hindlimb motor map) was consistent between animals, and hindlimb motor maps contained representations of contralateral hindlimb joints exclusively. After iSCI, rats exhibited hindlimb locomotor deficits on the side of the lesion with a plateau in recovery developing by 5 weeks. During the early recovery stage (first 3 weeks), the representation of the affected hindlimb disappeared within the contralatesional (de-efferented) cortex and emerged within the ipsilesional motor cortex. Specifically, ICMS applied on the ipsilesional motor cortex evoked movements of both hindlimbs, indicating that, after iSCI, the ipsilesional motor cortex functionally reorganizes to encode bilateral hindlimb movements. By the fourth week of recovery, the ipsilesional motor cortex lost its ability to produce bilateral movements and regained its normal control over the contralateral (non-affected) hindlimb. During the late recovery stage (12 weeks), the

representation of the affected hindlimb re-appeared within the contralesional cortex. These data suggest that the recovery involves the ipsilesional motor cortex during the early recovery stage and the contralateral motor cortex during the late recovery stage. These dynamic plastic changes in motor cortical areas may represent an adaptive strategy for functional compensation after SCI that would ultimately help identifying therapeutic strategies to harness cortical activity and catalyze functional recovery following iSCI.

Title: Short-term effect of repetitive electrical nerve stimulation on spinal reciprocal inhibition depends on the phase of passive stepping.

Authors: *H. OBATA[1], T. OGAWA[2], T. KITAMURA[3], N. KAWASHIMA[4], K. NAKAZAWA[2];
[1]Kyushu Inst. of Technol., Kitakyushu-Shi, Japan; [2]The Univ. of Tokyo, Tokyo, Japan; [3]Tokorozawa, national rehabilitation center for persons with di, Japan; [4]national rehabilitation center for persons with disabilities, Tokorozawa, Japan

Abstract: Introduction: Combination of electrical nerve stimulation (ES) and passive or active intermittent movements (i.e., pedaling and stepping) has been suggested to induce stronger short-term effect in the spinal circuits compared to either intervention alone. The purpose of the present study was to determine whether the effects of electrical stimulation and passive stepping are dependent on the phase of the stepping. Methods: In 10 healthy subjects, two interventions were assessed at intervals of over 1 week between interventions. ES to the common peroneal nerve (CPN) at the motor threshold intensity was applied during 1) swing phase (SW intervention); and 2) stance phase (ST intervention) of passive ground stepping for 30 min. We measured the H-reflex in the soleus muscle and spinal reciprocal inhibition from the tibialis anterior muscle before (baseline), as well as 5, 15 and 30 min after each intervention. Spinal reciprocal inhibition was assessed by conditioning the soleus H-reflex with ES to the CPN. Results: The amount of spinal reciprocal inhibition was significantly increased 5 and 15 min

after the SW intervention as compared to the baseline values ($P < 0.05$). The ST intervention did not have an effect. Neither intervention affected the H-reflex amplitude in the soleus muscle. Conclusion: These results show a phase-dependent effect of ES of the CPN on spinal reciprocal inhibition during passive stepping. Significance: The results suggest that phase-dependent timing of ES during intermittent passive movement is important for inducing changes in the spinal circuits.
