Abstract: Background: We have previously reported functional recovery in rodent spinal cord injury (SCI) models following human induced pluripotent stem cell-derived neural stem/progenitor cell (hiPSC-NS/PC) transplantation. In certain cell lines, however, there have been reports of tumorigenicity, which has raised the issue of "safety". Thymidine kinase/ganciclovir -mediated (TK/GCV) suicide is a system whereby the herpes simplex virus thymidine kinase (HSV-TK) converts ganciclovir (GCV) into a toxic product, which allows selective elimination of TK+ cells. The aim of this study is to evaluate the use of suicide gene therapy as a failsafe mechanism for tumorigenic changes following hiPSC-NS/PC transplantation for SCI. Methods: Efficacy of TK/GCV *in vitro* - A lentiviral vector was employed to introduce the HSK-TK gene into hiPSC-NS/PCs derived from a cell line that is known to have a high risk of tumorigenicity (Nori et al, 2015). Differentiation was induced by culturing these hiPSC-NS/PCs without FGF and LIF. Five days after the induction, GCV was administered to trigger

the apoptosis. Efficacy of TK/GCV *in vivo* - hiPSC-NS/PCs with the HSV-TK gene was transplanted into the injured spinal cord of NOD/SCID mice nine days after the injury. Eight weeks following the transplantation, GCV was intra-peritoneally administered for three weeks (GCV+ group). A control group was produced at the same time(GCV- group). Bio-imaging was used to monitor and compare cell proliferation through photon counts. Results: *In vitro* - When the cells were cultured with GCV, the nestin positive cells had noticeably decreased (GCV(+)18% vs GCV(-) 68%). With Tuj-1 positive cells, however, the drop was less pronounced (GCV(+) 58% vs GCV(-) 80%). *In vivo* - The photon count gradually increased in all mice transplanted with the hiPSC-NS/PCs. GCV+ group showed a decrease in the photon count ($-5.7x10^6$) whereas in the GCV- group, the photon count continued to increase ($+1.8x10^7$). Conclusion: TK/GCV-mediated suicide is cell cycle dependent, which explains why the undifferentiated nestin positive cells were affected more than the differentiated Tuj-1 positive cells in *vivo*. We believe that this approach will, therefore, allow us to conserve the functional recovery gained from the transplantation whilst treating the graft derived tumor at the same time.

Title: Impact of complete spinal cord injury on skin pressure ulcer healing in a mouse model

Authors: ***S. KUMAR**[1], M. L. YARMUSH[1,2], F. BERTHIAUME[1];
[1]Dept. of Biomed. Engin., Rutgers, The State Univ. of New Jersey, Piscataway, NJ; [2]Ctr. for Engin. in Med., Massachusetts Gen. Hosp. and Shriners Burns Hosp., Boston, MA

Abstract: Spinal cord injury (SCI) leads to loss of sensory and motor functions below the level of the lesion besides muscle atrophy, pressure ulcers (PUs), infections, and respiratory problems. PUs are a serious, costly, and life-long complication experienced by SCI individuals. SCI persons are at high risk for developing PUs because of lack of sensation, immobility, moisture, and multiple other risk factors. The prevalence of PUs in SCI ranges from 14-32%, and

recurrence rates have been reported to range from 31-79%. Based upon the clinical data, there are likely several physiological processes in wound healing affected after SCI. However, there have been no reports studying these factors in animal models of SCI. Therefore, there is a critical need for a PU animal model to investigate the effects of SCI on the dynamics of wound development and healing. We developed a mouse model of PU with or without SCI (complete transection at T10). All experiments were conducted using 10 week-old BALB/c male mice. A PU model was developed using 2 magnets applied on either side of a skin fold on the back of the mouse for 12 h. PUs were induced in both normal and SCI mice, and then mice were housed individually. First, the dynamics of development of the PUs and its healing processes were assessed via gross morphology. It was found that after a single 12 h magnet application, a PU developed within a few days. The wound tissue samples were prepared for histological evaluation at early time points. The wounded areas demonstrated tissue edema at day 0, immediately after a single 12 h magnet application, and disappearance of the epidermis by day 3, which persisted until day 7. Although the wounds in SCI mice exhibited more inflammation as compared to normal mice, the PU grades were very similar to that of regular mice. PUs in normal mice showed complete closure by 21 days as compared to 35 days in SCI mice. Thus, there was a significant delay in wound closing process in SCI mice ($p<0.001$). We also compared the healing time of 1 cm x 1 cm excisional wounds (in which case the full-thickness of the skin is excised on the back of the mice) between normal and SCI mice. Again, the healing time was significantly slower in SCI mice ($p<0.001$). The BMS score of all mice post-injury ($n=8$) was 0 at day 2 and 0.375 ± 0.18 at week 5, thus confirming the severity of the SCI. With these results, we show that skin healing is much slower after SCI in this mouse model, which is consistent with clinical observations in SCI patients. This animal model can be used to assess, in a systematic fashion, the impact of SCI on the dynamics of various cellular processes in wound healing, as well as a system to test compounds that may improve wound healing in SCI patients.

Sch. of Med. and Fac. of Medicine, Kyoto Univ., Kyoto, Japan

Abstract: The direct cortico-motoneuronal connection is believed to be essential for the control of dexterous hand movements, such as precision grip in primates. It was reported, however, that even after lesion of the corticospinal tract (CST) at the C4/C5 segment, precision grip largely recovered within 1 to 3 months, suggesting that the recovery depends on transmission through intercalated neurons rostral to the lesion, such as the propriospinal neurons (PNs) in the midcervical segments. To obtain direct evidence for the contribution of PNs to recovery after CST lesion, we applied a pathway-selective and reversible blocking method using double viral vectors to the PNs in 6 monkeys after CST lesions at C4/C5. Two kinds of viral vectors were injected into the cervical spinal cord of each monkey. The first was a highly efficient retrograde gene transfer vector, HiRet or its derivatives (FuG-E, NeuRet) carrying the sequences for tetracycline-inducible, green fluorescent protein-tagged enhanced tetanus neurotoxin light chain. This vector was injected into the ventral horn of the C6-Th1 segments, where motoneurons innervating distal forelimb muscles are located. The second was the adeno-associated viral (AAV) vector carrying the sequence for the highly efficient Tet-on sequence, rtTAV16. This vector was injected into the intermediate zone of the caudal C2 to caudal C4 segment, where the cell bodies of PNs are located, thus enabling tetracycline derivatives, doxycycline (Dox)-inducible blockade of PNs. CST lesions were then made between the injection sites of the two viral vectors, mostly in C4/C5. In 4 monkeys that showed nearly full or partial recovery, transient administering Dox for 1-3 weeks after recovery caused partial impairment of recovered-precision grip. In the other 2 monkeys, continuous administration of Dox outlasted the entire period of postoperative observation (3-4.5 months). In these monkeys, precision grip recovery was not achieved. At the end of the behavioral observation, by recording presumably PN-mediated field potentials in the deep radial motor nuclei evoked by stimulation of the contralateral pyramid under anesthesia, PN-transmission was significantly blocked in the affected side compared with the intact side in 4 of 5 monkeys examined. Anti-GFP immunohistochemistry could show that axons of double-infected PNs directly connected with motoneurons of forelimb muscles. These results provide evidence for causal contribution of the PNs to recovery of hand dexterity after CST lesions; PN transmission is necessary for promoting the initial stage recovery; however, their contribution is only partial once the recovery is achieved.

Title: Lateral olfactory tract usher substance (LOTUS) enhanced axonal regeneration and functional recovery after spinal cord injury in adult mice

Authors: ***S. ITO**[1], A. IWANAMI[1], S. SHIBATA[1], M. SHINOZAKI[1], N. NAGOSHI[1], S. KAWABATA[1], M. MATSUMOTO[1], K. TAKEI[2], M. NAKAMURA[1], H. OKANO[1]; [1]Keio Univ., Tokyo, Japan; [2]Mol. Med. Biosci. Lab., Yokohama City Univ. Grad. Sch. of Med. Life Sci., Yokohama, Kanagawa, Japan

Abstract: [Introduction]Lateral olfactory tract usher substance (LOTUS) is a membrane protein that functions as an axonal guidance molecule, and combines with the Nogo receptor 1 (NgR1) to antagonize several axonal growth inhibitors. It has been reported that in LOTUS knockout (LOTUS-KO) mice, motor function recovery after spinal cord injury (SCI) significantly deteriorated as compared with wild-type mice. The purpose of this study is to evaluate the effects of LOTUS on axonal regeneration and motor function recovery after SCI using LOTUS-overexpressing mice.[Method]Contusive SCI was induced at the Th10 level in LOTUS-overexpressing mice (LOTUS group) and wild-type mice (control group) as reported previously, and hindlimb motor function was evaluated until six weeks after SCI using BMS score, DigiGate system and rotarod test. 6 weeks after SCI, biotinylated dextran amine (BDA) was injected into the primary motor cortex of the mice in both groups to trace the corticospinal tract (CST). Two weeks after injection, electrophysiological analysis using spinal cord-evoked potential was performed as reported previously. After the mice were sacrificed, histological analyses were performed.[Result]In the LOTUS group, the BMS score showed significantly greater functional recovery compared with that in the control group at four weeks after SCI and thereafter (LOTUS group; 3.31±1.22 vs. control group; 2.35±0.38, $p<0.05$). DigiGate analysis revealed significantly longer stride length in the LOTUS group (3.67±0.53 vs. 2.97±0.23, $p<0.01$), and rotarod test showed significantly longer total run time in the LOTUS group (53.63±35.29 vs. 22.38±16.76, $p<0.05$) six weeks after SCI. Electrophysiological analysis showed significantly shorter latency in the LOTUS group eight weeks after SCI (3.91±0.68 vs. 4.95±0.79, $p<0.05$). Histological analyses revealed that the CST axons labeled with BDA significantly increased at the rostral

sites, but not at the caudal sites to the lesion epicenter in the LOTUS group compared to the control group. In contrast, the 5-HT positive serotonergic fibers significantly increased at the lesion epicenter and the caudal sites in the LOTUS group compared to the control group.[Conclusions]LOTUS overexpression promoted axonal regeneration after SCI, thereby contributing to motor functional recovery. In the future, we will evaluate the effects of exogenous LOTUS on the injured spinal cord in wild-type mice.

Title: Behavioral and histological effects of epothilone D after moderate spinal cord contusion injury in Fischer 344 rats

Authors: *B. SANDNER[1], M. MELANIE[2], R. PUTTAGUNTA[2], J. RUSCHEL[3], F. BRADKE[3], N. WEIDNER[2], A. BLESCH[2,4];

Abstract: Fibroglial scarring is a major obstacle for axonal regeneration after spinal cord injury. Previous studies have shown that local administration of the microtubule-stabilizing drug taxol or epothilone B (EpoB) reduce fibrotic scar formation after a moderate (150kDyne) contusion injury. Systemic administration of EpoB also promoted axon regeneration and functional recovery. In this study, we investigated the effects of epothilone D (EpoD), a less toxic analog of EpoB with a greater therapeutic index on fibrotic scaring and functional recovery after SCI. Adult Fischer 344 rats underwent a midthoracic moderate contusion injury (150kDyn), followed by intraperitoneal injection of EpoD (1.5mg/kg*)* at day 1 and 15 post- injury. Animals receiving vehicle injection served as controls. Eight weeks post-injury, there was a strong trend towards

improvement in sensorimotor recovery (reduced number of footfalls when crossing a regular horizontal ladder) in EpoD-treated animals compared to vehicle controls. Based on the variability in spinal cord displacement and the importance of displacement on functional parameters, we are currently analyzing groups subdivided into displacements of more or less than 1000 µm prior to any functional testing. Furthermore, hindlimb motor function in the BBB open field locomotor rating scale and gait analysis (Catwalk) will be analyzed. Adverse effects such as weight loss were not observed. Morphologically, parameters such as spared white matter (histological analysis of Eriocrome Cyanine staining), fibrotic scar tissue (laminin positive area) and number of serotonergic (5-HT positive) fibers will be investigated. Results of this study will give an independent insight, whether EpoD treatment may promote sensorimotor recovery following SCI and whether it may represent a candidate towards clinical translation.

Title: Using serial cystometry to evaluate effectiveness of treadmill training on recovery of lower urinary tract function in a rat contusion model of SCI

Authors: *F. QURESHI[1], P. KUNG[2], H. CHO[3], N. P. PHAGU[4], S. A. SISTO[1], W. F. COLLINS[4];
[1]PhD Program, Hlth. and Rehabil. Sci., [2]Sch. of Business, [3]Interdisciplinary Biol., [4]Neurobio. and Behavior, Stony Brook Univ., Stony Brook, NY

Abstract: Lower urinary tract (LUT) dysfunction is common in spinal cord injury (SCI). The aim of the study was to evaluate the effectiveness of treadmill training using serial measurements of LUT function over15 weeks pre- and post-SCI. Five female Sprague-Dawley rats (250-300g) underwent moderate spinal cord contusion (210 Kd) at T8. Treadmill training was started 2 weeks post-SCI and continued for 8 weeks. Pre-SCI and pre-, mid-, and post-treadmill training, LUT function was assessed using serial transurethral cystometry (STUC) with external urethral

sphincter (EUS) EMG recording. For each STUC session, the rat was anesthetized (Ketamine/Xylazine; 90/10 mg/kg, i.p.), and a sterile catheter (PE50) was inserted transurethrally into the bladder and connected in series to a pressure transducer to record bladder pressure and to a 60cc syringe attached to a syringe pump. EUS EMG recordings were obtained by inserting two sterile fine wire electrodes percutaneously into or near the EUS muscle. Repetitive reflex micturition events were elicited by continuous infusion of saline into the bladder. Bladder Pressure and EUS EMG data were acquired for ~2 hours after which the catheter and electrodes were removed and the rat was allowed to recover from anesthesia. For each micturition event, bladder threshold pressure (TP), peak pressure (PP) and contraction duration (CD) were measured as well EUS burst duration and frequency. All rats pre-SCI exhibited normal patterns of threshold-driven voiding bladder contractions with coordinated bladder and EUS activity and no large amplitude non-voiding contractions. Before training, SCI rats exhibited rhythmic non-voiding contractions (NVCs) with no clear TP and elevated PP. Rhythmic NVCs continued during bladder filling until leakage occurred (n=4). One rat showed a repeating pattern of 2-4 NVCs followed by a voiding contraction. Treadmill training reduced PP in every rat and improved LUT function in 4 rats characterized by reduced incidence of NVCs, increased frequency of voiding contractions, and increased EUS bursting activity during voiding. Return to normal micturition patterns occurred in 2 rats. In conclusion, STUC is an effective method for repeated evaluation of therapeutic interventions over time in individual rats following SCI.

Title: Post-synaptic effects of BDNF/TrkB signaling on functional recovery after cervical spinal cord injury

Authors: *H. M. GRANSEE[1], C. B. MANTILLA[1,2], P. SEKAR[1], W.-Z. ZHAN[1], G. C. SIECK[1,2];
[1]Physiol. & Biomed. Engin., [2]Anesthesiol., Mayo Clin., Rochester, MN

Abstract: Unilateral spinal cord hemisection at C_2 (SH) results in loss of descending premotor drive to phrenic motoneurons and paralysis of the ipsilateral diaphragm muscle (DIAm). Over time there is spontaneous neuroplasticity and gradual recovery of rhythmic DIAm activity after SH. Although both pre- and post-synaptic mechanisms likely contribute to the strengthening of spared contralateral synaptic inputs to phrenic motoneurons over time, their relative contribution to recovery post-SH is not clear. Following spinal cord injury, brain-derived neurotrophic factor (BDNF) acting through tropomyosin related kinase receptor subtype B (TrkB) regulates both pre- and post-synaptic plasticity and BDNF/TrkB signaling plays an important role in recovery. Previous studies found that increasing BDNF near phrenic motoneurons by intraspinal transplantation of BDNF-expressing mesenchymal stem cells (BDNF-MSCs) and upregulating TrkB in phrenic motoneurons by intrapleural AAV7-mediated transduction increase ipsilateral DIAm EMG activity after SH, although the extent of recovery is incomplete. Whereas BDNF availability may exert pre- and post-synaptic effects, TrkB expression in motoneurons likely exerts only post-synaptic effects. We hypothesized that post-synaptic effects at motoneurons play a predominant role in recovery post-SH and that by combining both AAV-TrkB and BDNF-MSCs treatment the synaptic mechanism could be elucidated. Adult Sprague-Dawley rats were intrapleurally injected with AAV7-TrkB or AAV7-GFP at 3 weeks prior to SH, and BDNF-expressing MSCs or wild type-MSCs were injected at C_2 at the time of SH surgery. DIAm EMG electrodes were implanted bilaterally to record activity across motor behaviors. Functional recovery during eupnea at 14D was evident in 100% of the BDNF-MSC/AAV-TrkB treated rats compared to 78% of control MSC/AAV-GFP treated rats. At 14D after SH, treatment with BDNF-MSC/AAV-TrkB or AAV-TrkB alone increased DIAm root mean square (RMS) EMG amplitude during eupnea, whereas control treatment had lower RMS EMG amplitude compared to pre-SH. Combined treatment with AAV-TrkB and BDNF-MSC had no additional benefit on extent of DIAm functional recovery during eupnea compared to AAV-TrkB treatment alone. Enhancing TrkB in phrenic motoneurons was sufficient to promote recovery of DIAm activity after SH, suggesting that post-synaptic mechanisms evoked by BDNF/TrkB signaling are sufficient to enhance eupneic recovery after SH.

Title: Locomotor recovery after spinal contusion at T10 and following a complete spinalisation at T13 in the cat

Authors: H. DELIVET-MONGRAIN, M. DEA, L. AHMED, J.-P. GOSSARD, *S. ROSSIGNOL;
Dept Neurosci., Univ. Montreal Fac Med., Montreal, QC, Canada

Abstract: Following a unilateral spinal hemisection at T10-11, cats recover quadrupedal locomotion and, after a second and complete lesion at T13, they can walk with the hindlimbs within 24hrs which is much faster than the 2-3 weeks needed after a single complete spinalisation. This suggests that the spinal cord (SC) below the hemisection undergo plastic changes leading to a much faster recovery of hindlimb spinal locomotion. To move closer to the clinical situation, we developed a model of bilateral spinal contusion at T10-11. Nine cats were implanted chronically with electromyographic (EMG) electrodes. The SC was contused using an Infinite Horizon impactor with a force of 800kdynes (8N) for 30s through a 5mm diameter flat circular tip. Thereafter, cats were trained 5 times a week on the treadmill and EMG recordings synchronized to video were made weekly. After 5wks, 2 cats were prepared for an acute experiment to record fictive locomotion (see abstract Gossard et al, SFN) while 3 other cats were perfused for histology. Four other cats were contused and trained for 5wks, then surgically spinalised and kept for 2 weeks for locomotor evaluation before the acute experiment. We found that the contusion produced very large lesions affecting all quadrants bilaterally. Only very few "normal" fibers remained in the ventral quadrants, with no residual grey matter at the epicenter of the lesion containing 5-7mm cavities. For most cats, hindlimb paralysis was complete during the first week following contusion, but quadrupedal locomotion gradually recovered thereafter. At the end of the fifth week, most of the cats could walk unaided on all four limbs and some could even step over obstacles on the treadmill. Moreover, 3 of the 4 spinalised cats walked with the hindlimbs within 24 hours of the spinalisation. We conclude that, after a very large bilateral spinal contusion leaving only sparse fibers in the white matter, neuroplastic changes occurring below the contusion must be part of locomotor recovery since spinal locomotion reappears with 24-48 hours, as after hemisection. Whereas in the hemisected model it could be hypothesized that the spinal changes below the hemisection were driven mainly from the important contingent of remaining descending fibers in the other half of the cord, the present results showing only sparse remaining fibers after severe contusion suggests that it is probably the increase of afferent inputs provided by locomotor training that may largely be implicated in inducing such major sub-lesional functional changes This conclusion is very important when considering potential therapeutic targets for improving locomotor recovery in humans with SCI.

Title: Reorganization of respiratory motor control following cervical spinal cord injury

Authors: *C. B. MANTILLA[1,2], H. M. GRANSEE[2], W.-Z. ZHAN[2], G. C. SIECK[1,2];
[1]Anesthesiol., [2]Physiol. & Biomed. Engin., Mayo Clin., Rochester, MN

Abstract: Animal models of incomplete spinal cord injury to the upper cervical spinal cord such as unilateral C_2 hemisection (SH) are widely used to examine the organization of motor systems underlying respiration. Premotor drive to phrenic motoneurons innervating the main inspiratory muscle in mammals, the diaphragm muscle, is primarily ipsilateral, although latent contralateral pathways are thought to underlie spontaneous recovery over time post-SH. The diaphragm muscle is active across a range of motor behaviors from ventilatory behaviors to higher force behaviors necessary for airway patency. Previous studies show that ipsilateral diaphragm EMG activity can be enhanced by interventions that increase premotor drive to phrenic motoneurons. Premotor drive to phrenic motoneurons measured by the root mean square (RMS) EMG activity at 75 ms is increased in response to airway occlusion, but not during sighs, although these behaviors require generating similar levels of force (~70% of maximal force in rats). We hypothesized that presence of sighs ipsilateral to SH in the absence of eupneic activity would reflect bilateral premotor drive to phrenic motoneurons during sighs compared to eupnea. Adult male Sprague-Dawley rats underwent bilateral diaphragm EMG electrode placement for chronic recordings followed by SH. Absence of ipsilateral diaphragm EMG activity was verified at the time of SH surgery and at 3 days post-SH. In lightly anesthetized, spontaneously breathing rats, EMG recordings were conducted during eupnea. Sighs occurred periodically every few minutes, and were determined as being present by contralateral diaphragm RMS EMG amplitude at least twice that of eupneic breaths. Sighs were evident in all animals post-SH, despite absence of eupneic activity, and the RMS EMG amplitude was 63 +/- 18% of pre-injury sigh levels. Consistent with the lack of increased premotor drive during sighs, RMS EMG amplitude at 75 ms was not significantly different compared to pre-injury eupnea or sigh. The results of the present study support the notion of primarily unilateral premotor drive to phrenic motoneurons for eupnea and bilateral projections for sighs. Reorganization of premotor drive to motoneurons following incomplete spinal cord injury is likely an important mechanism for recovery that can be directly addressed in therapeutic intervention.

Title: Combined chronic theta burst stimulation of motor cortex and trans-spinal direct current stimulation in rats promote coticospinal tract outgrowth caudal to a cervical spinal contusion and motor recovery

Authors: M. SHINOZAKI[1], *N. ZAREEN[2], D. RYAN[2], H. ALEXANDER[2], S. NAEEM[3], J. H. MARTIN[4];
[1]Keio Univ. Sch. of Med., Tokyo, Japan; [2]Physiology, Pharmacol. and Neurosci., [3]Sophie Davis/CUNY Sch. of Med., [4]The Grad. Center, CUNY, NY, The City Col. of the City Univ. of NY, New York, NY

Abstract: An important strategy for promoting motor function after SCI is to augment sprouting of the spared axons of motor pathways. We showed in a rat pyramidal tract lesion model that motor cortex (M1) electrical stimulation augments sprouting of spared corticospinal tract (CST) axons and promotes motor recovery (Carmel et al, 2010). In the present study we translated M1 stimulation to a moderate cervical contusion injury. We modified our published M1 stimulation protocol and used an intermittent theta burst electrical stimulation (iTBS) pattern. We combined iTBS with spinal cord cathodal DC stimulation to co-activate spinal circuits during M1 stimulation, based on our recent pyramidal tract lesion study (Song et al 2016). We examined CST axonal labeling caudal to the injury and several behavioral outcomes in 2 animal groups: injury only (n=14); injury + combined iTBS and cervical spinal DC stimulation (n=13). Bilateral contusions (Infinite Horizons; 200kdyn) were made at the C4 level. Stimulation began 7 days after injury, and continued for 10 days for 30 minutes daily. iTBS was delivered through epidural electrodes bilaterally over forelimb M1 and cervical cathodal DC stimulation, through cutaneous electrodes. Analyses were done blind. There were no differences in lesion volume between the two groups. Nor were there differences in the number of spared CST axons in the white matter for the two groups. We measured total CST axon length and axon varicosity number within the C6 gray matter. As expected, for both groups gray matter axon length increased as the number of spared CST axons in the white matter increased. However, this relationship was greater for the stimulated group, where there was approximately a 2-fold increase in axon length per spared white matter CST axon. A similar increase in CST axon varicosities (ie., presynaptic sites) was observed for the stimulated compared with non-stimulated group. Von Frey hair testing revealed

no change in either group, relative to uninjured controls. For the IBB test, there was no difference in initial post-injury scores for the two groups and only the stimulated group showed a significant improvement compared with the non-stimulated group (non-stimulated: 7.4%; paired t-test; p=0.31; stimulated: 17.7%; p=0.009). Analyses are in progress to determine treatment effect on locomotion (horizontal ladder walking and treadmill). Our findings show that combined M1 and spinal cord cathodal DC stimulation promoted spared CST axonal outgrowth and significantly improved forepaw manipulation skills after a moderate cervical contusion injury.

Abstract: Cervical spinal cord injury (cSCI) leads to long lasting impairments in forelimb function. The location and extent of cSCI determines the subsequent impairment. It has long been assumed that the degree of functional recovery is similarly determined by the lesion. There is growing evidence that this assumption is incorrect. We tested the hypothesis that functional recovery following chronic cSCI is primarily limited by ineffective neural plasticity. Rats were first trained to proficiency on the isometric pull task to assess volitional forelimb strength and given a C5/C6 hemicontusion. Repeatedly pairing vagus nerve stimulation (VNS) with forelimb movement beginning six weeks after cSCI promoted 75% more recovery of forelimb function compared to intense rehabilitation alone. In spite of significant forelimb strength enhancement,

we observed no differences in awake behaving forelimb muscular dynamics or forelimb pain between groups. We next used intracortical mappings of motor cortex and retrograde transsynaptic tracing from the forelimb musculature to examine neural plasticity. The addition of VNS as an adjuvant to rehabilitation substantially improved the anatomical and physiological connectivity of forelimb grasping musculature with motor cortex, without altering the extent of spinal damage. These findings suggest that neural plasticity, and not lesion extent, primarily limits recovery from cSCI. However, enhanced recovery from hemicontusion does not suggest that VNS paired with rehabilitation will improve recovery from cSCI in humans, because most patients have bilateral cervical spinal damage. To address this limitation, we repeated the behavioral assessments above in rats with midline cervical spinal contusions. Repeatedly pairing VNS with forelimb movement beginning eight weeks after bilateral cSCI again enhanced recovery of forelimb function compared to intense rehabilitation alone. These findings provide new hope for patients and suggests that plasticity-based therapies may prove to be clinically useful.

Title: Recovery of voluntary control following spinal injury in rodents

Authors: ***L. S. URBAN**[1], H. ZHONG[2], J. BURDICK[1], R. EDGERTON[2];
[1]Caltech, Pasadena, CA; [2]UCLA, Los Angeles, CA

Abstract: Recent studies in paraplegic humans have demonstrated a remarkable recovery of lower limb voluntary control when provided epidural and transcutaneous stimulation over the lumbosacral enlargement. Since the foundational research for these studies was conducted after complete spinal transection in animals, where no recovery was observed, the mechanism for this functional recovery in humans is unclear. To explore how epidural stimulation allows communication to occur across the spinal injury site, we have developed a novel behavioral task

in the rodent. Eight Sprawg-Dawley rats were trained to move their right hindlimb when prompted by an auditory cue. This was accomplished by initially pairing the cue with a vibration of a small motor attached to the animal's leg. The vibration intensity was chosen to evoke leg movement, and then slowly decreased until the animal responded to the auditory cue alone (which took one week). After training, each animal underwent an implantation surgery and (a month later) a spinalization. During the implantation, epidural stimulating electrodes were inserted over L2 and S1 spinal levels, and EMG recording electrodes were embedded in the hindlimb muscles (R-ST, R-VL, R-TA, R-Sol, L-TA). The spinal surgery consisted of a double hemi-section injury at the right T7 and left T10 spinal levels. This injury results in lower limb paralysis by eliminating all long tract descending connections, but preserves a continuous tract of neural tissue. Following injury, the animals received sessions of sub-threshold epidural stimulation and basic treadmill step training. After one month, the spinalized animals were able to perform the behavioral task, but only when provided epidural stimulation. These animals showed a significant increase in the reaction time to the auditory cue, as well as an increase in the duration the muscle response, suggesting reorganization of the underlying neural circuit. These results demonstrate a simplified behavioral task that mimics the results found in the human. This task is unique since the EMG activity is time-locked to the auditory cue, but can have a variable latency and amplitude. This provides a metric to judge optimal stimulation patterns and pharmacological interventions, as well as other injury models. This can also be used to study how the cortex reorganizes to enable recovery of voluntary control after the loss of all direct supraspinal connections due to spinal injury.

Title: The effect of CaV1.3 channel blocker on long-lasting root reflex

Authors: *M. JIANG[1], D. BIRCH[1,2], C. J. HECKMAN[1,3,2], V. M. TYSSELING[1,2];
[1]Dept Physiol, Feiberg Sch. Med., [2]Physical Therapy & Human Movement Sci., [3]Physical Med. and Rehab., Northwestern Univ., Chicago, IL

Abstract: After spinal cord injury (SCI), prolonged, involuntary muscle contractions, or spasms, can develop in muscles innervated below the level of injury. One source of these spasms is the increased excitability post-injury caused by an increase of persistent inward currents (PICs) in motoneurons. PICs are produced, in part, through the activation of the L-type calcium channel, CaV1.3. Recently, a new drug, SKP004C08 (SKP), has been developed to specifically block CaV1.3. In this study, we evaluated this new drug for its potential therapeutic effects on spasms. We used the *in vitro* sacral cord preparation to measure long-lasting reflexes (LLRs) in the sacral roots of mice with a chronic thoracic transection SCI. The ventral roots at sacral segment 2 - 3 (S2 - 3) were placed on metal electrodes to record LLRs evoked by stimulating the corresponding dorsal roots. The LLRs were evoked by single or a five pulse train stimulation of the dorsal root after blocking inhibitory synapsis with 5 μM strychnine, an antagonist of the glycine receptor, and 10 μM bicuculline, an antagonist of the GABAA receptor. Prior to application of SKP, the results showed that the spinal motor system in the SCI mouse was hyperactive as it frequently expressed a synchronized bursting firing among the ventral roots and showed less depression in repetitive firings in response to a short train stimulation. After SKP administration, however, the LLRs were significantly and dose-dependently reduced 10 - 90% of control levels as the concentration of SKP ranged from 20 - 200 μM. Interestingly, the LLRs were more resistant to SKP in the chronic SCI mouse than the control, acutely injured SCI mouse, suggesting the involvement of other channel types in the LLRs of the SCI mouse. These data suggest a potential therapeutic effect of SKP on spasms post-SCI and indicate a complex mechanisms underlying the LLR.

Title: Can arm cycle training effect postural control and voluntary trunk muscle activation in people with spinal cord injury?

Authors: *J. BROUSSEAU[1,2], R. MALIK[1,2], A. E. CHISHOLM[1,2], A. LYNN[2], A. WILLIAMS[1,2], T. LAM[1,2];
[1]Human Locomotion Lab., ICORD, Vancouver, BC, Canada; [2]Kinesiology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Objectives: For people with spinal cord injury (SCI), regular exercise is crucial for improving functional mobility, as well as reducing the risk of secondary health concerns such as cardiovascular disease and obesity. Seated arm cycling has been shown as an effective form of aerobic exercise for people with SCI, which also offers the potential to engage the trunk muscles. Recent studies have demonstrated motor preservation of trunk musculature below the level of injury for people with complete cervical and high thoracic SCI. Since there is potential to improve trunk muscle activation, it is important to develop interventions to target these muscles. Training trunk muscles may enhance seated balance control which can directly impact independence in activities of daily living and functional mobility. The aim of this study is to evaluate the effect of an 8-week arm cycle class on seated balance control and the voluntary activation of trunk muscles for those living with SCI.
Methods: Modeled after conventional spin classes, individuals with SCI attend a 1 hour arm cycle class every week for 8 weeks. Classes vary in difficulty by changing resistance levels, cycling cadence, and sitting posture (analogous to standing pedaling bouts in conventional spin classes) to challenge the cardiovascular system and encourage core stability. We evaluated seated balance control and voluntary trunk muscle activation patterns pre and post 8 weeks. Seated balance control was assessed by having participants sit on a forceplate while calculating their center of pressure (COP) during quiet unsupported sitting with eyes open (EO) and eyes closed (EC). We also tested the limits of stability (LOS) by asking participants to lean as far as they could in the 8 cardinal directions, and calculating the total distance the COP moved. EMG patterns were recorded from the rectus abdominus, external oblique and erector spinae (trunk flexion and rotation, lateral flexion, hollowing). We also recorded heart rate (HR) during each class to verify the aerobic intensity of the activity.
Results: Individuals with SCI showed limited trunk muscle activation and impaired static (EO and EC) and dynamic (LOS) seated balance control prior to joining the arm cycle class. Following 8 weeks of arm cycling individuals with SCI tended to show improvements in trunk muscle function and core stability.
Conclusion: Preliminary findings indicate that an 8-week arm cycle class could potentially improve postural control and elicit training effects in trunk musculature. Moreover arm cycle classes may provide aerobic benefits from an increase in HR reducing the risk of secondary health complications commonly found in those with SCI.

Title: Time course of sprouting of hindlimb corticospinal fibers after thoracic spinal cord injury in rats

Authors: *N. RUSSI, A. K. ENGMANN, M. P. SCHNEIDER, A.-S. HOFER, S. IMOBERSTEG, L. TRUSCELLO, K. FRICKE, R. SCHNEIDER, M. E. SCHWAB;

Abstract: In humans as well as in experimental animal models of CNS injury certain degrees of functional recovery are observed depending on the severity of the injury. Rodent studies investigating anatomical changes showed neurite outgrowth of both spared and axotomized fiber tracts, also referred to as sprouting, in different spinal cord and brain regions and different CNS lesion paradigms. Following a thoracic spinal cord injury in adult rats, axotomized fibers of the hindlimb corticospinal tract (CST), which is crucial for fine motor skills, were found to sprout into the cervical spinal cord at different rostro-caudal levels. Retrograde and anterograde tracings showed new projections of motor cortical hindlimb fibers to the cervical spinal cord. Microstimulations of the former hindlimb sensorimotor area were found to elicit forelimb, trunk, shoulder and head movements. However, the precise time course of cortical reorganisation as a consequence of cervical CST sprouting and its effects on physiological forelimb motor functions remain to be elucidated. A combination of three retrograde neuroanatomical tracers injected at different time points into three different locations in the spinal cord was used to study sprouting, target specificity of the new collaterals and cortical reorganisation following a thoracic bilateral transection of the dorsal spinal cord including the CST in adult rats. Preliminary results suggest major rearrangements of the new forelimb connections from the former hindlimb cortex over 1 to 12 weeks after the thoracic CST lesion. Animal behaviour on the irregular horizontal ladder and in the Montoya staircase test was assessed to study possible functional changes of skilled forelimb motor functions. Rats achieved a plateau of high performance with their (intact) forelimbs which was not disturbed in a major way by the new hindlimb-originating fibers. More challenging skilled reaching tests are currently being applied.

Title: Pharmacological targeting of ion channels leads to rapid and sustained behavioral improvements following spinal cord injury

Authors: *H. NATOLA[1], M. NOBLE[2], C. PROSCHEL[2];
[1]Neurosci. Grad. Program, [2]Biomed. Genet., Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: In central nervous system tissue, the injury response follows a stereotypical pathway, the ultimate result of which is glial cell, neuronal and axonal loss. In spinal cord injury (SCI), acute cell death is responsible for the motor deficit, but it is the slower degeneration of axons that survived the initial insult that prevents future recovery. Current approaches aim to either stop the injury progression, or attempt to replace lost neurons or oligodendrocytes by cell transplants. We however, have hypothesized that restoring function to surviving neurons will be sufficient to cause behavioral improvements and we have approached this idea in two ways. Previous work from our lab has shown that the transplantation of astroglial support cells, which will improve the environment for surviving cells, is sufficient to improve motor function following SCI (PLoS One. 6, e17328). Our recent work with acute spinal cord injury, however, looks to identify a pharmacological agent that would directly act on neurons to improve function and increase survival. To achieve this, we targeted ion channels that are critical for action potential propagation as a way of increasing neuronal activity.
We identified an FDA approved, ion channel-modulating drug that we find leads to rapid behavioral improvements when given 24 hours after spinal cord injury. The speed of recovery suggests reactivation of the surviving neurons, and remarkably the behavioral improvements are sustained even when the drug is no long administered. Furthermore, we find the drug is able to reduce cell death and consequent lesion volume as early as three days of treatment. Ongoing work investigates the mechanism of action for the rapid and persistent improvements we see.

Title: *In vivo* direct neuronal reprogramming of fibroblasts grafted to fill sites of spinal cord injury

Authors: ***A. ADLER**, M. TUSZYNSKI;
Neurosciences, UCSD, La Jolla, CA

Abstract: Previously we have demonstrated that neural stem cells (NSCs) derived from induced pluripotent stem cell (iPSC) and embryonic stem cell (ESC) sources extend large numbers of axons long distances when grafted to sites of spinal cord injury (SCI). We and others have reported that these grafts can support recovery of motor function, even in severe SCI models. However, major barriers to the clinical use of these grafts remain: (1) ESC-derived grafts are not autologous, necessitating immune suppression, and (2) without extensive long-term safety characterization of individual clones, iPSC-derived NSC grafts are occasionally teratogenic after implantation into sites of SCI.

Direct reprogramming strategies to convert fibroblasts to induced neurons (iNs) via the expression of lineage-instructive transcription factors can produce autologous neurons without progressing through an iPSC intermediate stage, and may represent a safer cell source for the treatment of SCI. Autologous fibroblasts are readily available clinically, robustly survive grafting into sites of SCI, and can be very rapidly reprogrammed to neurons. As such, in addition to an improved safety profile, we hypothesize directly-reprogrammable autologus sources of new neurons can allow more rapid intervention during the subacute phase of SCI compared to iPSC derivatives, and may accordingly encourage greater connectivity with actively regenerating host systems, leading to superior motor function recovery.

We have preliminary data demonstrating in vivo generation of rat iNs within acute SCI lesion sites. Transgenic GFP^+ rat fibroblasts were infected in vitro with doxycycline-inducible lentiviral constructs expressing neuronal lineage transcription factors, and then grafted to fill GFP^- immunocompetent rat dorsal column lesion injury sites. After administration of doxycycline for

a period of 3 weeks, graft-derived GFP^+ iNs extended long processes away from the injury site, and expressed neuronal markers Tuj1, NeuN, and Map2. Next we propose to assess synaptic connectivity with these grafts, and to perform behavioral tests of motor recovery.

Title: Investigating the long term changes in the spinal cord due to neuromuscular electrical stimulation through a dynamic learning mechanism

Authors: I. PEREZ[1], *D. S. WON[2], L. TONG[1], P. ARGUELLO[1];
[2]Electrical Engin., [1]California State University, Los Angeles, Los Angeles, CA

Abstract: Recent advancement of computational models of central pattern generator (CPG) spinal circuitry has led to accurate simulation of many characteristics of locomotion. Some of the behaviors that have been achieved include controlling the phases of locomotion (extension or flexion) and coordination of left and right limbs. Achievement of these simulated behaviors is made possible by a 2-level organizational principle of the CPG model: the rhythm generation level generates the intrinsic rhythmic behavior of the spinal cord, and a pattern formation layer is responsible to project the rhythmic behavior as patterns to the motoneurons.
One key characteristic of the spinal circuitry that is of great importance for understanding the process of post-injury rehabilitation but missing from current CPG models is the long term effects of afferent nerve stimulation on synaptic efficacy. Incorporating a learning mechanism for the spinal circuitry model will provide insight to changes of the spinal cord for rehabilitation purposes. The work presented here is framed within the context of developing a neuromuscular electrical stimulation therapy in a rodent model of spinal cord injury.
In order to incorporate the long term effects of neuromuscular electrical stimulation, the spinal circuitry model will incorporate a set of dynamic weights that are dependent on intracellular calcium concentration of the post-synaptic neuron. This type of learning mechanism is based on the modulation of NMDA and AMPA receptors that are responsible for the long term synaptic changes. The influx of calcium ions is known to be a second messenger in the post synaptic neuron for synaptic efficacy. With the addition of the learning mechanism in the spinal circuitry

model, changes of the synaptic efficacy due to simulated neuromuscular electrical stimulation are analyzed. In this work, we demonstrate the ability to control the operating point of the dynamic weights, signifying the efficacy of synapses between the afferent Ia fibers and the motoneurons in the CPG, by applying afferent stimulation to the CPG network. These capabilities have implications for studying the capability of using peripheral nerve stimulation to systematically modify and rehabilitate spinal cord locomotor function.

Inst. For Neurosci., Macaiba RN, Brazil; [5]Duke Univ. Dept. Neurobiology, Biomed. Engineering, Psychology and Neurosci, Durham, NC

Abstract: Biofeedback (BF) has been long used in rehabilitation for treatment of motor deficiency in neurological disorders. Studies have shown that BF is beneficial for ligament reconstruction, chronic pain treatment, cerebral palsy, balance training etc. In these treatments,

patients are reported to engage more intensively when BF is used. Moreover, it offers the opportunity to improve accuracy during functional tasks.
We have proposed a novel BF tool, using a realistic anatomical muscle model linked to online EMG, for improving motor control in spinal cord injury patients. Two key lower limb muscles engaged in locomotion, namely gluteus maximus (GMx) and rectus femoris proximal (RFP), used respectively for hip flexion and extension, were trained in our setup.
Patients were vertically supported in a orthostatic position, while they observed an anatomical avatar through a head mounted display. They were asked to alternatively flex and extend their hips. Seven SCI patients (one ASIA A, one ASIA B, five ASIA C) were trained for three sessions with our apparatus. Alternatively, in a control experiment no visual feedback was given to the patients.
Five patients reached significant levels of contraction for both left and right RFP and GMx muscles. In two patients (both ASIA C), stronger activations in the order of 5-10% ($p<0.01$, Ttest) were systematically observed when the anatomical avatar was shown compared to the control case for both RFP and GMx.

Title: Spinal to sciatic direct current stimulation caused long term reduction in spasticity in mice with spinal cord injury

Authors: W. MEKHAEL[1], M. HASSAN[2], S. SAMANDDAR[1], S. BEGUM[2], P. TORUNO[2], M. AHMED[2], M. SALEH[2], A. GORIN[2], M. MAISANO[2], M. AYAD[2], M. ANDRAWIS[2], *Z. AHMED[3];
[1]Physical therapy, [2]The Col. of Staten Island, Staten Island, NY; [3]Col. of Staten Island, Staten Island, NY

Abstract: Muscle tone abnormalities cause functional limitations and can severely override the weak ability to produce movements after spinal cord, or brain injuries. Muscle tone could be viewed as a background noise that when increased, could corrupt movement accuracy. In our previous study, we found that passing direct current from the lumbar spinal cord to the sciatic nerve reduces muscle tone in spastic spinal cord injured mice. In the present study, we tested the long-term effects of stimulation and the effects of repeated sessions of stimulation on muscle tone and on skilled and unskilled locomotion in spastic mice with spinal cord injury. To test spasticity, we constructed a computer-controlled motorized system that stretches, at different levels of speeds, the triceps surae muscle in awake restrained mice. Animals were stimulated transcutaneousaly for seven consecutive days (20 min/day) using a stimulation system manufactured in our lab. Animals were followed for four weeks after stimulation ended. Various indices of spasticity were significantly reduced during and for four weeks after stimulation. Skilled locomotion was tested using a computer-controlled ladder wheel that is similar to the horizontal ladder test. Spinal-to-sciatic stimulated animals showed significant improvement in skilled locomotion compared to sham, and sciatic-to-spinal stimulated animals. Animals also showed significant improvements in treadmill walking tested by the DigiGait system. We also studied the underlying electrophysiological and molecular mechanisms of spinal-to-sciatic stimulation. Treated animals showed significant increase in the rate-dependent depression (RDD) of Hoffman reflex. Spinal to sciatic stimulation affected the expression levels of VEGF, trkB, KCC2, and pKCC2. Also, we tested the safety of the stimulation using Nissil staining, NF200, TUNL assay, and microglia activation. None of these assays showed differences compared to control animals. We concluded that spinal to sciatic direct current stimulation is an effective therapeutic technique to ameliorate spasticity developed after spinal cord injury.

Title: Training induced muscular adaptations associated with improved cardiometabolic profiles in individuals with spinal cord injury (SCI)

Authors: S. GUZMAN[1], J. RAMIREZ[2], S. KESLACY[2], K. YAMAZAKI[1], *C. J. DY[3]; [1]Biol. Sci., [2]Sch. of Kinesiology and Nutritional Sci., [3]KNS, California State University, Los Angeles, Los Angeles, CA

Abstract: Debilitating spinal cord injury (SCI) results in marked reductions in functional neuromuscular activity below the area of lesion. Activity based therapies that target spinal locomotor networks have been associated with improvements in walking ability with varying levels of success after traumatic SCI. A typical regimen of locomotor training exposes the paralyzed individual with prolonged, full-body, load-bearing exercise of moderate intensity. Thus, in addition to promoting recovery of neuromuscular function, this type of training is also associated with providing benefits to health, including improved cardiometabolic function. The purpose of this pilot study was to investigate whether improved function of skeletal muscle mitochondria could explain the interaction between how locomotor training promotes dual benefits to the neuromuscular and cardiometabolic systems. We hypothesize that activity-based training that elicits pronounced electromyographic activity is associated with improvement in mitochondrial oxidative capacity (MOC) and overall cardiometabolic health. **Methods**: Able-bodied and SCI participants performed the MOC protocol. Rate constants indicative of skeletal muscle MOC were determined using near infrared spectroscopy and a repeated arterial occlusion protocol. In addition, muscle activity will be assessed using surface electromyography during stepping with BWST. Finally, blood samples will determine whether changes in performance or resting measures are associated with overall improvement in cardiometabolic health. **Results:** In order to complete the MOC protocol, arterial blood flow to the muscle was occluded using a rapid-inflation cuff system after electrical muscle stimulation was used to exhaust local oxygenation. Slopes of recovery were used to calculate the time constant to indicate the speed of recovery. The time constants correspond to the mitochondrial activity in the muscles of interest. We found that these time constant values were reproducible within subjects and can be used to differentiate variability in fitness across participants. **Conclusion:** Preliminary data are promising in determining methods to assess the role of training on mitochondrial capacity that takes place in parallel with recovery of neuromuscular function and overall cardiometabolic health.

Title: Acute intermittent hypoxia alters plasticity-related and hypoxia-related protein expression in a rat model of cervical spinal injury

Authors: B. M. ARNOLD[1], A. HASSAN[1], V. M. K. VERGE[2], *G. D. MUIR[1];
[1]Biomed. Sci, WCVM, [2]Anat. and Cell Biology, CMSNRC, Univ. Saskatchewan, Saskatoon, SK, Canada

Abstract: One promising approach to treating spinal cord injury (SCI) is through augmentation of spontaneous plasticity in uninjured neural pathways. Acute intermittent hypoxia (AIH) is a therapeutic intervention which has been shown to facilitate plasticity in respiratory and non-respiratory pathways after SCI. AIH, breathing alternating levels of normal (21%) and low (11%) oxygen for brief periods, increases phrenic nerve output (phrenic long term facilitation, pLTF) and tidal volume in rats with SCI. This is accompanied by changes in hypoxia- and plasticity-related proteins in the spinal cord. We have previously shown that AIH, when combined with specific task training on a ladder task, improves ladder performance in rats with cervical SCI. The purpose of this study is to determine whether the same hypoxia- and plasticity-related proteins associated with AIH-induced respiratory plasticity are also altered by AIH treatments in SCI rats that have undergone task training. Adult male Lewis rats received a dorso-lateral spinal cord lesion at the C2 vertebral level. Four wks after SCI, rats received up to 7 d of daily AIH treatment, consisting of 10 episodes of 5 min 11% O_2 alternating with 5 min 21% O_2. Control rats received continuous exposure to 21% O_2 for the same duration. AIH treatment was followed by daily ladder task training. Rats were sacrificed after training on treatment day 1 or day 7. Spinal cord segments C6-7 and L4-5 were dissected and processed for immunohistochemistry for plasticity- and hypoxia-related proteins. Expression of brain derived neurotrophic factor (BDNF), its high affinity receptor (trkB), and the phosphorylated form of trkB (ptrkB) was significantly increased in motoneurons of SCI rats treated with 7 d AIH compared to normoxia- treated control SCI rats. Expression of vascular endothelial growth factor (VEGF) was also significantly increased after 7 d AIH compared to normoxia-treated control rats, while hypoxia inducible factor 1α (HIF-1α) protein levels were significantly increased relative to control rats after either 1 or 7 d of AIH treatment. These results are consistent with previous work and suggest that similar mechanisms might underlie both respiratory and non-respiratory plasticity associated with AIH.

Title: Dose estimate of low force exercise needed to alter gene expression in paralyzed human skeletal muscle

Authors: *M. A. PETRIE[1], C. L. MCHENRY[1], E. FAIDLEY[1], M. SUNEJA[2,3], R. K. SHIELDS[1];
[1]Physical Therapy and Rehabil. Sci., The Univ. of Iowa, Iowa City, IA; [2]Intrnl. Med., Univ. of Iowa, Iowa City, IA; [3]Veterans Affairs Med. Ctr., DVA, Iowa City, IA

Abstract: The loss of physical activity after a spinal cord injury results in metabolic dysfunction. Rehabilitation often overlooks the importance of physical activity in paralyzed limbs for systemic metabolic health. There is a need for safe and feasible exercise interventions to increase physical activity levels for people with chronic paralysis. Low-force exercise using neuromuscular electrical stimulation has been shown to acutely increase the expression of key transcription factors that regulate fiber type; however, the number of sessions needed each week to induce change in paralyzed muscle is unknown. **Purpose:** The goal of this work was to develop an estimate for the dose of low-force exercise needed to train human paralyzed muscle. **Methods:** Seven people with a complete spinal cord injury (ASIA-A) of at least 1-year duration participated in this study. Subjects unilaterally trained the quadriceps muscle with a low-force exercise for at least 12 weeks while keeping the other limb untrained. Subjects trained with a range of sessions per week from 1 to 6. Each subject received two bouts of 60 contractions per day. The stimulation train consisted of 10 stimulus pulses delivered at a 5Hz stimulation frequency and a between train work rest ratio of 1 on to 2 off. Before and after training, subjects performed a muscle performance assessment to evaluate muscle fatigue. After training, subjects underwent a percutaneous muscle biopsy of the trained and untrained limb to determine a gene expression signature. **Results:** At the conclusion of the training, we had a range of training doses from 1.8 to 6.3 low force exercise sessions performed weekly. We found a positive relationship between the changes in fatigue index and the number of training sessions per week (R^2=0.81, $p<0.006$). We found a positive relationship between training dose and changes in gene expression. For instance, we found a positive relationship between the changes in fatigue index after training and the expression of some key metabolic genes like mitochondrial pyruvate carrier 1 (MPC1, R^2=0.63), mitochondrial pyruvate carrier 2 (MPC2, R^2=0.50), and myosin heavy chain

2 (MYH2, R^2=0.89). **Conclusions:** Taken together, this study suggests low-force training exercise should target at least 5 days of training per week using at least 6,000 stimulus pulses per session. Using this dose of exercise will help future studies maximize potential effects low force training on chronically paralyzed human skeletal muscle.

Title: Low force electrically induced exercise regulates distinct metabolic transcription factors in people with spinal cord injury (SCI)

Authors: *R. K. SHIELDS[1], M. A. PETRIE[1], A. SHARMA[2], M. SUNEJA[3,4];
[1]PT and Rehabil. Sci., [2]Biochem., [3]Intrnl. Med., The Univ. of Iowa, Iowa City, IA; [4]Veterans Affairs Med. Ctr., DVA, Iowa City, IA

Abstract: Low force and long duration exercise is associated with improved metabolic homeostasis in humans without paralysis. One method to induce long duration activity in people with paralysis is to activate the skeletal muscle at a low frequency to minimize force but recruit the entire muscle. **Purpose:** We compared the effect of two low frequency protocols (1 Hz and 3 Hz) on metabolic gene regulation in humans with chronic paralysis. We also assessed the fatigue induced and each subject's perception of the two protocols to determine the feasibility for a long term training study. We hypothesized that the 3 Hz protocol would be most effective at metabolic gene regulation and perceived as most feasible. **Methods:** Eight subjects with a spinal cord injury (ASIA-A) of at least 2 year duration participated in this study. Subjects completed 2 sessions of a unilateral muscle exercise using muscle stimulation at a 1 Hz or 3 Hz frequency. The opposite limb remained untrained to serve as a within subject control. Three hours after the completion of the long duration and low force exercise (1 or 3 Hz), the trained and untrained vastus lateralis muscle was biopsied. We extracted RNA from trained and untrained muscle samples and analyzed the exon expression using Affymetrix HTA 2.0 microarray gene chips. We

also tested the fatigability of the muscle and assessed the subjects' perception of each protocol for feasibility. **Results:** Over 30,000 genes were analyzed and determined to have patent hybridization signal. Of those 71 and 179 genes were increased by at least 50% three hours after a single session of 1 Hz and 3 Hz muscle stimulation, respectively. 10 of the top 20 most highly induced genes ($p < 0.05$) were common for each protocol (1 and 3 Hz) including PGC-1α, NR4A3, ABRA, FOSB, EGR1, and XIRP1. Only two of the most repressed genes ($p < 0.05$) were common among both protocols; MIR4524A and GHR. The 3 Hz protocol showed greater regulation of several major metabolic transcription genes as compared to the 1 Hz protocol; consistent with our findings of greater fatigue induced with the 3 Hz stimulation. Subjects reported the 3 Hz protocol was more feasible for routine and long term utilization. **Conclusions:** We demonstrate that 3 Hz stimulation yields greater gene regulation in human paralyzed muscle as compared to 1 Hz stimulation. The 3 Hz protocol regulated a family of genes that were also distinct from the 1 Hz protocol; most notably genes associated with insulin receptor regulation. The 3 Hz protocol was reported to be "more acceptable" than the 1 Hz protocol and induced greater fatigue. We conclude that the 3 Hz protocol is the optimal training protocol for long duration exercise in people with chronic spinal cord injury.

Title: The performance and retention of a skilled walking task among among people with an incomplete spinal cord injury

Authors: *A. E. CHISHOLM[1,2], A. M. M. WILLIAMS[1], G. EGINYAN[2], T. LAM[2,1];
[1]Intl. Collaboration On Repair Discoveries, Vancouver, BC, Canada; [2]Sch. of Kinesiology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Background: Many people with a motor-incomplete spinal cord injury (m-iSCI) can recover some basic walking ability; however they experience difficulty when performing more skilled walking tasks (e.g. stairs and obstacles). There is potential for task specific locomotor

training based on principles of motor learning to improve the motor control of walking in people with m-iSCI. The purpose of this study is to determine how well people with m-iSCI can learn a new skilled walking task, and retain their performance after a week.
Methods: Participants with m-iSCI (American Spinal Cord Injury Assessment; ASIA D) and age-matched controls performed a skilled walking task focused on foot height during the swing phase. They were presented with a virtual target that they were instructed to match during the swing phase along with real-time visual feedback of their foot height for 600 steps. The target height changed for each step based on a percentage of their maximum step height. We conducted a baseline and post-training test of 20 steps without visual feedback. A 20 step retention trial without visual feedback was repeated 24 hours, 48 hours and 1 week later. Following the retention trial at 1 week, participants performed 300 steps with visual feedback to re-learn the task. Foot trajectory error was measured as the vertical distance between the target and actual foot height. We also measured lower limb muscle activity and sagittal joint angles.
Results: SCI and control groups reduced their average foot trajectory error to 16.7 mm and 10.2 mm, respectively, in the last 20 steps of training. Performance was maintained during the post-test without visual feedback at 17.8 mm and 12.8 mm, respectively. However, average performance on retention trials increased to baseline levels for both groups (SCI: 86.2 mm, control: 43.1 mm). During the initial training session, it took SCI participants 39-87 steps and controls 30-53 steps to learn the task (i.e. 5 consecutive steps within 2 standard deviations of the final performance). Participants were able to re-learn the task faster at 1 week when visual feedback was given (SCI: 9-20 steps, control: 16-30 steps).
Conclusions: Preliminary findings indicate that individuals with m-iSCI were able to learn a skilled walking task at a similar level to abled-bodied adults. Although performance is not maintained after 24 hours, people are able to re-learn the task at a faster rate. Further data collection is warranted to understand the capacity and limitations of individuals with m-iSCI to acquire and learn new locomotor skills.

Title: H-reflex depression in spinal cord injury: Impact of long term vibration training

Authors: ***S. DUDLEY-JAVOROSKI**, C.-L. YEN, C. L. MCHENRY, M. A. PETRIE, R. K. SHIELDS;
Physical Therapy & Rehabil. Sci., Univ. of Iowa, Iowa City, IA

Abstract: Spinal cord injury (SCI) precipitates a range of secondary health conditions including lower limb fractures and involuntary spasms. We are currently studying whether the reintroduction of mechanical loads via vibration is an effective anti-osteoporosis countermeasure in SCI. Anecdotal reports from participants in this study indicated that after vibration training, lower limb spasms subsided for several hours. **Purpose:** We investigated spinal reflex excitability in the trained and untrained limbs of these participants in order to determine whether vibration training initiated changes in soleus H-reflexes. Altered H-reflex depression may indicate the presence of spinal reorganization. We hypothesized that vibration training would trigger partial restoration of H-reflex paired-pulse depression, which is typically lost after SCI. **Methods:** Five men with chronic complete (AIS-A) SCI received vibration training (30 Hz, 0.6 *g*) to one lower limb while seated in a wheelchair. The contra-lateral limb served as a within-subject control. Subjects received an average of 47 vibration sessions over an average of 29 weeks. At the end of their participation, we elicited soleus H-reflexes via paired-pulse stimulation (inter-pulse interval = 500 ms) to the tibial nerve in both the trained and untrained limbs. We examined the depression of the 2^{nd} H-reflex (H2) in relation to the unconditioned H-reflex (H1), which provides an index of post-activation depression within the spinal reflex arc. We examined H-reflex depression at rest (Pre), during a brief session of 30 Hz vibration (Vibration), and 5 minutes after vibration (Post). **Results:** In the Pre and Post epochs, 4 of 5 participants showed a between-limb difference in H2 depression in the hypothesized direction (Trained > Untrained; average difference = 29.19%) but it was not statistically significant ($p = 0.125$). During Vibration, all 5 participants showed a between-limb difference in the hypothesized direction (average difference = 34.98%; $p = 0.06$). **Conclusion:** These findings support that vibration training modulates post-activation depression in humans with chronic paralysis. Future studies will determine whether vibration training will reduce the incidence or severity of lower extremity spasms in individuals with SCI.

Title: Trunk muscle activation patterns during walking with robotic exoskeletons in high thoracic motor-complete sci

Authors: R. ALAMRO, A. E. CHISHOLM, ***T. LAM**;
Sch. of Kinesiology / ICORD, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Background: The International Standards for Neurological Classification of Spinal Cord Injury relies on sensory tests only to evaluate motor function in the thoracic segments of the spinal cord, which could result in uncertain assumptions about the motor function of these segments. Indeed, recent studies using targeted approaches to assess the trunk have revealed sparing of trunk muscle function in individuals with SCI classified with thoracic or cervical motor-complete injuries. Therefore, finding training techniques to recruit this preserved muscle function in the trunk could enhance their activation and potentially lead to better improvements in postural control and function. Robotic exoskeletons, such as the Lokomat and Ekso, are used in gait rehabilitation for people with SCI, but it remains unknown the extent to which they engage those trunk muscles that are normally activated during walking. The Lokomat and Ekso use different methods to provide gait training. The Lokomat provides gait training on a treadmill with the trunk passively supported by an overhead harness that provides weight support. However, the user's body is rigidly held within the Lokomat, which could imply lesser degree of recruitment of postural muscles. In contrast, gait training in the Ekso is provided overground and requires continuous participation from the users to maintain their balance while shifting their weight from one limb to the other in order to activate the Ekso's legs to walk. This mechanism could lead to better postural muscle activation.
Objective: To characterize and compare the activation patterns of the axial muscles during walking with the Ekso and the Lokomat in people with high thoracic motor-complete SCI.
Methods: 1 individual with T3 chronic motor-complete SCI. The participant performed 3 speed matched walking conditions: Lokomat-assisted walking (Loko-TM), Ekso-assisted walking overground (Ekso-OG), and Ekso-assisted walking on a treadmill (Ekso-TM). Electromyography (EMG) signals were recorded bilaterally from rectus abdominis (RA), external oblique (EO), and erector spinae (ES) and normalized to a standardized voluntary contraction (SVC).
Results: For Loko-TM condition, right RA mean EMG amplitude was 61% of SVC, EO 24% and ES 15%. In the left side, RA was 37%, EO 21% and ES 16%. For Ekso-OG, right RA was 141.3% of SVC, EO 238.9%, and ES 48.4%. In the left side, RA was 84%, EO 74% and ES 36.3%. For Ekso-TM, right RA was 187%, EO 356% and ES 63%. In the left side RA was 132%, EO 167% and ES 52%.
Conclusion: Based on the results, Ekso-assisted walking was better in activating trunk muscles than the Lokomat-assisted walking.

Title: Improvements in lower limb proprioceptive acuity as a result of end-point based training

Authors: *T. QAISER[1,2], T. LAM[1,2];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Intl. Collaboration on Repair Discoveries, Vancouver, BC, Canada

Abstract: Background: Human movement control relies critically on the ability to sense limb position and movement (proprioception). There is intriguing evidence from upper limb reaching studies that given appropriate feedback it is possible to improve proprioceptive sense through passive movement training. Furthermore, it has been suggested that individuals are more accurate at determining end-point limb location than the commonly assessed single joint angle position. Here we developed a robotic-based protocol for training proprioceptive sensation of the lower limb and to compare the effectiveness of end-point vs. joint-based proprioceptive training.
Methods: Baseline proprioceptive sense was assessed in able-bodied individuals with tests of knee joint position sense and end-point (heel) position sense using custom software controls of the Lokomat robotic exoskeleton. During knee joint position assessment, participants were asked to passively match their knee joint (with the help of a joystick) to a previously memorized position. The error was determined as the difference (in degrees) between the actual and memorized position. During end-point position tests, the participant's heel height was displaced upwards or downwards in a pseudo-random order from a previously memorized position. Participants were then asked to report whether the heel was higher or lower than before and the number of correct responses was scored. Subjects then underwent proprioceptive training, using the end-point position task described above, combined with visual feedback about their accuracy. After training, subjects repeated the knee joint and end-point position tests.
Results: Preliminary data show one participant improved knee joint position sense as a result of the end-point position training while remaining consistent in end-point position sense. Another participant started with high levels of initial proprioception and showed no improvements in either joint or end-point position sense.
Conclusion: This is the first study to test the idea whether lower limb proprioceptive sense could be improved with sensory training. Preliminary findings indicate that end-point based training might enhance proprioceptive acuity. Since these were individuals with intact proprioception, a ceiling effect may be possible. Implementation of lower position sense thresholds are needed to

further confirm the reliability of end-point based training intervention and to apply it to a population with sensory deficits such a spinal cord injury.

Title: Anabolic androgenic steroids modulate proteins related to glucose metabolism, stress response, GnRH and estrogen receptors in the GT1-7 hypothalamic cell line

Authors: *A. G. ALEMÁN-REYES[1], C. CALO-GUADALUPE[2], F. J. MARTÍNEZ-RIVERA[3], J. PÉREZ-LASPIUR[4], M. E. SANTIAGO-GASCOT[3], E. GARCÍA-SANTIAGO[2], I. OTERO-PAGÁN[5], Y. RODRÍGUEZ-PÉREZ[4], L. M. Hlth. Sci., [6]Dept. of Microbiology and Med. Zoology, Med. Sci. Campus, Univ. of Puerto Rico, San Juan, 00936, Puerto Rico

Abstract: The abuse of anabolic androgenic steroids (AAS) has been considered a major public health problem during decades. Supraphysiological doses of AAS may lead to a variety of neuroendocrine problems. Precisely, the hypothalamic-pituitary-gonadal (HPG) axis is one of the body systems mainly influenced by steroidal hormones. Fluctuations of the hormonal milieu result in alterations of reproductive function through changes in hypothalamic neurons expressing gonadotropin-releasing hormone (GnRH). Previous studies have shown that AAS

modulate the activity of these neurons through steroid-sensitive afferents. However, the potential molecular mechanisms induced by AAS in GnRH neurons remain undetermined. Here, we performed proteomic analyses of the murine hypothalamic GnRH (GT1-7) neuronal cell line after exposure to 17α-methyltestosterone (1μM). Two-dimensional difference in gel electrophoresis (2D-DIGE) and mass spectrometry analyses identified a total of 17 different proteins that were significantly affected by AAS. Proteins were associated to glucose metabolism (GAPDH), drug detoxification (GSTM1), cell cycle (ERH) and cellular transport (PEBP and ERP), among others. In addition, using Western blots, AAS exposure decreased the expression of GnRH and estrogen receptors (ER), without affecting androgen receptors (AR). Using Ingenuity Pathway Analyses (IPA) we studied protein predominant interactions with other proteins of signaling pathways. Particularly, signal transduction proteins pERK and p38MAPK were upregulated and downregulated, respectively, whereas AKT was unaffected. Together, our results suggest that androgenic compounds have the capacity to affect the neuroendocrine system by modulating key cellular processes for the control of reproductive function.

Abstract: Gonadotropin releasing hormone (GnRH) neurons, critical for reproduction, originate in the olfactory placode and enter the brain along vomeronasal and terminal axons during embryonic development. Alterations either in the development of this system or in the secretion of GnRH are associated with congenital hypogonadotropic hypogonadism (CHH) in humans, a condition characterized by failure of sexual competence. Kallmann syndrome (KS) associates congenital hypogonadism due to GnRH deficiency and anosmia, while a normal sense of smell is defined as normosmic CHH (nCHH). Here, we performed whole-exome sequencing in a cohort of 70 KS and 43 nCHH probands and identified several heterozygous missense mutations in the Anti-Mullerian Hormone *(AMH)* gene and in its receptors in nCHH individuals. Mutations in *AMH* resulted in impaired secretion of AMH by transfected COS-7 cells or reduced signalling activity of the secreted protein in the GN11 cell line derived from embryonic GnRH cells, which strongly suggests that these mutations have a pathogenic effect. We also show that AMH and its receptor (AMHR2) are expressed along the olfactory fibers and by GnRH neurons during GnRH migratory process. Pathohistological analysis of *Amhr2*$^{-/-}$ mice revealed defective embryonic migration of the neuroendocrine GnRH cells to the basal forebrain, leading to a significant reduction in the total number of GnRH neurons in the adult brains of these animals and reduced fertility. Our findings indicate that AMH signalling insufficiency contributes to the pathogenesis of nCHH and highlight a novel role for AMH in the correct development and function of GnRH neurons.

Title: Prenatal Anti-Mullerian Hormone (AMH) treatment leads to hypothalamic neuroendocrine deregulations and PCOS-like phenotype in mice

Authors: ***B. TATA**, P. GIACOBINI;
Inserm U1172, Bâtiment Biserte,, INSERM U1172, Lille, France

Abstract: Reproduction in mammals is dependent on the function of specific hypothalamic neurons that secrete GnRH. In females, the pulse amplitude and frequencies of GnRH is essential

to shape the differential synthesis and secretion of two gonadotropic hormones from the anterior pituitary, luteinizing hormone (LH) and follicle stimulating hormone (FSH). Alterations in the development of this system or in the secretion of GnRH are associated with a number of reproductive disorders in humans. Among these disorders, Polycystic Ovary Syndrome (PCOS), the most common form of female infertility, affects up to 10% of women, and is characterized by increased ovarian androgen biosynthesis, oligo-anovulation, with high GnRH/LH pulse frequency. Interestingly, AMH levels are also elevated in PCOS patients and we recently showed an extra-gonadal role of AMH, whereby AMH acts directly on GnRH neurons, increasing their activity. Important, PCOS patients exhibit hormonal imbalances and endocrine alterations during gestation, which can contribute to an increased risk that their offspring will develop PCOS. We hypothesized that prenatal exposure to elevated AMH could contribute to the hormonal and gonadal alterations observed in PCOS through precocious activation of the GnRH system.
To test this, we subjected pregnant mice to daily injections of AMH during the late gestational periods and studied the reproductive parameters and the development of the hypothalamic neuronal network's in their offspring. Prenatal AMH-treated (PAMH) female offspring exhibited anovulation, hyperandrogenism and elevated LH (i.e, the major hallmarks of PCOS) as compared to control females. Prenatal AMH treatment combined with injections of a GnRH antagonist rescued the reproductive phenotype of PAMH mice. These experiments underscore that the disruptions observed in PAMH mice result from prenatal AMH-dependent precocious hyperactivation of the GnRH system. Indeed, PAMH offspring exhibited severe defects in hypothalamic neuronal networks that regulate GnRH function. Herein, AMH excess *in utero* disrupts hypothalamic neuronal systems, which could underlie the neuroendocrine anomalies in PCOS. In conclusion, we generated a novel animal model to study the neuroendocrine pathological development of PCOS.

Title: Kappa opioid receptors are internalized in arcuate KNDy cells GnRH pulse termination in the ewe

Authors: *P. W. WEEMS[1], L. M. COOLEN[2], S. M. HILEMAN[4], S. HARDY[4], R. B. MCCOSH[4], R. L. GOODMAN[4], M. N. LEHMAN[3];

Abstract: The endogenous opioid peptide dynorphin (Dyn) is known to play an important role in mediating the negative feedback influence of progesterone on pulsatile GnRH secretion in sheep. Dyn action is mediated via its high affinity receptor, kappa opioid receptor (KOR). Recently we reported the presence KOR in kisspeptin/neurokinin B/dynorphin (KNDy) neurons of the sheep arcuate nucleus (ARC). The Dyn/ KOR interaction is believed to play a critical role within the KNDy model of GnRH pulse generation, acting as a "stop signal" terminating each pulse. KOR is an inhibitory G-protein coupled receptor and after repeated or sustained exposure to agonists, KORs are desensitized by receptor phosphorylation and endocytosis. The "KNDy hypothesis" of pulse generation predicts that KOR are bound and internalized by binding of Dyn, at the termination of each pulse. To test this hypothesis, GnRH pulses were artificially induced in unanesthetized, gonad-intact anestrus ewes via icv injection of 0.2 nmole neurokinin B (NKB) into the third ventricle. Portal blood samples were taken every two minutes prior to and following injection of NKB or vehicle to measure GnRH concentrations. Animals were sacrificed at times corresponding to either GnRH pulse onset or termination and brain tissue was collected for triple-label immunofluorescence analysis. 45μm hypothalamic sections containing the ARC were processed for immunofluorescent labeling of KOR in KNDy cells, using Dyn as a marker, and counterstained with Fluoro-Nissl to aid in the assessment of membrane-bound vs internalized KOR immunoreactivity via confocal microscopy. Numbers of KOR-immunoreactive endosome-like particles within the cytosol and not associated with the cell membrane were counted in the two 1 μm optical sections in the middle of each KNDy neuron (n = 20/animal). Animals that received NKB injection (n=4) showed significantly higher numbers of internalized particles compared to vehicle controls (n=2). Furthermore, there was a significant increase in the number of internalized particles during pulse termination (n=2) compared to onset (n=2) in NKB-injected ewes which was not seen in vehicle controls. Thus it appears that Dyn is released onto the KNDy network shortly after GnRH pulse onset activating and internalizing KOR on these cells resulting in pulse termination.

Title: Effect of contraceptive residues at central and peripheral levels of the snail (Lymnaea stagnalis) reproductive system

Authors: *Z. ZRINYI, G. MAASZ, R. HORVATH, Z. PIRGER;
Exptl. Zoology, Hungarian Acad. of Sci. Balaton Limnological, Tihany, Hungary

Abstract: Estrogens and progestogens in combined application are the most frequently used oral contraceptives. As endocrine disruptors they can also be traced in the environment, including aquatic surrounding. Their presence in worldwide relevant concentration in several European natural waters has also been demonstrated by our research group. It is well-known that their target is the reproduction of the animals living in the aquatic environment. In spite of it, only few data are available on the effect of sex-steroid mixtures, especially in worldwide relevant concentration range. Therefore, we have investigated the effect of estrogens (17-β-estradiol, ethynil-estradiol) and progestogens (progesterone, drospirenone, levonorgestrel, gestaden) in environmentally relevant concentration (10 ng/L progestogens, 1 ng/L estrogens) on the reproductive system of the pond snail (*Lymnaea stagnalis*). As a first step, the distribution of gonadotropin-releasing hormone (GnRH)-like peptide containing neurons were visualized in the CNS by immunohistochemistry, using a rabbit polyclonal anti-GnRH antibody, both in control and treated snails. The various GnRH analogs were then identified in the immunopositive neurons by single cell capillary microsampling technique. Their quantitative levels were measured by liquid chromatography coupled electrospray ionization mass spectrometry in total ganglion homogenates. Finally, the sperm number was counted by flow cytometry after nuclear staining. GnRH-like peptides expressing neurons were found in the buccal, cerebral and visceral ganglia as well as varicose fibers of neuropil tissue also displayed immunoreactivity. Quantitative IHC revealed the significant reduction of fluorescence intensity of the labeled neurons after treatments with hormone residues. In the immunopositive buccal, cerebral and visceral neurons three forms of GnRH analog were identified. The amount of GnRH analogs was significantly reduced in the treated snails, compared to the control. Finally, the total sperm number per animal also significantly decreased from ~1.6 million to ~1 million following contraceptive administration, as a possible consequence of the lowered GnRH level in the central neurons responsible for male reproduction. In summary, it appears that the simultaneous presence of 10 ng/L progestogens and 1 ng/L estrogens in the aquatic environment can lead to the impairment of the control of male reproduction at the highest regulating level, i.e. the CNS. It is concluded that the release of endocrine disruptors into aquatic ecosystem represents a serious environmental risk, exerting harmful effects on non-target organisms.

Title: Immunohistochemical detection of kisspeptin in the mouse pituitary

Authors: *Y. IKEDA, A. TAGAMI;
Aichi-Gakuin Univ. Sch. of Dent., Nagoya, Japan

Abstract: Kisspeptins encoded the Kiss1 gene are expressed in two hypothalamic regions, the preoptic area and the arcuate nucleus, and regulate the hypothalamic-pituitary-gonadal (HPG) axis. Hypothalamic kisspepsins bind to their receptor (Kiss1R) to release GnRH, and indirectly increase gonadotropin secretion in the pituitary. Thus, it has been considered that the primary site of the Kiss1/Kiss1R system in the regulation of the HPG axis is in the hypothalamus. Although both Kiss1 and kiss1R were found in the pituitary of rats and owes, it is controversial about the effects of pituitary kisspeptins on gonadotropin secretion. To understand the importance of pituitary kisspeptins, we evaluated the spatial and temporal distribution and the cellular localization of kisspeptins in the mouse pituitary, using immunohistochemistry. We performed single- and double-label immunohistochemistry using specific antibodies for kisspeptin and endocrine cell-lineage markers on sagittal and coronal sections of mouse pituitaries at various stages of embryonic and postnatal development and in adulthood. Kisspetin-immunopositive cells were detected in the anterior pituitary as early as embryonic day 13.5 through adulthood. Kisspetin was co-localized with Foxl2, the marker of aGSU cells, and partially with SF-1, the marker of gonadotropes. However, few co-localization of kisspeptin with Pit1, the marker of thyrotrope-/somatotrope-/lactotrope-lineage cells, was detected. We demonstrate that kisspeptins are expressed specifically by gonadotrope-lineage cells in the mouse pituitary, suggesting a possible involvement of kisspeptins in gonadotrope differentiation.

Title: Long term effects of prenatal stress on hypothalamic GnIH and GnRH expression

Authors: *A. G. GARCÍA-SOTO[1], L. GÓMEZ QUIROZ[2], W. PORTILLO MARTÍNEZ[4], L. JUÁREZ ROJAS[2], S. RETANA-MARQUEZ[3];

Abstract: Prenatal stress (PE) in mammals is involved in long term reproductive disorders. It causes alterations in adrenal and gonadal axes in adulthood. However, it is unknown whether neuroendocrine control of reproduction is disrupted by prenatal stress. Therefore, the aim of this study was to evaluate the content of gonadotropin-releasing hormone (GnRH) and gonadotropin-inhibiting hormone (GnIH) in the hypothalamus of adult male and female rats exposed to PE, as well as their sex hormone levels. Pregnant females were assigned to control group or stress by immersion in cold water. The pups were weaned on day 21, sexed and separated by gender. At the age of 3 months, the animals were euthanized and the hypothalamus was dissected. Blood samples were also obtained. Females were sacrificed at proestrus or diestrus stages of estrous cycle. Hypothalamic GnRH and GnIH content was evaluated by Western blotting. Sex hormones were quantified by High Performance Liquid Chromatography (HPLC). The results showed a decrease in GnRH content and an increase in GnIH content in prenatally stressed females at both stages (proestrus and diestrus). In males subjected to PE, an increase in GnIH and a decrease in GnRH were also observed. Estradiol levels were higher in prenatally stressed females at proestrus, and testosterone decreased in prenatally stressed males. These results indicate that PE is capable of disrupt the neuroendocrine control of reproduction both in females and males, causing endocrine disorders which may impair some reproductive aspects in both sexes.

Title: The estradiol feedback in the regulation of spontaneous ovulation depends on the excised-ovary

Authors: *M. B. CRUZ[1], R. LIBRADO-OSORIO[2], A. ESPINOSA-VALDEZ[1], K. MACÍAS[1], I. ARRIETA-CRUZ[2], A. FLORES[1], R. DOMÍNGUEZ[1];
[1]Univ. Autonoma De México, Mexico DF, Mexico; [2]Natl. Inst. of Geriatrics, Mexico City, Mexico

Abstract: In rats, estradiol (E2) secreted in the day of diestrus-2 (D2) stimulates preovulatory LH secretion. We have previously shown that one hour after removing the left ovary (ULO-L) E2 serum levels are similar to the control group, while the removal of the right ovary (ULO-R) reduces it. In present study we evaluated if this asymmetry is maintained until 11:00 h or 17:00 h of the expected proestrus day (Pe). In addition, if the ovulation occurs at the predicted day of estrus (Ee) or at the next vaginal estrous (Ev). At 13:00h of D2 groups of rats was ULO or unilateral sham operated (USO), and sacrificed at Ee and Ev. Other groups were sacrificed at 11:00 or 17:00 h of Pe. In USO or ULO sacrificed at 11:00 h of Pe the number of immunoreactive (ir-) cells to estrogen receptors (ER) alpha and beta in preoptic-anterior hypothalamic (POA-AHA) region were evaluated. Groups of ULO rats were injected with LHRH at 14:00 h of Pe, or with estradiol benzoate (EB) at 14:00 h of D2. 4/19 ULO ovulated at the Ee while 19/20 USO rats did it ($p<001$). When the rats had its Ev (24 h after Ee), 6/8 of the ULO-R ovulated, while 0/8 of the ULO-L did it. In ULO-L rats, the E2 serum levels at 11:00 h of Pe were higher than in USO rats (61.3±8.8 vs. 14.4±4.0, $p<0.001$). Such effects did not occur in ULO-R (21.8±7.4 vs. 14.4±4.0). The concentration of FSH in both ULO groups were higher than in USO (ULO-L: 21.4±0.14; ULO-R >100 ng/mL vs. 10.07±0.7, $p<0.001$). In addition, at 17:00 h of Pe the LH serum levels were lower (ULO-L: 0.9±0.008, ULO-R: 1.4± 0.019 vs. control: 22.9± 7.0, $p<0.001$). At 11.00 of Pe, the number of ir-ERalpha cells in the POA-AHA of ULO rats was lower than in control rats (OVX-I: 983.7 ± 52.5 OVX-D: 926.2 ± 42.6 vs. control: 1226.4 ± 53.8, $p<0.05$). In rats with ULO-R the number of ir-REbeta cells was lower than control (ULO-R: 605.2±78 vs. control: 1070.4±78.5, $p<0.0001$). Rats with ULO-R or ULO-L ovulated after LHRH injection. The injection of EB to ULO-R induced ovulation in all treated rats (10/10 vs. 3/10, $p<0.0031$), but not in ULO-L rats (3/9 vs. 1/10, $p=0.3034$).The results

suggest that at D2, the ovulation regulatory mechanisms throughout the E2 feed-back depend on the in situ ovary, and that the right ovary secrets more E2 than the left one.

Title: Impact of timing and duration of low-dose Bisphenol A exposure on extra-hypothalamic GnRH Neurons, social and locomotor behavior in adult Japanese medaka

Authors: *T. INAGAKI, J. A. O'LEARY, S. RAMAKRISHNAN;
Biol., Univ. of Puget Sound, Tacoma, WA

Abstract: Recent evidence indicates that chronic exposure to Bisphenol A (BPA), a xenoestrogen, in early life may disrupt development of normal brain function and behavior mediated by gonadotropin-releasing hormone (GnRH) pathways. In fish, previous work showed that chronic exposure to BPA (200 ng/ml) altered development of GnRH3 systems and locomotor behavior in medaka embryos and larvae. Yet impacts of timing and duration of BPA exposure and their consequences in adult brains and behavior are not well known. Here we examined the effects of different exposure to low-dose BPA on extra-hypothalamic GnRH3 systems, locomotor and social behavior in adult medaka fish (8-14 months) with GnRH3 neurons tagged with green fluorescent protein (GFP). Fertilized eggs were collected daily and exposed to BPA (200 ng/ml) with the following regimen- i) G0: no exposure (Group 0, control), ii) G1: life-long exposure (G1), iii) G2: during embryogenesis and early larval development (1-14 days post fertilization or dpf), iv) G3: only during neurogenesis (1-5 dpf) and v) G4: only during sex differentiation (5-14 dpf). Aside from G1, other subjects were raised to adulthood in regular fish water following initial exposure. Adult locomotor (distance covered, velocity) and social (mirror approach and mirror touching) behaviors were recorded for 3 minutes using Noldus Ethovision behavioral analysis system. Following behavior tests, the brains were dissected and sizes of extra-hypothalamic GnRH3-GFP neurons in the terminal nerve were measured. G1 fish showed significant hyperactivity compared to controls, for both the total distance covered ($p<0.05$) and the velocity of movement ($p<0.01$) compared to control fish. No differences in overall

locomotion were seen in other treatments. In using mirror approach to assess social behavior, G2 fish spent significantly more time near the mirror ($p<0.001$, 99.2% increase compared with control). However, fish in G1 ($p<0.01$), G2 ($p<0.001$) and G4 ($p<0.05$) spent significantly less time touching the mirror (67.6%, 79.8%, and 53.8%, respectively) in relation to unexposed controls. The soma sizes of GnRH3-GFP neurons were significantly smaller in G1 ($p<0.05$, 16.9% reduction compared with control) and G2 ($p<0.001$, 33.3% reduction compared with control). These data provide evidence that different timing and duration of BPA exposure differently affect extra-hypothalamic GnRH3 neural systems and social/locomotor behavior in adult medaka (Supported by NSF Career Award 1253126 to SR).

Title: Firing activity of gonadotropin-releasing hormone (GnRH) neurons across postnatal development in female mice is altered by prenatal androgenization

Authors: *E. A. DULKA[1], S. M. MOENTER[2];
[1]Mol. and Integrative Physiol., [2]Mol. and Integrative Physiology, Intrnl. Medicine, Obstetrics and Gynecology, Univ. of Michigan, Ann Arbor, MI

Abstract: Reproductive function is governed by the hypothalamic-pituitary-gonadal axis. GnRH neurons act as central regulators of reproductive function by releasing GnRH in a pulsatile manner. Pulses of GnRH control release of pituitary gonadotropins that regulate gonadal function. Disruption of GnRH pulses can cause infertility. Polycystic-ovary syndrome (PCOS) is the leading cause of infertility in reproductive-aged women. In patients with PCOS, release frequency of the pituitary gonadotropin luteinizing hormone (LH) is elevated suggesting an upregulation in GnRH release. In a prenatally-androgenized (PNA) mouse model, adults exhibit elevated LH levels, increased GnRH neuron firing, and increased excitatory GABAergic input to GnRH neurons. It is unknown when this increase in GnRH neuron activity occurs. In young girls with hyperandrogenemia, LH pulses are disrupted, suggesting that some aspects PCOS may

manifest prior to puberty. We hypothesized that 1) GnRH neuron activity increases across the postnatal period and 2) postnatal GnRH neuron activity is disrupted in the PNA model. To test if GnRH neuron firing rate changes across postnatal development in female mice, extracellular recordings (1hr duration) were conducted from GFP-identified GnRH neurons in acute brain slices at postnatal day (P) 7, 14, and 21 from control and PNA mice. PNA mice were generated by injecting dams with 250µg dihydrotestosterone on days 16-18 of gestation. Despite a lack of outward reproductive activity during the postnatal period, GnRH neuron activity was observed at all postnatal time points tested. In control mice, this activity increased with age, with firing rate higher at P21 than P7 (one-way ANOVA: $p<0.05$, n= 12-14 cells/group). In contrast to controls, firing activity in PNA mice did not increase across the postnatal period and was decreased at P21 compared to controls (two-way ANOVA $p< 0.05$ n= 11-14 cells/group). To further investigate the difference in firing rate observed at P21, the number and duration of action potential bursts, often associated with neurosecretion, were compared. Initial analyses found no difference in either parameter between control and PNA animals at P21. Together these data demonstrate that GnRH neurons are active even before puberty in female mice and that this activity increases over postnatal development. The observation that PNA treatment decreased GnRH neuron activity at P21 suggests that early GnRH activity may contribute to the adult PNA phenotype. Future experiments will address mechanisms underlying differences observed at P21 and if postnatal GnRH neuron activity is required for proper establishment of adult reproductive function.

Title: Gonadotropin-releasing hormone (GnRH) neuron excitability is increased during estradiol positive feedback

Authors: *C. E. ADAMS[1], S. SCHNELL[1,2], S. M. MOENTER[1,3,4];
[1]Mol. and Integrative Physiol., [2]Dept. of Computat. Med. and Bioinformatics, [3]Dept. of Intrnl. Med., [4]Dept. of Obstetrics and Gynecology, Univ. of Michigan, Ann Arbor, MI

Abstract: GnRH neurons form the final common pathway for neural control of fertility. GnRH triggers luteinizing hormone (LH) and follicle-simulating hormone (FSH) release from the pituitary; LH and FSH stimulate ovarian follicle maturation. During most of the reproductive cycle, estradiol suppresses GnRH neuron firing rates and GnRH/LH release (negative feedback) but switches to stimulatory action to induce a surge of GnRH and LH release (positive feedback); the LH surge initiates ovulation. In ovariectomized mice implanted with estradiol (OVX+E), GnRH neuron firing rates are suppressed in the morning by estradiol negative feedback (OVX+E AM, -FB) and elevated in the afternoon by estradiol positive feedback (OVX+E PM, +FB); no time-of-day dependent shift is observed in OVX mice. Many changes in ionic conductances of GnRH neurons are regulated by estradiol in a time of day-dependent manner. It is unclear if or how changes in ionic conductances isolated in voltage-clamp experiments drive the increase in GnRH neuron firing rates during positive feedback. We hypothesized that changes in ionic conductances alter baseline membrane potential. To test this, we measured membrane potential of GFP-identified GnRH neurons in acute brain slices prepared from OVX+E and OVX mice in the AM vs PM using an on-cell method. No difference in membrane potential was observed among groups ($p>0.1$). We thus hypothesized changes to ionic currents render GnRH neurons more excitable during positive feedback vs negative feedback. To test this, we studied GnRH neuron response to extrinsic stimuli (500 ms current injection, 0-40 pA, 2 pA steps) in the same animal models. Ionotropic $GABA_A$ and glutamate receptors mediating fast synaptic transmission were blocked to stop spike initiation due to activation of these receptors. The minimum current required to initiate spikes was lower during +FB relative to -FB and OVX AM/PM neurons ($p<0.05$). Once firing was initiated, GnRH neurons fired more spikes at each current step from 20-40 pA ($p<0.05$). Latency to first spike was compared in traces having 4-7 spikes; latency decreased during +FB (OVX+E PM 127±11, OVX+E AM 184±16, OVX PM 221±11, OVX AM 220±13 ms; $p<0.05$). Firing threshold of the first spike was hyperpolarized during +FB (OVX+E PM -47.5±1.1, OVX+E AM -39.1±1.7, OVX PM -35.6±1.7, OVX AM -37.5±2.6 mV; $p<0.05$). These data suggest GnRH neuron excitability is increased during positive feedback, thus both estradiol and some time of day-dependent cue are needed. We postulate increased excitability is due to reduced subthreshold potassium currents to increase spike initiation and decrease spike latency, and modifications of sodium channels to alter threshold.

Title: Characterization of the HPG axis in Fgfr3-deficient mice

Authors: *S. J. BONELLI, L. R. BROOKS, S. N. KALAVITY, S. I. KAVANAUGH, P.-S. TSAI;
Integrative Physiol., Univ. of Colorado Boulder, Boulder, CO

Abstract: The hypothalamic-pituitary-gonadal (HPG) axis coordinates communication between the brain and the gonad to initiate the onset of puberty and reproductive function in mammals. Defects in this axis have significant implications for the ability of mammals to reproduce. An example, hypogonadotropic hypogonadism, is a condition in which the hypothalamus or pituitary harbors a defect in the ability to secrete the hypophysiotropic neurohormone gonadotropin-releasing hormone (GnRH) or gonadotropins (FSH and LH), respectively. Neurons that secrete GnRH express two of the four receptors of the fibroblast growth factor (Fgf) signaling family, Fgfr1 and Fgfr3. Previously, Fgfr1 has been shown to be required for the proper birth and specification of GnRH neurons during prenatal development, but Fgfr3 does not appear to be required prenatally. Instead, it is hypothesized that Fgfr3 functions to maintain the GnRH neuron population postnatally. The goal of this work is to examine the function of the HPG axis in transgenic mice harboring a global heterozygote knockout of Fgfr3 ($Fgfr3^{+/-}$ mice) at postnatal day (PN) 30, 60, and 120. To assess hypothalamic function, GnRH neuron numbers and relative expression of GnRH mRNA are quantified in wildtype (WT) and $Fgfr3^{+/-}$ mice. Concentrations of FSH and LH in the pituitary and plasma of WT and $Fgfr3^{+/-}$ mice are quantified to assess the function of the pituitary, and the gonadal function is explored via immunohistochemistry for cleaved caspase-3 within the ovary of WT and $Fgfr3^{+/-}$ mice. Previous findings show a significant decrease (43%) in GnRH neuron number in $Fgfr3^{+/-}$ mice compared to WT at PN60. However, current data shows no significant difference in GnRH mRNA expression at PN60 or PN120, suggesting that the GnRH system may compensate for a deficit in GnRH neuron number by upregulating GnRH transcript levels.

Title: The effects of FOXL2 mutations on FSHβ transcription

Authors: *S. M. NEWTON, M. J. SUNSHINE, P. L. MELLON;
Dept. of Reproductive Med., Univ. of California San Diego, LA Jolla, CA

Abstract: Appropriate regulation of follicle-stimulating hormone (FSH) is required for normal female fertility. Previous studies have shown that the synergistic induction of FSHβ transcription by activin and progesterone requires the binding of SMAD proteins and the FOXL2 transcription factor. Human mutations in the FOXL2 gene have been identified in premature ovarian failure (POF) and blepharophiosis ptosis epicanthus inversus syndrome (BPES). To understand the involvement of FOXL2 in these reproductive disorders, we modeled human FOXL2 point mutations associated with BPES and/or POF in the mouse FOXL2 expression vector. We characterized the effects of these mutations on FSHβ induction in a gonadotrope cell line. Our results show that FSHβ expression is altered in the presence of FOXL2 mutants. FSHβ induction is differentially affected by the FOXL2 mutants in response to hormone treatments. Future experiments will involve the testing of FOXL2 binding patterns with proteins involved in the activation of FSHβ. These studies bring new insight into the pathophysiology of human reproductive disorders.

Title: Gonadotropin-releasing hormone (GnRH) neuron firing activity is higher on the afternoon of proestrus than diestrus during the estrous cycle of mice

Authors: *M. A. SILVEIRA[1], S. M. MOENTER[2];
[1]Dept. of Mol. and Integrative Physiol., [2]Dept. of Mol. and Integrative Physiology, Intrnl. Medicine, Ob.and Gy., Univ. of Michigan, Ann Arbor, MI

Abstract: GnRH neurons form the final central output regulating fertility. GnRH induces release of luteinizing hormone (LH) and follicle-stimulating hormone by the pituitary; these hormones activate gonadal steroidogenesis. Estradiol exerts negative feedback on GnRH neuron function for the most of reproductive cycle. Estradiol feedback switches to positive on the afternoon of proestrus to generate the GnRH surge. Increased GnRH release during positive feedback induces the LH surge, which triggers ovulation. Many electrophysiological studies of the neurobiological mechanisms for estradiol feedback have been done in a mouse model in which ovariectomized estradiol-replaced (OVX+E) mice exhibit daily LH surges. In this model, GnRH neuron activity is dependent on estradiol and time of day, with positive feedback increasing activity in the afternoon. Estradiol is not, however, the only ovarian factor that may play a role in the GnRH/LH surge during the reproductive cycle. Contributions from other factors may account for the observation that LH surge amplitude is lower ($p<0.01$) in OVX+E mice in the daily surge model than in proestrous mice. We monitored GnRH neuron firing activity as a function of the estrous cycle to test the hypothesis that GnRH neuron firing rate is elevated on the afternoon of proestrus compared to diestrus. We also compared firing rates on proestrus to those observed in the afternoon in OVX+E mice. To monitor firing rate, targeted single-unit extracellular recordings were made from GFP-identified GnRH neurons in brain slices from females in diestrus (negative feedback) or proestrus (positive feedback). GnRH neuron firing rate is elevated ($p<0.05$) on the afternoon of proestrus (0.3±0.09Hz, n=15) compared with diestrus (0.09±0.03Hz, n=15). The percentage of time cells are quiescent (≤1 event/minute, diestrus 71% vs. proestrus 43%; $p<0.05$) and the maximum duration of quiescence (43.3±4.6min diestrus vs 24.8±5.4min proestrus; $p<0.05$) were greater on diestrus, possibly suggesting decreased pulse frequency on diestrus compared to proestrus. Interestingly, the firing frequency of GnRH neurons on proestrus was not greater than that published for OVX+E mice during positive feedback (0.6±0.05 PNAS 102:15682), suggesting that peripheral estradiol alone can recapitulate

many of the positive feedback mechanisms increasing GnRH neuron activity. This suggests the lower LH amplitude observed in the daily surge model may not be attributable to the participation of other ovarian factors in changing GnRH neuron activity, but may be due to reduced excitation-secretion coupling in GnRH neurons or reduced pituitary response in this model.

Title: Prenatal androgenization alters prepubertal development of gonadotropin-releasing hormone (GnRH) neuronal network function and connectivity

Authors: *T. BERG[1], S. M. MOENTER[2];
[1]Mol. and Integrative Physiol., [2]Mol. and Integrative Physiology, Intrnl. Medicine, Obstetrics and Gynecology, Univ. of Michigan Med. Sch., Ann Arbor, MI

Abstract: GnRH neurons are the final pathway for the central network that regulates reproduction. GnRH signals the pituitary to release gonadotropins, which regulate ovarian follicle maturation and steroid production. The GnRH/pituitary system is persistently hyperactive in women with polycystic ovary syndrome (PCOS), a common cause of infertility. This over-activity drives irregular menstrual cycles and elevated androgen levels characteristic of PCOS. When and how the neuroendocrine dysfunction seen in PCOS arises is an open question. Recent evidence of hyperandrogenemia in early pubertal girls suggests that clinical precursors of PCOS are observed at a young age. Mice that are exposed prenatally to elevated androgens (PNA) have disrupted cycles and hormone changes similar to women with PCOS. In adult PNA mice, GnRH neurons receive increased GABAergic neurotransmission, which is excitatory, and have increased firing activity. We hypothesized that PNA increases connectivity of GABAergic synapses onto GnRH neurons before the onset of puberty. We used control and PNA mice aged 7-28 days and adults to study GABAergic transmission to GnRH neurons during prepubertal development and define when differences in PNA emerge. PNA mice were generated by injecting dams with 250µg dihydrotestosterone on days 16-18 of gestation. Whole-cell voltage-clamp recordings of GABAergic postsynaptic currents (PSCs) in GFP-identified GnRH neurons

were made while blocking ionotropic glutamatergic receptors. In control and PNA females, GABAergic PSC frequency, but not amplitude, increased during postnatal development ($p<0.01$). PSC frequency was increased in 21-day-old PNA mice compared to controls (n=6-7 cells/group $P< 0.05$). We tested if increased PSC frequency in PNA females is due to increased number of synaptic release sites and/or increased activity of afferents by blocking action potentials with tetrodotoxin. The remaining activity-independent 'miniature' (m)PSCs are proportionate to the number of release sites. mPSC frequency was greater in PNA than control mice ($p<0.01$), suggesting increased synaptic connectivity. These data suggest that PNA accelerates prepubertal development of GABAergic transmission to GnRH neurons. These changes may contribute to the increase in excitatory drive observed in adult PNA mice and perhaps dysfunction of the GnRH network in PCOS.

Title: Optical clearing of the intact rat brain permits three-dimensional imaging of the arcuate kisspeptin/neurokinin B/dynorphin (KNDy) neuron population

Authors: *A. M. MOORE[1], K. A. LUCAS[1], L. M. COOLEN[2], M. N. LEHMAN[1]; [1]Neurobio. & Anatom. Sci., [2]Physiol. and Biophysics, Univ. of Mississippi Med. Ctr., Jackson, MS

Abstract: Kisspeptin/Neurokinin B/Dynorphin (KNDy) neurons in the arcuate nucleus play a key role in the central regulation of fertility. The ability to study the morphology and connectivity of the complete KNDy circuit over different reproductive states is likely to reveal unknown features of the population. In recent years, optical tissue clearing techniques have been developed to image neuronal populations in three-dimensions (3D) without sectioning the brain. To date, the ability to image neuronal populations in the intact mammalian brain has largely been limited to the mouse. We aimed to modify 3Disco (3D Imaging of Solvent-Cleared Organs, Ertürk et al. 2012, Nature Protoc.) and iDisco (Renier et al. 2014, Cell) clearing protocols to achieve immunolabelling and subsequent optical clearing of brains from larger species. We provide here a preliminary report for immunolabelling, clearing and imaging of the intact adult

rat brain. Perfusion fixed brains (4% paraformaldehyde) from ovariectomized adult Sprague Dawley female rats (5-6 months of age) were rendered transparent through optimizing the incubation length and concentration of the clearing agents tetrahydrofuran, dichloromethane and dibenzyl ether (n=2/3 per variable). Upon establishment of a reproducible clearing protocol, immunofluorescent labeling of hypothalamic neurotransmitters and neuropeptides in the whole brain was performed. Whole rat brains were incubated in mouse anti-tyrosine hydroxylase (1:5000, Millipore) for 6 days to label dopamine neurons (n=2). Whole rat brains (n=2) and 1 cm thick sagittal sections containing the hypothalamus (n=2) were incubated with rabbit anti-kisspeptin (1:250, gifted by Dr. Caraty) and guinea-pig anti-neurokinin B (1:250, gifted by Dr. Ciofi) for 6 days to identify KNDy neurons. Ultramicroscopy imaging of $1cm^3$ brain volumes was performed using a bi-directional lightsheet microscope (LaVision Biotec) combined with InspectorPro software at 6.3x magnification and a 4µm optical interval to achieve cellular resolution. Mosaic z-stack images were stitched together using Fiji software and 3D reconstructions made using Imaris software to visualize dopamine neuron populations throughout the brain and KNDy neurons in the rostral to caudal extent of the arcuate nucleus. We are now extending the application of this protocol to image the KNDy neuron population in sheep hypothalamic blocks. In conclusion, we report here an optimized technique that provides versatile analysis of neuroendocrine circuits and broad opportunity to study a variety of cell populations throughout the central nervous system of multiple animal models.

Title: Estradiol-dependent suppression of gonadotropin-releasing hormone (GnRH) neuron firing activity by corticotropin-releasing hormone (CRH) in female mice

Authors: *C. PHUMSATITPONG[1], S. M. MOENTER[2];
[1]Mol. and Integrative Physiol., [2]Mol. and Integrative Physiol, Intrnl. Medicine, Obstetrics and Gynecology, Univ. of Michigan, Ann Arbor, MI

Abstract: GnRH neurons in the hypothalamus are the final central regulators of the reproductive system. GnRH regulates the production and release of luteinizing hormone (LH) and follicle stimulating hormone (FSH), which then activate gonadal cells leading to gametogenesis and steroidogenesis. GnRH neurons integrate various inputs that modulate action potential firing and thus secretion of GnRH. Stress typically has inhibitory effects on reproduction. CRH is released during the stress response and has been shown to be involved in stress-induced suppression of fertility/reproductive function. Intracerebroventricular injection of CRH decreases LH pulse frequency and amplitude and CRH antagonists reverse the inhibitory effects of stress on reproduction. We hypothesized that CRH inhibits GnRH neuron firing activity. To test this, mice were ovariectomized and either implanted with a capsule producing a physiological circulating level of estradiol (OVX+E) or not treated further (OVX) to examine the influence of estradiol on response to CRH. Targeted extracellular recordings were used to record firing activity before (con) and during bath application of CRH from GFP-identified GnRH neurons in brain slices; recordings were done in the afternoon when estradiol has a positive feedback effect to increase GnRH neuron firing. In OVX mice, CRH treatment (100 nM) did not affect the firing rate of GnRH neurons (con 0.90±0.46 Hz, CRH 0.84±0.59 Hz, n=6, $p>0.05$). In contrast, CRH decreased GnRH neuron firing activity in OVX+E mice with 6/9 cells responding to CRH as defined by a more than 25% reduction in firing rate from the control period (con 0.77±0.39 Hz, CRH 0.25±0.14 Hz, n=6, $p<0.05$). Inhibition by CRH is reversible as firing rates returned towards their control frequency after washout (wash period 0.51±0.37 Hz, n=6, $p>0.05$ compared to CRH). Preliminary data revealed pretreatment with 200 nM astressin, an antagonist that blocks both type 1 and 2 CRH receptors, prevented the suppressive effect of CRH on GnRH neurons (con 1.48±0.77 Hz, astressin 1.62±0.75 Hz, and astressin+CRH 1.41±0.84 Hz, n=3, $p>0.05$) suggesting that the effect of CRH on GnRH is mediated through CRH receptors. These results indicate that CRH inhibits GnRH neuron activity and that estradiol is required for CRH to exert this inhibitory effect. Further studies will aim to understand the specific neurobiological mechanisms of CRH effects on GnRH neurons by testing direct action on GnRH neurons and indirect action via modifying upstream neuronal input to GnRH neurons.

Title: Study about the modulation of estrogen and food condition on the interaction of leptin and nitric oxide to control LH and FSH secretion.

Authors: *L. OLIVEIRA[1], C. RODRIGUES FRANCI[2];
[1]Ribeirão Preto Med. School, Univ. of São P, Ribeirão Preto, Brazil; [2]Ribeirão Preto Med. School, Univ. of São Paulo, Ribeirão Preto, Brazil

Abstract: Leptin is a mediator of interaction between the mechanisms to control the reproductive function and the energy balance. However, their receptors are not express in neurons that produce gonadotropin-releasing hormone (GnRH) in the hypothalamus, indicating probably an indirect action through interneurons. Among likely neurons that modulate the secretion of GnRH neurons are NO (nitric oxide) neurons. Our aim was determine whether this interaction between leptin and NO, modulated by estrogen and/or food condition, may influence the secretion of Luteinizing Hormone (LH) and Follicle-stimulating Hormone (FSH). **Methods:** Wistar rats were subject to ovariectomy and stereotaxic implantation of intracerebroventricular (icv) cannula, a week before the experiment. From the fifth day, they were treated with estradiol cypionate (10 μg / rat) or vehicle (vegetable oil, 0.1 ml / rat). One group was kept fasting for 48 hours before the experiment and the other normally fed. On the day of experiment, the animals received icv microinjection of L-NAME (500μg/1μl; Sigma) or vehicle, and an hour later received isotonic saline (control) or leptin (3μg/1μl) icv microinjection. After two hours, they were decapitated to collect the blood that was centrifuged, and the plasma was separated and stored at -20ºC to measure hormones by radioimmunoassay. **Results:** The LH and FSH plasma concentration in fasting animals is lower than the fed group and leptin treatment restored and increased this content, respectively. However, the L-NAME treatment prevented this restoration and increased, highlighting the importance of NO. In control animals there was a higher plasma concentration compared to the groups treated with L-NAME in animals fed and fasted, and lower compared to the group fed leptin while in fasting was no significant difference, showing that probably in fasted there is another factor acting in the HPG axis, maybe NPY. In the estrogen-treated groups, the LH plasma concentration was higher than those treated with oil and FSH was lower, that can be explained by the estrogen negative feedback effect.

Title: Development of gabaergic altered brain wiring and plasticity in a mouse model of polycystic ovary syndrome (pcos)

Authors: *M. S. SILVA, M. PRESCOTT, R. CAMPBELL;
Physiol., Univ. of Otago, Dunedin, New Zealand

Abstract: Polycystic Ovary Syndrome (PCOS) is the most common neuroendocrine disorder resulting in female infertility and is typically associated with hyperandrogenism. Disruptions in brain circuits regulating Gonadotropin Releasing Hormone (GnRH) neurons are hypothesized to underlie some of the pathophysiological features of this disease. Specifically, increased GABAergic innervation of GnRH neurons has been identified in a prenatally androgenized (PNA) mouse model of PCOS. The present study aimed to determine when these circuit abnormalities develop and whether they can be modified by androgen blockade in adulthood. GABA inputs onto GnRH neurons were evaluated in brain sections collected from prepubertal [postnatal day (PND) 25], control and PNA GnRH-GFP female mice. Vesicular GABA transporter (VGAT) appositions to GnRH neurons (10-12 neurons/animal) were quantified using immunofluorescence and confocal microscopy. Prepubertal PNA mice (n=5), lacking any rise in plasma testosterone levels, presented significant enhanced GABAergic input to GnRH neurons compared to controls (n=4). Adult PNA and control females were treated with flutamide (25 mg/kg), an androgen receptor antagonist, or an oil vehicle for 20 days, from PND 40 to PND 60. As expected, VGAT appositions were significantly increased in PNA+oil (n=5) animals compared with control+oil (n=4) or control+flutamide (n=4) groups. In contrast, VGAT contact onto GnRH neurons in PNA+flutamide (n=7) females was restored to control levels and this was coincident with restored estrous cyclicity. These findings indicate that disruptions in the GABA-GnRH network in a PCOS-like condition are programed before the onset of puberty. However, blockade of androgen actions can ameliorate GABA-GnRH circuit abnormalities. These results provide important insights into the development and treatment of conditions such as PCOS that are evoked by prenatal androgen exposure.

Title: δ-$GABA_A$ receptors protect against the adverse effects of stress on reproductive function

Authors: *L. C. MELON[1], J. MAGUIRE[2];
[2]Neurosci., [1]Tufts Univ. Sch. of Med., Boston, MA

Abstract: Stress has significant negative impacts on reproductive function. About 30% of women experiencing impaired fecundity are diagnosed with functional hypothalamic amenorrhea (FHA), or secondary amenorrhea due to metabolic, physical or psychological stress. The mechanisms underlying attenuation of Gonadotropin releasing hormone (GnRH) activity following these stressors are unknown. GnRH neurons express functional $GABA_A$ receptors ($GABA_A$ R) and pharmacological modulation of $GABA_A$ R has long been shown to disrupt gonadotropin release, ovulation and other reproduction related events. A recent report (Bhattari et al., 2011) supports the functional regulation of GnRH neurons by extrasynaptic δ containing $GABA_A$ R (δ$GABA_A$ R). As this $GABA_A$ R subtype is particularly sensitive to stress-associated neurosteroids, we sought to determine whether δ$GABA_A$ R played an essential role in communication between the stress and reproductive axes. We developed a GnRH specific δ$GABA_A$ R KO mouse (GnRH-δ KO) to investigate if this Cre-mediated deletion of δ$GABA_A$ R in GnRH neurons would affect sensitivity of the reproductive system to psychogenic stress. This manipulation did not alter pubertal onset in these females, as there was no difference in the age of vaginal opening or first estrous for WT and GnRH-δ KO females. Baseline estrous cycling was monitored for 21 days, with GnRH-δ KO females displaying a marginally longer cycle length. Though GnRH-δ KO females displayed a shorter time to first litter than WT, this may be due to shorter time to plug (receptivity to male etc.), as time to 2nd litter was similar across genotypes. To determine the effects of stress on the fecundity of these females, animals were put in restraint tubes for 30 minutes daily for 21 days. Interestingly, WT females showed no change in estrous periodicity following stress, whereas GnRH-δ KO mice displayed an increase in cycle length. Analysis of corticosterone levels at the end of this stress period suggests neuroendocrine adaptation may have occurred for both genotypes, as cort following the 21st restraint session were similar to basal levels. Following this period of chronic stress, females were paired with WT studs. Stress reduced the number of litters born and pups per litter for GnRH-δ KO females only. These data suggest that δ$GABA_A$ R my not be integral for baseline activity of the reproductive system yet may protect GnRH neurons from the adverse effects of stress on reproductive function. Future work will determine a role for δ$GABA_A$ mediated tonic inhibition in sensitivity of GnRH neuron activity to stress hormones. These findings could identify novel targets for the treatment of stress-associated infertility.

Title: The rescue of declining GnRH neurons in FGF signaling-deficient mice is associated with changes in diverse gene expression

Authors: *P.-S. TSAI, S. I. KAVANAUGH, C. D. LINK, P. K. GONZALES, L. R. BROOKS; Dept of Integrative Physiol., Univ. of Colorado, Boulder, CO

Abstract: Vertebrate neuroendocrine systems respond dynamically to environmental cues to enhance adaptation and survival. Consistent with this notion, a defective postnatal gonadotropin-releasing hormone (GnRH) system can respond positively to environmental cues to restore the organism's declining reproductive function. Transgenic mice with GnRH neuron-specific deficiency in fibroblast growth factor (Fgf) signaling exhibited significant age-dependent decline in GnRH neurons and gonadal functions. However, if they were housed with opposite-sex (OS) littermates and allowed the opportunity for sexual interaction, their GnRH neurons and downstream gonadal functions were restored to normal levels. In this study, we used RNA-seq to interrogate genes that may mediate this experience-dependent restoration of the GnRH system. A total of 1,485 genes in the preoptic area (region housing GnRH neurons) were differentially expressed between same-sex (SS) and OS-housed transgenic mice. The upregulated genes include growth factors that are likely to be neurotrophic to GnRH neurons (Igf1, Igf2, Bdnf, Fgf10) and an R-type calcium channel excitatory to GnRH neurons (Cacna1e). The downregulated genes include Msx1, a GnRH transcriptional repressor and Nhlh2, a basic helix-loop-helix factor with a transcriptional role in GnRH neurons. These gene expression changes have largely been confirmed by quantitative PCR, and some exhibit significant sex differences. In sum, we have identified an array of genes whose expression is altered by sexual experience and may participate in the restoration of a suboptimal GnRH system. These results strongly support the extraordinary plasticity of the postnatal GnRH system. (Supported by NIH HD042634)

Title: Activation of KNDy neurons triggers hot flashes in mice

Authors: *A. A. KRULL[1,2,3], S. L. PADILLA[4,5], S. A. LARSEN[1], C. W. JOHNSON[3,4], A. J. CABRERA[1], J. BLAZIER[1], J. A. CORREA[1], R. D. PALMITER[4,5], D. K. CLIFTON[1], R. A. STEINER[1,2];
[1]Ob/Gyn, [2]Physiol. & Biophysics, [3]Neurosci. Grad. Program, [4]Biochem., [5]Howard Hughes Med. Inst., Univ. of Washington, Seattle, WA

Abstract: Hot flashes are vasomotor disturbances that create a perception that the body is over-heated and cause facial flushing and sweating. Menopausal hot flashes occur in response to a decline in plasma levels of estradiol (E2), which disrupts thermoregulatory centers in the brain. In response to reduced E2, estrogen-sensitive KNDy neurons (neurons expressing kisspeptin, neurokinin B, and dynorphin) in the infundibular/arcuate nucleus become super-activated—and may be the generator for hot flashes. We tested the hypothesis that KNDy neurons drive hot flashes in two ways. First, we assessed the ability of neurokinin B (NKB, one of the neurotransmitters expressed in KNDy neurons) to induce thermoregulation via vasodilation and cold-seeking behavior. We found that the NKB agonist senktide caused mice to migrate to a position on a thermal gradient 7.22 ± 1.49 ºC cooler than the position chosen by vehicle-treated animals. Also, senktide treatment elevated tail skin temperature by 4.35 ± 0.74 ºC compared to vehicle. Second, we experimentally activated KNDy neurons and studied the effects on adaptive thermal behavior and tail skin blood flow. Specific activation of KNDy neurons was accomplished by transducing *Kiss1*^{Cre} neurons in the arcuate hypothalamus with a virus containing a stimulatory DREADD receptor (AAV1-DIO-hM3Dq:mcherry). hM3Dq-expressing KNDy neurons can be activated by administration of the designer ligand, CNO. We found that CNO administration caused the animals to move to a position on a thermal gradient 4.18 ± 1.27 ºC cooler than the position they maintained after receiving vehicle alone, and elevated tail skin temperature by 2.75 ± 0.86 ºC. These observations suggest that acute activation of KNDy neurons in mice creates a sense of excessive warmth— a *murine* hot flash— causing the animal to behaviorally seek a cooler ambient temperature and exhibit adaptive peripheral vasodilation. We conclude that activation of KNDy neurons is likely the proximate source of menopausal hot flashes and that therapeutic measures to block KNDy neuronal signaling in women who suffer from hot flashes could prevent or attenuate these unpleasant vasomotor symptoms.

Title: Postnatal oxytocin production in infant mice

Authors: ***R. VAIDYANATHAN**, E. HAMMOCK;
Psychology, Florida State Univ., Tallahassee, FL

Abstract: Oxytocin (OXT) signaling through the oxytocin receptor (OXTR) facilitates species-typical social behavior and social recognition of a familiar conspecific. $OXT^{-/-}$ and $OXTR^{-/-}$ mice have similar social deficits. OXT production and OXTR expression in perinatal development are both sex-dependent in mice, with females showing earlier onset of OXT production and higher expression of *Oxtr* in the perinatal brain. Further, neonatal OXT manipulations have sex-specific effects, which may be influenced by underlying sex differences in OXT production and release, and/or sex differences in *Oxtr* expression. Because OXTR activation can promote OXT release, we hypothesized that it might also serve to enhance OXT production during development. In our experiments, we tested the hypothesis that congenital loss of OXTR would impair the development of OXT production in neonatal C57BL/6J mice in a sex-specific manner. In this study we describe a sexually dimorphic effect of OXTR inactivation on OXT production. Our preliminary results show that at postnatal day 8, male OXTR knockout mice but not female knockout mice, show a 50% reduction in *Oxt* mRNA levels compared to WT animals determined by qPCR. This further demonstrates that the development of OXT/OXTR signaling is sex-specific and suggests sex differences in the experience-dependent development of the OXT system.

Title: Neural activation of oxytocin receptor expressing circuits during pre-weaning development.

Authors: *M. TABBAA, E. A. D. HAMMOCK;
Florida State Univ., Tallahassee, FL

Abstract: Oxytocin (OXT) regulates species typical social behaviors. Emerging data indicate that OXT interacts with early life experience to influence behavioral development and adult social phenotype. In an effort to further inform how early experience and central OXT signaling affect neural activation and subsequent brain development, we examined the neural response to oral administration of OXT during a sensitive period of cortical development that coincides with peak transient oxytocin receptor (OXTR) expression in the cortex of mice. OXT or vehicle were administered orally to transgenic EGFP:OXTR reporter mice, both males and females, on postnatal day (PND) 14 or PND 21. Two doses of OXT were chosen: a low dose based on the concentration of OXT the offspring would experience from the dam's breast milk and a high dose analogous to concentrations used intranasally in human clinical trials. Animals were perfused 90 minutes after dosing. Immunohistochemistry revealed dense EGFP staining in cortical layers II/III in PND 14 OXTR:EGFP transgenic mice, consistent with our previous OXTR radioligand binding data, as well as in expected brain regions known to express OXTR such as the olfactory bulb, piriform cortex, amygdala, nucleus accumbens, hippocampus, and hypothalamus, among others. As expected, these patterns of EGFP expression were not seen in mice negative for the EGFP transgene. Furthermore, immunostaining for c-Fos revealed dense neuronal activation, including activation of OXTR-EGFP positive cells in several brain regions. These data will identify neural circuits activated by OXT received during maternal-offspring interactions or clinical treatment during development.

Title: Oxytocin receptor in peripheral tissues of the neonatal mouse

Authors: *M. A. GREENWOOD, E. A. D. HAMMOCK;
Psychology, Program in Neurosci., Florida State Univ., Tallahassee, FL

Abstract: Oxytocin (OXT) is an integral part of the neural regulation of social behavior across mammalian species, with a prominent role in maternal behaviors. Maternal OXT acts within the mother to transform her behavior and physiology to be able to deliver, nourish, and nurture her offspring. OXT is found in maternal peripheral fluids such as amniotic fluid, saliva, and breast milk. Is it possible that these maternal sources of OXT can be detected by OXT receptors (OXTR) located in the infant periphery? The aim of this project was to assess peripheral sites of OXTR for potential genotypic and sex differences in the newborn mouse. Receptor autoradiography was performed on 20μm sagittal sections of whole neonatal (PD 0) male and female C57BL/6J mice using the ^{125}iodinated-ornithine vasotocin ([^{125}I]-OVTA) radioligand. A competition binding assay was used to assess the selectivity of [^{125}I]-OVTA for peripheral OXTR. Radioactive ligand (0.05nM [^{125}I]-OVTA) was competed against concentrations of 0nM, 10nM, and 1000nM excess unlabeled OXT. Neonates with a genetic deletion of the OXTR (OXTR KO) were also used as control tissue to determine signal specificity. Autoradiographs demonstrated the high selectivity of the radioligand for infant peripheral OXTR. OXTR were identified in the oronasal cavity, ciliary bodies of the eye, whisker pads, skin, adrenal gland, and anogenital region in the OXTR WT mouse, but were absent in OXTR KO. Nonspecific binding that could not be fully competed away with unlabeled OXT was seen in areas with a high lipid content such as the scapular brown adipose tissue and the liver. In addition, male OXTR KO mice displayed evidence of hyperadiposity in these regions. Collectively, these data confirm OXT targets in the periphery of the neonate and suggest a role for OXT in modulating peripheral sensory inputs and contact-dependent social development.

Title: Sexually dimorphic oxytocin receptor expressing neurons in the hypothalamus

Authors: R. LEBLANC[1,2], K. SHARMA[3], M. HAQUE[3], K. NISHIMORI[2], *R. TERUYAMA[3]; [1]Baton Rouge Community Col., Baton Rouge, LA; [2]Grad. Sch. of Agr. Sci., Tohoku Univ., Sendai, Japan; [3]Dept of Biol. Sci., Louisiana State Univ., Baton Rouge, LA

Abstract: Oxytocin (OT) is a neurohypophysial hormone produced primarily in the magnocellular neurons of the paraventricular and supraoptic nuclei in the hypothalamus. OT plays an important role in reproductive physiology by inducing contractions of the uterus during parturition and the mammary gland during milk ejection. Recent studies revealed that OT also has important roles in social and reproductive behaviors, such as maternal and pair bonding. OT induces these behaviors by binding to OT receptors (OTRs) in various parts of the brain; however, the cellular characterization and distribution of OTR expressing neurons is not well described. Furthermore, differences in male and female reproductive behaviors suggest the presence of a sexually dimorphic distribution of OTRs in the brain. The present study was conducted to find sexually dimorphic OTR neurons in mice brains using OTR-reporter mice in which a part of the OTR gene was replaced with Venus, a variant of the yellow fluorescent protein, cDNA (OTR-Venus mouse). We found that a group of Venus cells that was exclusively expressed in the ventro-medial preoptic nucleus (VLPO) and the anterior region of the periventricular hypothalamic nucleus (Pe) in females, but not in these areas of males. Many of these Venus cells were bipolar neurons with thick processes extending into the ependymal layer of the third ventricle. To validate that the Venus cells express OTR, single-cell RT-PCR was performed on individually collected Venus cells dissociated from the hypothalamus of heterozygous Venus female mice. OTR mRNA was detected from Venus cells, suggesting that OTRs are expressed in Venus neurons in these mice. Because of the sexual dimorphic nature of the Venus neurons in the anterior Pe and VLPO, the presence of the female sex hormone receptor, estrogen receptor alpha (ERα), was evaluated by immunocytochemistry. All Venus neurons in the anterior Pe and VLPO were also immunoreactive to ERα. To support the hypothesis that OTRs neurons in the female anterior Pe and VLPO are regulated by estrogen, a group of OTR-Venus mice were ovariectomized and the presence of Venus cells in these regions was evaluated. Ovariectomy caused significant reduction in the number of Venus cells in these regions. Furthermore, estrogen replacement therapy restored the population of the Venus cells in

ovariectomized mice. These findings strongly suggest that OTR neurons in the anterior Pe and VLPO are sexually dimorphic and the expression of OTR is regulated by estrogen.

Title: Oxytocin receptor distribution in the prairie vole (Microtus ochrogaster) neocortex

Authors: ***A. M. SEELKE**[1], A. DUCHEMIN[3], T. C. SIMMONS[1], S. FREEMAN[2], K. L. BALES[1];
[1]Dept. of Psychology, [2]California Natl. Primate Res. Ctr., Univ. of California Davis, Davis, CA; [3]Biol., Ecole Normale Superieure de Cachan, Cachan, France

Abstract: The neuropeptide oxytocin (OT) is involved in the processes of labor and lactation, as well as social behaviors including the formation of pair bonds in prairie voles (*Microtus ochrogaster*). Prairie voles are socially monogamous and biparental rodents that exhibit well-characterized complex social behaviors, many of which are mediated by OT. The distribution of OT receptors in the prairie vole brain has been well documented in subcortical regions, including the limbic system and hypothalamus, however, the distribution of OT receptors in the neocortex has never been examined. He we describe the distribution of OT receptors through different regions of the neocortex. Subjects were 5 male and 5 female prairie voles. Their brains were removed, sectioned, and autoradiography for OT receptors was performed on the tissue. We measured the relative density of OT receptors in the nucleus accumbens (NAcc), primary somatosensory cortex (S1), primary auditory cortex (A1), primary motor cortex (M1), parietal association area (PAA), temporal association area (TAA), insular cortex (Ins), and limbic areas of the cortex (Lim). OT density was compared across areas and sexes using ANOVA. We found no significant sex differences, so all subjects were analyzed together. As expected, the NAcc exhibited high OT receptor density, but surprisingly, this value did not significantly differ from OT receptor density in the Ins, Lim, or Taa. The Paa and M1 exhibited significantly lower OT

receptor density, and the OT receptor density in A1 was lower still. Finally, the density of OTR in S1 was significantly lower than in all other areas. These results demonstrate a non-homogenous distribution of OT receptors throughout the cortex, with the highest density in association areas and the lowest density in primary sensory and motor areas. Oxytocin has recently been implicated in the induction of multisensory plasticity in the neocortex, and the high density of OT receptors in association cortex may be the force driving those effects.

Title: Oxytocin receptor activation depolarizes interneurons and induces GABA release in the rat olfactory cortex

Authors: ***S. W. HARDEN**[1,2], C. J. FRAZIER[1];
[1]Pharmacodynamics, [2]Col. of Dent., Univ. of Florida, Gainesville, FL

Abstract: Aberrant central oxytocin (OXT) signaling is implicated in a variety of neurodevelopmental disorders, including autism spectrum disorder (ASD), and is known to be involved in the modulation of complex social behaviors such as fear, mood, affection, and affiliation. However, relatively little is known about the physiology of central OXT signaling outside the hypothalamus (where OXT-synthesizing neurons reside). The olfactory cortex of rodents express OXT receptor (OXT-R), receives axonal projections from OXT-synthesizing neurons of the periventricular nucleus (PVN), and OXT release in this area is known to enhance social recognition in rodents. Whole-cell patch-clamp recordings reveal a subpopulation of OXT-responsive fast-spiking interneurons in the olfactory cortex which are directly depolarized by brief exposure to the OXT-R agonist TGOT. We further characterize these neurons electrophysiologically, morphologically, and immunohistochemically. We also report the same application of TGOT enhances spontaneous inhibitory post-synaptic currents (sIPSCs) onto adjacent pyramidal neurons. Together, these findings reveal a subpopulation of fast-spiking

interneurons as key components involved in the oxytocinergic modulation of neurotransmission in the olfactory cortex. These data represent a significant step toward better understanding how OXT modulates the flow of information in cortical networks to influence complex behaviors.

Title: Hypothalamic vasopressinergic innervation to amygdala: functional implications in anxiogenesis.

Authors: *V. S. HERNANDEZ[1], O. R. HERNÁNDEZ-PEREZ[2], L. ZHANG[1];
[1]Dept. of Physiology, Fac. of Med., [2]Neurosci. Division, Cell. Physiol. Inst., Natl. Autonomous Univ. of México, Mexico City, Mexico

Abstract: The magnocellular hypothalamic vasopressin (AVP) containing neurons are known for their role in the hydro-electrolytic balance control via its projections to neurohypophysis. We have recently demonstrated that these neurons possess multi-axonal processes projecting to non-neurohypophyseal limbic regions including medial (MeA) and central amygdala (CeA). The amygdala is a complex structure involved in anxiety and fear processing where vasopressin immunopositive fibers have long been observed. However, the origin, distribution, co-localization with classical neurotransmitters, and behavioral consequences of their activation remain unclear. To assess these issues, we performed a series of experiments: immunohistochemistry (IHC), application of retrograde tracers Fluoro-gold (FG) into amygdala, electron microscopy, in-situ hybridization (ISH) for vasopressin mRNA, behavioral tests for anxiety under pharmacological manipulation, and Fos quantification. AVP-IHC showed that the MeA was the most densely AVP inervated region (+++) followed by the rostral part of the CeA (++).The posterior CeA and baso-lateral amygdala (BLA) showed only a sparse innervation (+). A detailed anatomical charting of AVP fiber distribution in amygdala will be presented. ISH experiment showed presence of sparse AVP mRNA expression in the MeA and the bed nucleus

of stria terminalis (intra-amygdaloid division BSTIA). Fibers of two diameters were clearly observed. Using IHC, we observed co-localization of vGlut2 with AVP in thick fibers and of GAD65-67 with AVP in the thin fibers. FG retrograde tracing from MeA-CeA resulted in numerous AVP+ magnocellular neurons labelled with FG in both hypothalamic paraventricular (PVN) and supraoptic (SON) nuclei. Water deprivation for 24 hr (WD24) is known to potently up-regulate the hypothalamic vasopressinergic system with only a mild increase of plasmatic osmolarity. We used the elevated plus maze (EPM) to assess anxiety-like behavior. WD24 rats showed a reduced percentage of time spent in open-arms of the maze, from 28% ± 3.56% to 15.91% ± 1.67% (n=5, $p<0.01$). Bilateral microinjection of AVP into the CeA (1ng AVP/250nl/side) produced a similar increase in anxiety behavior (24% ± 2.20% (control group) to 10.47% ± 1.25% (AVP-treated); n=10, <0.001). Both cases were correlated with an increase in the number of neurons expressing Fos in CeA and MeA. Our results suggest that the hypothalamic hydro-electrolytic homeostatic system has a role in the modulation of the emotional behaviors processed by the amygdala.

Title: The lateral retinohypothalamic tracts surround the vasopressin neurons in the supraoptic nucleus of hypothalamus

Authors: *P.-C. CHEN[1], C.-T. WANG[1,2,3,4];
[1]Inst. of Mol. and Cell. Biol., [2]Dept. of Life Sci., [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan; [4]Genome and Systems Biol. Program, Natl. Taiwan Univ. and Academia Sinica, Taipei, Taiwan

Abstract: The hypothalamic-neurohypophysial system (HNS) secretes two neuropeptides vasopressin (VP) and oxytocin (OT) into the cerebrospinal fluid and peripheral plasma, which is separated by the blood-brain barrier. These two neuropeptides maintain individual homeostasis and contribute to a wide variety of social behaviors. Previous studies showed the retinal ganglion cells (RGCs) in the superior temporal quadrant of the retina can project their axons to hypothalamus through two branches of retinohypothalamic tracts (RHT), medial RHT (RHTm)

and lateral RHT (RHTl). Although RHTm has been extensively studied, the functional role of RHTl remains unclear. RHTl provides a massive input to the lateral hypothalamus area (LHA), i.e, the retinorecipient region of the ventral zone of the rostral region of LHA (LHAavr). This region is a perinuclear zone of the supraoptic nucleus (SON), a hypothalamic component of the HNS, and has been suggested as a source of GABAergic inputs to the SON. Although LHAavr has been reported surrounding the caudal two thirds of supraoptic nucleus (SON), corresponding to the major distribution of VP neurons, the evidence is missing regarding whether the axon terminals of RGCs directly project to VP neurons. Moreover, whether these RHTl projections to the LHAavr display eye-specific segregation remains elusive. To address these questions, we used intravitreal injection of the cholera toxin subunit B (CTB)-anterograde tracer to label LHAavr in 8-week-old Sprague-Dawley male rats. After 3 days, we performed immunostaining to identify the relative distributions of VP and OT neurons in the SON. We found that similar to the dorsal lateral geniculate nucleus (dLGN) and optic chiasm (Och), the LHAavr mainly received the inputs from the contralateral eye. Conversely, the suprachiasmatic nucleus (SCN) that received the projections from RHTm showed a relatively slight contralateral prevalence. Moreover, some of CTB signals closely surrounded the VP immunoreactivity or even localized to the VP immunoreactivity. These results imply the RHTl may involve in regulating vasopressin release.

Title: The spatial topography of oxytocin and vasopressin neurons in the paraventricular nucleus of the hypothalamus in the prairie vole

Authors: *R. J. ORTIZ, A. N. PERRY, B. S. CUSHING;
Biol. Sci., Univ. of Texas At El Paso, El Paso, TX

Abstract: Extensive research has demonstrated the critical role of the neuropeptides oxytocin (OT) and vasopressin (AVP) in regulating high levels of prosocial behavior, with the prairie vole (*Microtus ochrogaster*) serving as one of the primary model systems. The critical roles of OT and AVP in the regulation of pair bond formation and alloparental behavior in voles were first established over 25 years ago. Despite this, we still know very little about the spatial topography of OT and AVP neurons within the vole brain. This is largely due to an emphasis placed on

species differences in patterns of OT and AVP receptor binding, which can be quite striking. However, the assumption of a conserved organization of OT and AVP neurons in the brain is largely unfounded and mostly superficial. Like other rodents, OT and AVP are primarily synthesized in the paraventricular nucleus of the hypothalamus (PVH) and the supraoptic nucleus (SON). However, unlike the well-characterized rat PVH, the distribution of OT and AVP neurons in the vole PVH is not as well differentiated- much more like the pattern seen in mice. However, we hypothesized that the spatial topography of OT and AVP neurons in the vole PVH would differ from that of mice and rats, due to their unique physiology and prosocial behavior. To test this hypothesis, we used fluorescent immunostaining techniques to characterize the spatial topography of OT and AVP neurons in the same sections throughout the rostrocaudal extent of the vole PVH. While single labeling studies suggest a poorly differentiated organization of the vole PVH, our dual labeling studies revealed a more highly-ordered spatial distribution of OT and AVP neurons. Additional studies are under way to examine functional subdivisions within the vole PVH using retrograde tracers to identify neuronal populations projecting to the posterior pituitary, hypophyseal portal system and brainstem. The results of these and other experiments will provide a more accurate topographical reference for the vole PVH that will facilitate our understanding of how OT and AVP regulate prosocial behavior.

Abstract: Background: Numerous studies to date have shown Oxytocin (OT) to be an important modulator of social and emotional behavior. Modulation of cortical-subcortical networks have been hypothesized as a key underlying neural circuit. Few studies to date have used resting-state functional connectivity to assess OT's effect on these networks. None have reported this type of approach in women. The present study used a data-driven approach (graph theory & independent component analyses) to assess potential differences pre- and post acute intranasal oxytocin administration. Specifically, we hypothesized that oxytocin might trigger a general shift from cortical to subcortical processing as evidenced by a change in the connectome modularity structure between conditions.
Methods: In a double-blind placebo-controlled crossover study 25 women received intranasal OT on one, and placebo on another occasion prior to a 10-minute resting-state multi-echo fMRI scan. Data were pre-processed using multi-echo independent component analysis (ME-ICA) that has been shown a robust method for dealing with noise artefacts in rs-fMRI data. Subsequently, functional time-series were parcellated, using an anatomical parcellation and adjacency matrices were constructed from pairwise Pearson correlations. Graph analysis were performed to assess whole brain network properties (transitivity, modularity, efficiency, small-worldness and versatility) and local or nodal properties (degree, nodal efficiency, nodal versatility and betweenness centrality).
Results: Using graph theory analyses we show a moderate shift in modularity structure, where oxytocin drives the split of a new (yet unstable) subcortical module. Overall network properties showed resilience in other measures; small-worldness, transitivity, assortativity and efficiency, under OT conditions. At nodal level there were small differences in nodal degree that showed a partial correlation with a shift towards subcortical areas. However, these nodal differences, albeit significant across network densities, did not survive multiple comparisons corrections.
Conclusions: In sum, these findings indicate the human functional connectome to be resilient against external influences of OT in resting-state conditions. This fits with the increasing awareness that oxytocin's effect on brain dynamics are strongly dependent on context and the specific individual.

Title: Early life stress modulates adult dendritic spine density in basolateral amygdala in a sex-specific manner

Authors: *R. A. SKIPPER[1], K. M. SWANSON[1], C. L. WELLMAN[1], M. R. HERBST[2], J. J. QUINN[2];
[1]Dept. of Psychological and Brain Sci., Indiana Univ., Bloomington, IN; [2]Dept. of Psychology, Miami Univ., Oxford, OH

Abstract: In humans, stress can lead to a host of debilitating outcomes, such as specific phobias, anxiety disorders, and post-traumatic stress disorder. This has been modeled in rodents, with acute stress resulting in enhanced contextual fear conditioning and dendritic retraction in the amygdala. However, little research has been done to understand the effects of early life stress on emotional learning in adults, or whether there are sex differences in this effect. This is problematic, as many stress-related disorders are more prevalent in women than men and emerge early in life. We have previously shown that preweanling stress alters fear conditioning, extinction, and dendritic plasticity in the basolateral amygdala (BLA) of adult rats. Here we show that early life stress also produces long-term changes in dendritic spine density. Male and female Long-Evans rat pups were either stressed or unstressed, with equal numbers of males and females in each group. On postnatal day (PND) 17, stressed rats received 15 mild footshocks; unstressed controls were exposed to the same context without footshock. All then matured without manipulation until adulthood. On approximately PND 90, rats either underwent contextual fear conditioning or remained unconditioned. One day later, all rats were euthanized and brains were stained using Golgi histology. Dendritic morphology and spine densities of BLA pyramidal neurons was assessed. Among unconditioned animals, unstressed females had significantly fewer spines on BLA pyramidal neurons than did unstressed males. Further, females showed a stress-induced increase in dendritic spine density, while males did not. This is consistent with preliminary data from fear conditioned groups suggesting that stressed females but not males show enhanced contextual fear conditioning, but no sex-specific changes in dendritic length or complexity. Thus dendritic spine plasticity may be a key factor mediating sexually dimorphic effects of early life stress on contextual fear learning. These findings are relevant to the effects of early life stress and improper fear regulation among humans, including

individuals with early-developing post-traumatic stress disorder or those recovering from childhood trauma.

Title: Sex-dependent effects of isolation rearing in tests of anxiety and depression.

Authors: *D. MUSKIEWICZ, D. JOSHI, F. RESENDIZ GUTIERREZ, N. HALL, F. S. HALL;
Pharmacol., The Univ. of Toledo, Toledo, OH

Abstract: Background: Social isolation of mice after weaning (isolation-rearing) has been suggested to produce a variety of pathological behavioral phenotypes. In particular, it has been suggested to produce behavioral impairments indicative of a hyperdopaminergic state and behavior indicative of reduced serotonin function. Isolation-rearing has been extensively studied; however, most research has ignored sex as a factor. Some data suggests that males and females respond differently to this experience, and may be associated with sex-dependent differences in the propensity to develop certain psychiatric conditions. **Methods**: At the 21 days of age, male and female C57BL/6J mice (N=10 per experimental condition) were housed singly or in groups of 3-4 mice. Subjects remained in these conditions for 8 weeks. At this time, they were subjected to several behavioral tests of anxiety and depression, including the elevated plus maze, open field, light-dark test, and forced swim. **Results**: Sex-dependent effects on some measures of anxiety and depression, but not all measures, were observed in these tests. Most notably, isolation-reared female, but not male, mice spent less time in the center of an open field, indicative of increased anxiety. Isolation-reared female, but not male, mice also spent significantly more time in the closed arms of the elevated plus maze than socially reared female mice. In the light dark test isolation-reared female, but not male, mice had fewer transitions between the light and dark zones. Finally, forced swim results indicate decreases in depressive-like behavior (immobility) in male isolates, but not females, when compared to their social counterparts. **Discussion**: The present experiments found evidence that isolation-reared female, but not male, mice were less active in the center of an open-field, indicative of increased anxiety. By contrast, male isolates, but not females, were shown to have significant reductions in

immobility in a forced swim test, indicative of reduced depressive-like behavior. Collectively these data suggest that early social isolation has distinctly different effects in male and female C57Cl/6J mice, and that the development of anxious phenotypes may be much more pronounced in isolated females, while isolation in males, but not females, may reduce depressive-like behavior. As an animal model of the consequences of early social experience in humans, the present data suggests that early social experience may influence the etiology of anxious and depressive phenotypes in a sex-dependent manner. The mechanisms that might underlie such differences remain to be elucidated.

Title: Sex-dependent effects of isolation-rearing on pre-pulse inhibition of acoustic startle responses

Authors: Y. SABER, *F. S. HALL;
Pharmacol., Univ. of Toledo Col. of Pharm. and Pharmaceut. Sci., Toledo, OH

Abstract: Background: Social isolation of mice after weaning (isolation-rearing) has been suggested to produce a variety of pathological behavior phenotypes. One of the prototypical effects of isolation-rearing, associated with increased dopamine function in the ventral striatum, is impaired pre-pulse inhibition (PPI) of acoustic startle responses. PPI deficits in isolation-reared mice have been thought to model certain aspects of schizophrenia and other frontostriatal disorders. Some data suggests that males and females respond differently to isolation-rearing, resulting in sex-dependent differences in the propensity to develop certain psychiatric conditions. These experiments examined sex-dependent effects of isolation-rearing on PPI. **Methods**: At the age of 21 days of age, male and female C57BL/6J mice (N=10 per experimental condition) were housed singly or in groups of 3-4 mice for 8 weeks. Then, using an SR-LAB (San Diego Instruments, CA) startle system, they were subjected to an initial test to assess startle responses across a range of stimulus intensities, 70 to 130 dB, and a subsequent test of PPI at 3 different PPI values, 3, 6, and 12 dB above background using a startle stimulus of 120 dB and background noise of 65 dB. **Results**: There were small differences in startle responses between isolation-reared and socially reared mice that were slightly larger in males, but not statistically significant

overall. Consistent with many previous observations, reduced PPI was observed to result from isolation-rearing. Differences in PPI were observed only for the lowest pre-pulse intensity (pp3*)*. However, these differences were only observed in isolation-reared male mice, compared to socially reared male mice. Not differences were observed between isolation-reared female mice and socially reared female mice. **Conclusions**: The present experiments found evidence that isolation-reared male, but not female, mice had deficits in sensorimotor gating as assessed by PPI. PPI deficits in isolation-reared mice are thought to be indicative of increased ventrostriatal dopamine function, and reductions in glutamatergic afferents to the ventral striatum. By contrast, other work in our laboratory has shown that female, but not male mice, exhibit behavior indicative of increased anxiety. Collectively these data suggest that early social isolation has distinctly different effects in male and female mice, and that deprivation of certain types of early social experience may contribute differently to the development of mental disorders in males and females. This lays the groundwork for determining the epigenetic mechanisms that might ultimately underlie these effects.

Title: Gaba signaling in hippocampus may be modulated by early life stress in a sexually dimorphic manner

Authors: *O. O. KALEJAIYE[1], T. OBISESAN[2], M. C. GONDRÉ-LEWIS[3];
[1]Anat., Howard Univ. Col. of Med., Washington, DC; [2]Howard Univ., Washington, DC; [3]Anat., Howard Univ., Washinton, DC

Abstract: The separation of a maternal figure from its offspring at key neurodevelopmental time points is associated with many long-term behavioral and neurochemical deficiencies that lead to neuropsychiatric disease in adulthood. Our previous studies implicate maternal separation (MS) stress as an underlying risk factor for anxiogenic, depressive, impulsive, and alcohol-drinking behaviors in rats. These behaviors are linked with action at the GABA receptor, and some pharmacological agents that act at the GABA site show behavioral rescue of affective and addictive-like symptoms. In MS, we have shown that baseline levels of GABA receptors are

increased in the amygdala and prefrontal cortex of naïve adult rats. However, the extent to which MS induces GABAergic dysregulation in the hippocampus, a major component of the limbic system, is unknown. Furthermore, the possibility of sexually dimorphic effects of MS on GABA receptor expression, and in GABAergic neuron development and survival is important to investigate. To this end, we analyzed expression of GABAAα1, GABAAα2 receptor subunits, and the GAD67 GABA producing enzyme, in subregions of the P14 hippocampus of rats subjected to chronic MS and their non-separated male and female counterparts. To test if MS induces changes in GABA circuitry long-term, we evaluated the number of GAD67-positive neurons at P70 in the medial prefrontal cortex and whole hipoccampus, but also in specific subregions of rostral and caudal dentate gyrus (DG) and CA3, using immunohistochemistry and unbiased stereological techniques. MS stress resulted in a significant reduction in GABAAα1 but not GABAAα2 or GAD67 in the DG of P14 females. CA1 and CA3 at P14 showed no statistical difference in expression for GABAAα1, GABAAα2, or GAD67. Stereological data imply MS exhibited a significant effect on GABA neurons in the DG. In controls, females had higher numbers and density of GAD67 neurons in the DG compared to males. However, MS caused a reduction in GABA neurons such that the difference between males and females disappeared. Our findings implicate that MS stress may have sexually dimorphic effects at specific time points in neurodevelopment. Such effects may be region specific and may contribute to the neurocognitive deficits and affective behavior of MS animals.

Title: Age and sex-dependent impact of repeated social stress on rat prefrontal cortical neuronal function and synaptic transmission

Authors: *K. R. URBAN[1], E. GENG[2], M. SUAREZ[3], R. VALENTINO[1];
[1]Gen. Anesthesia, Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Neurobio., [3]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Chronic or repeated stress can lead to the development of psychiatric illnesses including depression, post-traumatic stress disorder, schizophrenia, and anxiety. These disorders are characterized by impaired cognition and are thought to arise from dysfunction in the circuitry of the prefrontal cortex. Previous studies have shown that an acute stressor can enhance glutamate transmission and thereby cognition, whereas chronic stress reduces glutamate transmission and impairs cognition. Notably, the bulk of existing research has been performed on adult, male rats, and has not attempted to elucidate distinct age-dependent or sex-dependent mechanisms of stress effects on cognition. Little is known about how age at the time of stress determines the outcome. In this study, male and female rats were exposed to 5 days of social defeat or control condition during early adolescence (32-38 days old), mid-adolescence (42-48 days old), or adulthood (68-72 days old). Twenty-four hours after the final defeat, 300 μM brain slices were obtained from the rats and excitability of layer 5 pyramidal neurons in the prefrontal cortex were recorded using whole-cell patch clamp. Repeated resident-intruder stress produced age- and sex-specific effects on PFC intrinsic and synaptic excitability. Neuronal excitability evoked by high current intensities was decreased in stressed male and female mid-adolescent rats, whereas neuronal excitability elicited by low current intensities was selectively increased in stressed male mid-adolescent rats. These effects were associated with stress-induced changes in action potential amplitude, half-width, threshold and neuronal input resistance. Additionally, social stress exposure generally decreased synaptic excitability as indicated by a decrease in the amplitude of spontaneous excitatory post-synaptic potentials, although these effects were most prominent in females. Together, the findings demonstrate depressive effects of social stress on intrinsic and synaptic PFC neuronal excitability that occur in adolescents of both sexes and adult females. These neuronal effects may underlie the ability of social stress to impair executive functions such as cognitive flexibility, and suggest a potential neuronal correlate for greater female susceptibility to stress.

Title: Sex, stress, and migraine: differential effects of stress on the migraine relevant responses of males and females

Authors: *D. KAUFMANN[1], K. C. BRENNAN[2];
[2]Dept. of Neurol., [1]Univ. of Utah, Salt Lake City, UT

Abstract: Introduction: Stress is a common and potent migraine trigger. Two thirds of migraineurs are females, and hormonal fluctuations are also associated with migraine triggering. We wish to examine the interactions of sex and stress in animal migraine models. Methods: Twenty one adult males and twenty two adult female C57Bl/6 mice were randomly divided into chronic stress and control groups. A chronic behavioral stress paradigm was administered randomly, in two daily sessions for forty days. After the end of the stress paradigm anxiety measures were evaluated behaviorally using the open field test and elevated plus maze. Mechanical allodynia was evaluated in both groups before and after administration of 10 mg/kg nitroglycerin (NTG), followed by evaluation of cortical spreading depressions (CSD). Results: Chronically stressed male and female mice displayed anxiety behavior in both the open field and elevated plus maze test compared to their control counterparts. In the mechanical allodynia test chronically stressed males and females had a significantly lower baseline pain threshold compared to controls. Both control and stress males and females showed a significant reduction in pain threshold after NTG administration. Chronically stressed male mice did not show a change in CSD frequency compared to non-stressed controls; however chronically stressed females showed a significant increase in number of CSDs compared to controls. Conclusion: Our work outlines the effects of stress and sex differences on migraine relevant phenotypes. Chronic behavioral stress elicited a pain phenotype in both sexes, but sexually dimorphic responses were observed in cortical excitability. These phenotypes underline the importance of both stress and sex differences in migraine, and open the door for further mechanistic evaluation. Title: Sex differences in the subcellular distribution of corticotropin releasing factor 1 in the rat hippocampus in response to chronic stress

Authors: *H. R. MCALINN[1], R. POULTON-KAMAKURA[1], A. G. DYER[1], B. S. MCEWEN[2], E. M. WATERS[2], T. A. MILNER[1,2];
[1]Feil Family Brain and Mind Res. Inst., Weill Cornell Med., New York, NY; [2]Harold and Margaret Milliken Hatch Lab. of Neuroendocrinology, The Rockefeller Univ., New York, NY

Abstract: The rat hippocampus presents sexually dimorphic responses to stress, and to opioids. Our previous studies demonstrated sex differences in the subcellular distribution of corticotropin releasing factor receptors (CRFR1) in hippocampal delta opioid receptor (DOR) dendrites. We recently found that chronic immobilization stress (CIS) impacts the subcellular distribution of DORs in females, but not males, in a manner that would promote drug-related learning. As CRF1 action in the stress response is activational and regulatory, this study examined sex differences in the influence of chronic stress on the subcellular distribution of hippocampal CRFR1. Male and diestrus (low estrogen levels) female rats were subjected to 10 days of CIS, followed by brain perfusion and fixation with acrolein and paraformaldehyde. Hippocampal sections were labeled for CRFR1 with silver intensified immunogold particles (SIG). The subcellular distribution of CRFR1 was analyzed using electron microcopy in dendrites of CA3 pyramidal cells in stratum radiatum and in interneurons in the hilus of the dentate gyrus. At baseline, control animals showed that significantly more CRFR1-SIG particles were on the plasmalemma of male CA3 pyramidal cell dendrites compared to females, suggesting more available CRF binding sites in the males. Moreover, the cytoplasmic and total density of SIG-labeled CRFR1 in hilar interneuron dendrites was greater in males than in females, indicating greater reserve pools of CRFR1 in the males. After CIS, the density of CRFR1-SIGs increased on the plasmalemma of CA3 pyramidal cell dendrites in males but did not change in any cellular compartment of the females. Further, the cytoplasmic and total density of CRFR1-SIGs in CA3 pyramidal cell dendrites was less in males compared to females after CIS. In the dentate hilus, the total density of CRFR1-SIGs decreased in interneuron dendrites in males after CIS but did not change in any cellular compartment in females. As a result, the density of SIG-labeled CRFR1 near the plasma membrane of interneuron dendrites was greater in males than in females after CIS. These results propose that at baseline, CA3 pyramidal cells in males can bind more CRF than females and that in response to CIS, these neurons in males may bind even more CRF. Likewise, at baseline, hilar interneurons in males have more CRFR1 than females and after CIS, CRF1 redistributes in these neurons to arrange for their insert into the plasmalemma. These findings offer a mechanism for the added sensitivity of hippocampal neurons to chronic stress in males that could attenuate learning and memory processes.

Title: Sex differences and dynamics of neuroimmune and neuroendocrine responses to stressors

Authors: *D. LOVELOCK, A. S. VORE, T. DEAK;
Behavioral Neurosci. Program, Dept. of Psychology, Binghamton Univ., Binghamton, NY

Abstract: Expression of inflammatory cytokines such as interleukin-1β (IL-1β) are impacted by stress exposure and have emerged as key factors regulating stress adaptation. Though our prior studies have examined the IL-1 response across the ovarian cycle in females, sex differences in the neuroimmune response to stress have yet to be examined. The goal of experiment 1 was to establish a timecourse of pro-inflammatory cytokine expression in response to footshock in both sexes. Adult male and female Sprague-Dawley rats (N=64, n=8/group) were exposed to intermittent footshock (1.0 mA, 5 sec each, variable ITI of 90 sec) for 60 or 120 min. Brains, serum, and peripheral tissue (spleen) were collected immediately after stress termination under no-stress conditions or 2 hr after stress cessation to assess functional recovery. As expected, females showed a greater peak CORT response than males, and in both sexes the CORT response was resolved by 2 hr post-stress. Splenic IL-1β was markedly increased at 1 and 2 hr and largely resolved by the recovery timepoint. Notably, no sex differences were observed in this splenic IL-1β response. To better understand adaptation in central cytokine responses to chronic stress, Experiment 2 tested whether prior habituation to a mild stress challenge (60 min of daily restraint for 5 days) would impact the IL-1β response evoked by 30 min of forced swim incurred immediately after the final session of restraint. We examined cytokine expression and indices of cellular activation (c-Fos) in the PVN, PFC, and HPC as well as plasma CORT concentrations using adult male Sprague-Dawley rats (N=40, n=8/group,). In (non-habituated) rats that experienced acute restraint followed by 30 min of swim, CORT was markedly increased, c-Fos expression was robustly induced in all brain regions examined, and IL-1β expression was induced specifically in the PVN (3.5 fold increase). Interestingly, prior repeated daily restraint substantially attenuated IL-1β and c-Fos expression in the PVN, suggesting a significant influence of recent stress history on central cytokine responses to stress. These findings indicate that recent stress history may differentially influence the neuroimmune response to a novel stress challenge in a site- and cytokine-specific manner.

Title: Sex differences in- and stress effects on- microglial activation in brain regions critical for emotion regulation

Authors: *J. L. BOLLINGER, K. E. COLLINS, R. PATEL, C. L. WELLMAN;
Psychological and Brain Sci., Indiana Univ., Bloomington, IN

Abstract: Susceptibility to stress-linked psychological disorders differs between men and women. Brain regions critical for emotion regulation, including medial prefrontal cortex (mPFC), orbitofrontal cortex (OFC), and basolateral amygdala (BLA) have been implicated in stress-linked psychopathology. Chronic stress can affect these regions in a sex-dependent manner, differentially remodeling neuronal morphology and disrupting behavior. Recent studies indicate a role for neuroimmune pathways and microglia in psychological health and disease. Activated microglia can regulate synaptic plasticity by releasing neuroactive factors and directly pruning dendritic spines. In male rats, stress increases microglial cell activation and inflammatory factor expression in mPFC, and this contributes to deficits in mPFC-mediated behavior. We recently demonstrated a dramatic sex difference in the neuroimmune profile of mPFC, alongside differential effects of stress on microglial activation and immune factor expression. To investigate the generalizability of sex-specific stress effects on microglial activation, we assessed microglial density and morphology in OFC and BLA in male and female rats following acute or chronic restraint stress. Control animals were unhandled except for weighing. On the final day of restraint, brains were processed for visualization of microglia via Iba-1 immunohistochemistry. Microglia were classified as surveillant, primed, reactive, or amoeboid, and counted stereologically. There were no basal sex differences in OFC or BLA. However, chronic stress reduced the proportion of primed to surveillant microglia in OFC in male rats only, suggesting decreased activation in males but not females. Acute and chronic stress reduced the proportion of primed to surveillant microglia in BLA in males, whereas acute but not chronic restraint reduced this proportion in females, indicating a sex-specific response to chronic but not acute stress. Thus, stress differentially alters the morphological activation state of microglia in brain regions critical for emotion regulation in males and females. These differences may contribute to the differential effects of stress on neural structure and function in males versus females.

Title: Sub-chronic variable stress induced sex-specific effects on glutamatergic signaling in the nucleus accumbens

Authors: *G. E. HODES[1], A. BRANCATO[1,2], D. BREGMAN[1], F. H. AHN[1], S. J. RUSSO[1]; [1]Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY; [2]Dept. of science for health promotion and Mother and child care, Univ. of Palermo, Palermo, Italy

Abstract: Men and women manifest different symptoms of depression and under current diagnosis depression is a predominantly female disease. Yet little is known of the mechanisms contributing to these important sex differences and how they may impact potential future therapeutics. Sub-chronic variable stress (SCVS) induces depression-like behavior in female mice, modeling females' higher susceptibility to stress and depression. Accumulating evidence indicates that altered neuroplasticity of excitatory synapses in the nucleus accumbens is a key pathophysiological feature of stress susceptibility. Here we investigated the effects of SCVS on pre- and post-synaptic aspects of excitatory synapses in the nucleus accumbens of female and male mice. Animals underwent 6 day-exposure to alternating stressors, including foot shock, tail suspension and restraint stress. Medium spiny neurons from the nucleus accumbens were filled with Lucifer Yellow and spine density and phenotype were examined using the semi automated program neuron studio. In a separate group of animals immunofluorescence staining was performed for vesicular glutamate transporter 1 and vesicular glutamate transporter 2, in order to label cortical and subcortical glutamatergic terminals. Immunostaining for PSD95 was employed to evaluate post-synaptic density. Females, but not males, demonstrated circuit specific pre-synaptic alterations that may contribute to stress susceptibility in the absence of post-synaptic alterations in PSD 95 puncta, spine density and phenotype. Taken together, our data indicate that susceptibility to stress in females, is associated with changes in the strength of distinct glutamatergic inputs to the nucleus accumbens, which contribute to the susceptible phenotype induced by SCVS in female mice.

Title: Male experience, female investment and offspring anxiety behavior: where father's nature meets mother's nurture

Authors: ***A. KORGAN**, E. O'LEARY, J. BAUER, A. FORTIER, T. PERROT, I. WEAVER; Psychology and Neurosci., Dalhousie Univ., Halifax, NS, Canada

Abstract: Programming of reproductive strategies and defensive (stress) responses in the adult rat is influenced by early life maternal care. The detection of a potential mate's past experience with predators could inform the dam about the stress level of a potential mate, the likelihood of paternal effects in offspring, and potential ecological threats. We examined whether a male's previous exposure to predator (cat) odor influences a female's attraction toward these males, subsequent mother-infant interactions and the development of long-term emotional (defensive) responses in the offspring. Our results show for the first time that variation among males in their predator encounters may contribute to stable behavioral variation among females in courtship and maternal care, even when the females themselves are not directly exposed to a predator. Furthermore, paternal predator experience is associated with long-term effects on chromatin plasticity and anxiety-like behavior of the young adult offspring. These results, together with our previous findings, suggest that paternal predator exposure can influence offspring development both directly and indirectly, through altering maternal behavior.

Title: Endothelial dysfunction diminishes conducted vasodilation leading to abnormal functional hyperemia in the awake mouse cortex

Authors: *M. A. SHAIK[1], S. H. KIM[1], D. N. THIBODEAUX[1], E. M. C. HILLMAN[2]; [1]Biomed. Engin., [2]Zuckerman Mind Brain Behavior Institute, Biomed. Engin. & Radiology, Columbia Univ., New York, NY

Abstract: Functional hyperemia refers to the increase in brain blood flow driven by increased local neuronal activity. Recent studies have provided evidence that endothelium-dependent conducted vasodilation is an active participant in brain neurovascular coupling. Studies in the peripheral vasculature have shown that endothelium-dependent vasodilation mechanisms can include fast, long-range endothelium derived hyperpolarization and slow, calcium-wave dependent nitric oxide and cyclooxygenase product activity. In anesthetized rodents, we have previously shown that localized endothelial disruption can interrupt propagation of endothelium-dependent vasodilation. However, to assess the role of different endothelium-dependent mechanisms on functional hyperemia, it is important to be able to spatiotemporally map changes in neurovascular coupling and assign them to different aspects of endothelial coupling.
To explore different aspects of conducted vasodilation, we developed a new paradigm to image the exposed superficial cortex of awake Thy1-GCaMP6f mice, longitudinally. Mice were implanted with long-term thinned skull cranial imaging windows and head fixation mounts under anesthesia and then allowed to recover prior to repeated imaging sessions. Neural activity was recorded via wide-field fluorescence, while simultaneously recorded hemodynamics were calculated from interspersed dual wavelength reflectance measurements. Animals were recorded in the resting state and during tactile whisker stimulation of different durations. Animal locomotion and behavior were recorded during imaging. To analyze this data, a mathematical model was developed to describe two components of the hemodynamic response - first, local coupling derived by convolving local neuronal activity with an estimated hemodynamic response function, and second, a superimposed conducted hyperemic component, derived from local coupling in a centralized, highly responding region. This analysis enables unbiased analysis of

neural activity, hemodynamics, local and propagated neurovascular coupling properties and the presence of unaccounted for hemodynamics or apparent uncoupling. This methodology allows analysis of local and conducted hyperemic components, and how they are affected by different inductions of endothelial dysfunction, either acute or longitudinal. Here, we demonstrate this approach in animals that have received an acute dose of the non-blood brain barrier-permeable COX-inhibitor ketorolac, finding that it significantly diminishes the local hyperemic response consistent with an effect on COX-dependent endothelial coupling.

Title: Genetic mechanisms regulating connectivity and function of non-image-forming parallel visual circuits

Authors: *O. S. DHANDE[1], A. H. PHAN[2], T. A. SEABROOK[3], J. T. WANG[3], P. L. NGUYEN[2], A. D. HUBERMAN[3];
[1]Dept. of Neurobiology, Stanford Univ., Stanford, CA; [2]Neurosci., Univ. of California San Diego, La Jolla, CA; [3]Neurobio., Stanford Univ., Stanford, CA

Abstract: How are parallel visual pathways built and how do their unique connectivity patterns influence visual processing? Retinal ganglion cells (RGCs) encode visual features such as contrast, motion and luminosity and convey that information to the brain in the form of distinct parallel pathways that each connect to unique sets of retinorecipient brain targets. The precise connectivity patterns and signals relayed by parallel optic pathways are critical for eliciting specific visually guided behaviors. Thus, understanding the mechanisms by which these pathways are built and establishing causal relationships between specific RGC subtypes and the behaviors they drive, is an essential but unresolved set of challenges. Using a microarray-based approach we assayed and compared the transcriptional profile of transgenically labeled RGC

subtypes including direction selective, luminance sensing, and alpha RGCs, paying particular attention to the transcription factors uniquely expressed by certain RGCs and not others. We discovered that transcripts for several T-box family transcription factors are highly enriched in intrinsically photosensitive RGCs that comprise the non-image forming (NIF) pathway; these same transcription factors are near absent in other RGC subtypes. Protein expression analysis of the developing retina supported our microarray analysis. We chose to focus on Tbx20, a transcription factor whose function in the nervous system is largely unknown. We generated mutant mice lacking Tbx20 in NIF RGCs using the Cre/loxP system. Loss of Tbx20 in these RGCs resulted in significant reduction in the number of intrinsically photosensitive RGCs and their central projections, specifically those projections that feed centers of the brain involved in driving pupillary light reflex (PLR). To test the functional integrity of the visual system we developed a suite of visual behaviors to probe the consequence of genetically ablating T-box-family-expressing RGC subtypes. To our surprise most behaviors tested including PLR were not significantly altered in Tbx20 mutant mice. However, when we removed Tbx20 together with the gene encoding the photopigment melanopsin, we observed near-complete loss of the PLR. These data suggest that Tbx20 RGCs play a role in driving PLR but their contribution is likely masked by a more dominant driving force from other melanopsin-expressing RGCs. The purpose and mechanisms of this redundancy are the focus of our current work and will be discussed.

Title: Mapping functional atlas of the awake rat brain: a resting-state fMRI study

Authors: *Z. MA[1], P. PEREZ[1], Z. MA[1], Y. LIU[1], C. HAMILTON[2], Z. LIANG[1], N. ZHANG[1]; [1]Biomed. Engin., [2]Neurosci. Program, Penn State Univ., University Park, PA

Abstract: Our understanding of human brain organization has been significantly advanced by connectivity-based parcellation approach. With the premise that each functionally specialized

brain region is characterized by a distinct set of connections, connectivity-based parcellation can partition the brain into functionally specialized parcels based on neuroimaging data. The organization of the brain can be further investigated by analyzing the whole-brain network constructed using the parcellation. Despite great advancements in human studies in recent years, the parallel research in animals are still significantly underexplored, which highlights a gap in understanding the organization of the animal's brain using this approach. To surmount this obstacle, in the present study, we obtained a functional atlas by parcellating the brain into functional parcels using resting-state fMRI data collected in awake rats. This functional parcellation exhibited higher averaged parcel homogeneity than the histology-based anatomical parcellation. More importantly, the majority of functional parcels was highly robust, reflected by high reproducibility across animals imaged on the same MRI scanner, or even on different scanners of different field strengths. A rat whole-brain functional network was constructed based on this atlas and then analyzed using graph theoretic approach. Our results showed that the hubs identified in the rat functional brain network are consistent with the hub regions of the rat structural brain network, suggesting the convergence of structural connectivity and functional connectivity in brain hubs. In addition, we found that the rat functional brain network was topologically organized in a similar manner as the human brain, characterized by a balanced brain specialization and integration. The translational value of the present study in terms of comparative functional neuroanatomy was highlighted by the homologous functional hub region of the cingulate cortex and a rich-club organization shared by both the rat and human functional brain networks. Given the high relevance between neuropsychopathology and miswired brain network, this study can also help the establishment of translational animal models for multiple neuropsychiatric diseases.

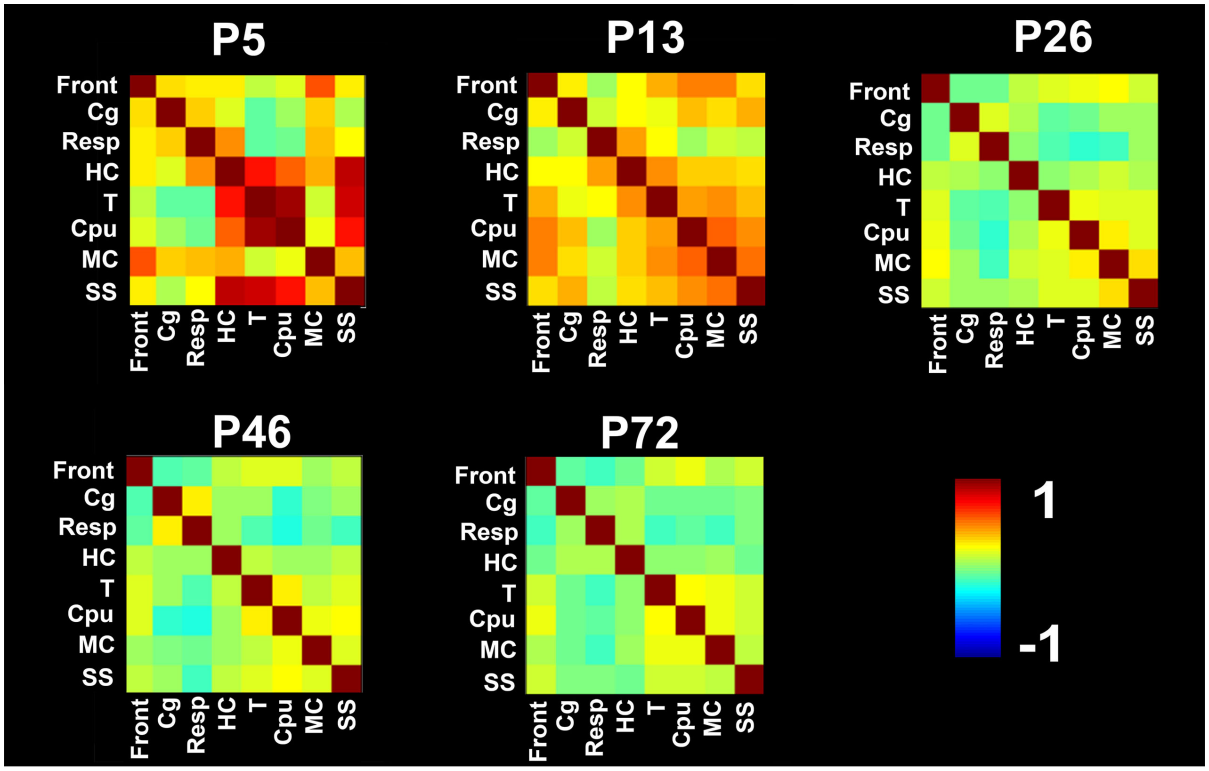
Title: Investigating the development of functional and structural connectivity in the rodent brain during ontogeny

Authors: *D. SHAH, I. BLOCKX, C. ANCKAERTS, J. PRAET, M. VERHOYE, A. VAN DER LINDEN;
Bio-Imaging Lab/University of Antwerp, Antwerp, Belgium

Abstract: Aim: Although much is known about the development and plasticity of afferent pathways in the brain, the ontogeny of interregional connections is relatively unknown and research (optical and electrophysiological techniques) is often hindered by the difficulty of investigating multiple brain regions simultaneously in vivo. In this study, the development of functional and structural brain connectivity was studied using the combination of specific *in vivo* MRI techniques. **Methods:** Brain functional connectivity (FC) and microstructural tissue characteristics were examined in developing healthy wistar rats (ages P5, P9, P13, P17, P22, P26, P31, P36, P46, P56, P72, and P86, N=8/age group), using resting state functional MRI (rsfMRI) and diffusion tensor imaging (DTI), respectively. Functional and structural maturation was investigated in regions of different brain networks i.e. somatosensory, motor, default-mode-like network (DMN), thalamus, striatum and hippocampus. **Results:** At early stages of brain development, i.e. between P5 and P22, FC in brain networks was hypersynchronous and decreased with age, leading to the formation of stable networks starting at P22-P26 (Figure 1). Structural measures (mean, axial and radial diffusion) also stabilized with brain maturation and correlated with functional measures. **Conclusion:** The results of this study show how functional and structural connectivity develops in the maturing brain. In addition, it provides an important application to study various clinical disorders that may be the result of interference with normal ontogeny (e.g., schizophrenia, dyslexia, epilepsy, and autism).



Maturation of functional connections in the developing rat brain. Functional connectivity matrices show hypersynchrony of resting-state neuronal activity patterns at early stages of brain development, which stabilize with maturation. Abstract: In humans, cognitively demanding tasks of many types recruit common frontoparietal brain areas. Pervasive activation of this "multiple-demand" (MD) network suggests a core function in supporting goal-oriented behaviour. A similar network might therefore be expected in non-human primates who readily perform similar tasks after training. However, an MD network in non-human primates has not been described.
Single-cell recordings from macaque frontal and parietal cortex show some similar properties to human MD fMRI responses (e.g. adaptive coding of task-relevant information). Invasive recordings, however, come from limited pre-specified locations so do not delineate a macaque homologue of the MD system, and their positioning could benefit from knowledge of where MD foci lie. Challenges of scanning behaving animals mean that few macaque fMRI studies specifically contrast levels of cognitive demand. We therefore sought to identify a macaque counterpart to the human MD system using fMRI connectivity in 35 anaesthetised Rhesus macaques.
Putative macaque MD regions, mapped from frontoparietal MD regions defined in humans, were found to be functionally connected under anaesthesia. To further refine these regions, an iterative process was used to maximise their connectivity, cross-validated across animals. Finally, whole-brain connectivity analyses identified voxels that were robustly connected to MD regions, revealing seven clusters across frontoparietal and insular cortex, comparable to human MD regions, and one unexpected cluster in the lateral fissure.
The proposed macaque MD regions can be used to guide future electrophysiological investigation of MD neural coding, and in task-based fMRI to test predictions of similar functional properties to human MD cortex.

Title: Comparison of wide-field optical mapping (WFOM) of neural activity and hemodynamics in awake mouse brain to resting state fMRI

Authors: *S. H. KIM, Y. MA, M. A. SHAIK, V. VOLETI, E. M. C. HILLMAN;
Biomed. Engin., Columbia Univ. Lab. For Functional Optical Imaging, New York, NY

Abstract: Resting state functional connectivity mapping (FCM) has become an increasingly popular method for human functional magnetic resonance imaging (fMRI). The blood oxygen level dependent (BOLD) signal measured in fMRI corresponds to local changes in deoxy-hemoglobin concentration. FCM is applied to fMRI BOLD data collected from subjects at rest to group brain regions of temporally correlated activity. While it is widely assumed that these BOLD signal maps directly reflect neuronal activity, the relationship between local neuronal activity and hemodynamic activity is not well understood, especially in the absence of stimulus. Interpretation of resting state FCM, therefore, requires a better understanding of the coupling between resting state hemodynamics and underlying neuronal activity.
In recent work, we developed a method for longitudinal wide-field optical mapping of both neural activity and hemodynamics over the superficial cortex of awake, behaving mice. Recordings of neural activity are achieved by macro-scale imaging of C57BL/6J-Tg(Thy1-GCaMP6f)GP5.17Dkim/J mice expressing calcium sensitive fluorescent protein GCaMP6f in excitatory neurons of layers 2/3 and 5. This technique has allowed us to develop model-based correspondence between spontaneous neural activity and resting state hemodynamics in the awake mouse brain. Here, we will describe measurements in which we compare these optical recordings of resting state neural activity and neurovascular coupling with resting state fMRI data acquired under light isoflurane in the same mice. Repeated wide-field optical measurements of the same mouse are achieved through an aseptic thinned-skull and headplate implant preparation. This approach allows precise explorations of the neural basis of fMRI data in health and disease.

Title: EEG dynamics suggest automatic detection of visual changes without attentional switch in hemianopic patients

Authors: *V. HADID[1], A. TRAN[1], D. K. NGUYEN[2], F. LEPORE[3];
[1]Univ. De Montréal, Outremont, QC, Canada; [2]Service de neurologie, CHUM Hôpital Notre-Dame, Montréal, QC, Canada; [3]Dept. de psychologie, Univ. de Montréal, Montréal, QC, Canada

Abstract: Loss of posterior visual cortex in one hemisphere due to surgery or stroke leads to blindness in the contralateral hemifield, known as homonymous hemianopia (HH). Affected patients retain the remarkable ability to unconsciously perceive visual stimuli presented in their blind field, a phenomenon termed blindsight. There is still some controversy about the mechanisms underlying such unconscious vision. In fact, there is no consensus about how this phenomenon can be objectively evaluated. To understand its nature, we measured the cerebral dynamic of blindsight with EEG. An oddball paradigm was used to elicit the visual mismatch negativity (where no attention or consciousness is required) determined by subtracting the waves elicited by the rare stimuli from the frequent stimuli. It is mainly characterized by a negative parietal wave around 150-250ms, followed by a frontal attentional switch at 300ms. To be sure that the control group would not focus on the oddball stimulus, frequent and rare moving dots were presented in periphery while participants carried out a Stroop task in the central visual field. Participants also carried out other control tasks to ensure that the results were not due to other parameters, such as physical attributes. This approach allowed us to measure objectively their ability to automatically detect visual changes presented in the blind field, independently of the "consciousness problem". The results revealed a visual mismatch negativity wave in the control and in the hemianopic group between 165-250 ms that was maximal in the parietal regions, showing an automatic detection of the changes. However, compared to controls, in which the localized negativity was followed by a frontal positivity between 300 and 400 ms, hemianopic patients had a diffuse negativity and no frontal positivity. Moreover, controls showed a desynchronization of the alpha/beta band (8-20Hz) around 250 ms in the frontal areas, whereas patients showed lower desynchronization that was however found only in the low alpha band. Desynchronization of the alpha/beta band reflects a higher attentional demand that can be interpreted in our controls as an upcoming attentional switch, and in our hemianopic group as a lack of attentional capture to visual changes. In conclusion, our results showed a distinctive cerebral dynamic in hemianopic patients that reflects unconscious detection of specific visual changes in the blind field, but a lack of orientation of their attention towards it. In light of these results, rehabilitation should focus on stimulating attentional capacities towards the blind field to make visual information more accessible.

Title: Abnormal resting state BOLD fMRI lag structure in idiopathic Parkinson disease

Authors: A. MITRA[1], *A. Z. SNYDER[2], M. C. CAMPBELL[1], A. TANENBAUM[3], J. M. KOLLER[3], J. S. PERLMUTTER[4];
[1]Washington Univ. Sch. of Med., Saint Louis, MO; [2]Radiol Dept, [4]Neurol., [3]Washington Univ. Sch. Med., Saint Louis, MO

Abstract: Parkinson disease (PD) is a progressive neurodegenerative disorder leading to motor disability and cognitive impairment. Degeneration of nigrostriatal dopaminergic neurons with consequent dysfunction of neural circuits involving the basal ganglia, thalamus, and cerebral cortex contributes to the clinical manifestations of PD. Prior studies of PD using resting-state blood oxygen level dependent (BOLD) functional magnetic resonance imaging (fMRI) have assumed that functional connectivity (FC) is adequately understood in terms of instantaneously correlated activity. These studies have generated a variety of findings, including increased as well as decreased FC in multiple areas of the brain. By relaxing the assumption of synchronicity and focusing on temporal lags between time series, we recently demonstrated highly reproducible patterns of temporally lagged intrinsic activity in normal human adults (Mitra et al., 2014, 2015). We refer to this analysis technique as resting state lag analysis (RS-LA). A previous study of adults with autism spectrum disorder indicated that RS-LA is a much more sensitive marker of intrinsic activity abnormalities than conventional FC (Mitra et al., in press). Here, we report RS-LA as well as conventional FC results in adults with idiopathic PD (n=40; off meds overnight) and demographically matched control participants (n=25). RS-LA analysis revealed highly significant group differences in ventral midline thalamus with extension to the subthalamic nucleus (STN), and striatum. The direction of signal propagation between the

caudate nucleus and specific regions of the cerebral cortex was reversed in PD as compared to controls (cortex->caudate in controls, caudate->cortex in PD). Opposite PD-related changes in lag structure were found between thalamus-STN and specific areas of cerebral cortex. Conventional FC analysis of the same data showed only comparatively modest effects (moderately reduced FC in PD). These results demonstrate that the lag structure of intrinsic brain activity is more altered in PD than the correlation structure computed at zero lag, i.e., convention FC. One implication of these results is that propagated infra-slow activity in the BOLD-fMRI band (nominally, 0.01 to 0.1 Hz) plays an important, although as yet poorly understood, role in normal brain function.

Title: Effects of continuous theta-burst transcranial magnetic stimulation on hemodynamic lag measured by BOLD fMRI

Authors: *D. J. LURIE[1], A. TAMBINI[2], C. GRATTON[4], J. POLINE[3], M. D'ESPOSITO[2]; [1]Psychology, [2]Helen Wills Neurosci. Inst., [3]Henry H. Wheeler Jr. Brain Imaging Ctr., Univ. of California, Berkeley, Berkeley, CA; [4]Dept. of Neurol., Washington Univ. in St Louis, St Louis, MO

Abstract: Continuous theta-burst TMS (cTBS) results in a sustained period of neural inhibition in targeted areas, and is often used to experimentally induce temporary “virtual lesions” in participants. Previous studies have observed local changes in Cerebral Blood Flow (CBF) at the site of cTBS stimulation. Likewise, reduction of CBF is also observed in patients with cerebrovascular disease, particularly in ischemic areas following stroke. Reduced perfusion is accompanied by a delayed BOLD hemodynamic response which can “lag” the rest of the brain

by up to 20 seconds. Thus, we hypothesized that cTBS may induce similar changes in hemodynamic lag under the coil. We tested this hypothesis in 27 healthy participants who underwent three sessions of cTBS and fMRI scanning. Each subject received cTBS on different days to left anterior insula/frontal operculum, left dorsolateral prefrontal cortex, and left primary somatosensory cortex. Resting BOLD and perfusion Arterial Spin Labeling (ASL) fMRI data were collected immediately before and after cTBS stimulation. We applied a cross-correlation based "lag mapping" analysis in which the BOLD time series from each voxel is compared to the average grey matter signal. By iteratively shifting the two signals relative to each other, it is possible to estimate the extent to which each voxel "leads" or "lags" the rest of the brain. Contrary to our hypothesis, we observed no consistent change in hemodynamic lag of the BOLD response at the site of cTBS stimulation. A previous analysis of the ASL scans from this dataset found high inter-subject variability in both the magnitude and direction (increase/decrease) of regional CBF changes under the coil. Even after accounting for this variability, we found no significant correlation between local changes in perfusion and changes in hemodynamic lag. These findings contribute to our understanding of the local (e.g. at the site of stimulation) physiological effects of cTBS. Moreover, these findings highlight important differences between true vascular lesions and the "virtual lesions" induced by cTBS.

Title: Investigation of the 5-HT2A/1A-agonist psilocybin on global and regional cerebral blood flow

Authors: *C. LEWIS[1,2], K. H. PRELLER[2], R. KRÄHENMANN[2], L. MICHELS[3], F. VOLLENWEIDER[2];
[1]Psychology, Arizona State Univ., Tempe, AZ; [2]Univ. of Zurich, Zurich, Switzerland; [3]Univ. Hosp. Zurich, Zurich, Switzerland

Abstract: Psilocybin, the active compound in psychedelic mushrooms, is a 5-HT2A/1A agonist. Seminal work in psilocybin neuroimaging research suggested hyper-frontal effects using positron emission tomography (PET) (Vollenweider et al., 1997; Gouzoulis-Mayfrank et al., 1999). However, recent work using arterial spin labeling (ASL) and blood oxygen level dependent (BOLD) functional MRI suggest global hypo-effects (Carhart-Harris et al., 2012). Therefore, we used ASL to investigate both global and regional effects of oral psilocybin on cerebral blood flow in a large sample to attempt to reconcile this seeming contradiction. In this placebo-controlled, double-blind study we used pseudo-continuous ASL perfusion MRI to measure regional CBF changes associated with two doses of oral psilocybin (low dose: 0.160 mg/kg; high dose: 0.215 mg/kg) in healthy controls (n = 29 in both groups, total N = 58) during a resting state scan. Participants from both the low and high dose groups reported profound subjective drug effects as measured by the Altered States of Consciousness Rating Scale (5D-ASC) with the high dose inducing significantly larger effects in four out of the 11 scales (Disembodiment, Complex Imagery, Elementary Imagery, and Audiovisual Synaesthesia). Controlling for sex and age, we utilized global normalization to infer the main effect of psilocybin on regional CBF and found psilocybin increases CBF in distinct right hemispheric frontal and temporal regions and bilaterally in the insula while decreasing CBF in left hemispheric parietal and occipital regions and the amygdala, globus pallidus, pallidum, insula, thalamus, and bilateral hippocampus ($p < 0.05$ FWE corrected). Using the traditional analysis of global effects, we found psilocybin significantly reduces CBF in various brain regions, including frontal, temporal, and parietal lobes, anterior cingulate, bilateral amygdale, insula, hippocampus, parahippocampus, caudate, and thalamus. Surprisingly, we were unable to find a significant dose effect of psilocybin on CBF, suggesting that the difference in subjective experience between the low and high dose groups is not coupled with CBF. Together, these results demonstrate a robust effect of psilocybin decreasing global CBF while having distinct regional right hemispheric frontal CBF increases and left hemispheric parietal and occipital decreases. This work was supported by Hefftner Research Institute and Swiss Neuromatrix Foundation.

Title: Striatal dopamine transporter availability decreases throughout the day in healthy volunteers

Authors: *C. E. WIERS[1], E. SHOKRI-KOJORI[2], C. WONG[1], D. TOMASI[1], G.-J. WANG[1], N. VOLKOW[1];
[1]Lab. of Neuroimaging, Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD;
[2]NIH/NIAAA, Bethesda, MD

Abstract: The Dopamine Transporter (DAT) has shown circadian fluctuations in animals, which have been associated with differences in dopamine release. However, circadian fluctuations of DAT have never been studied in humans. Here we investigated whether DAT availability was associated with the injection time of [11]Cocaine PET scans in healthy volunteers. We Based on preclinical findings that showed lower DAT in the afternoon than in the morning (Ferris et al., PNAS 2014) hypothesized that DAT availability would decrease with [11]Cocaine injection time. We moreover aimed to replicate that DAT availability decreases with age. A total of 130 healthy controls (15 females) underwent were imaged with an [11]Cocaine and PET scan for to measure DAT. Participants had a mean age of 34.3 years ± 8.1SD and a mean BMI of 25.6 ± 3.3SD. Mean injection time was 11.17 am ± .93SD, ranging from 9.05 am - 14.12 pm. Injection time was not associated with age, BMI or gender ($p>.05$). For hand- For the manually drawn striatal regions of interest (ROIs), [11]Cocaine injection time correlated negatively with Bmax/Kd in the putamen ($r=-.21$, $p=.017$) and ventral striatum ($r=-.22$, $p=.021$) but not caudate ($r=-.06$, $p=.52$). A The statistical paramateric mapping analysis corroborated similar these results, revealing that the: injection time correlated negatively with non-displaceable binding potential in the bilateral putamen: peak left = [-28, -10, 4], $t=3.56$, p-uncorrected<.0001; peak right = [28, -2, 6], $t=3.65$, p-uncorrected<.0001. As expected we also showed a significant negative correlation Age also correlated negativelybetween age and with Bmax/Kd in caudate ($r=-.42$, $p<.001$) putamen ($r=-.22$, $p=.011$) and ventral striatum ($r=-.35$, $p<.001$). The study confirms that in humans DAT in striatum decreases throughout the day in healthy volunteers, which suggests that diurnal variations of in DAT might underlie changes in striatal dopamine neurotransmission during the day throughout the day. The study further replicates the a negative association betweenfinding that DAT significantly decrease with age age and DAT in a larger sample than in used by previous studies.

Title: Optimizing spatial and temporal resolution and coil selection for BOLD protocols on the Siemens 3T Prisma

Authors: *S. A. MCMAINS[1], R. W. MAIR[1,2];
[1]Ctr. for Brain Sci., Harvard Univ., Cambridge, MA; [2]Athinoula A. Martinos Ctr. for Biomed. Imaging Harvard Med. Sch., Charlestown, MA

Abstract: Siemen's new 3 Tesla scanner, the Magnetom Prisma, includes increased gradient strength, multiple standard parallel array coils, and a faster reconstruction computer. This latter feature allows routine use of slice-accelerated EPI with multiband (MB) RF pulses and simultaneous multi-slice (SMS) acquisition of BOLD images, which makes increased temporal or spatial resolution possible. Here, we set out to answer questions the typical user may have, such as: are more receive channels better (coil study) and how will data be affected by a short TR or small voxels (protocol study)? The coil study (n=6) consisted of 3 resting state functional connectivity (fcMRI) scans of 6min each with each of the 20, 32 and 64ch coils: noSMS ($3mm^3$ voxels (V), TR/TE 3000/30ms, flip angle (F) 85^o), SMS3 ($2mm^3$ V, TR/TE 2000/30ms, F 80^o, 7/8 partial fourier), and SMS8 ($2mm^3$ V, TR/TE 750/36ms, F 57^o, not with 20ch). The protocol study (n=8) used the 64ch coil and 4 different BOLD protocols: Standard ($3mm^3$ V, TR/TE 3000/30ms, F 85^o), Enhanced ($2.2mm^3$ V, TR/TE 2000/35ms, F 80^o), Fast ($2.3mm^3$ V, TR/TE 650/34.4ms, F 54^o), and HighRes ($1.5mm^3$ V, TR/TE 2000/30ms, F 80^o). For each protocol, subjects performed one fcMRI scan, and two 5min task scans where they saw blocks of familiar or unfamiliar words. Measurements of interest were timecourse signal-to-noise (tSNR) calculated for each voxel after motion correction and detrending, correlations between major network seeds (fcMRI scans), and average t-maps (task scans). For the coil study, tSNR did not vary by coil for noSMS scans. For SMS scans, tSNR was lowest for the 20ch ($p<.001$), and highest for the 32ch ($p<.05$). The tSNR findings were mirrored in the fcMRI correlation matrices. For the protocol study, tSNR correlated strongly with voxel size. In addition, tSNR was higher for Fast than Enhanced ($p<.001$), after correcting for the number of timepoints. For the fcMRI analysis, Fast and Enhanced had a slight advantage over Standard, while HighRes had the weakest correlations. For the task, maps were best for Fast and worst for HighRes. While the 64ch coil was out performed by the 32, likely because the extra channels are around the neck,

and the coil body is larger, the difference was small and might be outweighed by the fact more people can comfortably fit in the 64. When comparing protocols, Fast and Enhanced had an advantage over the more traditional Standard. HighRes had the worst performance, but the hit in fcMRI and task maps may be worth the reduction in distortion and increased spatial precision that comes from smaller voxels for certain studies. Regardless, new SMS protocols allow the entire brain to be covered with good temporal and spatial resolution at little cost.

Title: BOLD is thicker than white matter: Surgically disconnected temporal pole exhibits resting functional connectivity with remote brain regions.

Authors: *M. J. SUTTERER[1], D. E. WARREN[3], J. BRUSS[1], T. J. ABEL[2], A. JONES[4], H. KAWASAKI[2], M. W. VOSS[5], M. CASSELL[6], M. A. HOWARD, III[2], D. TRANEL[1]; [1]Dept. of Neurol., [2]Dept. of Neurosurg., Univ. of Iowa Hosp. and Clinics, Iowa City, IA; [3]Dept. of Neurolog. Sci., Univ. of Nebraska Med. Ctr., Omaha, NE; [4]Brown Univ., Providence, RI; [5]Dept. of Psychological and Brain Sci., [6]Dept. of Anat. and Cell Biol., The Univ. of Iowa, Iowa City, IA

Abstract: Functional connectivity, as measured by resting-state fMRI, has proven a powerful method for probing relationships between brain areas in the context of behavior, development, and disease states. However, the precise relationship between functional and structural connectivity remains unclear. For example, functional connectivity has been reported in the

absence of direct anatomical connections (Tyszka et al., 2011; Vincent et al., 2007). To investigate this vexing issue, we capitalized on an opportunity to examine functional connectivity between brain areas that were surgically isolated from the rest of the brain by resection of connecting tissue. We hypothesized that anatomical isolation of a brain region should eliminate functional connectivity with the rest of the brain, and therefore predicted that the disconnected brain regions would not show functional connectivity with remote brain regions. We tested this prediction by recruiting from a post-resection population to study resting state functional connectivity of the intact but surgically disconnected temporal pole. Anatomical and functional MRI images were acquired from patient participants (N=5) recruited from the Patient Registry at the University of Iowa. Each participant had undergone temporal disconnection surgery (3 left sided, 2 right sided) for treatment of epilepsy. Surgical disconnection was confirmed during the procedure and by subsequent inspection of postoperative structural MRI data. Resting-state functional connectivity (RSFC) was measured via coactivation of whole-brain fMRI data with the average resting BOLD signal from the disconnected tissue mask in each patient participant. Contrary to our prediction that disconnected regions would not show RSFC with remote brain areas, we observed significant RSFC between the disconnected temporal pole and other brain regions in each of the five cases. We compared these maps to normative functional connectivity maps by applying the same seed regions to resting-state fMRI data from 25 healthy comparison participants. While comparison participants showed a broader pattern of RSFC than the disconnected cases, we observed significant spatial similarity (measured by eta^2) in the RSFC profile between healthy comparisons and the disconnected cases. While these findings do not impugn the methodology employed by studies of resting-state functional connectivity, they raise important questions about the influences of neurovascular coupling on the BOLD signal and analyses of RSFC data in isolation from behavioral measures. Further investigation of these issues should improve the power and validity of projects based on RSFC.

Title: Wide-field optical mapping of neural activity and cortical hemodynamics imaging during locomotion

Authors: *Y. MA, S. H. KIM, M. A. SHAIK, H. T. ZHAO, E. M. C. HILLMAN;
Biomed. Engin., Columbia Univ., New York, NY

Abstract: Understanding the relationship between neural activity and cortical hemodynamics, or neurovascular coupling is the foundation to interpret neuroimaging signals such as functional magnetic resonance imaging (fMRI) which measure local changes in hemodynamics as a proxy for underlying neural activity. Even though the stereotypical stimulus-evoked hemodynamic response pattern with increased concentrations of oxy- and total-hemoglobin ([HbO] and [HbT]) and a decrease in concentration of deoxy-hemoglobin ([HbR]) has been well-recognized, the linearity of neurovascular coupling and its dependence on brain regions and tasks haven't been thoroughly evaluated.
Longitudinal wide-field optical mapping of neural activity and cortical hemodynamics can be achieved across the entire, bilaterally exposed superficial cortex of awake, behaving mice. Neural imaging is achieved through wide-field fluorescence imaging in animals expressing genetically encoded calcium sensor (Thy1-GCaMP6f). Hemodynamics are recorded via simultaneous imaging of multi-spectral reflectance, and can also be supplemented by measurements of laser speckle flow. Our head-plate and restraint design allows animals to be implanted, recovered and then imaged repeatedly for 3 months. During imaging sessions, animals were allowed to stand or run freely on a saucer-wheel treadmill and could also receive timed whisker stimulation. Behavior of animals was also recorded using a near infrared camera during all imaging sessions. In prior work we have demonstrated that spontaneous changes in cortical blood volume in the resting state can be well-predicted by local changes in neural activity, given by absorption-corrected GCaMP fluorescence measurements. Here, we can use similar methods to compare coupling between bouts of locomotion versus resting state across the brain. Moreover, correlates of all aspects of observable behavior, and brain state interactions with the onset and cessation of locomotion can be explored.

Abstract: Light stimulus can elicit stable and robust electrophysiological activity of visual units in rodents or non-human primates even under deep anesthesia. However, fMRI BOLD responses were seldom used to assess visual activity in rodents under an anesthetic state. We build a light stimulation system equipped with an optical fiber (diameter 4 mm , length 5 m) and a white light LED as the light source. The flashing frequency (1, 5, 10 Hz with 50% duty cycle) and light intensity (0.1~23 cd/m^2) were administered to elicit BOLD responses of the visual system when male Wistar rats were anesthetized with dexmedetomidine (0.10 mg/kg/hr). A gradient-echo EPI was employed to obtain functional images with TR/TE = 3000/15 ms, seg = 2, in-plane resolution 312 x 312 micrometers, matrix size 80 x 80, and 10 slices with 1-mm thickness. A spin-echo EPI with TR/TE = 2000/35 ms and same geometry mentioned above was also used to provide complementary information. The testing stimulus was arranged into 5 blocks of 20 s-on/20 s-off cycles and synchronized with a 7T Bruker Biospec scanner via a custom-made LabView program. The light stimulus elicited strong BOLD responses on the lateral geniculate nucleus (LGN), superior colliculus (SC), and primary visual cortex (V1). The LGN preferred flashing in higher frequency and was sensitive to changes in light intensity, but V1 showed better BOLD response when low frequency was presented. A very weak light was sufficient to elicit SC activity, though neither frequency nor intensity preference was detected. As for the imaging sequences, SE-EPI showed better activity differentiation to various light intensities, while the BOLD activity detected by GE-EPI was saturated at a low intensity. The present study showed that light stimulation could elicit strong BOLD responses in the visual path of anesthetized rats, and two imaging sequences showed different response profiles with distinct features. These results provide a feasible setup and useful information to study the effect of learning and experience on visual pathway using BOLD fMRI experiments in the future.

Abstract: The functional specialization of the cerebral cortex depends in large part on its connectivity. While connectivity has traditionally been studied in humans with functional MRI, it may also be revealed by intracranial EEG (iEEG), which has a finer temporal resolution and the advantage of directly reflecting neuronal activity. A number of studies have investigated the correspondence between iEEG and MRI-based metrics of connectivity; however, the correspondence of these measures when connectivity is disrupted has yet to be examined. Corpus callosotomy, one treatment for intractable epilepsy, massively alters connectivity by severing the major fiber bundle connecting the cerebral hemispheres. This operation's disruption of inter-hemispheric connectivity has been documented using resting fMRI in a single patient (Johnston et al., 2008). To explore whether similar effects would be identified in electrophysiological measures of resting connectivity, we monitored three patients' resting intracranial EEG and mapped cortico-cortical evoked potentials (CCEPs), before and after undergoing anterior callosotomy.

Depth electrodes were placed bilaterally in frontal, parietal, and temporal lobes and insula in three epilepsy patients undergoing presurgical monitoring. All three patients then underwent anterior corpus callosotomy with electrodes intact, using stereotactic laser ablation. Electrodes were held in place with skull bolts, ensuring no migration during surgery. During clinical monitoring before and after callosotomy for each patient, we collected resting intracranial EEG (iEEG) during 3-6 minutes of quiet rest with eyes closed. We also mapped evoked potentials (CCEPs) using trains of bipolar stimulation at adjacent electrodes. Finally, we obtained 6 minutes of resting fMRI and DTI for each patient before electrode implantation and after electrode explant. To facilitate comparison with electrophysiology, BOLD time course extraction was performed using seeds at the location of each implanted electrode.
We found that inter-hemispheric iEEG connectivity, measured by resting iEEG and evoked potentials (CCEPs), was markedly altered following callosotomy in brain areas with projections to the lesioned section of the corpus callosum. These changes were paralleled by comparable effects in resting fMRI. Posterior to the callosotomy, both intra-and inter-hemispheric connectivity were relatively unchanged. These results provide further support for the correspondence of electrophysiological connectivity measures with fMRI.

Title: Accessing cortical inhibitory processes through the delay of the fMRI BOLD response.

Authors: *S. PROULX, R. FARIVAR;
Ophtalmology, McGill Univ., Montreal, QC, Canada

Abstract: Blood Oxygenation Level Dependent (BOLD) used in functional Magnetic Resonance Imaging (fMRI) allows an indirect measure of brain activity, but is blind to the ongoing interplay between excitation and inhibition. A recent study showed inhibition to not only reduce, but also

delay the BOLD response. Orientation of visual stimuli can be predicted from the spatial pattern of BOLD response *amplitudes* in the early visual cortex, and as inhibition is implicated in the cortical processing of orientation, we predicted that the pattern of BOLD *delays* will also allow to decode the orientation of the driving stimulus.

Amplitude and *delay* of BOLD responses induced by oriented visual stimuli were measured in 4 healthy subjects in a cyclic fMRI paradigm (Figure1). A Support Vector Machine (SVM) linear classifier was used to predict orientation of the two grating stimuli from either the V1 brain pattern of *amplitude* or *delay* of BOLD. Leave-one-out cross validation and random permutation tests (500 permutations) were performed to assess classification performance and significance. We obtained high and significant accuracies for prediction of stimulus orientation using both the *amplitude* and the *delay* of BOLD (Table1). Interestingly, similarly measured responses to a plaid stimulus, where cross-orientation suppression enhances inhibition, were delayed relative to grating stimulus in all subjects. These results confirm that the delay of BOLD responses carries neuraly-relevant information, and suggest that inhibition is implicated, implying that inhibitory processes *are* accessible with standard non-invasive fMRI exams.

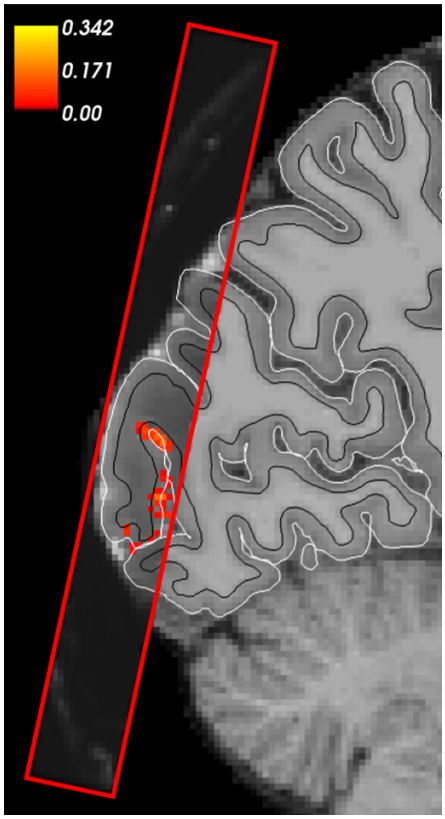

Figure 1: High-resolution BOLD fMRI at 3T with a custom 32-channel coil dedicated to the occipital cortex (1x1x1mm^3 GE-EPI; 13 slices; 10% gap; TR=1s; TE=68ms; red box). Activation extracted through cross-correlation of a sinusoid at stimulus period (12sec), and R-squared displayed on the overlayed heat map.

Title: Low density lipoprotein receptor-related protein 1 (LRP1) regulates glutamate signaling in the mammalian circadian clock

Authors: *J. COOPER[1], R. A. PROSSER[2];
[1]Biochem. and Cell. and Mol. Biol., [2]Univ. of Tennessee, Knoxville, TN

Abstract: The mammalian circadian clock in the suprachiasmatic nucleus (SCN) exhibits daily, iterative changes in its responses to glutamate: nighttime glutamate induces SCN clock phase shifts; daytime glutamate does not. Mechanisms gating SCN phase shifting emulate those that

modulate neuroplasticity throughout the brain. LRP1 is a multifunctional membrane receptor that influences neuronal responses to glutamate through its endocytic and cell signaling actions. Here we investigate LRP1 as a regulator of circadian clock phase shifting. SCN brain slices from adult male C57BL/6 (WT) mice were treated with glutamate (1mM) +/- LRP1 inhibitors (500nM RAP or 75µg/mL anti-LRP1 antibody) at ZT 16 or ZT 23 (ZT 0=lights on, ZT 12 = lights off) for 10 minutes. The following day we recorded SCN single-unit neuronal activity (SUA) to determine the time of peak activity (an output signaling clock phase). Concurrent application of RAP or anti-LRP1 with glutamate prevents the normal shifts, while RAP alone has no effect on clock phase. One LRP1 ligand, tissue-type plasminogen activator (tPA), is known to influence neuronal plasticity both independently and via LRP1 interactions. We previously reported that tPA gates SCN phase shifting through proteolytic activation of BDNF (Mou et al 2009). Here we tested the hypothesis that LRP1 influences SCN phase shifting via interactions with tPA in experiments using tPA knockout ($tPA^{-/-}$; B6.129S2-$Plat^{tm1Mlg}$/J) mice. Continued entrainment and glutamate-induced phase resetting in SCN slices from adult $tPA^{-/-}$ mice suggest involvement of redundant pathways. Additional experiments indicate a second plasminogen activator and additional LRP1 ligand, urokinase plasminogen activator (uPA), participates in clock phase regulation. Addressing potential LRP1/tPA interactions, RAP continues to inhibit glutamate phase shifts in $tPA^{-/-}$ slices, indicating LRP1 may influence the clock independently of tPA. Preliminary western blot data indicate LRP1 is present in the SCN with no apparent circadian rhythm in total expression but potential changes in LRP1 phosphorylation on Y4507. Dynamic changes in LRP1 localization may underlie LRP1's role in SCN clock phase shifting, and future studies are aimed at assessing LRP1 cell surface localization. Given LRP1's diverse set of extracellular ligands and ability to mediate multiple cellular effects, exactly how LRP1 participates in circadian clock phase regulation remains a mystery. These results indicate that LRP1 contributes to the processes orchestrating circadian clock timing, and demonstrate the utility of the SCN circadian clock as a model system with which to study the neuronal functioning of LRP1.

Title: Mapping the co-expression of clock proteins BMAL1 and PER2 with Enkephalin and Substance P in the rodent forebrain

Authors: *A. FREDERICK, J. GOLDSMITH, N. DE ZAVALIA, S. AMIR;
CSBN, Concordia Univ., Montreal, QC, Canada

Abstract: Despite rhythmic clock gene expression being found throughout the central nervous system, very little is known about their function outside of the suprachiasmatic nucleus. Understanding how clock genes are expressed across a variety of neural cell types is important to elucidating how these clock genes are regulated and how they may influence the function of each brain region. Using immunofluorescence and confocal microscopy, we quantified the co-expression of the clock proteins BMAL1 and PER2 with Substance P (SubP) and Enkephalin (Enk). Regions examined included the limbic forebrain (the dorsal striatum, ventral striatum, central nucleus of the amygdala, bed nucleus of the stria terminalis), the thalamus (medial habenula), the hypothalamus (paraventricular nucleus, arcuate nucleus) and the olfactory bulb. In most regions examined, PER2 and BMAL1 were homogenously expressed in nearly all cells (~90%), despite very different expression profiles of SubP or Enk in each nucleus. In nuclei that expressed both SubP and Enk, PER2 and BMAL1 were not preferentially co-expressed in one cell type or the other. The olfactory bulb was unique and did not express PER2 or BMAL1 throughout, and Enk was rarely found in the same cells that expressed the clock proteins (SubP was undetectable). This indicates that clock genes are not unique to specific cell types and further studies will be required to address which factors contribute to clock gene rhythmicity, focusing on how clock gene phase relationships, amplitudes and synchrony vary in different cell types.

Title: Continuous measurement of 28 neurotransmitters and other endogenous messengers for 24 hours in the striatum and prefrontal cortex by microdialysis in freely moving rats

Authors: N. MOORE[1], A. RASSOULPOUR[1], H. JANSSENS[1], L. YU[1], H. KOOIJKER[1], F. HELFRICH[1], J. ROESER[1], *M. G. VAN DER HART[1,2];

Abstract: Circadian rhythms (CR) can be observed in several physiological systems throughout the body. In the brain, the suprachiasmatic nucleus (SCN) drives the 'internal clock' and further regulates the CR directly or indirectly throughout the body. Disruption of the CR can have enormous effects on mood and concentration, and is observed in individuals with mood disorders and neurodegenerative disorders. Understanding the resultant neurochemical changes that occur across the CR can help to inform therapeutic strategies to treat disorders related to a disrupted CR. While previous microdialysis studies have explored the neurochemistry underlying circadian patterns, these studies have primarily examined only a few neurotransmitters in a single brain region.
In the current study, we investigated the changes in a large number of neurotransmitters and other endogenous neurochemicals with a single sample using in vivo microdialysis. We placed a microdialysis probe in either the prefrontal cortex (PFC) or striatum (STR) and collected samples every hour for 24 hours. Across the 24 hour period, differences in neurotransmitter release were observed in the PFC and STR for ACh, DOPAC, HVA and 1-met-HA. The following analytes increased during at least part of the dark cycle; ACh, DOPAC, HVA in the PFC only, 1-MetHA in the STR only, GABA, Gly and HA in both the PFC and STR. The levels of Kynurenine, Kynurenic acid, Xanthurenic acid, tryptophan and 5-HIAA were attenuated in the dark cycle in both brain areas. These data demonstrate the feasibility of monitoring many neurochemicals within one sample for prolonged periods of time. Furthermore, we observed distinct neurochemical changes in the PFC and STR that are altered across the CR. Future work will explore neurochemical changes in brain regions more directly invoved in the CR, such as the SCN and the pineal gland, to gain a better understanding of the neurochemical changes that underlie, and perhaps may drive the CR.

Title: Dopamine regulation of clock gene expression in the olfactory bulb

Authors: *N. DE ZAVALIA, P. SOLIS, S. AMIR;
Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: The olfactory bulb (OB) of rodents has been suggested to possess a self-sustaining circadian oscillator, which functions independent from the master circadian clock in the suprachiasmatic nuclei. It also contains the major forebrain dopamine (DA) system common to all vertebrates. The importance of DA in the regulation of circadian rhythms is suggested by clinical evidence of altered behavioral and physiological rhythms in patients with Parkinson's disease (PD) and by experimental findings in rodents showing that depletion of striatal DA, the primary neuropathology of PD, disrupts circadian rhythmicity.
The aim of this work was to study the regulation of the expression of major clock genes in the OB by DA.
First, we determined the rhythmicity and cellular expression of Per1, Per2 and Bmal1 in the OB by immunohistochemistry and western blot. PER1 was expressed in the glomeruli cell layer (GL), where it co-localizes with tyrosine hydroxylase expression. It was also expressed in the mitral (ML) and granular cell layers (GCL), while PER2 was only expressed in the ML. The levels of both proteins, PER1 and PER2, were increased at ZT 1 ($p < 0.05$). There was no rhythmical expression of PER1 in the GCL. BMAL1 was also expressed in the GL, GCL and ML. Subsequently, we studied the extracellular levels of DA in the OB by microdialysis and HPLC. DA was released rhythmically with a peak at the end of the light phase (ZT11-ZT12) and a trough at the end of the dark phase (ZT 23-ZT0). To decrease the levels of DA in the OB, we performed unilateral naris closure (UNO) in young adult rats (125-150 g). This method induced a significant down-regulation of the catecholamine biosynthetic enzyme tyrosine hydroxylase (TH) in DA neurons intrinsic to the OB 1 month after UNO (control: 109.3 ± 3.7 au, UNO: 78.8 ± 5.4 au, $p < 0.001$). Preliminary results showed a slight decrease of BMAL1 in the GCL, an increase in the GL and no change in the ML after UNO, although these changes were not found to be significant. The western blot showed an increase in the levels of BMAL1 and a decrease in the levels of PER2 in the OB, however these experiments have to be replicated.
These findings confirm the existence of a circadian oscillator in the OB and demonstrate significant circadian rhythms in proteins of major clock genes in subregions of the OB. They also demonstrate a circadian release of DA that contributes to the regulation of the expression of the major clock genes. Further studies have to be made to determine the exact extent of the DA contribution to the regulation of the circadian rhythms in the OB.

Title: Using *Drosophila melanogaster* as a model to study age related changes in the circadian clock

Authors: *J. A. CURRAN[1], K. TSANEVA-ATANASOVA[2], J. J. L. HODGE[1];
[1]Sch. of Physiology, Pharmacol. and Neurosci., Univ. of Bristol, Bristol, United Kingdom;
[2]Univ. of Exeter, Exeter, United Kingdom

Abstract: Circadian rhythms control a wide range of biological processes, ranging from metabolic activity to control of the sleep-wake cycle. It is well established that elderly individuals have increasing difficulties sleeping at night combined with generally going to sleep and waking up earlier. These age-related declines in circadian output are clearly observable in activity recordings in laboratory animals but what underlies these changes at a molecular and neuronal activity level are unknown. *Drosophila* makes an attractive system for studying this age-related decline in the clock output, with their short lifespan (~70 days) allowing for comparably manageable experimental timescales.
This study investigates how age impacts upon the circadian system of *Drosophila*, looking at changes in behavioural outputs, neuronal activity and gene expression. Behaviour was measured by recording the locomotor activity of male flies at various stages in the ageing process (1, 8, 15, 22, 29 days old), analysing the period and rhythm strength while in constant dark conditions. Changes in neuronal activity were investigated using whole-cell patch clamp electrophysiology to record from clock neurons (large ventral lateral neurons), with recordings made across the circadian day and at various ages. Finally changes in the molecular clock were investigated by analysing the relative expression of clock genes using quantitative RT-PCR.
At a behavioural level there was a significant age-related linear decline in the rhythm strength of circadian behaviour that was associated with an increase in period length. The linear decline in behavioural outputs of the clock demonstrate the suitability of *Drosophila* as a model to interrogate how ageing effects the circadian clock at other levels. Further experiments endeavour to understand how the disruption in behavioural rhythms are reflected by changes in the electrical activity of clock neurons.

Title: Characterization of innexin hemichannels in the circadian peacemaker neurons of *Drosophila melanogaster*

Authors: *E. FRITZ[1], P. FERNANDEZ[1], J. CAMPUSANO[1], J. C. SAEZ[1,2];
[1]Pontificia Univ. Catolica De Chile, Santiago, Chile; [2]Ctr. Interdisciplinario de Neurociencia de Valparaiso, Valparaiso, Chile

Abstract: Introduction: In invertebrates, innexins (functional analogs to connexins in vertebrates) form gap junctions and hemichannels (HCs). These proteins are fundamental for cell-cell communication during development and adulthood. In Drosophila melanogaster, seven out of the eight innexin-encoding loci are expressed in the nervous system. However, to our knowledge no extensive study has been performed to determine their function and/or gene expression. Based on the importance of the conserved nature of circadian rhythms across all species, we analyzed innexin expression and HC activity in Drosophila melanogaster peacemaker neurons.
Materials and Methods: Single cell mRNA extraction and RT-PCR was performed in ventral lateral GFP-expressing PDF-positive (GFP-PDF^{+}) neurons to detect innexin mRNA. HC activity was measured by dye uptake of HC fluoresccent permeability tracers.
Results: Innexin 1, 6, 7 and 8 were detected. In cultured GFP:PDF^{+} neurons we found HC activity that increased by exposure to extracellular divalent cations free solution (DCFS) and the increase was inhibited by Lanthanum (La^{+3}).
Discussion: Our data indicates that ventral lateral PDF^{+} neurons of Drosophila melanogaster express functional HC. We hypothesis that innexin hemichannels may affect the circadian rhythms of Drosophila melanogaster.

Title: Developmental lead, ecdysone-responsive genes, and circadian sleep in the fruit fly

Authors: *A. VAZQUEZ-MONTES[1], W. MELENDEZ-PACHECO[1], C. VALENTIN-RAMOS[1], P. CARRION-COLON[1], J. AGOSTO-RIVERA[2], H. ORTIZ-ZUAZAGA[3]; [1]Biol., Univ. Del Turabo, Gurabo, PR; [2]Biol., [3]Computer Sci., Univ. of Puerto Rico, San Juan, PR

Abstract: Metal contaminants, such as lead (Pb^{+2}) are persistent environmental neurotoxicants producing cognitive, behavioral, and physiological impairments in the developing brain. Early Pb^{+2} exposure disrupts learning and memory processes, locomotor activity, and sleep cycle disturbances in Pb^{+2}-exposed children and rodents. Sleep is a hormone-dependent physiological process that is regulated by circadian rhythms and has been widely characterized in the fruit fly. Ecdysone steroid hormone regulates circadian rhythms, and ecdysone-responsive genes have been identified as important regulators of the molecular clock machinery of circadian neurons in the adult. The goal of this research is to characterize the effects of developmental exposure to Pb^{+2} in circadian sleep and ecdysone-responsive genes in the adult fruit fly. Our hypothesis is that early exposure to Pb^{2+} will impair ecdysone-responsive genes and circadian sleep later in non-exposed adults. Flies were exposed to control or Pb^{+2}-contaminated food during development, but not in the adult stage. Sleep was tested using infrared-based activity monitors during constant darkness. Circadian sleep disturbances were assessed using rhythm strength and standard sleep parameters. Ecdysone-responsive gene activities were detected from total RNA collected from whole individuals and non-exposed adults using fluorescence probes and Real Time PCR. Our data show that developmental exposure to Pb^{+2} disrupts developmental transcriptional activation of ecdysone-responsive genes and produces dimorphic sleep phenotypes in non-exposed adult flies.
Overall, our studies will give insights related to early low-level exposure of persistent contaminants, such as Pb^{+2} and their contribution in the etiology of circadian sleep disorders using the fruit fly as the model.

Title: Functional imaging of sleep and wake states in zebrafish.

Authors: *A. ANDREEV[1], T. V. TRUONG[2], S. E. FRASER[2];
[2]Translational Imaging Ctr., [1]USC, Los Angeles, CA

Abstract: The zebrafish, with its small size and optical accessibility, has emerged as an attractive vertebrate, diurnal model system to decipher the basic mechanisms of sleep behavior, regulation, and function. We present our development of the toolset to allow brain-wide functional imaging and analysis, at single-celled resolution, of zebrafish larvae during sleep and wake behavior. As the sleep state is particularly sensitive to photo-induced effects imparted by the imaging itself, we first establish the necessary imaging conditions that minimally perturb the behaving animal, using two-photon selective plane illumination microscopy (2p-SPIM) as the modality of choice. Using 2p-SPIM, we capture zebrafish brain activity for periods up to 48 hours, measuring functional changes over different regions of the brain during natural sleep/wake cycle with cellular resolution. We characterize the brain activity due to visual and auditory stimuli to determine response thresholds during sleep and wake. Under this framework, we begin to characterize the similarities and differences between the natural sleep/wake states and similar states induced either via pharmacological means or optogenetic activation. Insights gained by our study will contribute to the understanding of the nature and function of sleep.

Title: Pharmacological profiling of zebrafish sleep-awake states

Authors: *Y. NISHIMURA, S. OKABE, S. SASAGAWA, S. MURAKAMI, Y. ASHIKAWA, M. YUGE, K. KAWAGUCHI, R. KAWASE, Y. SHIMADA, T. TANAKA;
Pharmacol., Mie Univ. Grad. Sch. of Med., Tsu, Mie, Japan

Abstract: Sleep-wake states are impaired in various neurological disorders. Impairment of sleep-wake states can be an early condition that exacerbates these disorders. Therefore, treating sleep-wake dysfunction may prevent or slow the development of these diseases. Although many gene products are likely to be involved in the sleep-wake disturbance, hypnotics and psychostimulants clinically used are limited in terms of their mode of action and are not without side effects. Therefore, there is a growing demand for developing new hypnotics and psychostimulants with high efficacy and few side effects. Towards this end, animal models are indispensable for use in genetic and chemical screens to identify sleep-wake modifiers. As a proof-of-concept study, we performed behavioral profiling of zebrafish treated with chemical and genetic sleep-wake modifiers. We were able to demonstrate that behavioral profiling of zebrafish treated with hypnotics or psychostimulants from 9 to 10 days post fertilization was sufficient to identify drugs with specific modes of action. We were also able to identify behavioral endpoints distinguishing GABA-A modulators and hypocretin receptor antagonists and between sympathomimetic and non-sympathomimetic psychostimulants. This behavioral profiling can serve to identify genes related to sleep-wake disturbance associated with various neuropsychiatric diseases and novel therapeutic compounds for insomnia and excessive daytime sleep with fewer adverse side effects.

Title: The effects of transient kcna2 knock-down on sleep-wake cycles in larval zebrafish

Authors: *K. KARLSSON, Dr.[1,2], S. SRDANOVIC[2], F. ÞÓR, 101[1], H. ÞORSTEINSSON[2]; [1]Reykjavik Univ., Reykjavik, Iceland; [2]3Z, Reykjavik, Iceland

Abstract: Relying on simple or genetically tractable animal models, a molecular vision of sleep that assumes there are cross-species common cellular sleep processes has been emerging. Recently a mutation in voltage-gated potassium channels has been shown to be associated with a short sleeping phenotype in rodents and flys. In order to replicate and extend these findings we use morpholino oliogonucleotides (MO) to knock-down Kcna2 in larval zebrafish and assess the effects on sleep-wake cycles. First, measuring arousal thresholds at four days-post-fertilization (dpf4) and dpf7 fish, we firmly establish criteria for sleep-wake measurements at these young ages. Second, three groups of fish were behaviorally assessed for sleep parameters: naïve fish and fish injected with control or Kcna2 MO: all groups underwent 24 hr behavioral monitoring of sleep-wake cycles at dpf4 and dpf 7 (i.e. while the MO is still active and after the effects have worn off). Third, the rate, duration and amplitude of spontaneous field potentials were measured at the level of tectum opticum and telencephalon at dpf4 and dpf7. We show that at dpf4 Kcna2 injected fish exhibit significantly less sleep behavior than do controls or naïve fish and exhibit higher rates and longer duration local field potentials. We show that MO knock-down of voltage-gated potassium channels results in a transiently short sleeping phenotype and increased rate of spontaneous activity due to global increasein membrane excitability. The current findings further establish zebra fish as an excellent model of sleep and are consistent with the notion that core neural pathways, common across phylogeny, control sleep-wake cycles.

Title: Glutamate regulates bmal1 protein in cultured bergmann glia cells

Authors: *L. D. CHI-CASTAÑEDA[1], S. M. WALISZEWSKI[2], R. C. ZEPEDA[2], L. C. R. HERNÁNDEZ-KELLY[1], M. CABA[2], A. ORTEGA[1];

Abstract: Glutamate (Glu), the major excitatory amino acid, activates a wide variety of signal transduction cascades. This neurotransmitter is involved in photic entrainment of circadian rhythms, which regulate physiological and behavioral functions. The circadian clock in vertebrates, suprachiasmatic nucleus, is based on a transcription-translation feedback loop, in which Brain and muscle aryl hydrocarbon receptor nuclear translocator (ARNT)-like protein 1 (BMAL1) acts as transcriptional activator of others clock genes. This protein is expressed in nearly all suprachiasmatic nucleus neurons, and other brain and peripheral regions. This study aimed was to investigate the role of Glu in the molecular mechanisms involved in the processes of transcription/translation of BMAL1 protein. To this end, primary cultures of *Gallus gallus* cerebellar Bergmann glia cells were stimulated with glutamatergic ligands, the results indicate that BMAL1 levels increased in a dose- and time dependent manner. Additionally, the phosphorylation of serine residues in BMAL1 under Glu stimulation was studied and the results show an increase in the phosphorylation of this protein. The increased expression of BMAL1 is most probably the result of its stabilization after being phosphorylated by the cyclic AMP-dependent protein kinase and/or the Ca^{2+}/diacylglycerol dependent protein kinase. The results strongly suggest that Glu regulates translationally BMAL1 in glial cells, and that these cells are important for the regulation of circadian rhythms in the cerebellum.

Title: Ventral anterior homeobox 1 is required for suprachiasmatic nucleus development as well as circadian output in adulthood allowing female fertility

Authors: *H. M. HOFFMANN[1,2], C. TRANG[1,2], B. HEREFORD[1,2], K. BHARTI[3], D. K. WELSH[2,4,5], M. R. GORMAN[2,6], P. L. MELLON[1,2];

Abstract: During the last century, our society has changed dramatically, and today many people work odd hours, travel across time zones, and have disrupted sleep patterns. These are all factors affecting circadian rhythms and leading to medical illnesses including diabetes, decreased cognitive capacity, and impaired fertility. Correct coordination and timing of hormone release in the hypothalamic-pituitary-gonadal (HPG) axis are required to maintain fertility. Female fertility is particularly sensitive to compromised circadian rhythms causing dysregulation of the HPG axis. Development of the suprachiasmatic nucleus (SCN), the brain's primary circadian pacemaker, is required for fertility. The SCN orchestrates the HPG axis by coordinating hypothalamic kisspeptin neurons and gonadotropin-releasing hormone (GnRH) neuron activity with peripheral tissues and light cycles. Mature GnRH neurons respond to kisspeptin by increasing GnRH release, which allows appropriate levels of sex steroids across the estrous cycle and the preovulatory luteinizing hormone surge. We here identify a novel homeoprotein required

for SCN development and function, Ventral Anterior Homeobox 1 (VAX1). H&E staining in the *Vax1 knock-out* mouse at P0 shows a complete loss of the medial portion of the hypothalamus, causing the partial or total absence of the medial preoptic area and anteroventral periventricular region, as well as the SCN. Indeed, VAX1 is necessary for expression of SCN markers: the SCN transcription factor, SIX homeobox 3, as well as two core SCN peptides, arginine vasopressin and vasoactive intestinal peptide, which demarcate the SCN shell and core regions respectively. Interestingly, in the adult brain, VAX1 is almost exclusively expressed in the SCN. Since the *Vax1* knock-out mouse is perinatal lethal, we generated $Vax1^{flox}$ mice and crossed them with $synapsin^{cre}$ mice, thus deleting VAX1 in mature neurons in the brain. $Vax1^{flox}$:$synapsin^{cre}$ mice had an impaired activity pattern and reduced activity of wheel running in constant darkness, which correlated with abnormal expression of SCN peptides and Per2::luciferase expression, indicating weak SCN output. In addition, $Vax1^{flox}$:$synapsin^{cre}$ females had prolonged estrous cycles and decreased fertility. Despite abnormal SCN output in $Vax1^{flox}$:$synapsin^{cre}$ males, they had normal fertility and sperm quality. This study provides a new model to address how weak SCN output impacts fertility, and confirms the high sensitivity of female, but not male, fertility to impaired SCN output.

Title: Hypothalamic lesion of A11 area disturb clock genes

Authors: C. PIÑA-LEYVA[1], M. LARA-LOZANO[1], B. FLORÁN-GARDUÑO[1], *J. A. GONZALEZ-BARRIOS[2];
[1]Physiology, Biophisics and Neurosciences, CINVESTAV, Mexico City, Mexico; [2]Hosp Regional Octubre, ISSSTE, Mexico DF, Mexico

Abstract: The A11 hypothalamic nucleus, also known as dopaminergic diencephalospinal tract, innervates the spinal cord. This descending tract is involved in the regulation of important mechanisms in the spinal cord such as nociception and locomotion, which are under circadian control. There are few studies focused on the physiological regulation of the clock genes in the spinal cord which control the circadian function. We evaluated the expression of the clock genes in the spinal cord and the subsequent alteration of the expression of these genes after lesion of

A11 nucleus by an injection of 6-OHDA (10 µg/µL). We used male Wistar rats to evaluate the expression of the transcripts per1, 2 y 3, bmal, clock, cry1 y 2 on cervical, thoracic and lumbar region of the spinal cord; the rats were lesioned by stereotaxic surgery, after 7 days we dissected the different regions of the spinal cord and extracted mRNA by a TRIzol® protocol. The expression of genes was evaluated by RT-qPCR using commercial taqman probes. The results shown that in the cervical region there are a downregulation the mRNA of per1, 2 and 3, bmal, clock, cry1 and 2, in the thoracic and lumbar regions there are downregulation of per1, 2 and 3, cry1 and 2 whereas upregulation of bmal and clock. Ours results show that dopaminergic depletion of the A11 nucleus alters the transcription of clock genes of the spinal cord of the rat, and suggest that the clock genes are regulated by dopamine receptors activation.

Title: Predicting estrous state and pregnancy outcome: applications of high temporal resolution temperature rhythm analysis in female mice

Authors: B. L. SMARR[1], I. ZUCKER[2], *L. J. KRIEGSFELD[3];
[1]Psychology, [2]Psychology and Integrative Biol., [3]Psychology and The Helen Wills Neurosci. Inst., Univ. of California, Berkeley, CA

Abstract: Female reproductive cycles and pregnancy induce predictable changes to physiology and behavior that are associated with major health and quality of life issues. Although well described at the population level, these changes exhibit substantial interpersonal variance; this variance, combined with low temporal-resolution data, has left female reproduction remarkably under-described. The miniaturization of electronic sensors and data storage enable high-resolution monitoring of individuals across long time windows. These extensive data sets permit more subtle and sophisticated individualized predictors of physiological state. To explore the power of such strategies in animal models of reproductive functioning, mice were implanted with temperature probes generating one data point per minute for several months. Not only does this high temporal resolution approach permit a fine-grained analysis of course rhythmic processes

(e.g., circadian rhythms), but decomposition of each daily waveform can be applied to reveal quantifiable traits predictive of reproductive state. Here we take advantage of a number of quantitative analyses of these high-resolution, long-duration data sets to stage estrus and to accurately detect and predict the outcome of pregnancies within the first 12 hours after a night of pairing. The validation of this approach underscores the potential to reveal novel insights in time-series data, including development, puberty, and illness outcomes. These approaches also have the potential to inform human-subject investigations to render a higher-quality description of healthy female reproductive cycles, pregnancies, and menopause for use in personal, predictive, and preventive biomedicine.

Title: $CBP^{Kix/Kix}$ mice have decreased gene model 129 (CHRONO) expression and increased free-running circadian period

Authors: *C. C. ANGELAKOS[1], S. G. POPLAWSKI[2], S. CHATTERJEE[2], G. PORCARI[2], J. B. HOGENESCH[3], T. ABEL[2];
[1]Dept. of Neurosci., [2]Biol., Univ. of Pennsylvania, Philadelphia, PA; [3]Mol. and Cell. Physiol., Univ. of Cincinnati, Cincinnati, OH

Abstract: The transcriptional coactivator CREB binding protein (CBP) is recruited by and heterodimerizes with the CLOCK/BMAL1 transcription factor complex to regulate clock gene activation. CBP overexpression enhances CLOCK/BMAL1-mediated Per1 activation, while CBP knockdown decreases circadian clock induction and oscillation. The mechanisms by which CBP regulates CLOCK/BMAL1-mediated transcription and circadian rhythms are not fully understood. We performed RNA sequencing in the hippocampus of mice carrying an inactivating triple point mutation in the CREB-binding (Kix) domain of CBP ($CBP^{Kix/Kix}$ mice), which blocks phospho-CREB binding to CBP. We found decreased expression of the circadian clock mediator

gene *Gm129* (CHRONO) in $CBP^{Kix/Kix}$ mice, which validated with quantitative PCR. CHRONO has recently been shown to regulate circadian rhythms by repressing CLOCK/BMAL1 function via direct interference of BMAL1-CBP binding, and *Chrono* knockout mice have prolonged free-running circadian rhythms. Activity monitoring of $CBP^{Kix/Kix}$ mice across the diurnal cycle in 12:12 hour light:dark revealed delayed activity onset as well as delayed peak activity in both male and female $CBP^{Kix/Kix}$ mice compared to sex-matched wildtype littermates. Similar to the prolonged circadian periods found in *Chrono* knockout mice, $CBP^{Kix/Kix}$ mice exhibited a 27-minute increase in free-running circadian period relative to wildtype littermates; however phase shifting in response to 15-minute light pulses at CT14 and CT22 did not differ between $CBP^{Kix/Kix}$ mice and controls. Quantification of CHRONO in the brain and liver of $CBP^{Kix/Kix}$ mice across the diurnal cycle are being performed. Together, these studies help to further elucidate the molecular machinery regulating the circadian clock and may contribute to our understanding of the contributions of epigenetic regulators to circadian rhythms.

Title: The RNA editing gene, Adar, suppresses sleep by regulating glutamatergic synaptic plasticity

Authors: N. HOFFNER[1], J. ROBINSON[2], J. PALUCH[3], D. DICKMAN[3], *W. JOINER[2]; [1]Dept. of Neurosci., [2]Dept. of Pharmacol., Univ. of California San Diego, La Jolla, CA; [3]Dept. of Neurobio., USC, Los Angeles, CA

Abstract: Sleep is an essential, homeostatic process that is highly conserved throughout the animal kingdom. However, its functions are still poorly understood. One leading hypothesis for a core function of sleep suggests that synaptic potentiation during waking is offset by a homeostatic reduction in net synaptic strength during sleep to maintain overall synaptic function within a stable physiological range. However, molecular mechanisms supporting this hypothesis are lacking. Here we address the relation between sleep and synaptic plasticity in the context of the RNA editing gene, *Adar*, which we have identified as a critical regulator of sleep pressure in

Drosophila. Loss-of-function alleles and RNAi knockdown of *Adar* lead to selective destabilization of the waking state and increased sleep, effects we have mapped to a subset of glutamatergic neurons in the CNS. We also find that *Adar* mutants post-transcriptionally upregulate the vesicular glutamate transporter, VGLUT, leading to over-activation of NMDA receptors, and that these effects are required for observed increases in sleep. Furthermore, by electrophysiological and genetic analyses we show that in *Adar* mutants the reserve pool of glutamatergic synaptic vesicles is selectively expanded, and that this change is required for increased sleep. The net effect of this expansion is sustained neurotransmitter release under conditions that would otherwise result in synaptic depression. We propose that the shift in the balance from synaptic depression toward synaptic potentiation in sleep-promoting neurons underlies the increased sleep pressure of *Adar*-deficient animals. Our results provide a plausible molecular mechanism linking sleep and synaptic plasticity.

Abstract: The symptoms of narcolepsy can occur during the course of several neurological conditions. Inherited disorders, tumors and CNS autoimmune diseases were the three most frequent causes for symptomatic narcolepsy. Among inherited disorders, Niemann-Pick type C, Prader-Willi syndrome and myotonic dystrophy type 1 (MYD1) were mainly reported. MYD1 is the most common adult-onset form of muscular dystrophy. Excessive daytime sleepiness (EDS) is the most frequent non-muscular complaint in MYD1. As EDS tends to persist despite successful treatment of sleep disordered breathing (SDB) in MYD1 patients, available evidence

suggests that MYD related EDS is primarily caused by a central dysfunction of sleep regulation rather than by sleep fragmentation or SDB. Methods: The subjects were 14 patients with MYD1 (6 male and 8 female, 12-70y. mean 39.4y). Patients gave informed consent for the lumbar puncture. This study was approved by Akita Univ. ethical committee. We checked clinical symptoms, polysomnography, MRI/CT and measured orexin levels. Results: Orexin levels were decreased to low levels in 4 cases (<110pg/ml). Two cases were intermediate levels (110-200pg/ml). Eight cases were normal levels (>200pg/ml). All of them had EDS. PSG result revealed SDB, most patients have complications of severe obstructive sleep apnea syndrome. Six cases were treated with continuous or bi-level positive airway pressure. Conclusion: Since majority of patients with idiopathic narcolepsy show undetectable orexin levels (<40pg/ml), the degree of reduction in MYD1 was small in contrast to them. The EDS symptoms of this disease would not be caused only orexin dysfunction or SDB. Although orexin levels in other genetic neurological conditions with or without EDS are not systematically studied, further studies of the involvement of the orexin system in symptomatic narcolepsy and EDS are helpful to understand the pathophysiological mechanisms for occurrence of EDS.

Title: Effect of "sleep-in-a-dish" on DISC1 protein homeostasis

Authors: *C. KORTH;
Heinrich Heine Univ. Dusseldorf, Dusseldorf, Germany

Abstract: **Background:** Sleep is a vital function when restorative processes occur. Disturbances in sleep-wake cycle and in circadian rhythms have been associated with many neurodegenerative

and psychiatric disorders. Previous studies show that sleep deprivation can induce tau phosphorylation, synaptic injury as well as impaired learning and memory in mouse models of Alzheimer disease (Rothman et al., 2012; Di Meco et al., 2014). An *in vitro* model that mimics cellular and molecular changes of sleep and wakefulness state was used (Hinard et al., 2012) to investigate disturbed proteostasis and the consequence for misfolded proteins clearance. Aggregation of DISC1 will be investigated, as it has been shown to be insoluble in brains of a subgroup of mental illness patients (Leliveld et al., 2008). **Methods:** Primary cortical cultures from tgDISC1 rats that exhibit insoluble full-length DISC1 (Trossbach et al., 2016) were treated with a mixture of waking neurotransmitters cocktail (Hinard et al., 2012), and used for biochemical analysis and for electrophysiological recordings, by multielectrode electrode arrays (MEA). **Results:** Electrophysiological recordings in cortical neurons from tgDISC1 stimulated with a waking cocktail show an induction of tonic firing that replaced the synchronized burst-pause firing pattern, as described previously as a sleep-like state (Hinard et al., 2012). Preliminary results indicate that blocking of burst activity leads to an increase in DISC1 aggregation as measured by quantitative Western blot. We will report more details of these analyses. **Conclusion:** We conclude that the "sleep-in-a-dish" model for simulating basic intercellular electrical oscillatory activity is suited to investigate clearance of misfolded proteins and thus a simple model for simulating the effects of sleep on protein homeostasis. Title: Synchronization of cortical dendritic activity during sleep spindles in rodents

Authors: *J. SEIBT[1,2], C. RICHARD[2], J. SIGL-GLÖCKNER[3], N. TAKAHASHI[2], D. DENIS[4], C. BOCKLISCH[2], M. E. LARKUM[2];
[1]Univ. of Surrey, Guildford, United Kingdom; [2]Charité-Universitätsmedizin, Berlin, Germany; [3]Bernstein Ctr. for Computat. Neurosci., Humboldt Univ. of Berlin, Berlin, Germany; [4]Insitute of Physiol., Univ. of Bern, Bern, Switzerland

Abstract: Sleep has now been linked to brain plasticity at many levels, with converging evidences from the molecular, cellular and behavioral fields. Studies in humans and animals support of specific role for spindle oscillations (9-16Hz) in this process but the underlying physiology remain elusive. It has been suggested that spindle bursts promote calcium increase specifically in dendrites, a condition that would favor dendritic plasticity processes (1, 2). Although this hypothesis is supported by computational modeling (1), to date, evidence that such a relation exists during natural sleep is missing.
To address this issue, we measured calcium activity from layer 5 (L5) dendrites in the somato-sensory cortex using 1-photon (fiber-optic) and 2-photon imaging in naturally sleeping rodents. Calcium imaging was combined with electroencephalographic (EEG) recordings to monitor behavioral states and underlying network oscillations.
Our results show that activity of population of dendrites during slow-wave-sleep was specifically correlated with spindle-beta (9-30 Hz) power changes. Two-photon imaging of single dendrites further suggests that this relationship was largely explained by an increase in synchronization of dendritic activity during spindles. Interestingly, this effect was specific to dendrites as L2/3 and L5 cell bodies did not show such correlation.
Our results support the current hypothesis of a direct link between spindles and dendritic activity regulation and further reveal an important, yet unexplored, functional coupling between spindle and beta oscillations (15-30Hz). Further (and ongoing) experiments probing the influences of experience on this relationship will reveal important information on the physiology of spindles and their role in learning and memory.

Title: Nicotine induction of orexin gene expression in SH-SY5Y cells is modulated by glucose

Authors: J. L. SABO[1], *J. K. MORRIS[2];
[1]Neurosci. Program, [2]Dept. of Biol., Baldwin Wallace Univ., Berea, OH

Abstract: Narcolepsy is a chronic sleep disorder characterized by overwhelming day time sleepiness, cataplexy, sleep paralysis, hypnagogic hallucinations, premature REM sleep initiation, and is considered neurodegenerative due to loss of neuropeptide HCRT/ORX containing neurons within the LHA. Prepro-orexin contains two CpG-island rich regulatory regions that are possibly important for differentiation of orexin neurons. Epigenetic alteration of nucleotides in the prepro-orexin promoter induces embryonic stem cell differentiation to an HCRT/ORX neuron while sirt 1 histone deacetylase inhibited differentiation. Prenatal nicotine exposure increased HCRT/ORX positive neuron numbers. In addition, narcoleptic patients treated with nicotine therapy report fewer narcoleptic phenotypes than with amphetamine-based medication. Together, these findings suggest orexin differentiation may occur through several mechanisms, converging on genetic regulation of prepro-orexin gene expression. To determine if nicotine regulates the prepro-orexin gene, a pLuc-wtorx plasmid, containing the minimal mouse prepro-orexin promoter was stably transfected into SH-SY5Y cells and selected with Zeocin (100 µg/mL). SH-SY5Y cells were incubated in EMEM or DMEM, 10% FBS for 12 hours, then replaced by medium containing nicotine (0, 5, 10, 50, 100, 500, 1000 nM). Luciferase concentration of supernatant samples of eight independent wells per group were repeatedly measured (0, 4, 12, 24 hours) by 570 nm luminescence endpoint reading at 22°C, 31°C, and 37°C, and again 10 minutes later. Optimum assay conditions were determined to be at 22°C. Luminescent intensity of nicotine (10 nM) was 39% higher than baseline ($\alpha = 0.05$; $p = 0.026$). Therefore, nicotine has a regulatory effect on the prepro-orexin promoter of the pLuc-wtorx SH-SY5Y cell line. SH-SY5Y stably transfected cells with a control plasmid did not express significant levels of luciferase activity. High glucose (25 mM) DMEM inhibited prepro-orexin expression while low glucose (5.5 mM) EMEM allowed nicotinic upregulation of the prepro-orexin promoter. Orexin expression appears to increase under fasting conditions, which may

increase food foraging behavior in rodents. The ability of nicotine to induce HCRT/ORX expression does not override this mechanism. Thus, regulation of blood glucose levels might be important in narcolepsy management and nicotine treatment efficacy.

Abstract: Prefrontal cortical modulation of cognitive processing, alertness, and affective states is disrupted by sleep deprivation. These wide-ranging effects are likely to be modulated by a large number of molecules. Recent data demonstrate the power of an untargeted metabolomic approach for detecting arousal state-dependent changes in scores of known and thousands of unknown molecules in mouse prefrontal cortex (FASEB J 30:1231.1, 2016). The present study is testing the hypothesis that sleep deprivation alters the metabolome in the frontal association cortex (FrA; mouse homologue of prefrontal cortex) and the M1 region of motor cortex. Adult, male C57BL/6J mice (n=19) were implanted with a standard array of electrodes for objectively assessing states of sleep and wakefulness. After recovery and conditioning to being handled,

microdialysis samples were obtained from the FrA and M1 during three experimental conditions: 1) ad lib sleep from 09:00 to 15:00 (n=7 mice; sample n: FrA=166; M1=164); 2) sleep deprivation during the same time interval (n=6 mice; sample n: FRA=143; M1=144); and 3) sleep deprivation from 21:00 to 03:00 (n=6 mice; sample n: FrA 143; M1=144). Dialysis samples were analyzed off-line using ultra-performance liquid chromatography coupled with high-resolution mass spectrometry (UPLC-HRMS) and an established metabolomics method (Anal Chem 82:3212, 2010). Partial least squares-discriminant analysis revealed distinct groups of analytes that clustered as a function of brain region and the three experimental conditions outlined above. Variable importance projection scores identified more than 30 metabolites in FrA and more than 20 metabolites in M1 that were associated with sleep deprivation. Hierarchically clustered heat maps suggest brain-region specific, differential increases and decreases in metabolite levels among treatment conditions. In FrA, behavioral state-specific changes were observed in tyrosine metabolism, inositol metabolism, and valine, leucine, and isoleucine degradation. In M1, changes in behavioral state were associated with differential alterations in major energy pathways, such as metabolism of alanine, aspartate, and glutamate, the TCA cycle, and butanoate metabolism. This study demonstrates the feasibility of using UPLC-HRMS to quantify analytes obtained from mouse cortex by in vivo microdialysis. The approaches used in this study offer a novel opportunity for characterizing behavioral state-dependent changes in biomarkers of brain metabolism.

Title: Effects of glycine injection into trigeminal motor nucleus on jaw-opening excitability duringsleep in rats

Authors: ***R. ODAI-IDE**[1], K. ADACHI[2], S. HINO[3], T. SHIMOYAMA[3], H. SAKAGAMI[2], S. WATANABE[1], G. J. LAVIGNE[4], B. J. SESSLE[5];

[1]Pediatric Dent., [2]Pharmacol., Meikai Univ. Sch. of Dent., Sakado, Japan; [3]Oral Surgery, Saitama Med. Univ.,, Kawagoe, Japan; [4]Univ. de Montreal, Montreal, QC, Canada; [5]Oral Physiol., Facuty of Dent., Univ. of Tronto, Tronto, ON, Canada

Abstract: The excitability of the jaw-opening reflex (JOR) is depressed during quiet sleep (QS). Because the systemic administration of glycine reduces sleep latency and the incidence of micro-arousals and increases JOR excitability during QS in rats, it has been hypothesized that the glycine receptor system in the trigeminal motor nucleus plays a role in the maintenance of sleep quality. In the present study, we investigated the effects of the microinjection of glycine or vehicle (isotonic saline) on JOR excitability and sleep quality in rats. Under general anaesthesia, 5.5-week-old male Sprague-Dawley rats (n = 20) received wire implantations for electrocardiographic (EKG) recording, for electromyographic (EMG) recording from bilateral anterior digastric (AD) and masseter (MA) muscles, for electroencephalographic (EEG) and electrooculographic (EOG) recording, and for electrical stimulation of the genioglossus muscle. Guide cannulae were implanted into the AD region of the trigeminal motor nucleus (AP: -9.7 mm, Lateral: 1.5 mm, from bregma) for microinjection (0.2 μl/side) of glycine (0.1, 0.2 or 0.4 M) or saline. During recovery from surgery (approximately two weeks), rats were habituated to the observation environment. Sleep-related physiological (e.g., EMG, EOG, EEG and EKG) activities were scored with epochs of 5 sec. During the quiet awake (QW) period before sleep (QWBS), genioglossus stimuli (200 μs) were applied to define the threshold for inducing the JOR in 3 stimulation trials separated by more than 5 min intervals. Then the animal was allowed to sleep freely and the JOR threshold was determined 3 times during QS as well as QW after sleep (QWAS). After the microinjection of glycine or saline, the JOR excitability and sleep-related physiological activities were determined again across the sleep-awake state. After the investigation, the brain was removed under deep anaesthesia and the microinjection site was confirmed in brain slices (20 μm). Compared with saline, each dose of glycine (0.1, 0.2 and 0.4 M) significantly ($P < 0.05$) reduced the JOR threshold during QS. Sleep latency and the incidence of micro-arousals were reduced, but not significantly, by 0.4 M glycine microinjection compared with saline. In all groups (saline; glycine [0.1, 0.2 and 0.4M]), the distribution pattern of EEG frequency bands (δ, θ, α and β) was altered across the sleep-awake state and the δ band was significantly ($P < 0.05$) increased during QS compared with QWBS and QWAS. These findings suggest that the glycinergic system in the AD region of the trigeminal motor nucleus may be involved in the maintenance of sleep quality without affecting brain EEG excitability.

Title: Sleep deprivation induces changes in dopamine actions & D1 receptor expression in the rat hippocampus

Authors: Q. NGUYEN[1], H. AZIZI[1], V. SUEN[1], A. KWOK[1], N.-G. KANG[1], R. SOMVANSHI[2], *U. KUMAR[2], B. R. SASTRY[1];

Abstract: Sleep deprivation is becoming increasingly common among teenagers and shift workers. For memory consolidation, sleep seems to be required. In rat hippocampus, the expression of metabotropic glutamate receptor 1α (mGluR1α) and γ-aminobutyric acid B receptor subunit 1 ($GABA_BR1$), and a hetero-dimerization between the two, are changed following sleep deprivation. Dopamine (D) receptors are also G-protein coupled. D is implicated in modulating sleep and is important in developing therapeutics in psychiatry. The objectives of this study are to examine whether the expression of D receptors and actions of applied D in the hippocampus change following sleep deprivation and, if so, whether these changes are reversible. Male Wistar rats were (a) allowed normal sleep (NS), (b) subjected to a 12-hour sleep deprivation (SD), or (c) sleep-deprived for 12 hours followed by a 24 or 48 hour sleep recovery (SR). Stratum radiatum stimulation-induced field excitatory post-synaptic potentials (fEPSPs), in the CA1 pyramidal layer in hippocampal slices, were measured in the presence of bath-applied D (25-400 μM) to construct a dose-response curve. In slices from NS animals, D depressed the fEPSP in a dose-dependent manner. In slices from SD animals, the depressant action was significantly decreased ($p<0.001$). SR for 24-48 hour was able to reverse this effect. Quinpirole, a D2 receptor agonist, did not have a significant effect on the fEPSP in concentrations of 1-400 μM. D1 receptor expression in the hippocampus was investigated with Western blot and immunohistohemistry. Both methods showed significantly decreased expression of D1 receptor following SD. D1 receptor levels recovered in 24-48 hrs of SR. In co-immunoprecipitation studies, no hetero-dimerization was observed between mGluR1α and D1 receptors. These results indicate that a 12 hr SD results in a down-regulation of D1 receptors and a reduction in D's depressant action in the rat hippocampal CA1 area. Both changes subside following a 24-48 hr

SR. These results have implications for therapies involving drugs targeting dopaminergic pathways in the mesolimbic system.

Abstract: Sleep is a critical process well-conserved across mammalian species, and perhaps most animals, yet its functions and underlying mechanisms remain poorly understood. A better understanding of genes and pathways that can influence sleep may shed new light on these functions. In this study, we report novel candidate genes identified by characterizing sleep-wake parameters for the large population of single-gene knockout mice at The Jackson Laboratory, a primary production and phenotyping center for the Knockout Mouse Program (KOMP2). Sleep-wake parameters were measured using a high throughput, non-invasive piezoelectric system that has been validated against EEG/EMG and human observations, and demonstrates a classification accuracy of over 90%. Knockout mice generated on a C57BL/6NJ (B6NJ) background, were monitored for sleep and wake parameters for five days under baseline conditions. Thus far, we have recorded over 5000 mice representing over 300 single gene knockout strains, and more than 1200 B6NJ control mice (males and females). Significant sleep-wake differences in both light and dark phases were found for a number of knockout lines compared to controls. Our study also integrated assessment of breath rates utilizing the piezoelectric system, uncovering a variety of

genes affecting cardio pulmonary traits. Utilizing multiple statistical approaches, more than 40 genes not previously implicated in sleep traits have been identified in this set of knockout mice, suggesting that a high percentage of gene products may influence sleep directly or indirectly. Additionally, sex differences were found for B6NJ mice and many of the knockout mouse strains. B6NJ female mice exhibited shorter bout lengths and less total sleep compared to males. Further studies investigating these genes and their correlation with other phenotypes and interaction with other known "sleep" genes has the potential to provide insight into the pathways regulating sleep and the functions associated with sleep. Incorporating breath rate as part of the screening protocol may be a promising supplemental tool in determining aberrant physiology in these knockout lines.

Title: An intersectional strategy to target nitrergic neurons in the cerebral cortex

Authors: *M. R. ZIELINSKI[1,3], D. N. ATOCHIN[2,4], P. L. HUANG[2], D. GERASHCHENKO[1,3];
[1]Harvard Univ., West Roxbury, MA; [2]Harvard Univ., Charlestown, MA; [3]VA Boston Healthcare Syst., West Roxbury, MA; [4]Cardiovasc. Res. Ctr., Massachusetts Gen. Hosp., Charlestown, MA

Abstract: In the neocortex, neuronal nitric oxide synthase (nNOS)-containing neurons are divided into type I and type II. Type I cells are more intensely stained in nNOS immunohistochemical or NADPH diaphorase staining procedures and have larger somata than type II cells. Type I nNOS neurons have unique anatomical and physiological properties. This is the only type of GABAergic neurons in the cerebral cortex that form long-range projections within the cortex and between hemispheres. This is also the only currently known type of GABAergic neurons in the cerebral cortex that are specifically activated during slow wave sleep. Studying these neurons using currently available tools represent a challenge. Electrolytic or excitotoxic lesions of type I neurons cannot be performed because they are sparsely distributed throughout the cortex. Moreover, these neurons cannot be targeted using only one genetic marker. We targeted type I neurons in the cerebral cortex based on the overlapping expression between nNOS and somatostatin (SST). Male homozygous nNOS floxed mice were mated with hemizygous, SST-Cre female mice (B6N.Cg-Ssttm2.1(cre)Zjh/J; the Jackson Laboratory). Female offspring that were SST-Cre positive and heterozygous for nNOS floxed transgene were then mated with homozygous nNOS floxed male mice. The offspring from this mating, which were homozygous for the floxed nNOS transgene and either SST-Cre positive or negative, were perfused with formalin. Brains of these mice were processed for nNOS immunostaining. In the mice homozygous for floxed nNOS and expressing Cre under the control of SST promoter, intensely stained nNOS neurons were absent in the cerebral cortex. nNOS staining was also absent in the caudal putamen and olfactory bulb, but we did not observe any differences in nNOS immunostaining in other brain regions in these mice compared to the wild-type control mice. In the mice homozygous for floxed nNOS but SST-Cre negative, normal pattern of nNOS expression was observed. These results indicate that nNOS floxed/SST-Cre double transgenic mice represent an animal model of selective ablation of nNOS expression in type I cells in the cortex. Intersectional nNOS/SST strategy results in a highly selective targeting of type I cells in the cerebral cortex and thus is very useful for studying anatomical and physiological properties of type I neurons.

Title: The neurochemical phenotype of lateral hypothalamic hypocretin/orexin and melanin-concentrating hormone neurons identified through single-cell transcriptional profiling.

Authors: *L. MICKELSEN[1], F. W. KOLLING IV[1,2], B. CHIMILESKI[1,2], C. NORRIS[2], C. E. NELSON[2], A. C. JACKSON[1];
[1]Physiol. and Neurobio., [2]Mol. and Cell Biol., Univ. of Connecticut, Storrs, CT

Abstract: The lateral hypothalamic area (LHA) orchestrates fundamental aspects of behavior including arousal, feeding, metabolism, stress and reward. Through its unique position at the intersection of multiple neural and humoral systems, the LHA drives essential behavioral programs that maintain homeostatic balance in physiology and behavior. Underlying the diverse functions of the LHA is an exceptionally heterogeneous population of neuronal cell types, typically defined by their neuropeptide expression. Two well-described neuropeptidergic neuronal populations, exclusively found in the LHA, are defined by their expression of hypocretin/orexin (Hcrt/Ox) or melanin-concentrating hormone (MCH). Hcrt/Ox and MCH neuronal populations are both important regulators of the sleep-wake cycle and metabolic function. Mounting evidence indicates that these cell populations may be diverse and that single markers may not adequately capture the complexity of their signaling repertoire. Outstanding questions remain concerning the neurochemical phenotype of Hcrt/Ox and MCH neurons and, in particular, their co-expression of other neuropeptides and the machinery for the synthesis and release of the fast amino acid neurotransmitters GABA and glutamate. In the present study, we undertook a single-cell transcriptional profiling approach to further our understanding of the neurochemical phenotype of Hcrt/Ox and MCH neurons. Using transgenic mouse lines that label each cell population, we optimized methods for the microdissection of brain slices, followed by fluorescence-activated cell sorting (FACS) into 96-well plates for the isolation of individual labeled cells. We then carried out gene-specific reverse transcription to convert mRNA into cDNA followed by qPCR to quantify the expression of 48 key genes at single cell resolution. These include housekeeping genes, neuronal and glial markers, neuropeptides, fast neurotransmitter components, transcription factors, receptors and calcium-binding proteins. Our single-cell transcriptional analysis of Hcrt/Ox and MCH neurons revealed unique expression patterns of neuropeptides and fast neurotransmitter components, demonstrating distinct neurochemical phenotypes. The transcriptional profiles of Hcrt/Ox and MCH neurons are consistent with known markers of each cell population while also exhibiting novel expression patterns. Identifying the underlying neurochemical phenotype of Hcrt/Ox and MCH neurons, and diversity within these cell populations, will further our understanding of how these neurons modulate postsynaptic excitability at their targets and participate in diverse behavioral outputs.

Title: Glutamate, nitric oxide, adenosine and sleep homeostasis: new development

Authors: A. A. LARIN, Y. KIM, S. A. KARPOVA, R. W. MCCARLEY, R. BASHEER, *A. V. KALINCHUK;
Psychiatry, VA Boston Healthcare System-Harvard Med. Sch., Boston, MA

Abstract: Recently we discovered a biochemical cascade which is triggered during sleep deprivation (SD) - initially in the basal forebrain (BF) and later in the prefrontal cortex (PFC) which receives dense projections from the BF. This cascade includes rapid production of intracellular inducible nitric oxide synthase (iNOS)-dependent NO followed by the increase in extracellular adenosine (AD). iNOS→NO→AD cascade is critical in promoting recovery sleep (RS); however, its triggers are unknown. We hypothesized that iNOS induction during SD is triggered by dramatic increase in extracellular glutamate (Glu). Here we investigated the temporal and pharmacological relationship between glutamatergic, nitrinergic and adenosinergic systems in the BF and PFC during long-term SD. Specifically, we: 1) examined the time course of Glu, NO and AD during 8h SD in the BF and PFC; 2) blocked Glu receptors (GluRs) in the BF during SD by infusing a selective inhibitors of NMDAR or AMPAR and measured the changes in SD-induced AD in the BF/PFC and RS; 2) stimulated GluRs in the BF by infusing NMDA or AMPA and measured the changes in AD in the BF/PFC and NREM sleep/delta power. Male rats were implanted with EEG/EMG recording electrodes and microdialysis guide cannulae targeting the BF and PFC for samples collection/drug infusion. Microdialysis samples were collected every 30 min during 8h SD and/or pharmacological manipulations. AD was measured using high performance liquid chromatography (HPLC) coupled with a fluorescence detector; Glu was measured using ultra HPLC (UHPLC) coupled with an electrochemical detector; NO (nitrate/nitrite) was measured using fluorescent assay kit. We observed that in the BF Glu dramatically increased at first 30 min-1 h of SD, followed by the increases in NO/AD at $1^{st}/2^{nd}$ h of SD, respectively. Further, Glu gradually decreased, while AD maximized at 4^{th} h of

SD and remained so till the end of SD. In the PFC, Glu increased within 2 h of SD and NO - at 3rd-4th h of SD; Glu returned to the baseline when AD increased at 5th h of SD. Next, a selective AMPAR inhibitor prevented AD increase during SD in both BF and PFC and attenuated NREM RS, while a selective NMDAR inhibitor did not show any effect on these parameters. Finally, the infusion of AMPA induced the increase in AD in both BF and PFC and NREM sleep/delta power, while NMDA was not effective. In summary, rapid increase in Glu during SD might be a trigger for the induction of iNOS/NO in both the BF and PFC, followed by the AD increase and RS generation. This effect is primarily mediated via AMPAR. The AD increase exerts a negative feedback on the extracellular Glu preventing its further rise during long-term SD which could be toxic for the brain cells.

Title: Tuberomammillary histaminergic neurons modulate pontine tegmentum areas involved in wakefulness and REM sleep generation

Authors: *M. GARZON, A. DÍEZ-GARCÍA, A. NUNEZ;
Dpt Anat, Histol and Neurosci. Fac Med. UAM, Madrid, Spain

Abstract: Histaminergic neurons (HA) are exclusively localized in the hypothalamic tuberomammillary nucleus (TMN). Histaminergic system is involved in sleep-wakefulness cycle (SWC) regulation through promotion of cortical activation and wakefulness generation in wake-on centers, such as the locus coeruleus (LC). The aim of the present study was to examine in rats (1) the electrophysiological effect of TMN electrical stimulation on neuronal activity of wake-on centers such as the LC, as well as REM sleep-on centers such as the oral pontine reticular nucleus (PnO), and (2) the anatomical presence of immunohistochemically-identified HA axons and HA receptors (H1 and H3) in those former areas. Electrical stimulation of the TMN with single pulses elicited orthodromic responses in electrophysiologically characterized LC neurons. TMN stimulation with pulse trains produced an increase in LC neurons activity and a decrease in delta-wave activity of the EEG. In contrast, TMN stimulation with pulse trains produced a

decrease in PnO neuron activity. Both excitatory effects in LC and inhibitory effects in PnO were blocked by the systemic (i.p.) administration of the H1 receptor antagonist pirilamine. Immunohistochemical studies showed small varicose HA-immunolabeled axons through the oral pontine tegmentum, including both LC and PnO. H1 and H3 receptors were also identified in both nuclei. In addition, dense HA innervation was detected in the hypothalamic perifornical area (PeFHL), known to be involved in sleep-wake regulation by wakefulness enhancement as also does TMN. Thus, our results indicate that TMN HA neurons have excitatory actions on LC and inhibitory effects on PnO. This suggests that TMN HA projections to both brainstem areas could be part of a neuronal network modulating SWC and arousal by enhancement of wakefulness in LC and suppression of REM sleep in PnO. Synergic TMN and PeFHL actions on these nuclei are also likely mechanisms in sleep-wake modulation. Supported by MINECO BFU2013- 43741-P

Title: Electrophysiological phenotype and optogenetic silencing of histaminergic neurons of the hypothalamic tuberomammillary nucleus in a transgenic mouse line.

Authors: ***A. FUJITA**[1,2], P. BONNAVION[3], M. WILSON[1], L. E. MICKELSEN[1], L. DE LECEA[4], A. C. JACKSON[1];
[1]Physiol. and Neurobio., [2]Biomed. Engin., Univ. of Connecticut, Storrs, CT; [3]Neurophysiol., Univ. Libre de Bruxelles (ULB)-UNI, Brussels, Belgium; [4]Psychiatry and Behavioral Sci., Stanford Univ. Sch. of Med., Stanford, CA

Abstract: Neurons that synthesize the monoamine neurotransmitter histamine (HA) exclusively reside in the tuberomammillary nucleus (TMN) of the posterior hypothalamus, extend fibers throughout the central nervous system and are interconnected with other neuromodulatory systems. Multiple lines of evidence suggest that HA neurons are well-positioned to drive transitions between global brain states and influence arousal and attention. *In vivo* single-unit recordings during the sleep-wake cycle have shown that putative HA neurons display slow pacemaking activity (1-5 Hz), which is tightly coupled to behavioral arousal, and exhibit a wake-

specific firing profile. Furthermore, loss-of-function manipulations have implicated HA transmission in cortical activation, behavioral arousal and cognitive function. Given the strong correlation between the excitability of HA neurons and behavioral arousal, we investigated the electrophysiological phenotype of identified HA neurons in brain slices and optogenetically modulated the excitability of HA neurons. In the present study, we undertook a characterization of HA neurons, identified in a transgenic mouse line, Tg(*Hdc*-Cre)IM1Gsat/Mmucd (GENSAT), that expresses cre recombinase in cells that express histidine decarboxylase (HDC), the synthetic enzyme and defining marker for HA neurons. We conducted an anatomical analysis of the specificity of this mouse line by crossing *Hdc*-Cre mice with a cre-dependent ROSA26-tdTomato reporter line to visualize expression of cre recombinase. Hdc-Cre::tdTom neurons were then observed via fluorescent and confocal microscopy and the specificity of this line was confirmed by immunohistochemistry using an anti-HDC antibody. We then carried out a systematic analysis of the passive and active membrane properties of both HA (tdTom+) and non-HA (td-Tom-) neurons in the TMN through cell-attached and whole-cell recordings at physiological temperature. Analysis of these data suggest that the membrane properties of HA cells are relatively uniform, while neighboring non-HA neurons displayed a heterogeneous range of membrane properties. Finally, optogenetic silencing through the selective, cre-dependent expression of archaerhodopsin (Arch) in HA neurons was examined both *in vitro* and *in vivo* as a first step in probing the role of the HA system in arousal. Together, these data suggest that the Hdc-Cre (GENSAT) mouse line may be a valuable transgenic tool for both the identification of HA neurons for electrophysiological recording and for the expression of cre-dependent viral reagents for the optogenetic interrogation of HA neurons and their role in physiology and behavior.

Abstract: Sucrose conditions flavor preferences (CFP) relative to saccharin in rodents. Murine genetic variance can determine the magnitude and persistence of such preferences and their underlying neurochemical substrates. Whereas some strains (e.g., BALB/c) display robust sucrose- and fructose-CFP, other strains (e.g., C57BL/6) display smaller sucrose-CFP and a lack of fructose-CFP. Moreover, these strains display initial preferences for non-nutritive sucralose-saccharin solutions relative to fructose that persists with experience with both solutions. Because adolescent exposure to nutritive (e.g., sucrose) and non-nutritive (e.g., saccharin) sweet solutions alters subsequent adult behavioral responsiveness, the present study examined whether early developmental (4 to 8 weeks of age) exposure to sucrose (10%), saccharin (0.2%) or water would differentially alter the magnitude and persistence of sucrose-CFP over 4 weeks in male and female BALB/c and C57BL/6 mice. At 4 weeks of age, 30 BALB/c (15 males (M), 15 females (F)) and 30 C57BL/6 (15 M, 15 F) received burettes of sucrose (10%, 5 M, 5 F of each strain), saccharin (0.2%, 5 M, 5 F of each strain) or water (5 M, 5 F of each strain) solutions in their cages in addition to pre-weighed food and water continuously for four weeks. One week later, all mice were food-restricted to 85-90% of their body weight, and received initial training with an unflavored saccharin (0.2%) solution. In CFP training, food-restricted mice alternately (10 sessions, 1 h) consumed a flavored (CS+, e.g., cherry) 16% sucrose solution and a differently-flavored (CS-, e.g., grape) 0.2% saccharin solution. Two-bottle CS choice tests (1 h) then occurred for five days per week over four weeks. Adolescent male mice of both strains across conditions gained significantly more weight than female counterparts. Adolescent sucrose consumption was significantly higher in BALB/c mice than C57BL/6 mice; the rank-order of adolescent sipper consumption for both strains was: sucrose > saccharin > water. One-bottle CS+/ sucrose training intake was significantly higher than CS-/saccharin training intake across all conditions in young adult BALB/c, but not C57BL/6 mice. Comparable magnitudes of sucrose-CFP in two-bottle choice tests were observed in BALB/c and C57BL/6 mice exposed to water as adolescents. In contrast, BALB/c mice exposed to sucrose or saccharin as adolescents displayed significantly higher magnitudes of sucrose-CFP preferences in two-bottle choice tests than C57BL/6 mice, indicating pronounced murine genetic variance in the effects of adolescent exposure to nutritive or non-nutritive sweeteners upon the magnitude of adult sugar-CFP.

Title: Prazosin alters fear and cocaine associated memories

Authors: *K.-A. E. REYES, R. P. TODD, B. A. SORG;
Washington State Univ., Vancouver, WA

Abstract: Drug addiction is a chronic disorder that creates persistent, unwanted memories. Reconsolidation of a memory is the process of retrieving (reactivating) a memory and then stabilizing it, thereby strengthening it. When a memory is reactivated, it can be disrupted using specific pharmacological agents that weaken the target memory. Here we examined the ability of prazosin, an alpha-1-adrenergic antagonist, to disrupt the reconsolidation of: a) memories associated with cocaine in a cocaine-induced conditioned place preference (CPP) task; b) memories associated with cocaine-induced self-administration; and c) memories associated with conditioned fear, a model used for post-traumatic stress disorder. Previous findings show that prazosin can enhance extinction, the process of diminishing a memory by creating a new memory that overrides the first, of CPP and fear conditioning (Bernardi and Lattal, 2010; Bernardi and Lattal, 2012). Here we sought to disrupt the reconsolidation of a cocaine-associated memory using both CPP and self-administration to understand the extent to which prazosin can disrupt appetitive memories and determine the ability of prazosin to disrupt the reconsolidation of an aversive memory using fear conditioning. Our findings show that prazosin enhances the extinction of an appetitive memory for a CPP task, disrupts reconsolidation of an aversive fear memory, and promotes reconsolidation in a self-administration model. These findings suggest that prazosin can potentially be used as a drug treatment for diminishing an addiction memory via extinction and can be used to disrupt the reconsolidation of stress related memories in rats.

Title: Investigation of the necessity of medial prefrontal cortex pyramidal neurons for food reward seeking and ingestion

Authors: *D. M. WARTHEN[1], A. BRUNAL[1], K. L. GASSMANN[1], N. P. ROGERS[1], N. K. SRINIVASA[1], L. S. ZWEIFEL[2], M. M. SCOTT[1];

Abstract: Dysfunction in the prefrontal cortex is associated with impulse control deficits and maladaptive reward seeking. We and others have shown that manipulation of neuronal activity in the medial prefrontal cortex (mPFC) alters reward seeking behavior in operant conditioning paradigms. Pyramidal neurons form the final output pathway from the mPFC, and therefore presumably mediate all effects of mPFC activity on behavior and cognition. While these neurons innervate a wide variety of targets throughout the brain, the necessity and sufficiency of specific subcortical mPFC projections in the regulation of feeding behaviors remains poorly understood. In prior work we showed that stimulation of mPFC-to-accumbens neurons using a G_q-coupled designer receptor (hM3d(Gq) DREADD) is sufficient to increase operant responding for a food reward in mice, without altering unconditioned food intake behavior. In our current work we assess the necessity of mPFC pyramidal neurons in general, while also selectively targeting those that project to the nucleus accumbens, in the regulation of food seeking and unconditioned feeding behavior. To produce neuron-selective silencing, we used an adeno-associated virus encoding a Cre recombinase-dependent Caspase-3 (AAV-flex-taCasp3-TEVp). When activated, this construct engages an apoptotic pathway, ablating the targeted cell. In initial experiments, we examined how a broad reduction in pyramidal neuron activity affects feeding, through delivery of AAV-flex-taCasp3-TEVp in combination with an AAV encoding Cre under control of the CamKIIα promoter to the PFC. To determine how specific subcortical projections from the PFC affect feeding behavior, we then selectively deleted mPFC neurons projecting to the nucleus accumbens, through mPFC injection of AAV-flex-taCasp3-TEVp and nucleus accumbens injection of canine adenovirus encoding Cre recombinase. Subsequently, we examined whether ablation of these neurons suppressed operant responding for food reward while also affecting binge-like overeating. Results from these studies complement our initial work, providing a clear

picture of the necessity and sufficiency of the PFC in regulating both the drive to feed and the act of food consumption.

Title: Environmental and pharmacological modulation of novelty habituation in rats - The rising of self-grooming as a de-arousal indicator

Authors: *M. ROJAS[1,2], B. MÉNDEZ[2], J. FORNAGUERA[2,3], J. C. BRENES[4,2];
[2]Neurosci. Res. Ctr., [3]Biochemestry Deparment, Sch. of Med., [4]Inst. for Psychological Res.,
[1]Univ. of Costa Rica, San José, Costa Rica

Abstract: Habituation usually refers to as the decrease of a response after repeated or prolonged presentations of a given stimulus. This phenomenon has been observed along different life forms (e.g. amoeba, plants, rats, humans). In animals, habituation is considered as a non-associative learning process, which serves as a first-order attentional system filtering information depending on its biological salience. In rats, habituation is normally evaluated through the analysis of exploratory behavior displayed in a wide, bright, novel arena, as the open-field test (OF). There, risk-assessment (RA) behaviors, including vertical and horizontal exploration, are intensely emitted during the first minutes of the OF. As time passes and no threats are encountered, the RA behaviors diminish and self-grooming (SG) gradually increase. The appearance of a non-exploratory, self-oriented behavior suggests that the defensive system has yielded control to a de-arousal, compensatory system. In support to the later, we have found that treatments that increase OF habituation, such as environmental enrichment (EE) or repeated OF exposures, also increase SG. Such treatments, interestingly, differ qualitatively and quantitatively in the way they potentiate SG. In the first experiment, we will show how EE modulates OF-habituation, specifically how the transition from defensive-to non-defensive behaviors takes place. Also, we will describe the differences in time course, subtypes, and syntaxes of SG between EE- and non-EE rats repeatedly exposed to the OF. In a second experiment, we tested whether pharmacological impairment of OF-habituation after the administration (i.p.) of scopolamine (muscarinic antagonist) or MK-801 (NMDA antagonist) is able to retard or abolish the appearance of SG. Amnesic drugs were daily administered during four consecutive days 20-min

prior to a 15-min OF. On days five to seven, rats were given vehicle and tested as previously mentioned. Results will be discussed in terms of the translational value of SG and OF-habituation as targets for developing new pharmacological treatments and to uncover the neurobiological basis of neuropsychiatric disorders related with sensory gating deficits, increased defensiveness, and pronounced stereotypies as observed in autism spectrum disorders, schizophrenia, and obsessive-compulsive disorder.

Title: Incentive motivation and neurobehavioral plasticity: the effects of unpredictable environmental enrichment in rats

Authors: *J. C. BRENES[1,2], M. SÁNCHEZ[3], M. ROJAS-CARVAJAL[3], J. FORNAGUERA[4], A. SEQUEIRA[5];
[1]Univ. of Costa Rica, Montes DE Oca, Costa Rica; [2]Neurosci. Res. Ctr., Univ. of Costa Rica, San Jose, Costa Rica; [3]Neurosci. Res. Ctr., [4]Biochem. Dept., [5]Natl. Inst. of Hlth. Res., Univ. of Costa Rica, Montes DE Oca, Costa Rica

Abstract: Environmental Enrichment (EE) is a model to study the relationships between behavior and experience-dependent changes in the brain. As compared to standard housing (SH), the idea behind EE is to ensure 1) greater levels of physical, social, and cognitive stimulation, 2) the opportunity of displaying more elaborated behaviors by fulfilling some ethological needs, and 3) the reduction of captivity stress. In this sense, having access to an EE cage may be rewarding for rats. It can be assumed that once EE is experienced, motivation to get enriched may gradually increase. Although the motivational properties of exercise have widely been tested in rodents exposed to running wheels, no evidence of such effects have been obtained in EE rats. It is well known that uncertainty about reward probability or magnitude may translate into stronger attribution of incentive salience to reward-related cues. To evaluate the motivation to get access to the EE cage, a group of rats were constantly kept in EE (CONEE), except during some hours three or four times per week, when rats were moved to standard cages in order to increase motivation for EE cage. Another group (RAMEE) was enriched in a semi-random manner and only during the 50% of total CONEE time (i.e. one month). Access to EE took place through a guillotine-controlled start box (30x30 cm) attached to the EE cages. There,

anticipatory activity and 50-kHz ultrasonic vocalizations (USV) were monitored twice per week before animals entered the cage. Both EE groups were tested simultaneously and were compared to a SH group. SH rats were also placed in the start box, but they had access to a standard cage. Animals were screened behaviorally (e.g., USV, open-field, and Barnes tests), and afterwards the expression of several genes (e.g., BDNF, CREB, p250gap) related to neural plasticity were measured in the medial prefrontal cortex, nucleus accumbens, and hippocampus. Data will be presented and discussed in terms of how uncertainty of motivationally relevant stimuli could boosted the effects of EE. Also, our data may provide evidence about how the benefits derived from EE may depend on individual differences in attributing motivational salience to such stimulation.

Title: Environmental enrichment alters perineuronal net staining in the rat prefrontal cortex following abstinence from sucrose self administration

Authors: *B. A. SORG[1], M. L. SLAKER[1], J. BARNES[2], J. W. GRIMM[3];
[1]Integrative Physiol. and Neurosci., Washington State Univ., Vancouver, WA; [2]Washington State Univ., Pullman, WA; [3]Behavioral Neurosci., Western Washington Univ., Bellingham, WA

Abstract: Perineuronal nets (PNNs) are aggregations of extracellular matrix molecules that form structures around a subset of GABAergic interneurons in the cortex. The staining intensity of the PNN marker, *Wisteria floribunda* agglutinin (WFA) is related to plasticity, where brighter WFA staining is associated with limited plasticity and dimmer WFA staining is associated with enhanced plasticity. Environmental enrichment (EE) reinstates plasticity during adulthood and diminishes both drug- and sucrose-seeking behavior in rodents. Long-term EE also decreases staining intensity of WFA within the visual cortex and cerebellum. We determined the impact of EE during abstinence on WFA staining intensity in the prefrontal cortex (PFC) of adult Long-

Evans rats trained to self-administer sucrose. PNNs within the prelimbic (PL), infralimbic (IL), and orbitofrontal (OF) regions of the PFC were assessed for staining intensity and number after 1 d or 30 d EE during abstinence followed by a cue-induced reinstatement test. Rats exposed to standard housing during 30 d abstinence from sucrose self-administration had brighter WFA staining within the IL compared to rats exposed to standard housing during 1 d abstinence. Rats exposed to EE prior to a cue-induced reinstatement test had brighter WFA staining in all regions examined compared with rats maintained in standard housing. The intensity of PNN staining within the PL corresponded to the total number of lever presses across all sucrose self-administration sessions. Conversely, naïve rats given 1 day of EE had decreased WFA staining intensity in the PL, no change in staining intensity the IL, and increased staining intensity in the OF. These findings demonstrate that PNNs within the PFC are dynamically influenced by time of abstinence, duration of EE exposure, and cue-induced reinstatement. These findings may have implications for reward-related plasticity and lasting changes in the PFC during abstinence.

Title: Sign-tracking is difficult to extinguish and resistant to multiple cognitive enhancers

Authors: *C. J. FITZPATRICK[1], T. GEARY[2], J. F. CREEDEN[2], J. D. MORROW[2];
[1]Dept. of Psychiatry, [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Loss of control over drug-seeking behavior and relapse in response to drug-related cues are hallmarks of addiction. Clinical studies have generally found that conditioned responses (CRs) to drug-related cues are resistant to extinction. Sign-tracking is a type of Pavlovian conditioned approach (PCA) behavior that can develop in response to repeated presentation of a conditioned stimulus (CS; e.g., a lever) preceding response-independent presentation of an unconditioned stimulus (US; e.g., food pellet delivery). Sign-tracking CRs are directed toward the CS, as opposed to goal-tracking CRs, which are PCA behaviors directed toward the US.

Moreover, sign-tracking is thought to underlie some aspects of addictive behavior, due to evidence that sign-tracking is difficult to suppress or control and that animals prone to sign-track also display more robust addiction-related outcomes such as cue-induced reinstatement of drug self-administration. We compared the effects of extinction training on sign-tracking and goal tracking CRs using a PCA procedure that exploits individual differences, such that identically trained rats developed one of three patterns of CRs: sign-tracking, goal-tracking, or an intermediate response (both CRs). We found that, while goal-tracking extinguishes completely within four days, sign-tracking behavior persists for over three weeks during extinction training. Moreover, two weeks after the final extinction session, sign-trackers but not goal-trackers show spontaneous recovery of their conditioned responding. In addition, we demonstrated that three different cognitive enhancers known to facilitate extinction of other learned behaviors—sodium butyrate (a histone deacetylase inhibitor), D-cycloserine (an NMDA receptor partial agonist), and fibroblast growth factor 2 (a pro-synaptic neurotrophic factor)—do not facilitate extinction of sign-tracking. These results indicate that sign-tracking is highly resistant to extinction training even when augmented with three classes of cognitive enhancers that are being investigated as pharmacotherapies for addicted patients. This work highlights one potential source of difficulty when attempting to control addictive behaviors.

Title: The orexin system is not involved in operant palatable food seeking

Authors: *S. Y. KHOO[1], G. P. MCNALLY[2];
[1]Sch. of Psychology, Univ. of New South Wales, Sydney, Australia; [2]Sch. of Psychology, Univ. of New South Wales, Sydney, Australia

Abstract: Background: The orexin system has been implicated in appetitive motivation and particularly for highly salient reinforcers. Orexin receptor antagonists have been shown to reduce operant alcohol, cocaine and opioid seeking behaviour in rodents, however results involving natural rewards have been inconsistent. We therefore examined the impact of dual and single

orexin receptor antagonists on operant self-administration of palatable food. Method: Male Sprague-Dawley rats (n = 14) were implanted with chronically indwelling guide cannulae targeting the lateral ventricle. After recovery, the received 10 days of self-administration training where each active lever press (FR1) was reinforced with one 45 mg palatable food pellet (23% fat, 44% carbohydrate, F06162, Bioserv). The effect of the 30µg of the dual orexin receptor antagonist TCS1102 on self-administration was tested at FR1, FR5, FR10 and progressive ratio schedules. The selective OX_2 receptor antagonist, TCSOX229 (100µg), and the OX_1 antagonists ACT335827 (150µg) and SB-334867 (30µg), were then tested against FR10 self-administration. Results: Central administration of 30µg TCS1102 or its vehicle had no significant effect on operant responding for palatable food at FR1, FR5 or FR10 schedules of reinforcement. TCS1102 also had no effect on progressive ratio responding or breakpoint. The single receptor antagonists, TCSOX229, ACT335827 and SB334867 also had no effect on FR10 responding for palatable food. Conclusion: The orexin system is not necessary for palatable food seeking at multiple schedules of reinforcement. The orexin system is also not involved in motivation for palatable food, as measured by a progressive ratio. Additionally, this is unlikely to be due to any limitations of the dual orexin antagonist TCS1102, because commonly used single orexin receptor antagonists also did not affect FR10 responding.

Title: Neuronal correlates of goal-directed and habitual reward seeking in dorsal striatum

Authors: ***Y. VANDAELE**[1], J. M. RICHARD[1], P. H. JANAK[1,2];
[1]Dept. of Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD; [2]The Solomon H. Snyder Dept. of Neurosci., Johns Hopkins Sch. of Medecine, Baltimore, MD

Abstract: Balance between goal-directed and habitual response strategies is necessary for efficient and flexible decision-making. An inability to “break the habit” and re-engage in a goal-directed strategy when circumstances change may render a behavior impervious to negative consequences, and could be involved in several psychopathologies including alcohol and substance use disorders. While the dorsomedial (DMS) and dorsolateral (DLS) striatum are

necessary for goal-directed and habitual responding, respectively, the neuronal correlates of these two response strategies in the dorsal striatum remain unclear. To address this question, we obtained simultaneous *in vivo* single unit recordings in the DMS and DLS within an instrumental procedure, early and late in training. In this discrete-trial procedure, rats must wait for lever insertion and complete a sequence of 5 lever presses to obtain a reward (sucrose 20% or grain-based pellet). We compared neural activity in DMS and DLS during acquisition of the task, after overtraining, and during a satiety-induced devaluation test, in order to distinguish the relative contributions of these structure to the expression of goal-directed and habitual response strategies. Using statistical classification approach, we found that activity in DMS and DLS during learning and after overtraining is correlated with separable aspects of sequence learning. The largest group of DLS neurons progressively shown sustained activity throughout the full action sequence, from the initiation to the termination. In contrast, DMS activity is predominantly linked to the cue signaling reward availability, lever insertion, and is frequently inhibited during the sequence of lever presses. The findings overall suggest that activity in DLS neurons may be more closely tied to completion of action sequences. These findings raise the possibility that differential striatal encoding of sequence learning contributes to the development of outcome-insensitive habits.

Title: Blocking is unaffected by increasing outcome value via changes in satiety state - implications for the role of value-based errors and model free systems in regulating learning

Authors: *M. P. GARDNER, J. CONROY, G. SCHOENBAUM;
Cell. Neurobio. Res. Br., NIDA IRP, Baltimore, MD

Abstract: A major division among models of learning is how value prediction is tracked. This difference is evident in the distinct mechanisms underlying how a cue becomes associated with the value of a reward. Model-free theories consider a predictive cue to store reward value independently of the predicted outcome; whereas model-based theories propose a direct association between the predictive cue and a full representation of the reward. A large body of

evidence suggests that both of these systems drive behavior. In particular, we know that rats use model-based information to change their conditioned responding if the predicted reward's value changes. Here we test whether this same information can also serve to modulate learning by using an unblocking design. To do this, we trained mildly hungry rats that a cue predicted food reward. Subsequently we paired that cue with a novel cue when the rats were much hungrier. Because hunger should increase the value of the reward, the question was 1) whether this increase in value would be predicted by the first cue, allowing this cue to block learning to the added cue or 2) whether the ability of the first cue to predict reward value for the purpose of changing behavior would not translate over to modulate learning signals. In this latter case we would expected to observe a failure of blocking to the new cue. Here we will present initial pilot data that favors the former result. Specifically, with appropriate control conditions included, we found that learning for the new cue was blocked, consistent with the proposal that value predictions from model-based systems act generally and in rapid sequence to first guide behavior and then modulate error driven learning. Coupled with recent data showing that such model based predictions are reflected in dopaminergic error signals, these data provide concrete new evidence for the complexity of associative learning mechanisms. As a next step, we hope to take brain regions considered to contribute to encoding and retrieval of model-based information, such as the orbitofrontal cortex, offline during different critical periods of the task in order to determine whether behavior shifts to a model-free strategy.

Title: *In vivo* electrochemical and optogenetic assessment of accumbal dopamine release events in a novel behavioral economics based food-seeking task

Authors: *S. SCHELP, K. J. PULTORAK, D. ISSACS, R. DAS, E. B. OLESON;
Univ. of Colorado, Denver, Denver, CO

Abstract: The mesolimbic dopamine system is strongly implicated in motivational processes. Currently accepted theories suggest that transient mesolimbic dopamine release events are involved in assessing the value of reward predictive stimuli and/or in generating motivated action sequences directed toward obtaining reward. During the pursuit of reward, critical associations are formed between the reward and otherwise neutral stimuli that begin to predict reward availability. Through these experiences, dopamine neurons, which initially represent the receipt of reward, begin to represent its earliest conditioned predictor (i.e., cue). The resulting concentration of dopamine release scales proportionally to the magnitude of reward predicted. Here, we are investigating the role of cue- and reward-evoked dopamine release on cue-motivated food seeking. To address this research question we developed a novel behavioral economics food-seeking task. In this task, food is provided to rats across 10 different unit-prices (i.e., response requirement/reward magnitude). Importantly, in this task, multiple pairings (>10/price/session; unlike with progressive ratio schedule) occur between each unit-price, reward and its predictive cue. Using fast-scan cyclic voltammetry we first determined that the concentration of accumbal dopamine time-locked to cue presentation decreases as a function of unit-price in this task. We next sought to assess the effect of optically augmenting release both at reward delivery and cue presentation. We selectively activated channelrhodopsin-2 expressing dopamine neurons within the ventral tegmentum during either cue or reward presentation (order counter balanced across animals). Our data reveal that optically facilitating dopamine release at the cue decreases motivation for food; whereas, facilitating release at reward delivery increases motivation for food. Interestingly, optically augmenting release at both cue presentation and reward delivery decreased response latency, consistent with an invigoration of responding that might be dissociable from value-based changes in motivation. It is possible that augmenting cue-evoked dopamine release decreases motivation in our task because we are violating the animal's expectation (i.e., the animal receives less than expected) and vice versa. Together these findings suggest that cue- and reward-evoked dopamine release play a causal role in action initiation, yet oppositely influence motivation in value-based behavioral economics based tasks.

Title: 99mTc-HMPAO SPECT imaging of brain-wide functional networks underlying optogenetic self- and passive stimulation in mice

Authors: *M. J. BROCKA[1], M. LIPPERT[2], A. KOLODZIEJ[2], T. WEIDNER[2], D. VINCENZ[2], J. TEGTMEIER[2], T. WANGER[2], A. OELSCHLEGER[2], F. STOEBER[2], F. ANGENSTEIN[2], J. GOLDSCHMIDT[2], F. OHL[2];
[1]Systems Physiol., Leibniz Inst. For Neurobio., Magdeburg, Germany; [2]Leibniz Inst. for Neurobio., Magdeburg, Germany

Abstract: Optogenetic methods for brain stimulation are increasingly applied in rodents for manipulating behavior and analyzing connectivity.The availability of appropriate transgenic mouse lines and established behavioral assays have contributed to widespread adoption of optogenetic methods, particularly for the study of neural correlates of motivation and reward. The VTA with its dopaminergic neurons is a key brain area for motivation and reward, and has been intensively studied using optogenetics. This self-stimulation has a strong appetitive and motivating value—if an animal can self-administer intracranial VTA stimulation, for example through lever pressing, it will do so even under adverse conditions. This self-stimulation therefore has a strong appetitive and motivating value. However, the VTA can also be stimulated passively — a condition in which no motivation is required. These two experimental paradigms can hence be used to investigate the difference in neuronal activity states of the VTA-reward network during a motivated state and an unmotivated state. Here we used a novel protocol for single-photon emission computed tomography (SPECT) imaging of regional cerebral blood flow (rCBF) to map the brain-wide activity differences resulting from optogenetic intracranial self-stimulation (optoICSS) and optogenetic intracranial passive stimulation (optoICPS). We expressed ChR2 targeted to dopaminergic midbrain neurons in the VTA of Th::Cre mice and trained the animals in an optoICSS task. Following training, mice were implanted with jugular vein catheters and intravenously infused with the rCBF tracer 99m-technetium hexamethylpropylene amine oxime (99mTc-HMPAO) during optoICSS, optoICPS, and baseline condition. We precisely matched the stimulation pattern and intensity for optoICSS and optoICPS to avoid any differences in neuronal stimulation. Mice were then imaged to measure the neuronal network activations during these three conditions. Compared to previous studies, which did not precisely match self and passive stimulation and used rather unspecific electrical stimulation, our findings show a surprisingly large similarity in VTA-related activity upon self and passive stimulation. The differences found are much more compatible with a higher level cognitive effect rather than with large brain wide differences in the two conditions.

Title: Exploring the neural mechanism by which optogenetic stimulation of ventral tegmental area dopamine neurons prevents extinction of cued approach behavior.

Authors: *C. M. REYES, S. M. NICOLA;
Albert Einstein Col. of Med., Bronx, NY

Abstract: When an environmental stimulus predicts a reward at a specific location, animals learn to approach that location in response to the stimulus. When the stimulus no longer predicts reward, the approach behavior extinguishes. Recordings from dopamine (DA) neurons during conditioned approach tasks have demonstrated that DA neurons in the ventral tegmental area (VTA) burst in response to the delivery of an unexpected reward; conversely, when predicted rewards are omitted, there is a characteristic pause in firing. This suggests that DA neurons encode reward prediction errors (RPEs), which serve to update the current state and alter the strength of cue-reward associations depending on the valence of the RPE (positive or negative). While RPEs presumably lead to changes in response probability, the neural mechanisms downstream of the RPE signal that mediate this behavior remain unknown.
Many NAc neurons exhibit cue-evoked excitations that are required for approach behavior. We hypothesized that negative RPE signals carried by the pause in VTA DA neuronal activity may result in decreased cue-evoked firing of NAc neurons in subsequent trials, lowering the probability of cued approach. To test this hypothesis, we used a conditioned approach task with a reward omission paradigm, and recorded from neurons in the NAc in *Th::Cre* rats that express channelrhodopsin in VTA DA neurons. During a 30 min baseline period, auditory cues predicted the availability of a sucrose reward contingent on entry into a receptacle. Sucrose reward was then omitted for the rest of the 90 min session, leading to a decrease in responding. Using multi-electrode recording of NAc unit firing, we found a reduction in the magnitude of cue-evoked excitations of NAc neurons on trials subsequent to the reward omission. Additionally, we found that optical stimulation of VTA DA neurons at the time when reward was omitted was sufficient to prevent extinction. By recording from NAc neurons during optical stimulation trials, we will be able to determine if the reduction in cue-evoked excitations is prevented, thereby suggesting a

mechanism by which phasic dopamine release modulates cue-evoked NAc neuronal excitations on subsequent trials.

Title: *In vivo* electrochemical and optogenetic assessment of accumbal dopamine release events in a novel behavioral economics based footshock avoidance task

Authors: ***K. J. PULTORAK**, S. A. SCHELP, D. ISSACS, R. DAS, E. B. OLESON; Univ. of Colorado Denver, Denver, CO

Abstract: The mesolimbic dopamine (DA) system has historically been implicated in motivational processing under appetitive contexts. Within an appetitive context, mounting evidence supports that transient accumbal DA release events increase in response to reward predictive cues, represent intrinsic reward value, and causally modify reward-seeking. Less, however, is known regarding the role DA plays in an aversive context. Using fast-scan cyclic voltammetry (FSCV), we recently demonstrated that accumbal DA release events are increased in response to aversive stimuli both when animals are presented with a cue signaling the opportunity to actively avoid electric foot shock as well during successful avoidance behavior. Here we investigate whether DA concentration scales as a function of the value of footshock avoided and whether optical stimulation of DA neurons causally modifies the price animals are willing to pay to avoid footshock. In order to assess these research questions, we first developed a novel behavioral economics task in which rats are provided the opportunity to operantly avoid electrical footshock across epochs wherein unit-price (response requirement/mA shock avoided) increases on a semi-exponential array. In congruence with previous appetitive research, the concentration of DA observed at the avoidance-predictive cue as well as at successful avoidance

decreased as a function of increasing unit-price. To assess causality, we optogenetically activated channelrhodopsin-2 expressing DA neurons within the ventral tegmental area to selectively augment DA release at either cue onset or during successful avoidance. Our preliminary results suggest that augmenting release at cue onset decreases the maximal price paid to avoid footshock; whereas augmenting release at successful avoidance increases the maximal price paid to avoid footshock. Next, we sought to assess the role of anxiety in our behavioral economic avoidance task by pre-treating rats with the benzodiazepine, diazepam. While at low doses, diazepam increased the maximal price animals pay to avoid footshock, a decrease in avoidance occurred in a high dose range—an effect perhaps due to the sedative effects produced by high dosages. Together, these findings suggest that transient, accumbal DA release events play an integral role in the assessment of and behavioral response to aversive stimuli as well as suggest that the neuronal circuitry underlying anxiety strongly influence the valuation of avoidance.

Title: Modulation of nucleus accumbens dopamine efflux and reward-seeking behaviour in rats following electrical and optogenetic stimulation of the afferent glutamate projection from the ventral subiculum

Authors: *D. LINDENBACH, G. VACCA, A. HARATIKIA, J. K. SEAMANS, A. G. PHILLIPS;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: In large part, appetitive behaviours are motivated by dopamine (DA) released in the nucleus accumbens (NAc). Glutamate projections from the ventral subiculum (hippocampus) can modulate basal levels of DA in the NAc, providing a mechanism by which environmental cues processed by the hippocampus can motivate behaviour. Transient activation of the ventral hippocampus causes protracted changes in DA efflux in the NAc, facilitating relapse to substance abuse, recapitulating psychomotor symptoms of schizophrenia and modifying affect (Grace, 2010). Given the prolonged elevation of DA efflux observed following brief trains of

brain-stimulation to the ventral subiculum, we tested the hypothesis that enhanced dopaminergic tone may be mediated in part by changes in DA transporter function, which in turn may increase reward-seeking behaviour. The ventral hippocampus was stimulated electrically or optically using bipolar electrodes or channelrhodopsin, respectively. Efflux of DA in the NAc was measured via microdialysis; methylphenidate was used to pharmacologically block the DA transporter. Changes in behaviour were assessed with motion chambers and a progressive-ratio lever-pressing task for a fixed food reward. Both electrical and optical stimulation of the ventral hippocampus enhanced DA efflux in the NAc. Of particular interest, methylphenidate treatment attenuated stimulation-induced DA efflux. The fact that a DA transport blocker decreased DA release is striking and provides compelling preliminary evidence for the hypothesis that the ventral subiculum increases DA release by altering DA transporter function in the NAc. Preliminary behavioural results showed that electrical stimulation enhanced locomotion and lever-pressing for food reward. Surprisingly, optical stimulation did not impact spontaneous movement. Overall, these data suggest that activation of the ventral hippocampus-->NAc glutamate pathway potentiates DA signalling via action potential independent mechanisms. Modulating DA transporter activity may be a therapeutic target for the treatment of disorders including substances abuse, schizophrenia and depression.

Title: On the forms of learning supported by rewarding optical stimulation of dopamine neurons

Authors: *I. TRUJILLO-PISANTY[1], P. SOLIS[1], K. CONOVER[1], P. DAYAN[2], P. SHIZGAL[1];

[1]Psychology (CSBN), Concordia Univ., Montreal, QC, Canada; [2]Univ. Col. London, London, United Kingdom

Abstract: Model-free and model-based reinforcement learning have been proposed as the poles of a continuum stretching from acquisition of simple habits to the creation of internal models that support prospective planning. Given the association of phasic activation of dopamine neurons with the former pole, we consider learning established by optical activation of midbrain dopamine neurons in a novel behavioral paradigm.

A cre-dependent viral vector coding for channelrhodopsin 2 was injected into into the ventral tegmental area (VTA) of five TH::Cre rats. Optical-fiber implants were aimed at the VTA and anchored to the skull. The rats were trained to hold down a lever for 2 s to receive an optical reward: a 1-s train of 5 ms, 473 nm pulses delivered to the VTA. The 45 trials per session consisted of a 4-min interval during which a reward of constant strength could be earned by holding down a lever for 2 s. The trials were grouped into 15 repeating triads. On the leading trial of a triad, the optical reward was strong (a high optical pulse frequency). On the middle trial, either a weak, moderate, or strong optical reward was offered, whose strength was determined randomly. On the trailing trial, the optical reward was weak. Thus, the strength of the reward was predictable on leading and trailing trials but unpredictable on middle trials. One lever was extended on leading and trailing trials and another lever on middle trials.

Model-free learning is typically incremental and slow, but abrupt changes in behavior can occur when new information is interpreted on the basis of an internal model. In the present study, abrupt changes in response latency were observed once the stimulation strength on the middle trials had been sampled. This suggests that activation of dopamine neurons can be used as a signal of the state within the trial, rather than just to engender learning.

The rats also showed evidence of having learned the pairwise sequence of trial types. Although the environment appeared the same at the start of leading and trailing trials, the strength of the stimulation the subject would be able to obtain differed. The rats behaved as if they knew what the strength of the stimulation would be: Initial response latencies were low on leading trials and high on trailing trials.

Our results suggest that specific activation of midbrain dopamine neurons can produce learning more sophisticated than the simplest model-free variant. Experiments entailing prospective choice will be required to determine whether the effects of such stimulation extend to model-based reinforcement learning.

Title: Effect of chemogenetic inactivation of midbrain dopamine neurons and their projections to the nucleus accumbens on cue-induced alcohol-seeking behaviour

Authors: *M. D. VALYEAR, I. TRUJILLO-PISANTY, F. LACROIX, P. SHIZGAL, N. CHAUDHRI;
Psychology/Center for Studies in Behavioural Neurobio., Concordia Univ., Montreal, QC, Canada

Abstract: Pavlovian cues that predict alcohol influence the vigour with which alcohol is pursued. We examined the impact of an alcohol-associated context and the contribution of dopamine receptors, midbrain dopamine neurons and their projections to the nucleus accumbens core (NAcC) to alcohol-seeking behaviour elicited by a discrete cue. Male, Long-Evans rats received 15% ethanol (EtOH) in the home-cage, followed by conditioning sessions in which a 10 s conditioned stimulus (CS; white noise or clicker; 15 trials/session) was paired with EtOH (0.2 ml/CS, 3 ml/session). Conditioning sessions occurred on alternating days in a distinct alcohol context where EtOH was dispensed into a fluid port during each CS trial. On the intervening days rats were exposed to a different non-alcohol context where a distinct auditory stimulus was played but EtOH was never delivered. In exp 1, the CS was presented without EtOH in both contexts. Alcohol-seeking elicited by the CS was elevated in the alcohol context and this effect persisted across several tests. Subsequent tests in the non-alcohol context showed that systemic injections (10 μg/kg sc) of a D1-like (SCH23390), but not D2/3 (eticlopride), receptor antagonist significantly attenuated alcohol-seeking elicited by the CS. We used this same training procedure with chemogenetics to determine if midbrain dopamine neurons were necessary for alcohol- (exp 2) or sucrose-seeking (exp 3) elicited by discrete CS presentations in a non-alcohol or non-sucrose context. In exp 2 and 3, male transgenic TH::Cre rats received infusions of a cre-dependent viral vector encoding the Gi-Coupled (hM4Di) designer receptor into the ventral tegmental area. The hM4Di receptor induces neuronal silencing when bound by clozapine-*n*-oxide (CNO). In exp 2 port entries elicited by the CS in the non-alcohol context were significantly attenuated by systemic injections of CNO (0, 10 or 20 mg/kg ip). In exp 3 systemic CNO (0 or 10 mg/kg ip) failed to significantly reduce CS port entries in the non-sucrose context. In exp 4 we targeted dopaminergic projections to the NAcC with the same methodology as exp 2 except that CNO (0 or 3 mM, 0.3 μl/hemisphere) was microinfused through intra-NAcC

cannulae. Inactivating the terminals of midbrain dopamine neurons in the NAcC was sufficient to reduce CS port entries in the non-alcohol context. Thus, the expression of alcohol-seeking elicited by a discrete cue depends crucially on the context in which the cue is encountered. When this contextual influence is controlled for, alcohol-seeking elicited by a discrete cue requires dopamine neurotransmission and dopaminergic projections to the NAcC.

Title: Reduced dopamine signaling changes the patterned activity of nucleus accumbens neurons in response to rewarding taste stimuli

Authors: *C. CHAN[1], D. S. WHEELER[1], E. A. PANTHER[1], S. M. CONWAY[2], M. F. ROITMAN[2], R. A. WHEELER[1];

Abstract: Phasic changes in mesolimbic dopamine signaling guide appropriate behavioral responses to rewarding and aversive stimuli by modulating the activity of nucleus accumbens (NAc) neurons. The experience of a palatable tastant elicits a transient increase in dopamine concentration in the NAc, while unpalatable taste stimuli decrease transient release events. Coincident with the change in dopamine signaling, the patterned activity of NAc neurons differentially encodes rewarding and aversive stimuli. While the predominant neuronal response to palatable taste stimuli is inhibitory, aversive stimuli evoke largely excitatory responses. However, the direct influence of dopamine signaling on the encoding of rewarding stimuli by NAc neurons remains largely uncharacterized. Here we examined the effect of chemogenetic inhibition of ventral tegmental area (VTA) dopamine neuron activity on the NAc encoding of a palatable sucrose tastant. hM4Di DREADD expression was virally induced in the VTA dopamine neurons of male Long Evans TH-Cre positive rats. Electrophysiological recording arrays were implanted in the NAc for unit recording, and intraoral cannula were implanted for tastant delivery. At test, animals were exposed to blocks of 45 intraoral sucrose (20%) infusions (0.2 ml over 6 seconds) before and after administration of CNO (2mg/kg, i.p.) or saline vehicle

(0.9%) in a counterbalanced design. Four animals were tested in the current study, with 60 and 54 units recorded in CNO-treated and saline-treated conditions, respectively. Consistent with prior reports, intraoral sucrose infusions evoked predominantly inhibitory responses in phasically responsive NAc neurons. However CNO administration altered the neural encoding profile of the sucrose taste, significantly reducing the number of observations of inhibitory responses, while increasing the incidence of excitatory responses. Saline administration did not affect the neural encoding of sucrose. These observations demonstrate that chemogenetic inhibition of VTA dopamine neuron signaling significantly alters the neural encoding of sucrose. This ongoing study will continue to examine the effects of reduced dopamine signaling on the behavioral and neural responses during various reward-related tasks, including taste reactivity and reward omission.

Abstract: We recently discovered that the primary motor cortex (M1) in non-human primates (NHPs) modulates with respect to the presence or absence of a juice reward at the end of the trial (Marsh et. al. 2015). Such a reward signal has also been observed in various deep brain (Schultz 2002) and cortical (Roesch and Olson 2003, 2004) structures. We investigated the dynamics of the reward signal in M1 under various reward probability structures and with multiple levels of reward. Experiments included (i) changing the percentage of the rewarding trials in a given session from 50% to 75% to 90%, (ii) structured sequence of rewarding and non-rewarding trials (R-NR-R-NR-R etc) and (iii) multiple levels of reward included one / two or three levels of juice reward at the end of a successful trial to see if M1 encoded the value of a trial.

We show that reward prediction signal (RPS) exists in M1. Increased certainty in the reward probability structure of the external environment modulates the RPS in M1. Modulation of the RPS represents the animal's confidence in understanding the reward landscape of the environment it is dealing with.

Title: Local control of dopamine release may produce reward-prediction rather than reward-prediction-error signals.

Authors: *A. HAMID[1,2], A. MOHEBI[1,3], J. D. BERKE[1,3,2];
[1]Psychology, [2]Neurosci. Grad. Program, Univ. of Michigan, Ann Arbor, MI; [3]Neurol., Univ. of California, San Francisco, San Francisco, CA

Abstract: Dopamine (DA) is closely involved in both motivation and reinforcement-driven learning. However, the message conveyed by dopamine signals is under active debate. Many studies have found a relationship between dopamine cell spiking and reward prediction errors (RPE), consistent with a role in learning. Yet voltammetry and microdialysis measures indicate that DA conveys a motivational signal - the temporally-discounted, estimated value of work - better than RPE (Hamid et al. 2015 Nat Neuro). Furthermore, DA release from terminals is not a simple function of DA cell spiking, but is also modulated strongly by local microcircuitry including striatal cholinergic interneurons. We therefore hypothesized a dissociation between DA cell firing encoding RPE, and DA terminal activity encoding value. We used fiber photometry, GCaMP6f and TH:Cre rats to monitor calcium dynamics in VTA DA cells and accumbens DA terminals simultaneously. Rats performed three different tasks that probe reward expectations and RPEs: 1) Two-armed bandit; 2) Probabilistically-rewarded linear track running; 3) Pavlovian approach. Initial data suggest that that there is indeed a dissociation between the

activity of DA cell bodies and terminals, and that these can even evolve in opposite directions as rats anticipate a delayed cue. We propose that DA targets tailor DA release to their own computational requirements, potentially converting an RPE-like spike signal into a motivational message.

Title: Anticipatory and reward-responsive neural activity of mesocorticolimbic DA circuitry in mice performing a sample-to-match task

Authors: *M.-A. T. VU[1,3], C. J. BURRUS[3], M. VAGWALA[4], S. D. MAGUE[4], L. K. DAVID[4], J. WANG[4], G. E. THOMAS[6], R. ADCOCK[1,3,4], S. H. SODERLING[3,5], K. DZIRASA[3,4,2]; [1]Ctr. for Cognitive Neurosci., [2]Biomed. Engin., Duke Univ., Durham, NC; [3]Neurobio., [4]Psychiatry & Behavioral Sci., [5]Cell Biol., Duke Univ. Sch. of Med., Durham, NC; [6]Univ. of Maryland Baltimore County, Baltimore, MD

Abstract: The mesocorticolimbic dopamine (DA) system has been shown to be important for cognitive functions such as reward processing, learning, and memory. Classic studies have shown that DA signaling following reward outcomes reflects reward prediction error; other studies additionally suggest a role for anticipatory DA signaling during goal-directed behavior prior to reward outcome. In this study, we investigated both anticipatory neural activity and reward-responsive neural activity in a cued T-maze sample-to-match task. We used wildtype mice and mutant mice with conditional postnatal disruption of actin-related protein 2/3 (Arp2/3) in excitatory forebrain neurons. This genetic mouse model of schizophrenia has been previously shown to exhibit cognitive deficits and aberrant prefrontal cortical signaling resulting in striatal hyperdopaminergia. During task performance, local field potential (LFP) and extracellular action

potentials were recorded from 6 brain areas: prelimbic cortex (PrL), nucleus accumbens (NAc), dorsal medial striatum (DMS), dorsal hippocampus (dHPC), mediodorsal thalamus (mdThal), and ventral tegmental area (VTA). Receiver operating characteristic (ROC) analysis of cell spiking in wildtype mice showed that PrL and VTA anticipatory and reward-response activity differentiated correct from incorrect choices. Mutant mice showed altered responses in these task-relevant regions as well as in NAc. Specifically, the mutant mice showed less reward-response differentiation in earlier learning, and greater anticipatory differentiation in later learning. Taken together, these data implicate both anticipatory signaling and reward-responsive signaling of mesocorticolimbic DA circuitry in this task, and that hyperdopaminergia may lead to increased task accuracy.

Title: Nigrostriatal signal inhibits saccadic eye movement during countermanding task in monkeys

Authors: T. OGASAWARA[1,3], M. TAKADA[3], *M. MATSUMOTO[2,1];
[1]Grad Sch. of Comprehensive Human Sci., [2]Fac. of Med., Univ. of Tsukuba, Tsukuba, Japan; [3]Primate Res. Inst., Kyoto Univ., Inuyama, Japan

Abstract: Response inhibition is the ability to suppress planned or on-going motor actions that would lead to unwanted outcomes. Since the basal ganglia “indirect pathway” is supposed to control body movements in an inhibitory manner, this pathway would be a candidate that

regulates response inhibition. Here we investigated how the nigrostriatal pathway that modulates the indirect pathway contributes to response inhibition. We recorded single-unit activity from projection neurons in the caudate nucleus and dopamine neurons in the ventral midbrain while monkeys performed a saccadic countermanding task. First, the monkey was required to gaze a fixation point. Then, the fixation point disappeared, and a saccadic target was presented on the right or left side of the point. In 70% of the trials, the monkey was required to make a saccade to the target (no-stop signal trials). In the remaining 30%, on the other hand, the fixation point reappeared as a "stop signal" with a random delay after the onset of the saccadic target (stop signal trials). The monkey was then required to cancel a planned saccade. We first recorded the activity of 41 projection neurons in the caudate nucleus. Compared with the activity in no-stop signal trials (i.e., trials in which a saccade was made), a significant excitation was shown in six neurons (14%) in response to the stop signal in stop signal trials (i.e., trials in which a saccade was canceled), while a significant inhibition was exhibited in 10 neurons (24%). These excitatory and inhibitory neurons might be involved in suppression or facilitation of a planned saccade, respectively. We also recorded the activity of 70 dopamine neurons in the ventral midbrain. In contrast to the caudate neurons, many of them (30/70, 43%) showed a significant excitation to the stop signal, whereas only a few neurons (3/70, 4%) displayed a significant inhibition. This indicates that dopamine neurons preferentially contribute to suppression, rather than facilitation, of a planned saccade. Notably, the dopamine neurons with a significant excitation to the stop signal were observed mainly in the substantia nigra pars compacta, but not in the ventral tegmental area, that send massive projections to the caudate nucleus. To test the causal relationship between the ability of response inhibition and nigrostriatal dopamine signaling, we injected haloperidol, a dopamine D2 receptor antagonist, into the caudate nucleus. We found that the performance of canceling a planned saccade was significantly reduced in stop signal trials. Our findings suggest that nigrostriatal dopamine signaling may be important for suppressing a planned saccade in the saccadic response inhibition paradigm.

Title: Subsecond dopamine signaling of reward and punishment is modulated by social context

Authors: *M. R. ROESCH[1], B. LEE[2], M. A. MYERS[2], B. S. CHAPPA[2], M. S. WALTERS[2], S. KANTOR[2], M. G. PECUKONIS[2], E. A. GREEN[2], D. POTEMRI[2], D. A. LAGOWALA[2], E. G. MELLINGER[2], H. T. GIRMA[2], R. T. TESFAY[2];
[1]Univ. of Maryland at Col. Park, College Park, MD; [2]Univ. of Maryland, College Park, MD

Abstract: Dopamine (DA) release is thought to reflect reward prediction errors, increasing and decreasing to events that are better (e.g., reward) or worse (e.g., punishment) than expected. Here we ask how DA release is modulated by social context. Social context molds our perceptions and understanding of the world, yet we know little about how DA signals are modulated in social situations. To address this issue we designed a paradigm where 3 different auditory cues predicted 3 different events: reward, shock, or nothing. In this task, two rats were placed side-by-side in a single behavioral box separated by a wire mesh. One of these rats - the recording rat - was equipped with a fast scan cyclic voltammetry electrode in NAc to record subsecond DA release. Five seconds after the onset of the auditory cue, a 'directional' light illuminated indicating which rat would receive the predicted outcome. During control sessions the conspecific rat was removed. Ultrasonic vocalizations, food cup entries, freezing, orienting, and approach were used to determine the recording rats' mental state and outcome predictions. Consistent with previous work, DA release increased to cues that predicted reward and during reward delivery. Phasic increases to reward were higher when rats were together. This likely reflects a reduction in reward expectancy as evidenced by fewer anticipatory beam breaks. It might also be argued that elevated DA release reflects higher perceived value; however appetitive vocalizations did not support this hypothesis. Cues that predicted shock inhibited DA release non-discriminately across trial types; DA was low for both self and conspecific-shock trials prior to shock onset. However, during shock trials, DA release was modulated by social context in two ways. First, reductions in DA release to cues that predicted shock were weaker in the presence of the conspecific. During these trials, rats increased appetitive vocalizations and froze less often, suggesting that they were seeking social interaction and were less fearful. Second, DA release on shock trials increased quickly when shock was administered to the conspecific, suggesting that recording rats were using the emotional reactions of the conspecific to verify personal safety. We conclude that DA release is modulated by social context in that rats use social cues to optimize predictions about their own well-being. Social context also appeared to reduce fear, increase social calls, and weaken DA signals associated with predicted shock. Finally, our results suggest, at least in this context, that DA does not signal the valence of positive and negative events from the perspective of the conspecific (i.e., empathy).

Title: The ventral tegmental area encodes differential behavioral strategies towards reward-paired cues

Authors: *L. FERGUSON[1,3], A. M. AHRENS[2], L. G. LONGYEAR[2], J. ALDRIDGE[2];
[1]Psychology, [2]Univ. of Michigan, Ann Arbor, MI; [3]Univ. of Texas at Austin, Austin, TX

Abstract: The ventral tegmental area (VTA) is important in mesocorticolimbic reward circuit. In this study we exploit individual behavioral differences in a Pavlovian approach task (Flagel et al., 2007) to examine the specific roles of dopamine and non-dopamine neurons in reward prediction error and in the attribution of incentive salience (i.e. the attribution of motivational value to reward predictive cues). In the Pavlovian task, an illuminated lever (conditioned stimulus, CS) is inserted into the cage for 8 seconds (the predictive cue). At lever retraction, a food reward (unconditioned stimulus) is delivered. Trials occur randomly. All animals learned the predictive nature of the CS, but some also found the cue to be attractive (attributed incentive value), approaching and interacting with the lever. These animals, "sign-trackers" (STs) were compared to animals that predominantly approached the location of reward receptacle ("goal-trackers", GTs). Dopamine neurons were characterized by spike waveform shape and firing rate and confirmed by a systemic apomorphine test. Firing rates and magnitudes of responses in relation to Pavlovian behaviors, cue presentation, and reward delivery were assessed.
We recorded from 89 dopamine and 90 non-dopamine neurons. Neural coding responses were characterized by firing rate changes to behavioral cues and by proportions of responsive cells (population coding). Population coding of GTs and STs differed in 2 important ways. Only dopamine neurons of STs responded during the lever interaction period, the last 7 seconds of lever presentation when STs engaged the lever. Dopaminergic coding of GTs and STs showed opposing responses to cue onset and cue offset. Cue onset predicts the pending reward while cue offset and cue engagement are redundant reflecting moments of greatest incentive value (period just prior to reward presentation). Dopamine neurons of GTs showed a significantly higher proportion of cells responding to cue onset, while STs had significantly higher proportion of cells responding to cue offset and interaction. Non-dopamine neurons of STs and GTs did not show significant differences to these cues in terms of population coding. Non-dopamine neurons from STs, however, did show enhanced firing rates to cue offset compared to cue onset. These are the first results to show that the different behavioral strategies expressed by rats are coded for

specifically by dopamine neurons in the VTA. These results support an important role for dopamine neurons in the attribution of incentive salience to reward-paired cues and underscore the consequences of potential differences in motivational behavior between individuals.

Title: Dopaminergic network dynamics during behavioral exploration

Authors: *A. C. KORALEK[1], R. M. COSTA[2];
[1]Champalimaud Neurosci. Programme, LISBOA, Portugal; [2]Champalimaud Neurosci. Programme, Lisbon, Portugal

Abstract: We are constantly faced with the trade-off between exploiting past actions with known outcomes and exploring novel actions whose outcomes may be better. When environmental rewards are stable, it is preferable to perform actions known to be rewarding. However, when environmental rewards are changeable, it is adaptive to explore alternative actions and revisit previous actions whose value may have changed. This exploration-exploitation balance is thought to be coded by dopaminergic neurons of the substantia nigra pars compacta (SNc). However, little is known about the ways in which environmental changes impact action selection, and even less is known about SNc network dynamics during exploration. We developed a novel behavioral paradigm in mice to investigate how changes in environmental stability affect behavioral variability. Mice were placed in environments with three equidistant nose poke ports and had to explore the environment to discover which sequence of three nose pokes was rewarded. Actions were variable as mice explored to find the rewarded sequence, but became stable as they learned to exploit the rewarded sequence. We then performed calcium imaging in freely behaving mice during task performance, which allowed us to simultaneously record activity in large populations of genetically-identified neurons and track the same populations throughout training. We saw an evolution of single-cell responses associated with

task-relevant events over the course of learning. In addition, we observed changes in SNc network dynamics during periods of exploration versus periods of exploitation. These experiments support a role for dopaminergic networks in behavioral exploration.

Title: Analysis of dopamine-dependent circuit activity by functional and molecular MRI

Authors: ***N. LI**, A. P. JASANOFF;
McGovern Inst. for Brain Research, Dept. of Biol. Engin., MIT, Cambridge, MA

Abstract: The neurotransmitter dopamine (DA) has received special attention because of its roles in reward behavior and the control of movement. The relationship between DA release and broader circuit function is complicated by the diverse modulatory roles of DA acting on its multiple receptors. In this work, we aim to relate spatial patterns of striatal DA release to broader brain-wide activity patterns detectable by noninvasive neuroimaging. We apply a combination of molecular-level functional magnetic resonance imaging (fMRI) with an MRI-detectable DA sensor with conventional blood oxygenation level dependent (BOLD) fMRI to directly compare regional DA release and population neural activity in the rat brain. Data reveal three-dimensional multimodal activity profiles that vary as a function of stimulus properties. Comparison of these maps illustrates spatiotemporal relationships between dopamine dynamics and BOLD activation. Results from rodent studies will facilitate better understanding of dopamine's effects on distributed circuit function and inform interpretation of reward related striatal BOLD signals in multiple species. Ultimately these studies could contribute to diagnostic and therapeutic strategies for addressing DA-related neurological diseases such as addiction and Parkinson's disease.

Title: Dopamine signals the value of work selectively in accumbens core and ventral prelimbic cortex.

Authors: *J. R. PETTIBONE[1,3], J.-M. T. WONG[2], A. MOHEBI[1,3], R. T. KENNEDY[2], J. D. BERKE[1,3];
[1]Psychology, [2]Chem., Univ. of Michigan, Ann Arbor, MI; [3]Neurol., UCSF, San Francisco, CA

Abstract: Dopamine (DA) is a key modulator of neural circuit functions in both the striatum and the frontal cortex. We recently demonstrated that DA release in ventral striatum signals motivational value, across both fast and slow timescales (Hamid et al. 2015 Nat Neuro). A critical remaining question is whether DA provides a single, global signal to all targeted striatal and cortical subregions. One alternative possibility is that striatum and cortex each receive distinct DA signals, and yet a third possibility is that DA release patterns are organized by cortical-striatal loops, to provide a common modulation of interconnected circuit components. We performed minute-by-minute microdialysis in various subregions of medial frontal cortex and striatum in rats performing a trial-and-error choice task, measuring a battery of 20 neurochemicals including DA, acetylcholine, serotonin, norepinephrine, adenosine, GABA and glutamate. Striatal and cortical subregions were sampled simultaneously within each session, and probes were advanced along a dorsal-ventral axis between sessions. We replicated our prior finding that striatal DA covaries with reward rate, a proxy for the estimated value of work, and that among small-molecule neurotransmitters this relationship is unique to DA. However we found that this DA value signal is specifically localized to accumbens core (R2= 0.12, p= 1.35e-16, n=7), rather than shell (n=8) or dorsal-medial striatum (n=11). Within frontal cortex we also found a clear relationship between DA and reward rate, but focally within ventral prelimbic cortex (R2= 0.10, p= 1.18e-14, n=7) rather than more dorsal (ACC, n=7; dorsal prelimbic, n=8) or ventral (infralimbic, n=4) subregions. These matching “hotspots” of value signaling in ventral prelimbic cortex and accumbens core show an intriguing correspondence to human brain areas encoding subjective value in fMRI studies (Bartra et al. Neuroimage 2013). We conclude that, rather than providing a uniform signal to all targets, or separate information to cortex and

striatum, DA release is tailored to the functional demands of specific cortical-basal ganglia loops.

Title: The role of the ventral pallidum in a nucleus accumbens dopamine-dependent sensorimotor transformation

Authors: *J. D. LEDERMAN[1], S. LARDEUX[2], S. NICOLA[3];
[1]Psychiatry, Yeshiva Univ. Albert Einstein Col. of Med., Bronx, NY; [2]Psychiatry, [3]Dept. of Psychiatry, Albert Einstein Col. of Med., Bronx, NY

Abstract: Dopamine in the nucleus accumbens (NAc) is a well-established modulator of reward-seeking behavior. In a discriminative stimulus (DS) task, nearly half of all NAc neurons are excited by cues that predict sucrose reward contingent on approach to and operation of a lever. These excitations precede approach movement onset, predict movement onset latency, are reduced by blockade of dopamine receptors within the NAc, and are causal to approach movement initiation. Dopamine receptor blockade decreases, and activation increases, the probability of cued approach. The ventral pallidum (VP) receives a prominent GABAergic projection from the NAc. This projection is essential for translating limbic sensory, value and motivation signals into motor output, but how it does so is unknown. In this study we ask how VP neurons fire in response to reward-predictive cues, how this firing relates to the motor response, and how dopamine receptor blockade in the NAc alters this firing. Rats were food-restricted and trained on a discriminatory stimulus (DS) task. The DS was an auditory cue, presented at variable intervals, which directed the rat to approach and press a lever to obtain 10% sucrose reward. A lever press during the 10s DS resulted in reward delivery and cue termination. Trained animals were implanted with microelectrode arrays in the VP and infusion cannulae in the NAc. During a 45 min baseline period, animals performed the task while VP neurons were recorded. D1 antagonist was then infused into the NAc, and behavior and recording continued an additional 2 hr and 15 min. Video tracking of head-mounted LEDs enabled detection and

measurement of locomotion. Our results show that approximately half of the neurons in the VP were excited by DS presentation and these were typically those that are inhibited preceding locomotion. Changes in activity of VP neurons were highly correlated with both initiation and cessation of spontaneous locomotor movements (i.e., movements during the inter-trial interval that were typically not directed towards the lever) in that neurons that showed inhibition during movement onset were excited during movement cessation, and vice versa. The majority of DS-excited neurons were inhibited during spontaneous movement initiation. Bilateral infusion of D1 antagonists into the NAc reduced the number of neruons showing DS- and movement-related inhibitions and moderately decreased DS- and movement-related excitations. These results suggest that the dopamine-dependent DS-evoked excitation of NAc GABAergic projection neurons promotes approach movement initiation via inhibition of a subset of VP neurons.

Title: Primate dorsal striatum signals uncertain object-reward associations

Authors: *J. K. WHITE, I. E. MONOSOV;
Neurosci., Washington Univ. In St. Louis, Saint Louis, MO

Abstract: In order to survive, animals attend to and approach objects that have consistently predicted rewards. However, to learn, and to maximize foraging, animals must also approach objects associated with variable or uncertain rewards. To date, the mechanisms that direct behavior towards uncertain objects are not well understood. Reward-driven behaviors are in-part dependent on the caudate-putamen complex, also called the dorsal striatum (DS). Here we asked if DS contains a mechanism to mediate behaviors aimed at objects associated with uncertain rewards. We found that single neurons in the internal-capsule bordering regions of DS (icbDS), particularly in the putamen, signaled reward uncertainty associated with visual objects. We recorded neurons across the DS while monkeys viewed conditioned stimuli (CSs) that predicted juice rewards of varied amounts (0.25ml, 0.125ml, 0ml) and probabilities (100%, 50%, 0% 0.25ml). We discovered a subset of neurons in icbDS that selectively responded with strong excitation to CSs that predicted uncertain rewards (50%). Their uncertainty response often

included a strong ramp-like component that terminated at the time of the trial outcome. In a series of additional control experiments we also found that icbDS uncertainty neurons did not encode information about punishment or action-kinematics. Next, we tested if icbDS uncertainty responses depended on the presence of the CS object by varying the presentation of certain (100%) and uncertain (50%) cues such that the CSs were either present until trial outcome (2.5 seconds) or removed 1.5 seconds before trial outcome. We found that the icbDS uncertainty response was mostly ablated by removing the CS prior to the trial outcome. Because this finding indicated that icbDS uncertainty responses were strongly dependent on the uncertain object, we hypothesized that icbDS neurons may play a role in object-reward associative learning. Therefore, we next recorded from icbDS uncertainty neurons while monkeys learned three novel CSs associated with 100%, 50%, or 0% 0.25ml of juice. Before the monkeys learned the stimuli, icbDS uncertainty neurons responded similarly to all three CSs, with a sharp ramp-like excitation. As the CS-reward associations were learned, the response to certain cues (100% and 0%) was ablated but a strong response to the uncertain CS remained. In sum, we show that icbDS neurons signal uncertainty of object-reward associations - a critical variable for monitoring and learning from objects. These results demonstrate a novel role of the striatum, particularly of the putamen, in signaling uncertainty and in forming new associations between objects and rewarding outcomes.

Title: Ventral tegmental area GABA neurons modulate motivation and attention to a cue predicting sucrose reward in a rat operant task

Authors: *C. E. BASS[1], P. M. FULLER[2], M. J. BRUNO[3], R. V. BHIMANI[3], J. PARK[3], K. HAUSKNECHT[3], R.-Y. SHEN[3], S. HAJ-DAHMANE[3], K. T. WAKABAYASHI[3];
[1]3435 Main St., Univ. At Buffalo SUNY, Buffalo, NY; [2]Beth Israel Deaconess Med. Ctr., Boston, MA; [3]Univ. at Buffalo, SUNY, Buffalo, NY

Abstract: Dopaminergic neurons projecting from the ventral tegmental area (VTA) to cortical and limbic regions such as the nucleus accumbens (NAc) regulate motivated behaviors including responding to cues associated with the availability of reward. Less understood is the role of VTA-GABAergic neurons in mediating this behavior. Up to 25% of VTA neurons are

GABAergic interneurons that inhibit DA neurons, while ~5% are GABA projecting neurons (GPN) that synapse in reward processing regions including the NAc. We hypothesized that VTA-GABA neurons serve to inhibit mesolimbic DA, decreasing the motivational significance of associated cues. We tested this hypotheses using a rat model of cue-mediated responding for a natural reward (sucrose). In this task, male Long Evans rats were trained to nosepoke for sucrose reward during a distinct, intermittent audiovisual cue that was presented approximately every 30 s during a 1-hr session. After a successful nosepoke, sucrose solution (10%) was delivered into a cup next to the nosepoke. During this task, several indices can be measured, such as the response ratio (the number of successful responses to a predictive cue), the latency to nosepoke during a cue (the time taken to enter the reward receptacle to consume reward), and the overall accuracy in the responding to the cue. Criterion performance was defined as 85% of all reward-predictive cues during a session. While previous studies using microinjections of pharmacological agents have demonstrated that VTA-GABA neurons play a role in reward-seeking and consumption in this task, the contribution of specific sub-populations of VTA-GABA neurons has not been explored. To address this, rats trained on this task were infused in the VTA with adeno-associated viruses (AAV) targeting GABA neurons to deliver excitatory Designer Receptor Exclusively Activated by Designer Drugs, (DREADDs) or channelrhodopsin-2 (ChR2). Immunohistochemistry revealed that ChR2 expression occurred in approximately 25% of the neurons which were also TH negative. In addition, *in vitro* whole cell recordings from VTA DA neurons revealed that optical stimulation (470 nm, 1 ms) readily elicits inhibitory synaptic currents (IPSCs) abolished by the $GABA_A$ receptor antagonist picrotoxin (100 μM). Finally, CNO stimulation of VTA-GABA neurons expressing excitatory DREADDs during the cued-reinforcement task resulted in a decrease in performance in all metrics of this task, suggesting that VTA-GABA neurons play a key role in cue-mediated reinforcement and attention for a natural reward such as sucrose.

Title: Chunked action sequences are sensitive to reward devaluation.

Authors: *E. GARR[1,2], A. R. DELAMATER[1,2];
[1]Psychology, Grad. Center, CUNY, New York, NY; [2]Psychology, Brooklyn College, CUNY, Brooklyn, NY

Abstract: Actions can become chunked together to form whole units of behavior. This is an especially important idea in instrumental conditioning in which sequencing actions together can save time and increase reward. Yet despite the possible increases in reward, it is also possible that chunking can cause each action to become driven by its preceding action rather than its consequence. This account provides a tantalizing explanation for why actions are sometimes insensitive to changes in reward value. Yet, there is no convincing empirical evidence that chunking results in insensitivity to reward devaluation (i.e. habits).
To test the hypothesis that action chunking leads to habits, we conducted an experiment in which rats pressed a left and right lever in sequence for a pellet reward. If a rat pressed the left lever and then the right lever, a pellet was delivered and the lever retracted for 1.5 seconds. Any other two-press sequence (left-left, right-left, right-right) resulted in retraction of the levers for a 5 second timeout and no reward. Prior to the beginning of the experiment, rats were assigned to either the extensively trained group (60 days of training) or the moderately trained group (20 days of training). The rats in the moderately trained group were trained to the point of asymptotic accuracy to prevent chunking, while the extensively trained group was trained well beyond asymptotic accuracy to ensure chunking. Following training, two reward devaluation tests were given. Prior to each test, rats were given unlimited access to either the pellet type that was earned during training (devalued) or a differently flavored pellet type that was not earned during training (valued). All rats were then given a 5 minute extinction test in which no rewards were earned for pressing the levers. Each rat was tested while sated on both pellet types over two different days. During training and across both groups, there was an increase in accuracy and speed across sessions, while there was a decrease in inter-response time (IRT) and sequence entropy. Results from the devaluation tests show that rats from both groups were goal-directed (i.e. not habitual). The frequency of left-right sequences was lower during the devalued extinction test. Interestingly, the mean IRTs indicate that the extensively trained rats were more goal-directed in that they showed a longer pause between left and right lever presses during the devalued test. The moderately trained rats did not show a difference in IRTs between valued and devalued test days. These results do no support the prediction that chunked actions become habitual. Rather, action chunking may lead to even greater sensitivity to reward devaluation.

Title: Nucleus Accumbens Shell neurons modulated by feeding do not encode palatability but they integrate external cues relevant to stop licking palatability but they integrate external cues relevant to stop licking

Authors: *M. A. VILLAVICENCIO CAMARILLO[1], A. I. HERNANDEZ-COSS[2], I. O. PEREZ[3], S. S. SIMON[5], R. GUTIERREZ[4];
[1]Ctr. De Investigación Y Estudios Avanzados, Mexico, Mexico; [2]Bioelectrónica, [4]Farmacología, [3]Ctr. de Investigación y de Estudios Avanzados, Mexico, Mexico; [5]Duke Univ., Durham, NC

Abstract: It is well known the role of Nucleus Accumbens Shell (NAcSh) in emotional responses to reward and consumption. Opiod manipulations in NAcSh alter behavioral affective reactions to sucrose and electrical stimulation of NAcSh disrupts oromotor behavior. However, it is not known how NAcSh integrates both, hedonic and motor components of consumption. To address this issue we designed 2 variants of a Brief Access Task (BAT) where we carefully controlled oromotor behavior (licking), while rats consumed graded-hedonic sucrose solutions. In a gustatory-cued variant of the task (gcBAT), a group of rats licked a spout to obtain in each trial 1 out 5 different sucrose concentrations (0, 3, 5.8, 11.7 or 20%) to obtain in each lick a 10-µL drop for 5 s. After this opportunity window (OW) additional licks did not deliver any liquid and rats had to notice the absence of reward to stop licking for 1-3 s in order to initiate a new trial. Therefore, rats had to emit bouts of rhythmic licking of similar length (~5 s) to receive variable sucrose solutions. We trained another group of rats in an auditory-cued variant (acBAT). Here a white-noise was turned on at the end of the 5-s OW and lasted up the required 1-3 s pause in licking was achieved. Then the auditory cue was added to guide rats to distinguish the end of the OW and helped them to stop licking faster than the gcBAT. We found that the auditory cue helped rats to refrained licking in 0.6 s while rats that only used the absence of reward as a cue lasted 1.33 s. Then, multichannel recording was made in the NAcSh during the 2 tasks. In both tasks, we found few neurons (<3 % in each task) that, controlling for licking behavior, encoded the differences in the hedonic value. Instead, neurons with modulations relative to consumption were more common (66 and 68 % in each task). From these neurons we found a subset that also

responded tonically after the OW, being more common in the acBAT than in gcBAT (51 vs 26 %). An additional subset of neurons (some consummatory-related) responded phasically with the reward termination. This kind of neurons where more frequent in the acBAT and responded in a more precise fashion. This stronger neuronal control may result in the faster reaction time for refrain licking observed in the acBAT, which will be evaluated in further experiments. So far, we showed neurons in NAcSh that either track oromotor activity, monitor external cues relevant for feeding maintenance or that integrate both, oromotor and contextual aspects of feeding. Our data indicate that NAcSh may act by signaling the pertinence of sustain feeding guided by external cues and that the circuits involved in monitoring consumption marginally do so based on palatability information.

Title: Cell specific role of ΔFosB in aggressive behavior in male mice

Authors: *H. ALEYASIN[1], S. GOLDEN[2], A. TAKAHASHI[1,3], M. FLANIGAN[1], M. PFAU[1], C. MENARD[1], G. HODES[1], M. HESHMATI[1], J. MULTER[1], L. BICKS[1], J. TAI[1], E. HELLER[4], S. RUSSO[1];
[1]Icahn Sch. of Med. Mount Sinai, New York, NY; [2]Natl. Inst. of Drug Abuse (NIDA), Baltimore, MD; [3]Univ. of Tsukuba, Tsukuba, Japan; [4]Perelman Sch. of Medicine, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Aggression is an innate social behavior that helps individuals to defend their territory against competitors and increases the probability of successful mating. However, extreme aggression can have devastating consequences on society. Recent studies implicate brain reward structures, such as the ventral striatum (vStr), in mediating the motivational and rewarding aspects of aggressive behavior in mice. DeltaFosB is a truncated splice variant of the *FosB* gene that plays a key role in both natural and drug reward, which we hypothesized to be involved in mediating aggression reward. Here we show that DeltaFosB is selectively induced in dopamine receptor 1-expressing GABAergic medium spiny neurons (D1-MSNs) of the vSTR in aggressive

mice after confrontation with a subordinate intruder mouse. Viral overexpression of deltaFosB in the D1 or D2-MSN populations of the vStr of aggressive mice differentially modulates aggressive bahavior and aggression reward. These findings support the notion that deltaFosB in vStr modulates aggressive behavior in a cell-specific manner. Considering the role of deltaFosB in reward-related behaviors, such as drug addiction, sexual pleasure and alcohol drinking, our data point to a new role of deltaFosB in regulating rewarding aspects aggressive behavior in mice.

Title: Sex differences in behavioral and neural responses to palatable food reward

Authors: ***E. B. SINCLAIR**[1], K. L. KLUMP[2], C. L. SISK[1];
[1]Neurosci. Program, [2]Psychology Dept., Michigan State Univ., East Lansing, MI

Abstract: The sex difference in eating disorder prevalence is the most significant in all of psychiatry. Women are significantly more likely than men to suffer from eating disorders, particularly those associated with the core, maladaptive symptom of binge eating, defined as the consumption of a large amount of food, typically palatable food (PF), in a short period of time. To study binge eating, our lab uses an individual differences rat model of binge eating, which defines binge eating prone (BEP) and binge eating resistant (BER) rats based on consistently high and low consumption of intermittently-presented PF intake, respectively. Using this model, we have demonstrated that 1) females consume significantly more PF than males, and 2) females are more often classified as BEP as compared with males. One potential explanation for this sex difference is that PF is more rewarding to females, leading to more frequent bouts of binge eating on PF. Here, we here tested the hypothesis that females have more robust behavioral and neural responses to PF reward than do males. To investigate behavioral responses to PF, adult male (N=18) and female (N=17) Sprague-Dawley rats were exposed to the Conditioned Place

Preference paradigm using PF (~15g Betty Crocker™ vanilla frosting) as the unconditioned stimulus, paired with the initially non-preferred chamber. CPP consisted of a pre-conditioning test day, 8 total pairings alternating stimulus-paired and non-stimulus-paired days, and a post-conditioning test day. To investigate neural responses to PF, 24 hours after the CPP post-test day, male (N=13) and female (N=12) rats were exposed to PF for one hour prior to sacrifice to induce the expression of the neural activation marker Fos. Thereafter, brains were harvested and processed for quantification of Fos immunoreactivity in the medial prefrontal cortex, the nucleus accumbens, the central and basolateral amygdala, the arcuate nucleus, and the lateral hypothalamus. In the CPP paradigm, females displayed a more robust preference for the chamber paired with PF as compared with males. In addition, Fos expression was significantly higher in the infralimbic cortex of the medial prefrontal cortex and in the nucleus accumbens shell of females as compared with males. These data suggest that PF may be more rewarding to females than to males, possibly due to heightened responsiveness of neural substrates that mediate the hedonic and motivational responses to PF, which may in part explain sex differences in binge eating proneness.

Title: A permissive role of serotonergic neurons on hedonic behavior

Authors: *A. GIORGI[1,2], G. MADDALONI[1], S. MIGLIARINI[1], M. GRITTI[3], R. TONINI[3], A. GOZZI[2], M. PASQUALETTI[1,2];

Abstract: By densely innervating multiple forebrain targets, serotonin-producing neurons affect complex physiological and behavioral responses, an effect that may involve cross-talk with additional neurotransmitter systems. To selectively manipulate endogenous serotonergic activity in the living brain and identify the brainwide substrates modulated by serotonin (5-HT) neurotransmission, we generated two novel DREADD (Designed Receptors Exclusively Activated by Designed Drugs) conditional knock-in mouse models (*hMD3q* and *hM4Di*) that, crossed with Pet1-*Cre* transgenic mice, allowed us to activate (*hM3Dq*) or inhibit (*hM4Di*) 5-HT

neurons firing in a time-controlled manner by systemic administration of Clozapine-N-Oxide (CNO). By using functional magnetic resonance imaging (fMRI) and *c-Fos* immunostaining, we demonstrate that chemogenetically evoked 5-HT results in region-specific activation of cortical and subcortical brain substrates involved in emotional responses, plus a specific and robust activation of focal terminals of the dopamine (DA) reward-systems, suggesting a possible 5-HT-mediated modulation of reward processing. To probe this hypothesis, we chemogenetically inhibited 5-HT raphe neurons during a sucrose preference test and show that serotonergic neurons exerts a permissive role for the expression of this hedonic behavior. We also demonstrate that the same inhibition does not induce depressive-like behaviors, arguing against contribution of confounding hypo-hedonic states. Collectively, our results document a previously unreported permissive role of 5-HT neurons on hedonic behavior and corroborate the emerging view of a central role of 5-HT neurotransmission in reward processing.

Title: No evidence of compulsive feeding in mice exposed to a junk food diet

Authors: *T. LONDON, K. H. LEBLANC, A. KRAVITZ;
Natl. Inst. of Health/ NIDDK, Bethesda, MD

Abstract: An abundance of studies have implicated a major role for striatal dopamine neurons in compulsive food consumption and obesity (Johnson & Kenny, 2010, Wang et al., 2001, Davis et al., 2009, Geiger et al, 2009). However, the evidence is still conflicting on which subregion of the striatum – the dorsomedial striatum (DMS), dorsolateral striatum (DLS) or nucleus accumbens (NAcc) – is primarily involved in compulsive food consumption. To assess this, a cohort of mice were given 5 weeks of ad libitum access or restricted access(2h/day) to a junk food diet followed by measurements of compulsive feeding. We assayed compulsive feeding in two ways: we exposed the mice to a shock-paired tone while measuring their consumption of a freely- available junk food diet and secondly during an operant nose-poking task for chocolate pellets. We hypothesized that the ad libitum and restricted access group would be more compulsive as a result of the diet and have also increased striatal neural activation. While a subset of mice engaged in compulsive feeding behaviors in both assays, these mice were not

necessarily from the junk food diet groups. Counter to our hypothesis, similar numbers of mice in all three groups engaged in compulsive feeding. Fos immunohistochemistry in the dorsal striatum also did not reveal differences between compulsive and non-compulsive mice. Our results suggest that regions outside of the striatum may mediate compulsive behavior, at least under the conditions of our study. We are following up by examining Fos immunostaining in other related brain regions. Determining the physiological and behavioral factors that underlie compulsive food intake, as well as identifying which brain regions are involved could facilitate treatments for obesity.

Title: High-running mice have reduced incentive salience for a sweet-taste reward.

Authors: *Z. THOMPSON[1], E. M. KOLB[2], L. HIRAMATSU[3], M. CADNEY[3], T. GARLAND, Jr.[3];
[1]Neurosci. Grad. Program, Univ. of California Riverside Dept. of Cell Biol. and Neurosci., Riverside, CA; [2]Dept. of Biol. Sci., USC, Los Angeles, CA; [3]Biol. Dept., Univ. of California Riverside, Riverside, CA

Abstract: Animals tend to seek activities that are rewarding, either psychologically or physically, and avoid those that are not. Although much is known about the reward system in mammals, questions remain, especially concerning the comparison of behavioral rewards. To what extent can one rewarding behavior substitute for another? How does the strength of a reward influence its ability to substitute for another reward? In humans and rodents, some rewarding substances have been shown to partially substitute for other rewarding substances or behaviors, but this substitution is not always reciprocal. To explore whether physical activity can be subject to "reward substitution," female mice from a selective breeding experiment for high voluntary wheel-running (HR mice) and their control counterparts (C) were allowed access to wheels along with sweet solutions as a potentially competing reward (saccharin, Sweet 'N Low, Equal, Splenda, sucrose). Fluid consumption and wheel running were measured daily. Home-cage activity (without access to wheels) was measured for a different generation of mice that had

access to the same sweeteners. Wheel running was not significantly affected by exposure to the artificial sweeteners. Sucrose significantly elevated wheel running in C but not HR mice. Fluid consumption increased in a dose-dependent manner with saccharin, sucrose, Sweet 'N Low, Equal, and Splenda. HR mice had a significantly smaller increase in fluid consumption with the artificial sweetener blends as compared with C mice, despite running ~2.6-fold more than C. These results suggest that HR mice have a reduced incentive salience for artificial sweeteners and this is likely attributable to the stronger competing reward of wheel running that has evolved in these lines. Title: The effect of active or passive chocolate delivery on cue-induced responding following periods of forced abstinence and associated changes in DeltaFosB labeling

Authors: *E. W. TUPLIN, M. R. HOLAHAN;
Neurosci., Carleton Univ., Ottawa, ON, Canada

Abstract: Recent evidence following cocaine administration has revealed that the onset of craving is delayed and tends to amplify during the abstinence period. The craving associated with addictive-like substances is mediated, in part, by changes in dopamine (DA) concentrations in the Nucleus accumbens (NAc) and has been associated with changes in DeltaFosB expression and changes in spine density. The craving response for palatable food may be similar to the pattern of craving for drugs of abuse and may show similar changes in neural substrates. The present work examined whether active (through operant conditioning) or passive (through classical conditioning) delivery of chocolate flavored pellets resulted in a delayed and amplified craving response during various periods of forced abstinence from chocolate and associated changes in DeltaFosB labeling and spine density within the NAc. Male rats were trained for 1 hr./day/10 days using either classical (VI 30s chocolate delivery) or operant (FR2 lever press for chocolate delivery) conditioning followed by one extinction session at 24 hr., 7D, 14D, or 28D where lever pressing resulted in presentation of the cues associated with training but no

chocolate pellet. Overall, rats trained in the operant procedure showed 4x greater bar pressing responses than the rats in the classical conditioning procedure during all extinction sessions. Nose poke rates during the extinction sessions were similar between the two training procedures but rats trained with the classical conditioning procedure showed a peak in nose poke behavior 7 days following the end of training with a gradual decline over time; the operant conditioning groups showed similar levels of nose pokes at all time points. Locomotor activity was slightly higher in the operant-trained groups and showed a peak at the 14-day test interval. DeltaFosB assessment revealed 2 - 3 times more labeled cells in the NAc in the operant-trained groups than the classically-conditioned groups with both training conditions associated with peak levels at the 7 day test. This coincided with increased spine densities at the 7 day test in both training conditions. The results indicate that cues may gain longer-term motivational significance when paired with active, rather than passive, delivery of chocolate pellets, which is also associated with increased DeltaFosB labeling.

Title: Endocannabinoids control the neural substrates of interval timing in the nucleus accumbens

Authors: *J. F. CHEER[1], M. ANAYA[2], N. ZLEBNIK[2];
[1]Anat. and Neurobio., [2]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Cannabinoids disrupt time estimation by interfering with dedicated brain circuits. The ability to perceive and respond to temporally relevant information in the environment is critical for adaptive survival, and corticostriatal circuits play a central role in timing behavior. Our previous work demonstrated that phasic dopamine release in the nucleus accumbens (NAc) encodes interval timing and that CB1 receptor activation accelerates the perception of time and shifts temporally-engendered patterns of phasic dopamine release. In the present study, we examined the causal role of NAc dopamine release in interval timing and explored how endocannabinoid signaling orchestrates timing-mediated NAc network dynamics. We demonstrate that optogenetic stimulation of ventral tegmental area dopamine neurons during the

timing interval interfered with timing mechanisms and accelerated time estimation. Additionally, interval timing was encoded by progressive increases in accumbal gamma frequency power of the local field potential. Augmenting levels of the endocannabinoid 2-AG resulted in a leftward shift in the estimate of interval duration and disrupted interval encoding by attenuating gamma frequency oscillations in a CB1 receptor-dependent manner. These results reveal a significant role for the interplay between dopamine and endocannabinoids in accumbal network dynamics that guide timing behavior and may have important implications for the use of pharmacotherapies targeting the endocannabinoid system and for the recreational use of plant-based and synthetic cannabinoids.

Title: Temporal modulation of tonically active neurons (TANs) in monkey ventral striatum related to reward size and delay to obtain it.

Authors: *R. FALCONE[1], D. WEINTRAUB[3], B. RICHMOND, 20814[2];
[2]Lab. of Neuropsycology, [1]NIMH, Bethesda, MD; [3]Neural Surgery Br., NINDS, Bethesda, MD

Abstract: Tonically active neurons (TANs) are cholinergic striatal inter-neurons that are thought to play a role in reward-related and motivational processes. In primates these neurons are frequently described as having a pattern of responses with a period of inhibition followed by excitation. Are these two phases of response representing the same information? We recorded neuronal responses from 63 TANs in two monkeys while they performed a task in which 9 combinations of reward were offered by mixing 3 sizes (2, 4 or 6 drops of water) and 3 delays (1, 5 or 10s). A visual cue predicting the combination being offered was presented throughout the trial. The monkeys were required to respond in one of two periods represented by the appearance of a yellow or a purple dot. On the appearance of yellow dot the monkeys could refuse the offer by releasing a bar immediately or accept by releasing when a purple dot appeared. If a purple dot appeared, the monkeys could accept by releasing immediately or refuse by waiting for the yellow dot. To capture response feature that might represent the information we used principal component (PC) analysis of the responses elicited by the visual cue. The principal components

from all conditions regardless of cue were extracted and the scores of those were examined. We focused on the period immediately following the onset of the visual cue, but before any action were required. We found that for basically all of the TANs the cue-elicited responses were related to the two factors, reward size and delay through the spike count and/or principal components as seen through ANOVAs with reward size and delay as factors and spike count or coefficient for PC1 as dependent variable. The TANs could be divided in two sets of 27 and 36 cells respectively, characterized by a strong ($R2 = 0.82$) and weak ($R2 = 0.11$) coefficient of correlation between the percentage of variance explained of PC1 and the percentage of variance explained of spike count from 2-way ANOVAs. Thus, there appear to be two groups of TANs, the first for which the modulation is represented by the number of spikes, and the second for which the modulation is greatly underestimated by the spike count, and can only be represented as a temporal modulation of the response. That is, for the group having basically no correlation between the first PC and the spike count, there is a temporally modulated code carrying information about reward size and delay to reward.

Title: Learning and context shape the reward response patterns of serotonin and dopamine neurons

Authors: *W. ZHONG[1,2], Y. LI[1], M. LUO[1];
[1]Natl. Inst. of Biol. Sciences, Beijing, Beijing City, China; [2]Grad. Sch. of Peking Union Med. Col., Beijing City, China

Abstract: Learning and context influence our response to rewarding stimuli. After learning that a sensory cue predicts reward, we prepare ourselves to gain the reward. On the other hand, we become more hesitant if the cue is paired with an aversive stimulus. Rewards activate both dopamine neurons in the ventral tegmental area (VTA) and serotonin neurons in the dorsal raphe nucleus (DRN). It is well established that learning produces phasic responses of dopamine (dopamine) neurons to the reward-predicting cues and decreases the responses to the reward itself. However, it remains unclear how learning affects the responses of serotonin neurons. Here, we show that serotonin neurons and dopamine neurons are differentially shaped by learning. Moreover, aversive contexts suppress the responses of both dopamine neurons and serotonin neurons to rewarding stimuli. We trained mice using the paradigm of classical conditioning, which repetitively presents a previously neutral auditory tone (conditioned stimulus; CS) before sucrose (unconditioned stimulus; US). Throughout the entire classical conditioning process, we monitored the activity of DRN serotonin neurons using cell type-specific fiber photometry of Ca^{2+} signals. As a comparison, we also recorded the activity of dopamine neurons from the VTA. During the initial phase of conditioning, both serotonin neurons and dopamine neurons showed similar activation pattern to primary reward (US). As learning develops, the activity of serotonin neurons gradually ramped up following the CS onset and peaked upon the US delivery. In contrast, the dopamine neurons became strongly activated by the CS and only mildly activated by the US. We also tested the effect of aversive stimuli. For both serotonin neurons and dopamine neurons, the responses to rewards decrease when a mouse was head-restrained or placed in a fearful context that was previously associated with footshock. Therefore, both learning and context shape the anticipatory and consummatory responses of serotonin neurons and dopamine neurons to rewards. Moreover, our results indicate that the activity of DRN serotonin neurons positively encode “beneficialness” - the net confidence level of an organism in the probability of getting rewarded at the current state.

Title: Mu opioid receptor signaling in the nucleus accumbens drives cued approach to palatable food via excitation of NAc neurons only in the absence of hunger

Authors: *K. CAREF, S. M. NICOLA;
Dominick P. Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: The nucleus accumbens (NAc) has long been implicated as a key node in the circuitry that regulates food intake, but its specific contribution has remained elusive. Activation of NAc mu-opioid receptors (MORs) by local agonist injection selectively augments the consumption of palatable food, suggesting that opioids within the NAc regulate consumption. However, *endogenous* NAc opioid ligands may not play this role because blockade of MORs in the NAc does not consistently reduce consumption. Therefore, we set out to test an alternative hypothesis: that the NAc's endogenous opioids promote approach to food-associated stimuli rather than consumption. Because it is likely that the neural circuitry maintaining approach behavior differs depending on an animal's homeostatic state, we trained both sated and food-restricted rats on a cued approach task in which an auditory conditioned stimulus (CS) predicted availability of a heavy cream reward. In response to the CS, animals approached a receptacle in which cream was delivered. To establish a common neural substrate for cued approach in both sated and food-restricted rats, we first performed neural recordings in the NAc while rats performed the task. In both groups, many neurons were excited by the CS, and the peak magnitudes of these excitations were similar. However, food-restricted rats exhibited both a higher proportion of CS-excited neurons and a longer-duration response, suggesting that in a state of hunger more neurons are recruited to participate in the signal that drives approach. Next, we examined the contribution of endogenous MOR activation to both behavioral performance and CS-evoked neural activity. Rats trained on the cued approach task were surgically implanted with bilateral cannulated microelectrode arrays that allowed for simultaneous unit recordings and drug injections within the NAc. After obtaining a behavioral and neural recording baseline of ~30 min, the MOR antagonist CTAP was infused bilaterally into the NAc, allowing a pre- vs. post-injection comparison of behavior and neural activity. In sated rats, both CS-evoked receptacle approach and the magnitude of NAc neurons' CS-evoked excitations were attenuated following CTAP injection. Strikingly, in food-restricted animals, CTAP caused neither a reduction in cued approach behavior nor a reduction in the magnitude of CS-evoked excitations. Together, these results suggest that the NAc's endogenous opioids act at MORs to promote food seeking in the absence of a drive for caloric intake derived from energy deficit, a mechanism that could conceivably contribute to the development of obesity.

Abstract: Ratio tasks are widely used in studies of operant and motivational processes in behavioural neuroscience. Here we demonstrate the application of the recently developed mouse touchscreen fixed (FR) and progressive ratio (PR) tasks in the investigation of 3 distinct manipulations. We show that within-session analysis of response rates can substantially extend the interpretative value of these simple operant schedules.
First, the influence of liquid reinforcer type on performance was investigated. This revealed distinct schedule-dependent effects on task performance. Specifically, whilst PR breakpoint did not differ, response rate was sensitive to reinforcer type. In contrast, consistent reinforcer type-dependent differences in total trials completed and response rate were detected on the FR schedule. These results demonstrate the sensitivity of touchscreen FR and PR to reinforcer type and highlight a disparity between the schedules.
Second, we investigated the effects of diet-induced maternal obesity on FR/PR behaviour. The adult offspring of mouse dams maintained on a high-fat/high simple sugar diet (HFD) during pregnancy and lactation achieved significantly higher PR breakpoints under the most challenging inter-reinforcer response increment. HFD mice also completed a higher number of FR trials. Response rate analysis indicated a corresponding increased pattern of responding in HFD animals. These results indicate that HFD offspring exhibit both higher motivation and an

increased capacity for operant responding for a palatable food reinforcer relative to controls. Finally, we demonstrate that mouse FR operant output can be bi-directionally modulated by chemogenetic manipulation of accumbal cholinergic interneuron activity. Mice expressing $G_{\alpha q}$ Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) in these neurons completed significantly fewer FR trials at an increasingly slower rate than animals expressing G_i DREADDs which maintained a higher response rate for longer. PR performance was unaffected by these manipulations. These results indicate a specific role for cholinergic interneuron signalling in the mediation of satiety processes that influence operant output.
In conclusion, these experiments demonstrate the versatility of ratio schedules in the investigation of diverse developmental and neural manipulations. The analysis of within-session response rate data is also shown to yield further insight into the behavioural profile of animals performing ratio schedules.

Title: Social reward signals in primate lateral hypothalamic neurons: comparison with prefrontal and midbrain dopamine neurons

Authors: *A. NORITAKE[1], M. ISODA[2,3];
[1]Physiol., Kansai Med. Univ., Hirakata, Japan; [2]Kansai Med. Univ., Hirakata, Osaka, Japan; [3]Syst. Neurosci., Natl. Inst. for Physiological Sci., Okazaki, Japan

Abstract: Other individuals are one of the primary factors that influence one's fitness and survival. In a finite resource environment, others can be direct competitors and therefore one would devalue a context in which they acquire a reward (e.g., food, money, or territory) very

often, even though one's own reward may eventually be unchanged. It remains elusive what neural substrates underlie such subjective reward valuation via taking others' reward into account. To address this issue, we devised a social Pavlovian conditioning procedure using two monkeys facing each other (SfN2014; 364.09). In the procedure, a visual conditioned stimulus (CS) differently signaled each monkey's reward probability. We have demonstrated that the monkeys lower their own reward value as their opponent's reward probability increases (SfN2014; 364.09). We have also shown that neurons in the dorsomedial prefrontal cortex (DMPFC) code a variety of social reward information (SfN2014; 364.10), while presumed dopamine (DA) neurons in the midbrain code a single piece of information expressed in a subjective value scale (SfN2015; 615.11). Here, we studied activity of lateral hypothalamic (LH) neurons to gain insight into how differences in neural coding between DMPFC and DA neurons might be generated. The LH area has anatomical connections with both the DMPFC and the midbrain containing DA neurons. Moreover, LH neurons play a role in motivational behavior (Noritake and Nakamura, SfN2010-2013). Furthermore, a recent neuroimaging study reveals a possible functional link between the hypothalamus and social behavior (Noonan et al., 2014). We found that in response to the CS, 137 of the 384 neurons we recorded initially (0.15-0.45 s following CS onset) showed monotonically increasing or decreasing activity with increasing self-reward probability and about one fourth of them (n = 31) additionally showed monotonically decreasing or increasing activity with increasing other-reward probability, respectively. A further test revealed that the response profile of LH neurons as a population was consistent with subjective reward coding, similar to DA neurons. In a later phase (0.7-1 s), however, LH neurons now exhibited multiple reward signals, like DMPFC neurons, such as self-reward probability, other-reward probability, both-reward probability, and subjective reward value. Our findings delineate distinct and shared coding of social reward signals in cortico-subcortical networks and suggest that LH neurons may play a unique role in social foraging behavior by representing a multitude of reward information in different temporal domains.

Title: Intact reward sensitivity in mothers undergoing long-term opioid maintenance treatment

Authors: *M. EIKEMO[1,2,4], M. L. PEDERSEN[3,1], P. LOBMAIER[2,1], N. KUNØE[2,1], M. SARFI[2,1], S. LEKNES[3,1];
[2]Norwegian Ctr. for Addiction Res., [3]Dept. of Psychology, [1]Univ. of Oslo, Oslo, Norway; [4]Div. of Mental Hlth. and Addiction, Oslo Univ. Hosp., Oslo, Norway

Abstract: Reduced sensitivity to non-drug rewards (anhedonia) is common across a range of drug use disorders. In opioid dependent individuals, anhedonia often persist in opioid maintenance treatment (OMT) with methadone or buprenorphine. It remains unclear whether the reduced reward sensitivity is caused by the opioid medication per se or by associated lifestyle factors (unemployment, recurring relapse to drug use etc.). We measured reward sensitivity and experience in a unique group of mothers in long-term OMT (n = 23) who have maintained the stable lifestyle required to retain custody of their children for > 7 years. Twenty-seven healthy comparison mothers were also tested. Reward responsiveness was measured using a simple decision making task with skewed rewards. Accuracy and reaction time data were fitted using a drift-diffusion model (DDM) of decision making to investigate sub-processes of the choice behavior. The DDM enabled simultaneous assessment of participants' (1) a priori reward preference (starting point), (2) drift rate (evidence accumulation efficiency), (3) boundary separation (speed-accuracy trade-off) and (4) non-decision time. Self-report of predicted hedonic capacity, quality of life, trait hedonia and health was also measured. Both groups of women showed a clear behavioral bias toward the high-reward probability option, comparable to that seen in healthy controls (meta-analysis, n = 653) in previous studies using this task. Further, no group differences were seen in the sub-processes of decision making as assessed by the DDM. In line with the modeling results, self-reported hedonic capacity (state or trait) did not significantly differ between the groups. In summary, mothers in stable long-term OMT display normal reward responsiveness. Therefore, the anhedonia reported by previous studies of opioid maintenance treatment are more likely to result from non-opioid factors such as an unstable lifestyle or male gender.

Title: Dynamic activity in affective circuits predicts choices to invest in risky ventures

Authors: *L. TONG, B. KNUTSON;
Stanford Univ., Stanford, CA

Abstract: Venture capitalists make significant financial decisions on risky propositions that may unfold over long time horizons based on minimal and incomplete prior information -- often presented in the form of a brief "pitch." While research has begun to explore behavioral factors that influence these decisions, little is known about the neural mechanisms involved. Based on the recently proposed Affect-Integration-Motivation (AIM) framework, affective neural responses related to anticipation of gain and loss may motivate approach and avoidance decisions, even about uncertain and risky propositions. This framework has been implicated in a number of domains, including risky gambles and consumer behavior. In this study, we test the applicability of the AIM model in predicting choices to invest in venture capital.
Healthy young adults (n=20) viewed 16 videos of pitches for startup companies while undergoing functional magnetic resonance imaging (fMRI). The videos were actual startup pitches that had been presented to venture capitalists, and shared similar features including visual context, presentation structure, timing, and personnel. After watching each video, subjects rated whether they would invest in each company, as well as their affective response (in terms of valence and arousal) to each pitch. Neural activity acquired during video presentation was used to predict subjects' investment choices. At the whole brain level, bilateral putamen activation at the end (but not the beginning) of each video, was parametrically related to subsequent choices to invest. Furthermore, a volume of interest analysis was conducted to establish whether temporal dynamics of nucleus accumbens (NAcc) activity during video presentation predicted subsequent investment decisions. Both the level and linear trend of NAcc activity across the second half of each video positively predicted subsequent choices to invest ($ps<0.05$), but neither of these variables reliably correlated with investment choices during the first half of each video. These findings provide preliminary evidence that the dynamics of affective neural responses may motivate investment in uncertain and risky ventures, and identify initial targets for further characterization of affect dynamics.

Title: Acute inactivation of the nucleus accumbens shell leads to long-lasting impairments in cue-paired choice behaviour

Authors: *M. M. BARRUS, M. TREMBLAY, V6T 1Z4, C. A. WINSTANLEY;
Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The mechanisms by which salient cues can invigorate maladaptive decision making are an important and understudied component of both gambling and substance use disorders. The cued rat gambling task (CrGT) was designed to address the impact that cues may have in promoting maladaptive choice. In the CrGT, animals choose between four options associated with different magnitudes and frequencies of reward and punishing time-out periods. Favoring options associated with smaller per-trial rewards but smaller losses and avoiding the tempting "high-risk, high-reward" options maximizes profits. Rats' choice of the disadvantageous risky options was significantly greater when these options were paired with salient-win related cues. Furthermore, dopamine D3 receptor agonism increased choice of the disadvantageous options, whereas D3 antagonism had the opposite effect; this effect did not hold in the absence of the win-paired cues.
The precise regional contributions to this behavior have not been elucidated, but the nucleus accumbens is likely involved given the evidence for its role in reward-related behaviors and the relative abundance of D3 receptors. Accordingly, work was performed in order to investigate its potential contributions to behaviour on the CrGT. Animals were given infusions of a GABA agonist cocktail into either the shell (n=24) or core (n=12) of the nucleus accumbens during the first six sessions of the CrGT, and then tested drug free for an additional ~25 sessions. Infusions into the shell during task acquisition resulted in lasting impairments in choice behavior that lasted over the animal's lifespan. These animals adopted a disadvantageous preference for the risky options, and maintained that preference even after drug was no longer on board. These results suggest the shell plays a critical role in establishing optimal patterns of choice behavior, and that interfering with this process results in long-lasting perturbations in decision-making behaviour.

Title: Engaging with salient win-paired cues blunts locomotor responding for cocaine: implications for the reward deficiency hypothesis of addiction.

Authors: *J.-M. N. FERLAND[1], D. LINDENBACH[2], C. VONDER HAAR[3], C. D. HOUNJET[3], A. G. PHILLIPS[2], C. A. WINSTANLEY[3];
[1]Djavad Mowafaghian Ctr. for Brain Hlth., [2]Psychiatry, [3]Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Drug addiction is a psychiatric disorder characterized by persistent drug-seeking and relapse. Studies in clinical populations have shown that active and abstinent addicts demonstrate impaired decision-making on the Iowa Gambling Task (IGT), a validated measure of cost/benefit decision-making. Furthermore, poor IGT performance in these subjects was associated with greater drug craving and relapse, suggesting poor decision-making may play a pivotal role in the development and maintenance of addiction. Using rodent analogues of the IGT, the rat gambling task (rGT) and cued rat gambling task (cRGT), disadvantageous decision-making was found to be exacerbated in risk-preferring animals after cocaine self-administration. However, while risk-preferring rGT rats showed greater responding for cocaine, all cRGT animals showed comparable drug-seeking. These findings indicate that risk-preference is uniquely and adversely affected by cocaine self-administration, but suggest that win-paired cues may enhance sensitivity to cocaine. Recent literature shows exposure to uncertain rewards can sensitize the locomotor response to acute amphetamine, raising the interesting possibility that engaging with risk or uncertainty itself may enhance responding to psychostimulants. The current study sought to determine whether a more cognitively engaging task like the rGT or cRGT would produce a similar result in response to cocaine and whether this effect extended to responding for win-paired cues. Thirty two male Long-Evans rats were tested for cocaine-induced locomotor activity prior to and after rGT and cRGT training. Animals were also subjected to a conditioned reinforcement paradigm after behavioural training to determine how task experience may affect responding to reward- paired cues. Results showed that prior to any behavioural training, risk-preferring animals demonstrated a blunted locomotor response to cocaine. After training, rGT rats demonstrated a significant increase in cocaine-induced locomotor response. However, cRGT rats did not show this potentiation, indicating that repeated exposure to win-paired cues may blunt the response to cocaine, possibly accounting for greater cocaine self-administration seen in the previous study. Interestingly, conditioned reinforcement data show no significant differences by task or by behavioural phenotype. In-vivo microdialysis data suggest basal and cocaine-mediated dopamine efflux may account for the behavioural differences observed. Collectively these data demonstrate that experience with salient cues with uncertainty may affect susceptibility to abuse drugs like cocaine.

Title: Deep-brain stimulation of the subthalamic nucleus leads to selective decreases in risky choice in risk preferring rats on a rodent analogue of the Iowa Gambling Task

Authors: *P. J. COCKER[1], W. K. ADAMS[1], O. VONDER HARR[1], M. TREMBLAY[1], C. BAUNEZ[2], C. A. WINSTANLEY[1,2];
[1]Psychology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Neurosci., Institue de neurosciences, Marseille, France

Abstract: Intro One major concern with dopaminergic treatments for Parkinson's disease (PD) is the development of side effects such as increased impulsivity and poor decision-making. These can even present as *de novo* psychiatric diseases such as gambling disorder or drug addiction. Deep brain stimulation (DBS) has been used as a treatment for PD for many years with great success. Interestingly, DBS of the subthalamic nucleus (STN) has been reported to reduce the incidence rate of decision-making deficits in human subjects. Methods The current study sought to assess the effects of DBS in the STN on decision-making behavior in otherwise intact rats. Rats were trained on a rodent analog of the Iowa Gambling Task until stable baseline behavior was obtained (30 sessions). Electrodes were then implanted into the STN bilaterally. After recovering, the effects of stimulation with the electrodes were assessed using an A-B design in which half of the rats served as control while the other half underwent stimulation. Stimulation continued for 10 sessions in a row. Two weeks after stimulation, brains were examined for electrode placement. Results Overall, stimulation of the STN had no effect on choice behavior. However, when rats were divided by risk-preference, and the data re-examined, choice was significantly affected in the risk-preferring rats. Specifically, choice shifted from risky options that delivered high rewards, but also had high periods of time out, towards safer options that delivered fewer pellets on any given trial, but had higher overall payouts. This effect even persisted slightly beyond the stimulation, but eventually returned to baseline levels by ten sessions post-stimulation. Discussion This study demonstrates that stimulation of the STN can lead to considerable shifts in behavior for otherwise healthy animals. Of particular interest is the relatively selective and beneficial effect on animals that exhibit a preference towards riskier choices. These data suggest that STN-DBS may be useful in reversing or attenuating impulse control disorders that may arise through dopamine agonist therapy.

Title: Risky choice on a cued gambling task in rats is not associated with elevated responding for conditioned reinforcement.

Authors: *C. A. WINSTANLEY, M. TREMBLAY;
Psychology, Univ. British Columbia, Vancouver, BC, Canada

Abstract: Drug-paired cues are believed to play an important role in maintaining the addicted state, and in triggering relapse. Salient stimuli are also omnipresent in casinos, and may likewise sustain or exacerbate gambling behaviours. Cues that are predictive of a reward increase the release of brain dopamine, and this dopamine efflux is maximal when the reward is probabilistic. Therefore, it has been suggested that both repeated choice of uncertain options, and repeated exposure to cues that predict reward with maximal uncertainty, may sensitise the dopamine system and thereby predispose subjects to the development of an addiction disorder. Previous studies show that the addition of reward-concurrent audiovisual cues that increase in complexity with the size of the reward can increase rats' choice of disadvantageous "high-risk, high-reward" options in a rat model of the Iowa Gambling Task (IGT), known as the rat gambling task (cued rGT). We therefore wanted to test the hypotheses that a) increased risky choice on the cued rGT reflects greater sensitivity at baseline to conditioned reinforcement (CRf) i.e. the degree to which a reward-paired cue comes to act as a reinforcer for which the animal will work, and b) repeated choice of risky options may itself precipitate greater sensitivity to the ability of reward-paired cues to act as conditioned reinforcers. Subjects were 32 female rats. Responding for CRf was tested either before (n = 16) or after (n = 16) acquisition of the cued rGT. In the cued rGT, rats chose between four options associated with distinct magnitudes and probabilities of reward (1-4 sugar pellets) or time-out penalties (5-40s). The optimal strategy was to favour options associated with smaller per trial gains, but shorter penalties, similar to that in the IGT. As expected, a majority of rats performing the cued rGT developed a preference for the disadvantageous risky options. However, contrary to our hypotheses, higher rates of responding for CRf prior to training on the cued rGT was associated with a better choice strategy, less motor impulsivity, and more trials completed on task. Furthermore, cued rGT training did not increase rats' motivation to respond for CRf. Instead, there was no evidence of any association between responding for CRf and risky choice when the CRf test occurred after cued rGT training. These

results suggest that rats' performance of simple cue-driven behaviours does not readily inform our understanding of how cues influence more complex tests of cost/benefit decision making.

Title: Reward-concurrent audiovisual cues increase risky decision-making in Iowa and Vancouver gambling tasks

Authors: *M. V. CHERKASOVA[1], J. J. S. BARTON[2], L. CLARK[3], A. J. STOESSL[1], C. A. WINSTANLEY[3];
[1]Neurol., [3]Psychology, [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Reward cues can potently influence behaviour. In addicted individuals, exposure to contextual cues - e.g. drug paraphernalia - is believed to trigger cravings, drug use and relapse. Yet, mechanisms through which cues influence such outcomes remain poorly understood. As one mechanism, cues may influence decision-making processes. This hypothesis is supported by our work in rats, but remains largely untested in humans. Here, we examined the effects of reward-paired audio-visual cues (money images and casino-like jingles) on decision-making in healthy human volunteers. Decision-making was assessed using two paradigms: 1) the Iowa Gambling Task (IGT), which is an ecologically valid model of real life maladaptive risky choice; 2) the Vancouver Gambling Task (VGT), which evaluates the degree of risk preference and allows to model choice parameters under Prospect Theory. One group of participants completed the IGT with reward-paired cues present and the VGT without the cues; the other group completed the VGT with the cues and the IGT without the cues. Cues increased in perceptual saliency with increasing magnitude of rewards. On the IGT, there was a trend-level cues x gender interaction ($p = .07$): cues had no effect in females but tended to bias choice towards the maladaptive risky options in males. On the VGT, cues resulted in riskier choice in both males and females at intermediate reward probabilities ($p = .009$). There was also a trend for a cues x gender interaction on the value function parameter ($p = .09$), which describes subjective perception rewards' value as their magnitude increases. In males, cues tended to enhance the perceived difference in value between smaller and larger reward; in females, cues tended to decrease that

perceived difference. There was also a significant effect of cues on the probability function parameter describing subjective perception of reward probabilities ($p = .02$): cues augmented the typical distortion in probability perception, where low probabilities are overestimated, high probabilities are underestimated, and intermediate probabilities are poorly discriminated. Though the interaction with gender was not significant, the effect was likely driven by females, who showed a significant effect of cues ($p=.02$), while males did not ($p = .60$). Together, the results suggest that salient reward-paired sensory cues do result in riskier choice, albeit through different mechanisms in males and females. In males, the cues appear to increase the perceived value of larger rewards, presumably making them more attractive and worthy of risk. In females, cues appear to promote risk through enhancing distortions in probability perception.

Title: Dissociable contributions of dorsal and ventral regions of the striatum on a rodent cost/benefit decision-making task requiring cognitive effort

Authors: *M. SILVEIRA, M. TREMBLAY, C. A. WINSTANLEY;
Univ. OF British Columbia, Vancouver, BC, Canada

Abstract: Successful decision-making requires evaluating a given option's benefits in light of its associated costs, and notably perturbations in such cost/benefit decision-making are a feature of almost every mental illness. Our lab has validated a rodent Cognitive Effort Task (rCET), a variation of the 5-choice serial reaction time task, wherein animals can choose to expend greater visuospatial attention to obtain larger sucrose rewards. Previous work indicates that the choice to apply cognitive effort is neurochemically dissociable from attentional ability, and that a corticolimbic circuit including medial prefrontal and anterior cingulate cortices, in addition to the basolateral amygdala, mediates such effortful decisions. Outputs from these key areas converge

in the striatum, which can be functionally divided into dorsal and ventral components. Notably, while dorsal striatal contributions to decision-making have not been directly investigated, it has been proposed that the ventral striatum (i.e. nucleus accumbens) functions as a "corticolimbic interface" that integrates signals from these areas, and that the resulting signal outflow may bias the direction and intensity of behavior. To address the role of these striatal areas in cognitively effortful decision-making, 26 male Long-Evans rats were trained on the rCET and following confirmation of a stable behavioural baseline, the dorsomedial striatum (DMST) and later the core region of the nucleus accumbens were temporarily inactivated via a cocktail of baclofen-muscimol. Temporary inactivation of the DMST decreased all animals' choice of the high-effort, high-reward option, impaired attentional accuracy, and robustly increased premature responding without impairing general indices of motor ability. This profile suggests the DMST may set the behavioural program required for optimal task performance, and when this process is impaired, animals can no longer successfully complete high reward/high effort trials. In stark contrast, following temporary inactivation of the ventral striatum, subjects were fundamentally unable to perform the task, as reflected by a drastic decrease in the number of trials completed and an increase in omitted responses once a trial was initiated. Together, these data suggest the striatal subregions have dissociable roles in cognitively effortful decision-making, and that the striatum is part of a larger cortico-limbic-striatal network whose function is to optimize decisions requiring cognitive effort costs.

Title: A modified version of Lima-Dill model predicts approach-avoidance behavior of rats facing a predator-like robot

Authors: ***S. KIM**, H.-S. JIE, J.-S. CHOI;
Biopsy Lab, Korea Univ., Seoul, Korea, Republic of

Abstract: An ecological model by Lima and Dill (1990) (LDM) describes risky decision-making of animals under predatory threat in natural situation. Widely referenced, yet such model was not simulated or tested in laboratory conditions. The current study modified the LDM (m-LDM) to

analyze animal's subjectively perceived danger and aimed to simulate a dynamic predatory situation where animal has to evaluate not only the risk but also the gain. Previously in our laboratory, we developed an approach-avoidance conflict (AAC) paradigm which utilizes a bait (food pellet), a robot predator (Jawbot) and food-deprived rats. Whenever the animal approached the pellet under Jawbot's guard, it was attacked by snapping jaws, which elicited immediate withdrawal reflex. Most rats failed to procure food bait, and all showed pattern of approach which peaked initially and then diminished, leading to more avoidance in the later phase. We have also shown that such pattern is modulated by the value of the bait and the defensive neural circuit in the brain (e.g. amygdala). In the current study, a computer simulation of m-LDM was performed to compare with behavioral data acquired from the previous study in our lab. In the simulation, m-LDM incorporates the cumulatively experienced predation risk over number of prey-predator encounters, which takes a form of cumulative distribution function of geometrical distribution. The key parameter, d* (perceived net risk), determines how fast the perceived predation risk will increase to asymptote and reflects perceived probability of death adjusted by perceived probability of gain on a given single encounter. The simulated m-LDM predictions with varying d* values for each animal were fitted to the normalized data of each animal's cumulatively experienced attack duration, and have shown acceptable goodness of fit (all adjusted $R^2 > .85$). The d* showed negative correlations with approach and preference for risky area, while showing positive correlations with preference for safer area. Also, the variables shown to modulate AAC in the previous study (food/amygdala lesion) were found to have consistent effect on d* as exclusion of food increased d* and amygdala lesions reduced d* to a very small number. Together, the current results indicate that m-LDM is a succinct yet efficient framework that can describe modulation of animal's risk-taking behavior in AAC situation at the neurobiological as well as the conceptual level.

Title: Behavioral differences between alcohol preferring AA rats and Wistar rats in rodent gambling task, focus in opioidergic mechanisms

Authors: *V. OINIO, M. SUNDSTRÖM, A. RAASMAJA, P. PIEPPONEN;
Univ. of Helsinki, Fac. of Pharm., Helsinki, Finland

Abstract: Co-morbidity with gambling disorder (DSM-V) and alcohol dependence is well reported and it is possible that these two share common neuronal pathway that is not present with non-alcohol gamblers. Opioid antagonist naltrexone is used in the treatment of gambling disorder and it has been shown to have best effect with gambling disorder patients with familial history of alcoholism. We have previously found that administration of opioid agonist morphine induces risk aversive behavior in AA rats and opioid antagonist naltrexone does not have any effect to this behavior. Now we have studied whether the same effect occurs also in "normal" rat strains. The aim of the study was collect data from different aspects of decision making behavior that included rational decision making, risk aversive behavior and effect of opioidergic drugs to the risk aversion. Wistar rats were trained to perform operant behavior task of reward guided decision making consisting total of 50 sessions. The rats executed operant self-administration tasks where there was free choice of two different value sucrose rewards by pressing levers. SS (Small - Sure) lever always delivered one pellet and LL (Large - Lucky) lever delivered three pellets at different probabilities. After adapting rational decision making behavior (LL lever probability 100%), probability of gaining three pellet reward from LL lever was decreased over time (50%, 33%, 25%). We found that Wistar rats expressed similar decision making pattern as AA rats in rational choice and probability discounting. On the other hand, naltrexone induced favoring of large but uncertain rewards, thus making wistar rats behave less risk aversive. Results obtained from this study suggest that there are neurobiological differences in risky decision making of gamblers that are genetically prone to alcohol dependence compared to "normal" population.

Title: A dual role for the rostromedial tegmental nucleus in processing aversive costs

Authors: *P. J. VENTO, T. C. JHOU;
Med. Univ. of South Carolina, Charleston, SC

Abstract: The proper grading of the relative cost versus the benefit of engaging in a particular action is a critical component of daily life, and impairments in cost-benefit decision-making underlie several neuropsychiatric disorders, including mania and addiction. The rostromedial tegmental nucleus (RMTg) encodes negative reward prediction errors and sends robust inhibitory projections to dopamine neurons in the ventral tegmental area (VTA), but the functional role of the RMTg in mediating decision-making in response to negative stimuli remains unknown. Accordingly, the present experiments tested the hypothesis that the RMTg is required to properly inhibit behaviors that lead to negative consequences, and that this relies on inputs to the VTA. Using a progressive shock task in rats where lever pressing for food reward is punished by footshock of gradually increasing intensity, we found that lesions of the RMTg caused a robust increase in shock breakpoint, or the maximum shock rats tolerated to receive reward. This punishment resistance observed in RMTg-lesioned rats was not the result of several non-specific factors, but instead likely arises from an inability to properly encode aversive stimuli or impairments in behavioral inhibition. To more directly test this, we used the inhibitory light-sensitive proton pump archaerhodopsin to inhibit RMTg neurons at restricted time points in the progressive shock task. We found that inhibition of VTA-projecting RMTg neurons caused a significant increase in shock breakpoint when optical inhibition was solely restricted to the period of time that overlapped with footshock exposure. Interestingly, we observed a similar increase in shock breakpoint when RMTg inhibition occurred in the window leading up to the lever-press response when rats were presumably choosing between whether to press the lever or not. These data suggest that the RMTg plays a crucial role in the encoding of aversive consequences, but the RMTg also appears to be important in modulating the decision to engage in behaviors that ultimately lead to these same negative events.

Title: 5alpha-reductase type 2 contributes to emotion and mood regulation

Authors: *M. BORTOLATO[1], L. J. MOSHER[1,2], S. C. GODAR[1], K. M. MCFARLIN[1,2];
[1]Pharmacol. and Toxicology, Univ. of Utah, Salt Lake City, UT; [2]Pharmacol. and Toxicology, Univ. of Kansas, Lawrence, KS

Abstract: The enzyme 5α reductase 2 (5αR2) catalyzes the conversion of progesterone and testosterone into potent neuroactive metabolites. We recently showed that 5αR2 is present in key brain areas for emotional regulation; the functions of this enzyme in behavioral regulation, however, remain poorly understood. Based on these premises, we hypothesized that 5αR2 may be implicated in the regulation of emotion and mood. To test for this possibility, we tested the behavioral reactivity of 5αR2 knockout (KO) and heterozygous (HZ) mice, as compared with their wild-type (WT) littermates. Our results evidenced that 5αR2 KO male mice displayed reduced preference for natural rewards (saccharin and sex), as well as reduced proclivity to novelty-seeking and risk-taking responses, as signified by their reduced exploration of novel objects and the open arms of an elevated plus maze. Finally, 5αR2 KO male mice displayed a reduction in dominance status. No significant differences were found in sensory and motor changes, as well as object-recognition memory. Taken together, these results provide the first-ever demonstration that 5αR2 is directly involved in behavioral regulation, and strongly support a pivotal role of this enzyme in motivation.

Title: Effects of experiencing softness on empathy and memory.

Authors: *T. TAKANO[1], K. MOGI[2];
[1]Tokyo Inst. of Technol., Yokohama, Japan; [2]Sony Computer Sci. Labs., Tokyo, Japan

Abstract: Recent studies have shown that somatosensory stimuli affect our social emotion. For example, physical warmth (e.g. holding a cup of hot coffee) promotes good reputation, while touching soft materials leads to flexible impressions of others (LE Williams, JA Bargh, 2008).

Haptic stimuli can change social judgment related to others. Those phenomena have been suggested to be related to affectional bond (attachment). Attachment is built up through physical communications with a caregiver in childhood, where the warmth from physical proximity provides a sense of safety (J Bowlby, 1958). Appropriate haptic stimuli are thought to nurture attachment, which is constructed in a subject's childhood. There are few adult attachment studies focusing on physical warmth. Adult attachment does not explicitly depend on physical proximity as much as child attachment, while attachment behavior in adulthood is difficult to observe. However, it is possible that physical warmth would have some effects on one's sense of safety, not only in childhood but also in adulthood. Subjects are likely to see those with a good reputation as having a trustworthy personality, inducing reciprocity (L Mui, et al., 2002), and leading to empathizing with more a familiar person (in-group) than a stranger (out-group) (X Xu, et al., 2009). Positive emotions attuned to in-group members would be stronger than those attuned to out-group ones.
Emotion is significantly related to memory. It is relatively easy to recall where we were and what we were doing in situations where some emotions were aroused. There are studies suggesting that long-term memories are intensified by emotional arousal (MM Bradley, et al., 1992).
Here we investigated two hypotheses. We studied whether tactile stimuli of soft materials promote a subject's empathy, using a hard chair or a soft chair. We also studied the effect of a sense of safety on a subject's memory. A recent study showed that experiencing roughness (using hand wash or touching an object) increases subjects' empathy (C Wang, et al., 2015). The present study illustrated the effects on empathy of haptic senses in a more general spectrum than hands. Our findings suggest the importance of feeling a sense of safety in promoting social abilities.

Title: Anger produces an opposite effect on positive and negative memory previously associated with a transgressor: An evidence from facial electromyogram

Authors: ***T. MINAMOTO**, M. HARUNO;
Nat'l Inst. of Info and Comm Technol., Suita, Japan

Abstract: Anger-related event enhances vengeful and avoidance motivation toward a transgressor, while it reduces approaching motivation. Although such an event is known to affect the following cognition and behavior toward the transgressor, a retroactive effect on acquired memory and related physiological features are less known. Using an associated memory paradigm and measurement of facial electromyogram (EMG), we investigated how an anger-provoking social interaction affected pre-learned emotional memory and sought physiological hallmarks associated with the retroactive effect. A total of twenty-two experimental groups joined the present study. Each group included five participants, where one of them was the test subject and the others were confederates. At the study phase, the test participant was instructed to pair three kinds of emotional adjectives that describes personality trait (positive, negative, and neutral) with four confederates. The phase was repeated until memory performance went beyond 50% accuracy. Anger was elicited by administering the social rejection task and dictator game where the transgressor acted in selfish manner as a dictator. In the social rejection task, one confederate always gave denial comments on participant's hobbies or favorites. In the dictator game, the same confederate repeatedly (14 times out of 15 trials) selected unfair monetary distribution between him/her and the test subject to maximize their own profit. Facial EMG was measured at the left corrugator region, while the test subject was engaged in the two tasks. Paired memory was tested, where the test subject selected a confederate's face in response to an adjective word presented on a monitor. The memory performance showed that positive adjectives associated with the control confederates are more recognized than those with the transgressor, indicating that anger experience suppresses retrieval of positive memory previously associated with the transgressor, possibly due to reduction of approaching motivation. Analysis of the facial EMG showed greater amplitude in the unfair distribution condition than the fair condition: $F\,(1, 21) = 4.79$, $p < .05$. Importantly, the EMG amplitude was positively correlated with memory performance of negative personality adjectives associated the transgressor: $r\,(18) = 0.68$, $p < .01$. The result indicates that the physiological response in the left corrugator region may reflect vengeful and avoidance motivation, which results in greater retrieval of negative aspects of the transgressor.

Title: Vicarious reward enhances the mirror neuron system activity: An EEG study

Authors: *T. INOMATA, T. ZAMA, Y. INOUE, S. SHIMADA;
Meiji Univ., KANAGAWA, Japan

Abstract: Mirror neuron system (MNS) is the brain regions that show activity as if an individual is acting when observing the behavior of others. A previous fMRI study has shown that the magnitude of MNS activity correlates with the reward system activity evoked by vicarious reward that was received by others whom the individual had cheered for [Shimada, S., Matsumoto, M., Takahashi, H., Yomogida, Y., & Matsumoto, K. (2016). Coordinated activation of premotor and ventromedial prefrontal cortices during vicarious reward. Social Cognitive and Affective Neuroscience, 11(3), 508-512.]. In the previous electroencephalography (EEG) studies, MNS activity was indexed by mu-suppression which is the attenuation in mu-band (8-13 Hz) power related with the motor activity. We investigated whether the magnitude of mu-suppression during observation of other's action was modulated before and after the vicarious reward was received by the other. The Experiment consisted of four sessions in the following order: i) 1st Observation session (ob1), ii) Cheering session, iii) 2nd Observation session (ob2), iv) Action session. In the ob1 and ob2 sessions, the subjects observed the movie, in which one (blue or yellow) right hand performed a gesture of Rock-Paper-Scissors game (RPS). In the cheering session, the subjects were instructed to cheer for a particular (blue or yellow) player in the two-player RPS game. In the Action session, subjects were instructed to perform a RPS gesture by themselves with his/her right hand. The magnitude of mu-suppression in ob1 and ob2 session was submitted to the 2 (before and after the cheering session) × 2 (player) repeated-measure ANOVA. The result showed that there was a statistically significant interaction between session and player in the left motor area (C3: $F(1, 10) = 8.44$, $p < 0.05$). There was no main effect in two factors. Subsequent analyses (Tukey's honestly significant difference) revealed that the magnitude of mu-suppression for cheered-for player became larger after cheering than before, while that for non-cheered player was smaller after cheering than before ($p < 0.05$). The result suggests that the vicarious reward enhances the MNS activity, which is likely to underlie the sense of unity with the cheered-for others.

Title: Asymmetries of facial expressions and facial perception: An indication of Macchiavellian intelligence or of "grin and bear it" survival of the nicest

Authors: *B. PREILOWSKI;
Tuebingen Univ., Ravensburg, Germany

Abstract: Experimental data about asymmetries of facial expressions and facial perception will be presented and discussed as a possible indication of Macchiavellian intelligence or of a "grin and bear it" survival of the nicest.
Lateral asymmetries of facial emotional expressions reflect differences between unconscious and consciously controlled motor functions of the face. Facial perception also shows lateral asymmetries, especially with regard to the recognition of emotions. Interestingly, judging facial emotions is preferentially based on the expressions of the facial half, which can be consciously controlled. Thus there is the possibility to be deceived in face-to-face interactions with regard to an important aspect of communication.
Comparative studies have shown a correlation between cerebral cortical development and the capacity for deceptive behavior, which has been described as an indication of Macchiavellian intelligence. However, it can be argued that such a Darwinian trait is of doubtful value in a human society of individuals with a wide range of sensory, motor and cognitive developmental capacities. Human communities thrive on cooperation of highly diversified specialists. This cooperative interdependence in turn often requires the ability to suppress the momentary actually felt emotion and attempting to put a positive face even on a negative situation. In addition to avoiding negative interactions, the motivational and reward values of positive emotional expressions go both ways: Positive emotional expressions - even when deliberately produced - are rewarding also for those who have to "grin and bear it."

Title: Social conditioned place preference in young children

Authors: *B. L. THOMPSON, M. CHOU, D. BARON, S. TAKATA;
Div. of Occup. Sci. and Occup. Therapy, USC, Los Angeles, CA

Abstract: Neurodevelopmental disorders disrupt neural circuitry involved in complex mental processes including cognition and affect. Affective processing is a more difficult construct to test in young children as it often depends on intact language skills. Key experiments have revealed important components of emotional development in children but less understood are the internal states determining affect, which directly impact, and possibly even drive specific behavioral output. Though challenging to assess, skill sets in domains influenced by affective processing are crucial for establishing capacity in developing executive function. Strategies that probe more complex internal responses, such as feelings, drives, and motivations independent from language, become necessary for populations of children with language impairments and even typically developing (TD) children. In this study we built upon our previously established paradigm of conditioned place preference (CPP) for use in young TD children by adapting the task for a social unconditioned stimulus. To our knowledge, this was the first study to differentiate rewarding, non-rewarding, and aversive characteristics of social stimuli in children. The paradigm utilized straightforward Pavlovian conditioning methods for TD children aged 30-60 months of age in a custom-built child friendly arena. During the training trials a novel social experimenter was present in one room and interacted with the child in a prescribed manner. When tested, children exhibited a conditioned preference for the social interaction room, thereby establishing that social stimuli are sufficiently salient and reinforcing for conditioning. The social CPP paradigm provides a continuous measure for describing associative learning, and social behavior phenotypes generating a dynamic range of possible behaviors. Our future studies will use this paradigm to determine what drives social deficits in specific neurodevelopmental disorders, such as ASD. Social CPP provides an exceptional opportunity to determine whether the social interaction phenotype in children with ASD is due to an aversion to social interactions or a lack of reward from social interactions. It is unique in that it represents the first assessment of social motivation in the absence of the social stimulus. This distinction is necessary for facilitating individualized intervention strategies that seek to improve social interactions in children. Translational studies like this are necessary for understanding the biological underpinnings of human behavior and social interaction disorders.

Title: Neurologic nudges to purchase health insurance

Authors: ***P. J. ZAK**[1], J. BARRAZA[2], E. TERRIS[2];
[1]Claremont Grad Univ., Claremont, CA; [2]Ctr. for Neuroeconomics Studies, Claremont Grad. Univ., Claremont, CA

Abstract: In 2016 the U.S. government began assessing penalties on people who do not have health insurance, but many people have not purchased insurance. We measured peripheral neural activity, EEG, and eye tracking as people who primarily spoke English or Spanish at home watched TV commercials about health insurance programs. Fully 23% of respondents wanted to be sent to the state health insurance website during a one-week follow-up But, ads failed to equally engage subsets of the target audience. Spanish-speaking participants were substantially under-engaged by the tested ads using multiple neurologic measures. Spanish-speaking viewers did not find the ads difficult to comprehend. Rather, our analysis shows that Spanish-speaking participants had significantly less emotional resonance with ads. Our research has shown that emotional resonance is necessary for an action to occur after an ad. Our results indicate that ads specifically designed to emotionally engage Spanish-speaking individuals are likely to be more effective.

Title: Burnout and mental health in a sample of university students

Authors: C. CAMILLERI, *S. SAMMUT;
Psychology, Franciscan Univ. of Steubenville, Steubenville, OH

Abstract: Background: Depression, anxiety, stress and burnout rates are an increasingly significant problem among university students nationwide. These problems can prove to be a significant negative influence on students' chances to be academically successful during their undergraduate years and effective in the post-graduation years.
Aim: The purpose of this study was to assess levels of burnout and its correlations to depression, anxiety and stress among college students, as well as their relationship with various factors (e.g. number of majors, extracurricular activities, studying hours, etc.) that could potentially influence the overall well-being of the student.
Methods: Prior to administration of the survey, approval from the IRB was obtained (IRB Approval #2015-9). Students were sent an invitation to participate in the survey via their student emails. Surveys were administered through SurveyMonkey®. The survey consisted of various demographic questions, the 21-item Maslach Burnout Inventory-Student Survey (MBI-SS), and the 21-item Depression Anxiety Stress Scale (DASS-21). The final analyzed sample consisted of 494 college students attending Franciscan University of Steubenville.
Results: The results indicated that professional efficacy (PE) was significantly negatively correlated with depression, anxiety, and stress. Exhaustion (EX) and cynicism (CY) were both positively correlated with negative mental health scores and negatively correlated with PE. PE scores were significantly positively correlated with increased hours of study, while on the contrary, CY scores were significantly negatively correlated. There was no significant difference in EX scores in relation to study hours. PE was also positively related to students' confidence in their post-graduation plans. The correlations between burnout and both paid employment and extracurricular activities were unclear potentially due to ambiguity in interpretation.
Conclusion: A key role of the undergraduate years is to prepare the students for the workforce. In part, the success of this endeavor is dependent on the direct motivations and experiences of the students, as well as their mental health. These factors collectively contribute to the accomplishments of the students, their satisfaction with their past and present achievements, as well as their continued effectiveness as they move beyond the undergraduate years. Thus, given the relationship between mental health and student success, we propose that broader strategies that actively address both professional/academic success and mental health together may provide more effective outcomes in addressing student well-being.

Title: Relationship-specific encoding of social touch in the somatosensory corticessomatosensory cortices

Authors: J. T. SUVILEHTO[1], *V. RENVALL[1], L. NUMMENMAA[1,2];
[1]Dept. of Neurosci. and Biomed. Engin., Aalto Univ. Sch. of Sci., AALTO, Espoo, Finland;
[2]Turku PET Ctr. and Dept. of Psychology, Univ. of Turku, Turku, Finland

Abstract: Background:
Social touch is an important form of affective communication. Patterns of social touch depend on the relationship between toucher and the person being touched. However, it remains unresolved how the brain represents the relationship-specific aspects of social touching.
Methods:
We studied 5 heterosexual couples (10 subjects) using functional magnetic resonance imaging (fMRI). During the fMRI scan the subject's partner and two researchers, one female and one male, took turns in 1) touching the subject's upper thigh, or 2) bringing their hand to close or 3) moderate proximity from the subject's thigh. Stimulation was performed in 6-second blocks. Data were analyzed with multi-voxel pattern analysis (MVPA). In addition to whole-brain cortical mask, regions of interest were drawn in the primary (SI) and secondary (SII) somatosensory cortices, anterior cingulate cortex (ACC), insula, and orbitofrontal cortex (OFC). A linear support vector machine classifier was trained to distinguish the individual touching the subject (partner vs. male researcher vs. female researcher; naïve chance level 33%), and the different combinations between touchers and their actions (touching vs. close proximity vs. moderate proximity, naïve chance level 11.1%).
Results
When classifying the individual touching the subject (irrespective of the action type), accuracies were significantly above the chance level in whole-brain mask (46.3%), SI (39.3%), SII (36.9%), ACC (37.1%), OFC (35.7%), and insula (35.4%), $p < 0.05$. In whole-brain cortical mask

classification, accuracy for distinguishing between the nine action types was 28.3% ($p < 0.001$). Significantly above-chance-level accuracies were also observed in SI (21.4 %), SII (18.2), ACC (16.7%), OFC (15.9%), and insula (15.4%); $p < 0.01$. Confusions occurred most often within an action category, across different actors.
Discussion:
These findings suggest that many cortical areas are involved in processing the social features of interpersonal touch. Even though whole-brain classification was by far the most robust, already primary somatosensory cortex (SI) encodes relationship-specific aspects of social touch and touch anticipation.

Title: Vasopressin effects on human social responses are sex, dose, and context dependent

Authors: *R. R. THOMPSON[1], J. RILLING[2], D. PRICE[3];
[1]Dept Psychol / Neurosci, Bowdoin Col., Brunswick, ME; [2]Anthrop., Emory Univ., Atlanta, GA; [3]Psychiatry, Maine Med. Ctr., Portland, ME

Abstract: Arginine vasopressin (AVP) and its homologues have complex effects on social behavior in non-human vertebrates, some of which are sexually dimorphic, as well as dose- and context-dependent. We previously demonstrated that a single dose of AVP can induce antisocial responses to same-sex faces in men, but pro-social responses in women. Here we follow that work up by showing that AVP's behavioral effects are not only stimulus- and dose- dependent, but also modified by the individual's relationship status. In single men, intranasal delivery of 20IU AVP, but not 40IU, reduced positive ratings of the faces of other men, but not in men involved in romantic relationships. In women, the higher dose of AVP selectively increased positive ratings of the faces of other women. Additionally, there may be long term effects of single doses of AVP; on a follow up test 3-21 days after drug administration, single men given 20IU rated all faces, including those previously seen on the day when placebo had been given, less positively than men given 40IU, whereas men in relationships given 20IU rated all female faces less positively than did men given 40IU. In women, female faces previously seen after

40IU tended to be rated more positively than those seen after placebo, whereas male faces tended to be rated less positively. On the other hand, male faces previously seen after 40IU tended to be rated more positively in women who were in a romantic relationship, whereas female faces previously seen after 40IU were rated less positively. Together, these results suggest that AVP produces complex effects on human social responsiveness that are sex- and dose-dependent, modified by relationship status, and could be long-lasting.

Title: Performance decrement induced by increasing social incentive

Authors: *A. SUGIURA[1,2], Y. YOMOGIDA[3], K. IIJIMA[2,3], T. HASEGAWA[1], K. MATSUMOTO[3];
[1]Dept. of Life Sciences, GSAS, Univ. of Tokyo, Tokyo, Japan; [2]Japan Society for the Promotion of Sci., Tokyo, Japan; [3]Brain Sci. Institute, Tamagawa Univ., Tokyo, Japan

Abstract: When we are promised with a large amount of money as a result of successfully doing a task, we are likely to perform well compared to when we are promised a small amount. However, increasing incentive sometimes result in a paradoxical decrease of performance, which is called as choking under pressure. Similar to increasing money, increasing social incentive, such as decreasing indebtedness, may result in choking. In the present study, we examined how an increase in indebtedness will affect performance. In the experiment, a participant was asked to earn money for the three partners who had previously given effort to earn money for the participant. Since the participant felt indebtedness to pay back for the partner, her/his social incentive should increase according to the amount of money that was received from each partner,

resulting in the increase of performance, if the subjects did not choke on the pressure to pay back. The participant was instructed that the maximal amount of money that could be received from one partner was 5000 yen (approximately corresponding to $50), and the three partners had earned 4000 yen (Big), 2100 yen (Medium) and 300 yen (Small) for the participant. After receiving the money from each partner, the participant went into the scanner to earn back for each partner in an achievement task, where they had to stop a stopwatch in the range of 5 ± 0.05 sec after it started moving automatically. The amount of money that can be earned back in one trial was either 1000 yen or 100 yen (as control). The control condition was introduced to create a condition where there are no incentives for the subject to succeed since the amount that can be paid back is low, and to control for the effect caused by the simple increase in the amount of money. Forty trials (20 trials each for 1000 yen and 100 yen) were done for each partner and the participants were told that the actual earnings that would be given back to one partner were determined by the result of 5 randomly chosen trials done for that partner, which meant that the optimal strategy is to engage every trial with their best effort. Preliminary data (N = 7) have shown that participants' performance increased for the Medium partner compared to Small partner ($t = 2.00$, $p = .092$), but decreased for the Big partner compared to the Medium partner ($t = 1.98$, $p = .093$), although the incentive to succeed had monotonically increased. This trend was not present in the control (100 yen) condition. The behavioral results suggest that in the Big condition, participants choked on the pressure to pay back to the partner. Subsequent analysis will test for brain regions that will show the effect of performance decrement although there is a rise in incentive.

Title: The influence of personality and genetic factors on peer pressure susceptibility

Authors: ***M. NICULESCU**, E. A. AGUILAR, C. R. PARSONS, P. V. CARPER, R. S. BOYLE, J. K. KUTCH, V. J. TRANCHITELLA;
Lebanon Valley Coll, Annville, PA

Abstract: Our purpose was to develop a peer pressure model and identify personality influences and genetic correlates to susceptibility. We hypothesized participants would be persuaded by confederates to approve or disapprove of risky behavior. Furthermore, we expected that personality traits would affect how participants viewed risky behavior and the degree to which they were influenced by their peers. Finally, we postulated an interaction between specific personality traits (reward dependence, novelty seeking, and harm avoidance) and type of peer pressure (risk-promotion vs. risk-averse) on susceptibility. Participants completed personality questionnaires and viewed a movie clip portraying a college-aged man engaging in risky behavior. During a guided discussion, two confederates expressed approval (risk-promotion group) or disapproval (risk-averse group) of questions about risk-taking (i.e. studying abroad as a requirement, how integral partying is to college, and if the drinking age should be lowered), followed by participants rating their feelings aloud on a rating scale from 1 (absolutely not) to 10 (absolutely). Finally, saliva samples were collected for DNA analysis. Participants in the risk-promotion group answered all questions regarding risky behavior more positively (M = 24.00, SD = 3.89) than participants in the risk-averse group (M = 7.49, SD = 3.61), $p < .001$. Further, those who scored high in reward dependence were more likely to agree with the group (M = 8.07, SD = 2.33) about lowering the drinking age than those who scored low in reward dependence (M = 6.58, SD = 2.70), regardless of condition, $p = .035$. Also, those that scored high in novelty seeking were more likely to agree with the risk-promotion group that partying is an integral part to college life (M =8.83, SD = 1.11) than those that scored low in novelty seeking (M = 7.62, SD = 0.96), while in the risk-averse group, those that scored low in novelty seeking agreed with the group (M = 8.87, SD = 1.20) more than those that scored high in novelty seeking (M = 8.56, SD = 1.03), $p = .013$. Conversely, those that scored high in harm avoidance agreed with the risk-averse group significantly more (M = 9.07, SD = 1.10) than in the risk-promotion group (M = 7.07, SD = 1.62), with those that scored low in harm avoidance scoring in between in both groups (promotion: M = 8.09, SD = 1.10 and averse: M = 8.71, SD = 0.77) when answering if study abroad should be a college requirement, $p = .042$. In conclusion, peer pressure susceptibility is influenced by personality characteristics, and genetic correlates to novelty seeking (dopamine), harm avoidance (cannabinoid), and reward dependence (opioid) are currently being investigated.

Title: Observational learning computations in neurones of the human anterior cingulate cortex

Authors: *M. R. HILL[1,2,3,5], E. D. BOORMAN[3,4,7], I. FRIED[6,8];
[1]EPFL, Ctr. For Neuroprosthetics, Geneve, Switzerland; [2]Div. of Biol. and Biol. Engin., [3]Computation and Neural Systems, [4]Dept. of Humanities and Social Sci., Caltech, Pasadena, CA; [5]Div. of Neurosurg. and Neuropsychiatric Inst., Univ. of California Los Angeles, Los Angeles, CA; [6]Div. of Neurosurg. and Neuropsychiatric Inst., Univ. of California Los Angeles, Los Anglese, CA; [7]Ctr. for Functional Magnetic Resonance Imaging of the Brain, Univ. of Oxford, Oxford, United Kingdom; [8]Functional Neurosurg. Unit, Tel-Aviv Med. Ctr. and Sackler Fac. of Med., Tel-Aviv Univ., Tel-Aviv, Israel

Abstract: When learning from direct experience, neurones in the primate brain have been shown to encode a teaching signal used by algorithms in artificial intelligence: the reward prediction error (PE) — the difference between how rewarding an event is, and how rewarding it was expected to be. However, in humans and other species learning often takes place by observing other individuals and to date the single-cell mechanisms that underpin such observational learning remain largely unknown. Here we show that, when subjects observed other players in a card game, neurones in their rostral anterior cingulate cortex (rACC) encoded both the expected value of an observed choice before the outcome of that choice was revealed, and the PE after the outcome was revealed. Notably, during the same task neurones recorded in the amygdala and the rostromedial prefrontal cortex did not exhibit this type of encoding. Our results suggest that humans learn by observing others, at least in part through the encoding of observational PEs in single neurones in the rACC. These findings provide the first single-cell evidence of the nature of the computation at work during observational learning in humans and have broad implications for our understanding of the neuronal circuitry underlying these processes.

Title: Cultural values moderate neural predictors of giving.

Authors: *B. PARK, J. L. TSAI, E. BLEVINS, B. KNUTSON;
Psychology, Stanford, Stanford, CA

Abstract: Can brain activity predict choices to share resources with others, and is this moderated by culture? We predicted that while neural activity in circuits associated with anticipatory affect (i.e., Nucleus Accumbens or NAcc) would predict choices to give to others. However, these effects might also depend on cultural variables, such as the match between givers' interpersonal values (e.g., desire to influence others vs. adjust to others) and targets' emotional expressions (e.g., excited versus calm). Based on previous findings that influencing others is associated with excitement whereas adjusting to others is associated with calm (Tsai et al., 2007), we predicted that givers who value influence (vs. adjustment) would offer more money to excited (vs. calm) targets, and that this cultural modulation would be mediated by enhanced activity of NAcc in response to excited (vs. calm) targets. To test this prediction, we asked European American (n=18) and Korean (n=18) subjects to play a modified dictator game as they underwent functional magnetic resonance imaging (FMRI). On each task trial, subjects chose whether or not to give a specific proportion of their endowment (i.e., $12) to targets whose avatars varied with respect to positive expression (excited versus calm), ethnicity (Caucasian versus Asian), and sex (male versus female). One randomly selected trial was actualized at the end of the experiment. Consistent with predictions, behavioral results indicated that subjects who valued influencing others (vs. adjusting to others) offered more to excited than calm targets, regardless of target avatars' ethnicity and sex (Interpersonal goals X receiver expression $B = .01$, $t = 3.20$, $p = .001$). Neurally, NAcc activity generally predicted choices to give overall ($B = .04$, $t = 2.74$, $p = .006$). However, NAcc activity also varied such that subjects who valued influence more and adjustment less showed enhanced NAcc activity towards excited targets versus calm targets (Interpersonal goals X receiver expression $B = .01$, $t = 2.19$, $p = .029$). Together, these results indicate that while NAcc activity predicts willingness to give to others, but this effect can be moderated by cultural variables related to interpersonal values. These findings may have implications for the cultural specificity of appeals for charitable giving and policy related to the distribution of resources.

Title: Generalization learning mechanisms support adaptive decisions to trust

Authors: *O. FELDMANHALL[1], J. DUNSMOOR[2], L. HUNTER[3], S. LACKOVIC[2], A. TODOROV[4], E. A. PHELPS, 10003[2];
[1]NYU, New York, NY; [2]New York Univ., NYC, NY; [3]New York Univ., New York City, NY; [4]Princeton Univ., Princeton, NJ

Abstract: Over the course of repeated encounters an individual can learn to trust through trial-and-error. However, in our everyday lives we constantly encounter new individuals where judgments of trustworthiness are blind to reputation. In these cases, what mechanism drives an individual to trust? The ability to generalize across stimuli and situations is an essential feature of survival that has robustly shown to be deployed under numerous cognitive domains. In two experiments, we test whether reputations of previously encountered individuals generalize to new individuals as a function of perceptual resemblance. In a learning task, subjects played an iterative trust game with three partners, one who was very trustworthy, one who was somewhat trustworthy, and one who was not trustworthy. After learning which partners could be trusted, in a generalization task, subjects could choose their partners for a future trust game. On each trial, subjects were presented with a new player who was morphed with one of the original three partners. Results reveal subjects successfully learned to invest more with the trustworthy partner. Subsequent behavior in the generalization task revealed that responses generalized to related stimuli: as perceptual resemblance became increasingly similar to the original trustworthy partner, subjects were significantly more likely to choose the novel player, whereas the opposite effect was observed for novel players perceptually resembling the untrustworthy player. Dovetailing with previous research dissociating the role of the dorsomedial PFC and amygdala in trustworthy and untrustworthy behavior respectively, morphs of the trustworthy partner was parametrically modulated by activity in the dorsomedial PFC, while morphs of the untrustworthy partner recruited greater BOLD activity in the amygdala. Moreover, untrustworthy morphs were systematically less likely to be selected than the trustworthy morphs, demonstrating an asymmetric stimulus generalization. Together, these data not only demonstrate how and where stimulus generalization mechanisms support complex social choice, but also that social stimuli bearing even the slightest perceptual resemblance to negatively experienced stimuli disproportionately elicit aversive responses. In other words, it is better to be safe than sorry.

Title: Dorsal raphe regulation of aggression via the medial orbital frontal cortex

Authors: ***J. NORDMAN**, Z. LI;
Natl. Inst. of Mental Hlth., NIH, Bethesda, MD

Abstract: Violence and aggression are serious concerns for modern society. Current therapeutic strategies are limited due to a lack of understanding about the neurological mechanisms underlying aggression and the environmental triggers that cause it. A number of studies have demonstrated that serotonin is a critical regulator of social behaviors like aggression. In this study we show that serotonin inhibits aggression via the dorsal raphe/medial orbital frontal cortex pathway. We performed circuit mapping analysis which showed that dorsal raphe neurons project onto a number of aggression loci within the mouse brain (e.g. medial orbital frontal cortex, medial amygdala, and ventromedial hypothalamus). c-Fos labeling revealed that optogenetic activation of the dorsal raphe increases activity in those brain regions. To determine which synaptic targets of the serotonin system regulate aggression, we optogenetically silenced neurons of the dorsal raphe as well as their projections onto loci of the aggression circuit. Silencing of the dorsal raphe and it's projections onto the medial orbital frontal cortex inhibited aggression during a social interaction test, while silencing the projections to other downstream targets (medial amygdala and ventromedial hypothalamus) did not. Finally we present a novel FRET based serotonin sensor for use *in vivo* to discern serotonin induced activity related to aggression. This study will help elucidate the role of serotonin in regulating predatory aggression and provide possible therapeutic targets in the fight against pathological aggression and violence.

Title: Playback of 50-55 kHz ultrasonic vocalizations reduces alcohol intake and negative-affect in rats selectively bred for high- and low-alcohol consumption

Authors: *C. L. DUVAUCHELLE[1], J. M. RENO[2], N. THAKORE[1], W. T. MADDOX[2]; [1]Pharmacol. & Toxicology, [2]Psychology, Univ. of Texas, Austin, TX

Abstract: Rats selectively bred to drink alcohol to intoxicating levels (P and HAD-1) have been shown to *spontaneously* emit a significant proportion of negative-affect associated ultrasonic vocalizations (USVs), with approximately equal proportions in the negative-affect range (22-28 kHz) and positive-affect range (50-55 kHz) (Reno et al, 2015; Thakore et al, 2016). In addition, the proportion of negative-affect USV emissions is sensitive to alcohol intake (Reno et al, 2015), and increases in the proportion of negative-affect USVs are associated with increases in alcohol consumption (Thakore, et al 2016). These findings are unique to these selectively bred alcohol rats, as all other rats emit close to 100% 50-55 kHz USVs. 50-55 kHz USV emissions are reliably associated with stimulant drugs (Ahrens et al 2009, 2013, Maier et al 2010, 2012) and alcohol anticipation in alcohol-dependent rats (Buck et al 2014) in common rats. However, USVs in the 50-55 kHz range are not importantly associated with alcohol intake or motivation in rat lines selectively bred for alcohol consumption (Reno et al, 2015; Thakore et al, 2016). The high proportion of spontaneously emitted negative-affect USVs in these high-alcohol drinking rats suggests a strong direct link between excessive alcohol consumption and negative affect. Playback of positive-affect USVs enhance socialization, approach behaviors and positive-affect in Wistar rats (Wohr and Schwarting, 2007, 2009, 2012, Sefer, et al 2014). Due to the

importance of negative-affect USVs and their large proportion in high alcohol drinking rat lines, it was of interest to determine whether playback of positive-affect USVs emissions might reduce subsequent alcohol intake and reduce negative-affect USVs in these animals. To explore this hypothesis, rats selectively bred for high (P and HAD-1) and low (NP and LAD-1) alcohol consumption were presented with positive-affect USV Playback or No Playback during 20 days of handling sessions (approx. 20 min/day for 20 days). 24 hrs after the final playback session, animals were given either: 1) 24-hour alcohol access on alternating days for 4 weeks, OR 2) were recorded for USVs over 4 weeks. Two findings are of interest. First, we found that rats exposed to 50-55 kHz USV playback showed: 1) suppressed alcohol intake, and 2) emitted fewer negative-affect USVs. Although these effects were transient (lasting 1-2 weeks), the effects were observed in all bi-directional lines tested. These results indicate USVs not only reveal the emotional phenotype of the sender, but also influence alcohol intake and emotional responses in the receiver.

Title: Fight or escape: A novel paradigm to study approach/avoidance behavior to provocation

Authors: *U. M. KRÄMER[1], M. BUADES-ROTGER[2], F. BEYER[3];
[2]Neurol., [1]Univ. of Luebeck, Luebeck, Germany; [3]Inst. of Cognitive Neurosci., Univ. Col. London, London, United Kingdom

Abstract: When confronted with a menace, one must decide between two possible responses: fight or flight. Whereas previous paradigms to study aggressive behavior provided only the option to retaliate but no “flight” option, we developed a novel paradigm that gives participants the option to (temporarily) escape the interpersonal conflict. The paradigm (Fight or Escape, FoE) is set up as competitive reaction time task which entitles the winner to punish the loser. Participants alternatively faced a highly or lowly provoking opponent, but were also given the chance to avoid the encounter before each trial. In two behavioural studies, we validated the paradigm by showing that participants avoid the highly provoking opponent more often but also

behave more aggressively when deciding to "fight" and by relating participants' behavior to established behavioral and personality measures of approach/avoidance behavior. Specifically, participants' behaviour in the FoE was found to correlate with the fear potentiation of the startle reflex. In an fMRI study with the FoE, we found increased activity in OFC, precuneus, and the motor network related to the decision to fight. When, on the contrary, participants decided to escape, we observed widespread activation in areas of the so-called mentalizing network, including temporal pole and superior temporal gyrus, as well as dorsal mediofrontal cortex. The results suggest that the decision to engage or not in a fight is governed by social-evaluative processes. By providing more behavioral options to participants, the paradigm has a higher ecological validity compared to previous aggression paradigm and can be useful to delineate the neural underpinnings of interindividual variability in responding to interpersonal provocation.

Title: Protein phosphatase 2A is required for rapid antidepressant responses of NMDA receptor blockade

Authors: *C.-H. CHANG[1], P.-W. GEAN[2];
[1]Dept. of Pharmacology, Natl. Cheng-Kung Univ., Tainan, Taiwan; [2]Dept. of Pharmacology, Col. of Medicine, Natl. Cheng-Kung Univ., Tainan, Taiwan

Abstract: NMDA receptor (NMDAR) blockade has a fast-acting antidepressant effect in patients with major depression and in chronic stress model of mice. Furthermore, our previous study has shown that MK801 treatment, a NMDAR antagonist, reduces acute stress-induced aggression and depression-like behavior in the post-weaning socially isolated mice. However, the underlying mechanism remains unclear. In this study, we reported that MK801 treatment decreased the level of phosphorylated eukaryotic elongation factor 2 (p-eEF2), an inactive form of eEF2, and increased hippocampal BDNF expression. Moreover, the *Bdnf* shRNA transfection in the hippocampus blocked the anti-aggressive and anti-depressant effects of MK801 treatment,

suggested the hippocampal BDNF expression was required for the MK801 effects. In addition, MK801 rapidly increased activity of protein phosphatase 2A (PP2A) and the intra-hippocampal infusion of okadaic acid, a PP2A inhibitor, blocked beneficial behavioral effects of MK801 and reversed eEF2 dephosphorylation and BDNF induction. Taken together, our data suggest that MK801 activates PP2A which dephosphorylates eEF2 and induces BDNF expression, resulting in antidepressant effects of NMDAR blockade.

Title: Dopaminergic modulation of aggression and anxiety: A zebrafish model

Authors: E. HELMKE, Y. TAVERAS CRUZ, M. DOUMA, A. DE VENECIA, J. NEEDHAM, J. STEFANI, *S. SASZIK;
Psychology, Northeastern Illinois Univ., Chicago, IL

Abstract: Dopamine is a neurotransmitter that governs complex social behaviors and motor function. Using the Zebrafish (*Danio rerio*) model, our goal is to gain a better understanding of how variations in cortical dopamine levels effect behavior. Apomorphine (APO, dopamine agonist) and 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP, dopaminergic neurotoxin) were used to increase and decrease dopamine, respectively. Adult zebrafish were randomly selected and assigned to 1 of 3 groups: [control, MPTP (150 μM), and APO (150 μM)], and dosed for two minutes. Within each treatment group, groups of 3 fish were recorded in 300 mL of water in a novel tank. Distance (cm) and velocity (cm/sec) were calculated for each fish as a way of assessing motor function and social behavior. Nearest neighbor distance (NND) (cm) and thigmotaxis (sec) were also calculated as measures of social behavior. After analysis of the data, there was no significant difference in distance (Control, M = 73.69 $\pm$ 2.9cm; MPTP, M = 70.88 $\pm$ 2.6cm; APO, M = 76.59 $\pm$ 3.8cm) or velocity (Control, M = 5.34 $\pm$ 0.2cm/sec; MPTP, M = 5.46 $\pm$ 0.2cm/sec; APO, M = 5.55 $\pm$ 0.2cm/sec) across the three groups. This indicates that the motor system was still functional. Both APO and MPTP fish maintained smaller nearest neighbor distances than control fish (Control, M = 5.44 $\pm$ 0.6cm; MPTP, M = 4.84 $\pm$ 0.7cm; APO, M = 5.20 $\pm$ 0.3cm). These results may have occurred due to increased chasing and striking in APO fish, characterizing an aggressive phenotype, and grouping together for protection because of fear and anxiety in MPTP fish. Thigmotaxis significantly increased in the MPTP group (Control,

M = 10.99 ± 0.7sec; MPTP, M = 11.04 ± 0.6sec; APO, M = 8.33 ± 0.7sec). These results suggest that although the motor system remains fully functional, there are detectable changes in social behavior. Further research is required to better understand the effect of pharmaceuticals that manipulate cortical dopamine levels on the regulation of complex social behaviors. Based on our results, manipulation of the dopaminergic system through administration of both APO and MPTP has the ability to alter social behavior, producing an aggressive phenotype in APO fish, and an anxiety phenotype in MPTP fish. The biological mechanisms of social behavior are complex. Alteration and manipulation of the dopaminergic pathway may help to better understand how behaviors such as aggression and anxiety are modulated.

Title: Role of hippocampal neurogenesis in behavioral responses to an operant model of frustrative nonreward

Authors: *M. C. TSUDA, R.-M. KARLSSON, H. A. CAMERON;
Section on Neuroplasticity, NIMH/NIH, Bethesda, MD

Abstract: A common characteristic of several psychiatric disorders is irritability, which is defined as aberrant responses to frustration, or the absence of an expected reward. The hippocampus has been implicated in response to frustration. The present study investigated the role of adult hippocampal neurogenesis in behavioral responses to frustration induced by loss of an expected reward. We used valganciclovir to inhibit adult neurogenesis in male mice expressing the herpes simplex virus thymidine kinase (TK) under a GFAP promoter. Both TK and wild-type (WT) littermate controls were mildly food restricted and trained in operant chambers to lever press for food tablets on fixed ratio (FR) schedule where a light cue above the lever was paired with the reward. A progressive ratio (PR) test followed FR, and mice that reached 150 lever presses in the PR either received (rewarded group) or did not receive (frustrated group) a reward. Mice in both groups were shown the light cue associated with reward. After the PR, mice remained in the operant box for an additional 10 min where lever

pressing had no scheduled consequence. Immediately after the 10 min period, mice were tested in the resident-intruder test of aggression. A negative control group spent time in the operant chamber but did not receive light cues or rewards during FR and PR. WT mice exposed to the frustration condition showed greater lever pressing and greater aggression relative to rewarded mice. Frustrated TK mice showed even greater lever pressing than WT mice in the same condition but showed baseline levels of aggression. These results suggest that adult hippocampal neurogenesis affects behavioral responses to frustration induced by the loss of an expected reward.

Title: Computational account of empathy toward human and computer: a study by reinforcement learning model.

Authors: ***N. SAITO**, K. KATAHIRA, H. OHIRA;
Psychology, Grad. Sch. of Envrn. Studies, Nagoya U, Nagoya-Shi, Japan

Abstract: There are two components in empathy: affective empathy (AE) and cognitive empathy (CE). A theoretical model regarding empathy has proposed that AE and CE are mutually associated (Decety & Jackson, 2004). Although empirical studies have found that CE was impact on AE (Lamm et al., 2010), it is unclear how AE and CE interact and produce empathetic behaviors. It is necessary for learning through observing others to produce empathy (Behrens et al., 2008) Thus, examining learning processes in empathy sheds light on revealing how empathy is produced. Reinforcement learning (RL) model is widely used to examine learning processes that how one's action is modulated and then represented, and it applies for the observational situations (Suzuki et al., 2012). It is necessary to update the presumed action values for another person to yield appropriate empathy, and the RL model can explain it. In the present study, we assessed both AE and CE at the same time while taking the learning aspects of empathy into consideration. We aimed to establish a computational account of empathy using the RL model. To this end, we set a task in which participants were required to predict other's choice through observation of the stochastic avoidance learning. Participants performed three types of 2-armed

bandit tasks. In the Self task, participants were instructed to avoid an aversive sound, whereas in the Other task and the Computer (COM) task, they were required to predict other's choice on the basis of feedbacks. The COM task was set as a non-emotional condition to compare with the Other task. The parameters of the simulated reinforcement-learning model were divided into direct recruitment of one's own valuation process (i.e., using the other's reward) as AE, and prediction of the other's choices using the other's action as CE. The learning rate for other's outcomes and actions were corresponded with the valuation and the prediction processes, respectively. These parameters were validated by correlation analyses with peripheral physiological responses and the dispositional empathy scores. The results showed that learning rate for the other's outcomes was correlated with participant's attention to the other's outcomes measured by heart rate deceleration, whereas learning rate for the computer's outcomes was not correlated with heart rate deceleration. Moreover, learning rate for the other's action was correlated with the CE trait, but that for the computer's action was not correlated with any empathic traits. Results of this study suggest that people use their own physiological responses to learn another's action value on the state from another's behavior, but it can apply for only human.

Title: Sepsis causes long-term changes in emotional behavior and HPA axis reactivity in the mouse.

Authors: *J. L. SPENCER-SEGAL, K. SOMAYAJI, M. NEWSTEAD, S. J. WATSON, T. J. STANDIFORD, H. AKIL;
Univ. of Michigan, Ann Arbor, MI

Abstract: There are millions of sepsis survivors in the United States alone. More than one third of these patients suffer from long-term psychiatric morbidity including post-traumatic stress disorder, anxiety, and depression, which are often comorbid. A better understanding of the mechanisms of psychiatric pathology in this patient population will hopefully lead to effective strategies for prevention and treatment. To investigate this in the mouse, we measured sickness behavior, hypothalamic-pituitary-adrenal (HPA) axis reactivity, and emotional behavior in a naturalistic mouse model of sepsis, cecal ligation and puncture (CLP). Male and female C57/Bl6 mice underwent CLP, sham laparotomy, or no surgery, followed by open field test at 14 days. A separate group of mice underwent locomotion testing at 1, 5, and 14 days after CLP, followed by forced swim stress and euthanasia with blood collection. CLP, but not control or sham mice showed weight loss and decreased locomotion that recovered between 5 and 14 days after surgery. At 14 days, despite physiologic recovery, CLP mice showed increased anxiety-like behavior in the open field test, and increased corticosterone response to forced swimming. These results demonstrate lasting changes in emotional behavior and HPA axis reactivity in mice after recovery from sepsis, suggesting long-term CNS effects of this acute illness similar to those seen in humans.

Title: Negative affect-associated USV acoustic characteristics predict future excessive alcohol drinking and alcohol avoidance in P and NP male rats

Authors: *J. M. RENO, JR[1], N. THAKORE[2], L. K. CORMACK[3], T. SCHALLERT[3], R. BELL[4], W. T. MADDOX[3], C. L. DUVAUCHELLE[2];
[1]Univ. of Texas At Austin, Austin, TX; [2]Pharmacol. & Toxicology, [3]Psychology, Univ. of Texas, Austin, TX; [4]Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Negative emotional status plays an important role in alcohol use disorders, such that individuals experiencing greater levels of adverse emotional events are more vulnerable to developing alcohol use disorders (AUDs). Indeed, negative life events (e.g. abuse, trauma, discrimination) contribute to negative emotional status and to the risk of developing AUDs. Ultrasonic vocalizations (USVs) emitted by rats serves as a well-established model of emotional status that can reflect positive and/or negative affective responses in real-time. When applied to rats selectively bred for high- and low-alcohol consumption, USVs can provide an emotional phenotype of alcohol vulnerable and alcohol-resistant individuals. Though most USV studies are limited to assessing only USV counts, each individual USV is a multi-dimensional data point consisting of several acoustic characteristics with the potential to provide further insight into the neurocircuitry underlying emotional response. To determine whether acoustic characteristics can be used to differentiate between rats selectively bred for high- and low-alcohol consumption, we recorded USVs emitted from alcohol-naïve and alcohol-experienced P and NP rats and utilized advanced statistical analyses (linear mixed models-LMM and linear discriminant analyses-LDA) to analyze USV acoustic characteristics (e.g., frequency in kHz, USV duration, power and bandwidth) of negative (22-28 kHz) and positive (50-55 kHz) affect –related USVs between rat lines (e.g., high versus low drinkers). Using these analyses, we were able to develop a model to determine rat line membership purely on the acoustic characteristics of their 22-28 kHz USV emissions. In other words, with the use of advanced statistical techniques and negative USV emissions, we can confidently identify the future drinking levels of individual animals most likely to be vulnerable to excessive alcohol drinking and those most resistant to alcohol abuse. The differences in USV characteristics may indicate differences in affect-related motivation to consume alcohol and associated neural pathways mediating emotional response. Characterizing these differences would allow for the targeting of dysregulated emotional states seen in human alcohol abusers.

Title: How do rats learn to fear alarm calls?

Authors: *S. C. FURTAK[1], C. CALUB[1], T. H. BROWN[2];
[1]Dept. of Psychology, California State Univ., Sacramento, CA; [2]Dept. of Psychology; Dept. of Cell. and Mol. Physiol., Yale Univ., New Haven, CT

Abstract: Auditory emotional communication is thought to play an essential role in the survival of many species of birds and mammals. Auditory communication of negative affective states has been extensively studied in rats and other rodents. Rats emit 22 kHz ultrasonic vocalizations (USVs) in association with pain, fear, anxiety, or distress. As social alarm or distress signals, these 22 kHz USVs are believed to play an essential role in group survival. Whereas the capacity to produce these USVs is innate, appropriate reactivity to them requires experience. Specifically, 22 kHz USVs fail to elicit freezing behavior (the classical fear index) in naïve laboratory rats. This fact raises the question: How do rats learn to react fearfully or defensively to these ethologically-important social signals? A possible clue came from the discovery that laboratory rats actually *do* react fearfully to alarm calls (evidenced by USV-elicited freezing behavior) if they experienced foot shocks on the previous day. Several lines of evidence lead to the hypothesis that acquired fear of 22 kHz USVs is based on "autoconditioning"—an emotional learning process in which self-generated 22 kHz USVs serve as Pavlovian cues that become associated either with foot shocks or with an internal fear state. The present experiment tested this hypothesis by attempting to devocalize rats in the Experimental group through a unilateral transection of the recurrent laryngeal nerve. Animals in the Control group underwent a nerve-sparing sham operation. Both groups received unsignaled foot shocks and were subsequently tested, in a novel context, for freezing levels in response to the playback of a pre-recorded 22 kHz USV from a conspecific. Recurrent laryngeal nerve transection failed to prevent or even diminish USV-elicited freezing. Both groups showed significant and comparable USV-elicited freezing. It turned out that some Control animals failed to vocalize during conditioning and some Experimental animals did vocalize during conditioning. The animals were next re-grouped into Vocalizers versus Non-Vocalizers and reanalyzed based on whether they vocalized during conditioning. Again, there were no significant group differences in USV-elicited freezing. These results are obviously incompatible with the autoconditioning hypothesis. We therefore consider

several alternative associative and non-associative mechanisms for acquired fear of USVs. Additional research is needed to understand the neuroethology of emotional communication in rodents and related mammals. The results of such research across multiple social species will help illuminate the evolution of auditory emotional communication.

Abstract: The epigenetic mediation of events that occur early in development is a widely discussed phenomenon. However, the underlying molecular mechanisms remain somewhat diffuse. In recent years, the programming of the hypothalamic-pituitary-adrenal (HPA) axis via glucocorticoid receptors was identified as an important factor in this process. The serotonin (5-HT) system has been suggested as another vital factor in this respect. Moreover, various studies show an effect of corticosteroids on number and functionality of 5-HT receptors. This goes together with various findings linking changes in the 5-HT system to early life stress exposure. To further elucidate the role of 5-HT in developmental programming by early life stress, we employed a B6.Tph2 mouse line. Mice of this line were bred towards a constitutive knock out of the *tryptophan hydroxylase 2* (*Tph2*) gene. Tph2 is the rate-limiting enzyme of the serotonin synthesis in the brain. Tph2 -/- animals of this line have been shown to be completely depleted of 5-HT in the brain. For our experiments, we exposed animals of this line to maternal separation, a well-established model of early life stress. Using this paradigm, all pups of a litter, regardless to sex and genotype, were separated from their mother for 3 hours per day. This separation is

repeated from postnatal day 2 to postnatal day 15. After this period of stress exposure, the animals were allowed to grow up under normal conditions. From postnatal day 60 onwards, male and female offspring were tested in diverse behavioural tasks to assess motor activity (open field), anxiety-like behaviours (dark-light-box, open field, elevated plus maze) as well as aggressive behaviour (resident-intruder test). Following the behavioural screening, brains were harvested for molecular analyses. We found several effects of a genotype-by-environment interaction on the display of anxiety-like behaviours and aggression. In particular, in Tph2 -/- animals we observed a different level of coping following maternal separation. These findings seen in the light of the observed molecular changes provide more insight into the role of brain 5-HT in the mediation of early life stress.

Title: The role of central interleukin 1 in aggressive behavior of male mice

Authors: ***A. TAKAHASHI**[1,2,5], H. ALEYASIN[2], M. E. FLANIGAN[2], A. BRANCATO[2], C. MENARD[2], M. L. PFAU[2], V. KANA[3], J. WANG[4], G. E. HODES[2], B. S. MCEWEN[5], S. J. RUSSO[2];

Abstract: Human studies have shown that there are correlations between peripheral cytokines and aggression trait. Like humans, outbred CD-1 mice show individual differences in aggressive behavior with approximately 70% of mice exhibiting a spectrum of aggressive behavior (termed Aggressors: AGG) and 30% showing no aggressive behavior (termed non-aggressors; NON). In this study, we examined neuroimunnological mechanisms of individual differences in aggression

in male CD-1 mice. Aggressive behavior of CD-1 males toward BALB/c intruder males were first characterized by resident intruder test for 3 days to define aggressors and non-aggressors. Peripheral and central cytokine/chemokine levels were measured by using ELISA following the resident intruder test. We found that aggressive encounter caused a phasic increase of interleukin 1 beta (IL-1β) in the blood in both AGG and NON; however, there was no difference between groups. There were also no pre-existing difference in IL-1β between AGG and NON nor were there any differences in the number of leukocytes or release of IL-1β following incubation with lipopolysaccharide. By contrast, we found significant higher levels of central IL-1β in the midbrain dorsal raphe nucleus (DRN) in NON versus AGG. To examine the role of IL-1β in the DRN, we injected a IL-1 receptor antagonist into either lateral ventricle or directly into the DRN. Our result showed that both i.c.v. injection and intra-DRN microinjection of IL-1 receptor antagonist increased aggressive behavior. Therefore, IL-1 receptor mediated pathway in the DRN has an inhibitory role on aggressive behavior.

Title: Profiles of animals exposed to an incentive downshift

Authors: *I. D. ANNICCHIARICO ISEDA[1], L. CUENYA[2];
[1]Psychology, Texas Christian Univ., Fort Worth, TX; [2]Lab. de Psicología Exptl. y Aplicada, Inst. de Investigaciones Médicas Alfredo Lanari - Univ. de Buenos Aires, Buenos Aires, Argentina

Abstract: Consummatory Successive Negative Contrast (cSNC) is one of the phenomenon most commonly observed when animals are confronted to an incentive downshift. It occurs when animals having an exposure to an unexpected downshift, from a high palatable reward (e.g., 32% sucrose solution) to a less preferred one (e.g., 4% sucrose solution), show an abrupt and transient suppression of the consummatory response. Control animals that have always access to the small reward do not show this suppression. Previous studies show that cSNC is a consequence of an aversive emotional state experienced when a negative discrepancy between the expected and the obtained reward occurs. Some researchers call this discrepancy frustration and pose that it is closely related to fear and anxiety. Consistent with this view, the administration of the

benzodiazepine chlordiazepoxide reduces the size of cSNC, increased hypothalamic-pituitary-adrenal activation levels happen after animals have exposure to downshifting situations, and lesions in the lateral amygdala attenuate the cSNC while lesions in the corticomedial and central nuclei eliminate it. Most jobs have addressed this phenomenon based on the analysis of mean-level responses of all experimental animals. However, there is a range of individual differences in the animals' responses to a reward devaluation event that suggests that experimental animals do not have a homogenous response; selective breeding studies also support this idea. Here we used a data analytic method for identifying heterogeneous samples to analyze divergent behavior patterns in cSNC in rats. Specifically, we analyzed the data of 53 animals with latent class growth analysis (LCGA). This particular technique is highly relevant for longitudinal data with relatively small samples. We found two profiles: animals showing negative contrast and no recovery, and animals expressing both negative contrast and recovery of consummatory response. Our results are consistent with previous literature who imply that individual differences do exist when animals have exposure to an incentive downshift.

Title: Central amygdala circuits controlling feeding and appetitive behaviours

Authors: *A. DOUGLASS[1,2], H. KÜCÜKDERELI[1,2,3], M. PONSERRE[1], M. MARKOVIC[4], J. GRÜNDEMANN[4], P. ALCALA MORALES[1], C. STROBEL[1], A. LÜTHI[4], R. KLEIN[1]; [1]Max Planck Inst. Life Sci., Munich, Germany; [4]Friedrich Miescher Inst. for Biomed. Res., Basel, Switzerland

Abstract: The central nucleus of the amygdala (CeA) has long been described as regulating feeding behaviour. However, the cellular heterogeneity of this region has rendered the precise role of the CeA in food intake a challenge to investigate by conventional methods. Neurons within the mouse CeA that express protein kinase C-δ (PKCδ) are known to mediate the anorexigenic effect of malaise and satiety signals, likely via local inhibitory connections within the CeA. With the aim of identifying the neural players in the CeA that promote food intake, we have identified a population of PKCδ-negative neurons that express Htr2a. Using deep-brain calcium imaging, in which GCaMP6s was expressed in the CeA of Htr2a-cre expressing mice,

we found that CeA^{Htr2a} neurons display distinct activity patterns during food consumption. In line with these results we found that chemogenetic and optogenetic-mediated activation of CeA^{Htr2a} neurons increased feeding in satiated animals, promoted reward-related behaviours and rescued the appetite suppressing effect of malaise-inducing drugs. Virus-mediated ablation of these neurons further substantiated the role of these cells in food intake and motivated behaviour. We further probed that local interactions between $CeA^{PKC\delta}$ and CeA^{Htr2a} neurons as well as the efferent projections of CeA^{Htr2a} neurons to brain regions with described roles in food intake and energy homeostasis and found that the functions of CeA^{Htr2a} can be segregated based on projection target. Together, these data suggest that the CeA influences feeding behaviour through both local inhibitory connections. Our study has demonstrated that in addition to the classical role of the CeA in mediating fear and appetite suppression, CeA^{Htr2a} neurons within this region encode appetitive and reward-related behaviours.

Title: iRat as a tool for social neuroscience

Authors: L. F. SCHUSTER[1], N. W. BUTLER[1], D. BALL[2], S. HEATH[2], J. TAUFATOFUA[2], *L. K. QUINN[3,1], J. WILES[2], A. A. CHIBA[1];

Abstract: The accretion of tools for measuring and analyzing neural properties is accelerating our knowledge of the numerous ways in which the brain represents the environment. Yet, the bulk of this knowledge is accrued through laboratory studies that are typically limited to investigating an individual animal and the singular capacity of an animal's brain to process

stimuli. Thus, despite the sophisticated techniques for measuring brain function and even for controlling one brain with the neural activity of another, techniques for studying direct neural responses to the environment in the presence of another relevant social companion have not been developed. For the most part, this is due to the inability to adequately control the relevant behavioral variables in neural recording experiments involving multiple animals.
Here, the design affordances offered by synthetic agents present an opportunity to develop a socially relevant research companion for the rat while maintaining adequate control over experimental variables. We endowed the iRat (intelligent rat animat technology) navigating robotic rat, with ecologically sound social behaviors in order to use it as a tool for studies in cognitive and neuroscientific research. We determined the minimum characteristics necessary for a rat to view iRat as a socially relevant companion.
To do this we undertook extensive social interaction studies with pairs of rodents in order to hypothesize the most relevant features for developing a social companion for the laboratory rat. Preliminary investigations indicate that temporal coordination of pack following behavior, mutual play, and submissive social retreat, may be sufficient. In order to test whether the iRat garnered social attention from the laboratory rat, we undertook a replication of the "jail-break" experiment in which a rat unlocks the cage of a trapped conspecific. In this case, the experiment was conducted with real rats and with trapped iRats. If iRat is sufficiently relevant to the laboratory rat, we expected the laboratory rat to release iRat from his trappings. We found that an iRat that showed the above social behaviors, including releasing the rat from his enclosure, was released significantly more often than an iRat that did not show these behaviors. By successfully developing a socially relevant companion for the laboratory rat, the basic neuroscientific questions that can be addressed with this tool are boundless.

Title: The role of estrogen receptors in response to positive emotional stimuli in rats observed in a seminatural environment

Authors: *O. LE MOENE, A. ÅGMO;
Dept. of Psychology, Univ. of Tromso Fac. of Hlth. and Sci., Tromso, Norway

Abstract: We studied the differential role of estrogen receptors (ER) α and β in socio-sexual interactions among rats exposed to two positive stimuli. Ten groups of 7 rats (4 females and 3 males) were housed for 8 days in a semi-natural environment (SNE) consisting of an open area and a complex burrow system. The introduction of the rats into the SNE was set as experimental day 0. Females had been ovariectomized about 2 weeks before the introduction. On day 5, each female was given a different treatment: Control females: 1 ml/kg peanut oil; estradiol females: 18 µg/kg 17β-estradiol benzoate; females α: 10 mg/kg propylpyrazoletriol (PPT); females β: 10 mg/kg diarylpropionitrile (DPN). On day 6, agonist treatment was repeated for females α and β while the other females received peanut oil. On day 7, all females received 1 mg/rat of progesterone. Four hours after the injection of progesterone, the rats were exposed to a natural anxiolytic stimulus (smell of lavender oil). Fifty min later they were given access to a palatable food (35 g of chocolate pellets). The rats were observed for 15 minutes without any stimulation to define a baseline, and for 15 minutes during each of the stimuli. The frequency and/or duration of all socio-sexual interactions were recorded. We found no difference in behaviors between females β and control females. Estradiol females presented the more salient profile by displaying more paracopulatory behaviors, mores lordoses and having a higher lordosis quotient than control females and females β. Females α also displayed more paracopulatory behaviors than control females and females β. Notably, females α displayed more lordoses than control females and females β only during the lavender phase. Regarding the stimulations, females displayed more paracopulatory behaviors during the lavender phase, and males emitted less nose-offs during that phase compared to the two others. The behavioral changes observed in both males and females confirm that the stimulations elicited different reactions from the rats. The lavender phase was marked by reduced aggressivity from the males and enhanced sexual behaviors in females. A possible explanation is that the novel olfactory stimulus increased females' arousal and thus stimulated sexual interactions. The effects of estrogens seemed to be limited to sexual behaviors and did not seem to regulate the reaction to positive stimuli. The fact that only females α showed a pattern similar to the one of estradiol females, and that females β were not different from the controls, suggest that the effects of estrogens on sexual behaviors depend on the ER α.

Title: Gender effect of humor on decision-making: a behavioral and electrophysiological report

Authors: *J. A. FLORES[1], I. RUBIO[2], G. CAMPOS[3], E. RODRIGUEZ[4];
[1]Psychology, Pontificia Univ. Católica De Chile, Santiago de Chile, Chile; [2]Computat. ingineering, [4]Psychology, [3]Pontificia Univ. Católica de Chile, Santiago de Chile, Chile

Abstract: Female show poorer decision-making performance when compared with male in the Iowa Gambling Task (IGT). Evidence suggests this could be related to a stronger emotional reaction during punishments, which negatively affect female's risky decision-making performance. Recent evidence shows a gender specific down-regulation of negative emotions (NE) in which women seems to down-regulate NE in a non-automatic fashion activating reward related regions. Because humor effectively increase reward related activity, we expected humor to down-regulate the women´s NE of punishment during IGT thus increasing decision-making performance. EEG was recorded from female & male participants exposed to either humorous or non-humorous short films before their decisions were made. IGT performance & feedback related negativity (fRN) were measured. Preliminary data show a statistical difference in IGT performance in male & females, obtaining more long-term advantageous decisions during the humorous condition when compared with non-humorous condition. Additionally, we observed a significant decrease in fRN amplitude in females during the humorous condition, which has been related in previous studies with changes in emotional valence.

Title: Investigating rapid versus delayed onset antidepressant action in rodents: a behavioural and computational approach.

Authors: *C. A. HALES[1], E. S. J. ROBINSON[2], C. J. HOUGHTON[3];
[2]Physiology, Pharmacol. and Neurosci., [3]Computer Sci., [1]Univ. of Bristol, Bristol, United Kingdom

Abstract: Major depressive disorder (MDD) is one of the most common psychiatric disorders. Until the recent discovery of the rapid onset antidepressant action of ketamine (an NMDA

receptor antagonist), pharmacological treatments for MDD were limited to drugs with delayed efficacy. In this study, acute and chronic treatments were used to investigate the effect of rapid vs delayed onset antidepressants in rats on: (1) judgement bias, a behavioural measure of affective state and (2) the decision making processes underlying bias using the diffusion model. Male Lister hooded rats were trained on a reward-based judgement bias task where correct responses to two distinct tones corresponded to obtaining high or low value reward. Judgement bias was measured by recording responses to a midpoint ambiguous tone following: (1) acute treatment with conventional antidepressants: fluoxetine (0.3, 1.0 mg/kg), reboxetine (0.3, 1.0 mg/kg), venlafaxine (1.0, 3.0 mg/kg) or vehicle; (2) chronic treatment with fluoxetine (0.0, 1.0 mg/kg); (3) acute treatment with ketamine (0.0, 0.3, 1.0, 3.0 mg/kg); and (4) acute treatment with phencyclidine (PCP; 0.0, 0.3, 1.0, 3.0 mg/kg), an NMDA receptor antagonist with no known antidepressant properties. Behavioural data were modelled using the diffusion model to investigate the changes in decision making processes that underlie biases induced by pharmacological treatments.
Acute treatment with conventional antidepressants had no effect on judgement of the ambiguous tone, however a positive bias was induced in rats chronically treated with fluoxetine (pairwise group difference: $p=0.021$). Acute treatment with ketamine (1.0 mg/kg) also caused a positive bias (one sample t-test: $p=0.012$), whilst PCP had no effect. Diffusion modelling revealed that a more positive drift rate underlies the bias following ketamine treatment (main effect of treatment: $p=0.047$, post-hoc test: $p=0.034$), whereas there was a more positive decision starting point across sessions where chronic fluoxetine induced a bias (session*group interaction: $p=0.016$, post-hoc test: $p=0.041$).
Positive biases were induced in this judgement bias task specifically by pharmacological treatments with known antidepressant properties, over time frames that match the rapid vs delayed antidepressant efficacy of these drugs. Diffusion modelling revealed that the drugs have different effects on decision making processes which may help explain their different rates of onset of efficacy. This combination of behaviour and computational modelling may provide a useful approach to further investigate the mechanisms underlying rapid antidepressant effect.

Title: When focal brain damage is a good thing: Neural correlates of improvements in personality and behavior following a neurological event

Authors: *M. KING, J. BRUSS, D. TRANEL;
The Univ. of Iowa, Iowa City, IA

Abstract: Research on changes in personality and behavior following brain damage has largely focused on negative outcomes. On occasion, however, it has been noted that there are patients who actually show improvements on various personality dimensions following lesion onset. In the current work, we investigated the neuroanatomical correlates involved in this phenomenon. Using the Iowa Scales of Personality Change (ISPC), an instrument developed to measure changes in real-world executive functioning, social behavior, emotionality, irascibility, and distress following neurological damage, we identified a group of patients rated by an informant (e.g., close family member or friend) as having improved on one or more dimensions of personality and behavior following a neurological event. Informants rated patients on various personality characteristics, assessing the person's personality characteristics and behavior prior to the onset of a lesion ("Before" rating) compared to the person's personality characteristics and behavior following the onset of the lesion ("After" rating). A personality dimension was defined as an acquired improved characteristic if the "After" score on the ISPC represented a decrease in personality disturbance over the longstanding rating of the characteristic ("After" < "Before"). Using the same method, we also identified a comparison group of patients rated by informants as having acquired personality disturbances on one or more dimensions of personality following lesion onset ("After" > "Before"). To examine the neuroanatomical correlates of the observed changes in personality following lesion onset, we conducted a lesion mapping analysis. We compared patients who showed personality improvements following lesion onset to those who showed personality disturbances following lesion onset, calculating voxelwise proportional differences in lesion locations between the groups. We found that improvements on personality dimensions were related to damage to the anterior temporal lobe bilaterally, extending into the parahippocampal gyrus on the right side. To a lesser extent, improvements on personality dimensions were related to damage to the left superior temporal gyrus and the right posterior-inferior parietal lobule. This work illustrates neuroanatomical correlates involved in improvement in personality dimensions following brain lesions. Future work investigating compensatory reorganization of neural networks following lesion onset (e.g., using resting state fMRI), may help further explain the neuroanatomical correlates involved in improvement following brain damage identified in the current study.

Title: The neural underpinnings of adolescent emotion regulation in the context of reward pursuit.

Authors: S. J. DEWITT[1], *F. FILBEY[2];
[1]The Univ. of Texas at Dallas, Dallas, TX; [2]Univ. of Texas At Dallas, Dallas, TX

Abstract: *Rationale:* The ability for adolescents to regulate reward anticipation is an important question given the propensity for risk-taking behavior observed during this period of development. The goals of the present study were to test the efficacy of directed emotion regulation in early adolescence (12-14) in the context of active reward pursuit and to identify the brain and behavioral profile associated with regulatory ability. *Methods:* 17 (8 males) healthy adolescents (mean age: 13.24) were consented (with parental consent as well) to participate in the study which included an fMRI scan and behavioral assessments. Participants were trained on a cognitive reappraisal task known as distancing, which they then used during an in-scanner modified monetary incentive delay task. Activation in a known regulatory region of the prefrontal cortex, the bilateral dorsolateral prefrontal cortex (DLPFC), as well as a putative reward region, the bilateral nucleus accumbens (Nac), was investigated using a region of interest approach. Subjective ratings of reward anticipation were collected following each trial of the task. Behavioral measures of Impulsivity and sensation seeking (IMPSS) and subdomains of the Junior Temperament and Character Inventory (JTCI, harm avoidance and novelty seeking) were collected to investigate a behavioral profile of regulatory success. *Results:* Task results indicate that when told to regulate, adolescents had slower decision reaction time ($F\ (1,16) = 14.95, p \leq 0.001$) and lower ratings of reward anticipation ($F\ (1,16) = 14.81, p \leq 0.001$). At the neural level, adolescents selectively recruited regions of the emotion regulation network, particularly right DLPFC ($F\ (1,16) = 13.30, p \leq 0.01$) and bilateral anterior cingulate gyrus (ACG) (*left:* $F\ (1, 16) = 6.42, p \leq 0.05$); right: $F\ (1,16) = 6.78, p \leq 0.05$) when asked to regulate reward anticipation. Bilateral Nac showed no attenuation in response to the regulatory strategy. Activation in this region demonstrated a positive correlation with impulsivity and sensation seeking summary scores ($r = 0.50, p \leq 0.05$) and an inverse correlation with harm avoidance summary scores ($r = -0.67, p \leq 0.05$). *Conclusion*: The current findings demonstrate the ability in early adolescence to regulate behavior during active reward pursuit. Regulation appears to be achieved through recruitment of specific regions of the emotion regulation network and is done within the context of persistent reward activation.

Title: Autonomic responses during Pavlovian learning in monkeys with orbitofrontal cortex lesions

Authors: ***J. HWANG**, P. L. NOBLE, E. A. MURRAY;
Section on Neurobio. of Learning and Memory, Lab. of Neuropsychology, NIMH/NIH, Bethesda, MD

Abstract: Previous work has shown that the subgenual portion of the anterior cingulate cortex in macaques contributes to autonomic arousal during anticipation of positive (rewarding) events (Rudebeck et al., 2014, PNAS). Because orbitofrontal cortex (OFC) is involved in stimulus-based reward learning, we wondered whether this region, too, contributed to either the learning or maintenance of autonomic arousal associated with positive events. Accordingly, we evaluated autonomic responses in rhesus monkeys (Macaca mulatta) that had sustained bilateral excitotoxic lesions of OFC (n=4) and unoperated controls (n=2). Monkeys were trained on a task in which Pavlovian conditioning of stimulus-reward associations was superimposed on instrumental conditioning of active visual fixation. The Pavlovian conditioning procedure and the instrumental fixation task proceeded independently. Small fluid rewards were earned for maintaining gaze on a central fixation spot for 4 s. On some trials, one of two Pavlovian stimuli (CS+, CS-) was presented on the monitor screen for 1 s during the 4-s fixation period. The CS+ was always followed by a large fluid reward; the CS- led to no reward. If the subject broke fixation when a CS was presented during the fixation period, the fixation spot was extinguished but the Pavlovian trial continued unaffected by the oculomotor behavior. We recorded pupil size as a measure of autonomic response. Controls exhibited an increased pupil size to the CS+, compared to the response to the CS-, within a couple of training sessions (2 ± 1) and continued to show the conditioned pupil response in anticipation of reward across at least 4 consecutive sessions. By contrast, monkeys with OFC lesions required more sessions (20 ± 7 sessions) to acquire the conditioned autonomic response and three out of four failed to sustain it for 4 consecutive sessions even with an extended period of training (50 sessions). Training with a second set of stimuli yielded a similar result. Thus, in line with a previous finding that the

primate OFC is important for regulating cardiovascular arousal upon omission of reward (Reekie et al., 2008, PNAS), the present results suggest that OFC is involved in acquiring appropriate autonomic responses to cues predicting positive events.

Title: Neural mechanisms of mood induced modulation of reality monitoring in schizophrenia

Authors: *K. SUBRAMANIAM, D. MATHALON, S. NAGARAJAN, S. VINOGRADOV; UCSF, San Francisco, CA

Abstract: This study investigates the neural basis of how a positive mood can modulate cognition in schizophrenia, specifically, in reality monitoring (RM) abilities. RM is the ability to accurately distinguish the source of self-generated items from the source of externally-derived information. In a prior fMRI study, we found that healthy control subjects (HC) showed increased medial prefrontal cortex (mPFC) signal during accurate identification of self-generated items vs. externally-presented items, which correlated with self-generated information recall. We have also shown that HC in a positive mood show increased mPFC and posterior cingulate cortex (PCC) activation. Based on these findings, we predicted that both mPFC and PCC would reveal positive mood sensitive effects that enable better RM performance.
Participants completed a mood-induction RM fMRI task. In the MRI scanner, we induced positive, neutral and negative mood states through autobiographical recall. Subjects then completed the recall phase of the RM task. The RM task consisted of an encoding phase prior to scanning and a recall phase in the scanner. In the encoding phase, subjects were presented with "noun-verb-noun" sentences. The final noun was either presented by the experimenter, or left blank for subjects to generate themselves. During the recall phase, subjects viewed the noun pairs from the sentence list and had to indicate whether the second word was previously self-generated or externally-presented.
HC showed better RM source-memory performance overall than SZ, and showed an influence of

mood on overall RM accuracy. This accuracy difference was driven by HC performing better in the positive vs. neutral mood but not in the negative mood condition. Specifically, HC recalled more self-generated information and marginally more externally-presented information in the positive vs. neutral mood condition, showing increased mPFC and PCC signals, which predicted better self-generated word recall. In SZ, however, we found that both positive and negative mood states enhanced externally-presented information recall only. When compared to HC, SZ showed reduced mPFC and PCC activation during positive vs. neutral mood states and demonstrated poorer self-generated information recall during positive and negative mood states.
These data have several interesting implications: 1) SZ do not show the normal relationship between positive mood and better RM, suggesting impairments in how hedonic experiences influence neurocognitive systems that support self-referential processing; 2) They may also show more sensitivity to the effects of a negative mood, in terms of enhancing source-memory recall.

Title: Sex differences and commonalities in the epigenetic modulation of mGlu2-dependent structural plasticity of key limbic brain regions by rapid and slow acting antidepressants

Authors: *C. NASCA[1], B. BIGIO[1], T. LAU[1], D. ZELLI[1], H. CATES[3], J. NI[2], L. BRICHTA[2], P. GREENGARD[2], E. J. NESTLER[3], B. S. MCEWEN[1];
[1]Neuroendocrinology, [2]Lab. of Mol. and Cell. Neurosci., The Rockefeller Univ., New York, NY; [3]Lab. of Mol. Psychiatry, Mount Sinai Sch. of Med., New York, NY

Abstract: Speed of action, treatment resistance and sex-dependent effects are major issues for treating depression, a global health problem with a prevalence twice as high in women than men and less than 50% of affected people respond to current treatments. Excitatory amino acids, principally glutamate, are key players and normalizing their activity, through the use of external drugs, like acetyl-L-carnitine (LAC) and ketamine, is important for reactivation of

neurochemical and structural plasticity. Such plasticity is impaired in val66met mice (hets) with a BDNF loss-of-function that are resistant to SSRIs. Here, using behavioral, molecular, structural, pharmacological and next-generation sequencing approaches, we find that both susceptible male and female hets screened at the light-dark test for light avoidance show depressive-like traits (e.g.: passive behavior) and, as shown by ChIP, have reduced acetylation of histone-3-lisyne-27 (H3K27ac) in the promoter gene Grm2 that leads to reduced expression of the metabotropic glutamate receptor 2 mGlu2 in the ventral dentate gyrus (vDG), a mood regulatory region. Such decrease in mGlu2, inhibitor of glutamate release, in the vDG is concomitant with dendritic atrophy of vDG neurons in both male and female hets. While such vDG alterations and depressive-like traits are found, and corrected in both sexes by a short term treatment with a novel rapid-acting antidepressant candidate LAC in both sexes (with different doses), we find meaningful sex differences in the male-specific structural atrophy of stellate neurons in the medial amygdala (MeA), a limbic brain region important for social behavior, which is a hallmark of depression in humans. Indeed, male, and not female, hets show retraction and decreased branching of MeA stellate neurons that are corrected by LAC while elevating mGlu2 in the vDG. Viral overexpression of mGlu2 in vDG of male hets rescues depressive-like traits, as does LAC (an mGlu2 modulator), and corrects atrophy of MeA stellate neurons. LAC is an energy-promoting agent and a novel antidepressant candidate with actions similar to HDAC inhibitors and faster than those of SSRIs, which we found also upregulate mGlu2 in the vDG. A RNAseq specifically targeted to the vDG and MeA is underway to reveal other mediators involved in LAC rapid antidepressant effects in both sexes. These findings prove mechanistic insights in the neurobiology underlying speed of action and treatment-resistance and reveal brain interconnectivity in higher level cognitive brain regions with implication for the development of drugs with better profiles of efficacy and tolerability and with emphasis on sex dependent treatment regimens.

Title: Effects of the multimodal antidepressant vortioxetine on the psychostimulant effects of MK-801-induced changes in locomotor activity and attentional processes

Authors: *D. SMITH[1], T. M. HILLHOUSE[3,4], C. R. MERRITT[2], A. L. PEHRSON[5], C. SANCHEZ[5], J. H. PORTER[2];
[2]Dept. of Psychology, [1]Virginia Commonwealth Univ., Richmond, VA; [3]Dept. of Pharmacol., Univ. of Michigan, Ann Arbor, MI; [4]Psychology, Weber State Univ., Ogden, UT; [5]Lundbeck Res. USA, Inc, Paramus, NJ

Abstract: Vortioxetine is a multimodal antidepressant approved for the treatment of major depressive disorder (MDD) and clinical studies have shown that cognitive functions such as attention, processing speed, executive function, and memory may be improved by vortioxetine in patients. While the exact mechanisms are unknown, vortioxetine's multimodal serotonergic activity may be responsible for these effects. In addition to inhibiting serotonin (5-HT) reuptake, vortioxetine is an antagonist at 5-HT_{1D}, 5-HT_3, and 5-HT_7 receptors, an agonist at 5-HT_{1A} receptors, and a partial agonist at 5-HT_{1B} receptors. This unique pharmacologic profile at serotonin sites has been hypothesized to selectively modulate glutamate transmission and may be an important factor in vortioxetine's effects on cognition (Pehrson & Sanchez 2014). The present study examined the possible interaction of vortioxetine with glutamatergic mechanisms in two behavioral tasks. The first aim examined the effects of vortioxetine on the psychostimulant effects of the noncompetitive glutamatergic NMDA antagonist MK-801 on locomotor activity, and the second aim examined attentional processes in a signal detection task in rats. MK-801(0.2 mg/kg) produced significant increases in locomotor activity, while 10 mg/kg vortioxetine did not affect locomotor activity. When given in combination, vortioxetine did not affect the MK-801-induced hyperlocomotion. In the signal detection task, 0.1 mg/kg MK-801 produced a significant decrease in percent hit (light intensity dependent) and correct rejections as compared to vehicle controls. When given alone, 10.0 mg/kg vortioxetine did not alter signal detection performance on any dependent measure; however, the combination of 10.0 mg/kg vortioxetine and 0.1 mg/kg MK-801 exacerbated the deficits produced by MK-801 alone on all dependent measures. Given recent demonstrations that acute vortioxetine enhances frontal cortex pyramidal neuron firing (Riga et al. 2016), vortioxetine may potentiate MK-801-induced signal detection impairments by enhancing membrane depolarization in glutamatergic cells, thereby increasing MK-801 occupancy at NMDA receptors. Thus, these data suggest that vortioxetine's serotonergic mechanisms may selectively enhance glutamate neurotransmission in systems that regulate attentional processes but not locomotor activity.

Title: Evaluation of the role of transcription factor CREB in noradrenergic neurons in response to antidepressant treatment: study on novel transgenic mouse model

Authors: *G. KREINER, K. RAFA-ZABLOCKA, W. BUCZEK, M. BAGINSKA, I. NALEPA;
Dept. Brain Biochem., Inst. of Pharmacology, PAS, Krakow, Poland

Abstract: Decreased noradrenaline and serotonin levels in the central nervous system represent one of the crucial statements of the monoaminergic hypothesis underlying the pathophysiological basis of depression. Current treatments for depression are primarily based on the modulation of noradrenergic or/and serotonergic signal transduction pathways. There have been several attempts to identify a protein that could serve as a convergence point for antidepressant treatment, the prominent example being the cyclic AMP response element binding protein (CREB) transcription factor. The generally accepted statement is that chronically given antidepressants enhance CREB levels and activity, thus implicating its important function in the mechanism of antidepressant treatment. Nevertheless, the data are not conclusive and the feedback from the analysis of transgenic models was somehow surprising as most of these studies demonstrated that the inactivation of CREB contributes rather to antidepressant-like behavior. However, these loss-of-function studies possesses many caveats: mutation was targeting CREB not selectively in the brain and compensatory effects of cAMP response element modulator (CREM) were not taken into consideration.
The aim of this study was to evaluate the function of CREB in the mechanisms of antidepressant treatment by exploiting novel transgenic mouse model characterized by the selective and functional ablation of CREB based on the Cre/loxP system where the deletion of CREB was restricted only to the noradrenergic cells and maintained in CREM deficient background ($Creb^{DBHCre}$Crem-/- mice).
$Creb^{DBHCre}$Crem-/- mice did not show any abnormalities in their basal phenotype (weight gain, movement, anxiety- or depressive-like behavior). Also the mRNA levels of various neurotrophins, adrenergic receptors and cytokines investigated in selected brain structures were not changed in these mutants except for interleukin 10, an anti-inflammatory cytokine, which expression was profoundly diminished compared to control animals. Functional ablation of CREB resulted in a treatment-resistant phenotype after acute desipramine administration (20

mg/kg, i.p.) in tail suspension test, which effect was not observed in mice with only single CREB deletion. Our preliminary results provide further evidence for the important role of CREM as a compensatory factor and indicate that these mice may represent an unique tool to dissect the role of CREB in the mechanism of antidepressant drugs action.

Title: Epigenetic regulation of adult hippocampal structural neuroplasticity by chronic stress and antidepressants: is there a role for DNA 5hmC?

Authors: *A. MATEUS PINHEIRO[1,2], P. PATRICIO[1,2], N. ALVES[1,2], A. MACHADO-SANTOS[1,2], M. MORAIS[1,2], J. CORREIA[1,2], J. BESSA[1,2], J. MARQUES[1,2], M. BRANCO[3], N. SOUSA[1,2], L. PINTO[1,2];

Abstract: The adult central nervous system (CNS) is endowed with considerable regenerative and neuroplastic potential. Neuroplasticity, in its different forms, is dynamically modulated by intrinsic genetic factors in conjugation with environmentally imposed factors of our everyday life. Nowadays, stress-exposure is a common environmental etiological factor leading to various pathological marks in neurochemical and neuroplastic phenomena, many of them underlying the so-called stress-related disorders. Moreover, several studies have shed light on how epigenetic mechanisms serve as mediators of the pathological effects of stress on brain homeostasis. Here, we aimed to study the effects of stress on the epigenetic landscapes of the dorsal and ventral hippocampal dentate gyrus (DG). Furthermore, we aimed to explore how chronic exposure to stress impacts on the DG epigenome and its repercussions to fundamental emotional and cognitive modalities. We have exposed young-adult Wistar-Han rats to a pre-validated unpredictable chronic mild stress (uCMS) protocol during 6 weeks and performed a battery of behavioral tests to analyze emotional and cognitive dimensions. After sacrifice, we have

analyzed cytogenesis and dendritic morphological rearrengements. In addition, we have conducted genome-wide analysis of methylation and hydroxymethylation in these areas.
So far, results demonstrate that stress exposure compromises different forms of hippocampal structural plasticity, producing a time-dependent manifestation of different anhedonic, anxious-like and cognitive deficits . Moreover, hydroxymethylation pathways are likely to be involved in the pathological effects of stress exposure, as they are differentially regulated in control and stress-exposed animals. Indeed, we have found a downregulation of TET3 enzyme in the dorsal hippocampal dentate gyrus (DG), correlated with an overall decrease in 5hmC levels in the same region, quantified by oxRRBS. Moreover, 5hmC alterations in the dorsal DG were reversed after chronic fluoxetine treatment.

Title: Signatures of central metabolic syndrome are associated with depressive-like phenotypes and rescued by an antidepressant candidate

Authors: *B. BIGIO[1,3], D. ZELLI[2], A. A. MATHE'[4], V. C. SOUSA[4], P. SVENNINGSSON[4], B. S. MCEWEN[2], C. NASCA[2];

Abstract: The ventral dentate gyrus (vDG) has emerged as a target for resilience to stress and antidepressant action, including rapid actions. Previous research has shown that agents that influence energy metabolism, such as the epigenetic molecule acetyl-L-carnitine (LAC), exert rapid antidepressant-like effects. However, very little is know about the role that energy regulation plays in the occurrence of depressive-like phenotypes and responsiveness and/or

resistance to antidepressants. Here, we implemented a micro-dissection approach to screen global gene expression, using RNAseq, in the vDG of the SSRI-resistant BDNF Val66Met heterozygous male mice (hets) and in the Flinders-Sensitive-Line male rats that received oral administration of LAC or regular water. In hets, behavioral assessments were carried out using the forced swim (FS), light dark and social interaction tests after 1 day of treatment. In naïve FSLs and also in FSLs subjected to an acute stress to study if a stress episode could impact the responsiveness to a drug, behavioral assessment was done using the FS after 6 and 7-days of treatment. We report that LAC oral administration exerts rapid antidepressant-like effects by improving central energy regulation in the vDG of endogenously depressed hets and FSLs. RNAseq for the vDG identified the insulin (Insr), glucose receptors (Glut-4) and Cartpt, a regulator of appetite, as metabolic markers for predisposition to depression in hets and FSLs. These alterations are concomitant with activation of the mineralocorticoid receptors (MR) that boosts down-regulation of the metabotropic glutamate receptors 2, mGlu2, inhibitors of glutamate release. While correcting a MR-boosted mGlu2 decrease, LAC short term treatment corrects changes in the metabolic markers InsR, Glut-4 and Cartpt in the vDG of hets and FSLs. Also, in FSLs, after acute stress during LAC treatment, a subset of FSLs continued to respond to LAC (rFSL), whereas the other subset did not respond (nrFSL), suggesting that the acute stress episode altered the responsiveness to the drug. It is noteworthy that the occurrence of some resistance to LAC is associated with a unique gene expression profile in the vDG of nrFSLs with robust changes in metabolic regulators of fatty acid elongation, such as Evolv7 and Cybr5, and in markers of synaptic reorganization, such as NPAS4. These findings establish brain energy regulation as a factor to be considered for the development of better therapeutics and suggest that agents like LAC, by reducing a MR-boosted glutamate overflow, could rapidly ameliorate depressive disorders and could also be considered for treatment of insulin-resistance in depressed subjects.

Title: Sex differences in antidepressant effects of kappa opioid receptor antagonists

Authors: *A. LAMAN-MAHARG[1], M. ZUFELT[1], T. COPELAND[1], R. SNYDER[2], T. FENNELL[2], F. I. CARROLL[2], B. C. TRAINOR[1];
[1]Univ. of California, Davis, Davis, CA; [2]Res. Triangle Inst., Research Triangle Park, NC

Abstract: Psychosocial stress leads to activation of kappa opioid receptors (KOR) which, in turn, facilitate depression-like behaviors. This has generated a strong interest in the development of KOR antagonists as a potential novel class of antidepressant. However, most studies showing stress-induced activation of KOR focus on more short-term effects of stress and only study males. New evidence suggests that long-term effects of stress (over weeks or months) have important implications for KOR function, and that there may be sex differences. We examined the effects of social defeat stress on KOR action using California mice (*Peromyscus californicus*), a monogamous species in which social defeat can be studied in both males and females. Behavioral observations were conducted two weeks after three episodes of social defeat or control conditions. A 10 mg/kg i.p. injection of KOR antagonist norBNI decreased immobility in a two day forced swim test (FST) in control male California mice, but norBNI had no effect on immobility in control or stressed female California mice at doses of 0.5, 1, 10, or 25 mg/kg. Similar results were observed in male and female C57Bl/6 mice. To examine possible sex differences in the pharmacokinetics of norBNI, we used liquid chromatography-mass spectrometry to quantitate norBNI in plasma and whole brain of male and female C57Bl/6 mice at 1 hr, 5 hrs, 48 hrs, and 3 weeks after i.p. injection with 10 mg/kg norBNI. There were no sex differences in the pharmacokinetics of norBNI. Interestingly, we have shown that AZ-MTAB, a shorter acting KOR antagonist, reduced immobility and had anxiolytic effects in female California mice. A 10 mg/kg i.p. injection of U50,488 significantly increased freezing in the elevated plus maze in control and stressed female California mice, and this effect was significantly decreased with a 10 mg/kg i.p. injection of AZ-MTAB. A 10 mg/kg treatment of AZ-MTAB also significantly decreased U50,488-induced increases in immobility in the FST in both control and stressed California mouse females. Ongoing studies are investigating potential mechanisms underlying sex differences in the effects of norBNI and AZ-MTAB. These data indicate that KOR antagonists may have novel antidepressant effects in the context of stress-induced psychiatric disorders, but that the mechanism of action may be different in males and females.

Title: Changes in cortical astroglial cells in response to stress and antidepressant treatment

Authors: *S. SIMARD[1], G. COPPOLA[2], S. ABDIRASHID[1], R. THEDE[1], S. LAHAIE[1], S. HAYLEY[1], N. SALMASO[1,2];
[1]Neurosci., Carleton Univ., Ottawa, ON, Canada; [2]Child Study Ctr., Yale Univ., New Haven, CT

Abstract: An emerging body of work has suggested a potential role for astroglial cells in both the etiology and treatment of depression. Much of this work has focused on changes within the hippocampus and amygdala. However, recent evidence has shown decreases in expression of proteins associated with glial plasticity, such as glial fibrillary acidic protein, in cortical astroglial cells of depressed-suicide human patients that were examined post-mortem (Torres-Platas et al, 2011). This is supported by evidence from rodent models that have suggested that cortical astroglial cells may be involved in the pathophysiology of depression (Banasr et al, 2008). In the current study, we have employed a chronic unpredictable stress (CUS) paradigm in conjunction with chronic administration of a selective serotonin reuptake inhibitor, fluoxetine, as an antidepressant treatment in transgenic mice that express green fluorescent protein in astroglial cells in order to examine changes in cortical astroglial cells. Mice were exposed to CUS (or control conditions) for five weeks and injected with fluoxetine (or vehicle control) for the final three weeks of the study. Performance on behavioural tests associated with anxious and depressive behaviours were examined. As expected, CUS significantly increased anxiety and depressive-like behaviours on the forced swim test, sucrose preference test, open field and elevated plus maze. Interestingly, however, fluoxetine did not always reverse the effects of CUS and in some cases, exacerbated the effect of CUS. Fluorescence Activated Cell Sorting (FACS) was used to isolate GFP+ astrocytes for RNA extraction and sequencing. Protein and gene expression patterns were examined in cortical astroglial cells in response to CUS and fluoxetine and correlated with behavioural changes.

Title: Antidepressant effects of AMPA receptor potentiation in a model of treatment-resistant depression

Authors: *S. W. WHITE[1], R. S. GADEPALLI[2], J. M. RIMOLDI[2,3], K. J. SUFKA[1,3]; [1]Dept. of Psychology, [2]Dept. of Biomolecular Sci., [3]Res. Inst. of Pharmaceut. Sci., Univ. of Mississippi, University, MS

Abstract: Recent research in this lab has identified a stress-vulnerable, treatment-resistant, and ketamine sensitive Black Australorp genetic line that displays homologies with the clinical presentation of treatment-resistant depression (TRD). Testing in pre-clinical rodent models of depression has shown that ketamine, an NMDA antagonist, exerts its antidepressant effects through AMPA receptor activation. Indeed, AMPA potentiators possess antidepressant effects in rodent models of depression. However, antidepressant effects of AMPA receptor activation have not been tested in a preclinical model of TRD. This research sought to determine if AMPA receptor activation produces antidepressant effects in the TRD Black Australorp genetic line. Separate groups of 5-6 day old male cockerels were given IP vehicle or one of three doses of the AMPA potentiator LY392098 (2.5, 5.0, and 10.0 mg/kg) 15 min prior to a 90 min isolation test period in which distress vocalizations (DVocs) were recorded. Vehicle treated animals displayed high DVoc rates in the anxiety phase (first 5 min) that declined to about half the initial rate during the depression phase (30-90 min), a pattern typical of other behavioral despair models. The AMPA receptor potentiator LY392098 significantly attenuated behavioral despair as indicated by increased DVoc rates in the depression phase at the 2.5 mg/kg dose. This AMPA-mediated antidepressant effect is consistent with findings in rodent models of depression and generalize to an avian model of TRD.

Title: A novel δ opioid receptor agonist NC-2800 produces the anxiolytic-like and antidepressant-like effects in animal models.

Authors: *A. SAITOH[1], E. NAKATA[2], L. GOTOH[1], M. HIROSE[2], J. SAKAI[2], T. KOMATSU[2], H. FUJII[3], M. YAMADA[1], H. NAGASE[4], T. YAMAKAWA[2];

Ltd., Saitama, Japan; [3]Dept. of Medicinal Chem., Sch. of Pharmacy, Kitasato Univ., Tokyo, Japan; [4]Intl. Inst. for Integrative Sleep Med. (WPI-IIIS), Univ. of Tsukuba, Ibaraki, Japan

Abstract: δ Opioid receptor (DOR) agonists have been proposed to be attractive targets for the development of the novel antidepressants and/or anxiolytics. Recently, we succeeded in synthesizing a novel small molecule DOR agonist, named NC-2800, containing the morphinan structure. NC-2800 showed highly selective and effective DOR agonistic activity in functional cAMP assays using recombinant cells stably expressing opioid μ, δ or κ receptor, respectively. In this study, we investigated the anxiolytic-like and antidepressant-like effects of NC-2800 using animal models in rodents. In the rat elevated plus maze test, which is an animal model of innate anxiety, NC-2800 (1, 3 and 10 mg/kg, p.o.) significantly increased the time spent in the open arms 120 min after administration. The magnitude of the NC-2800-induced anxiolytic-like effects was similar to that produced by diazepam (3 mg/kg, p.o.), a benzodiazepine (BZD) anxiolytic. Interestingly, in contrast to diazepam, NC-2800 caused no significant performance changes in the Y-maze test, the ethanol-induced sleeping test and footprint test in rats. In the olfactory bulbectomized (OBX) rat, which is an animal model of depression, repeated administration of NC-2800 (1 mg/kg/day, s.c.) significantly decreased the total score of hyperemotional responses from day 1 to over the entire period on day 14. On the other hand, fluoxetine (10 mg/kg/day, s.c.), a selective serotonin reuptake inhibitor (SSRI) antidepressant, significantly reduced the total score on day 14 only. The inhibitory effects of NC-2800 were greater than those of fluoxetine in OBX rats. No significant changes in the body weight gain of OBX rats were observed between vehicle and NC-2800 treatment groups, while the fluoxetine treatment group significantly decreased the body weight gain. In conclusion, we suggest that NC-2800 is a novel orally available DOR agonist for anxiolytics/antidepressants with high efficacy and a rapid onset therapeutic effect without producing the adverse effects associated with BZDs and SSRIs. This study was supported by the Japan Agency for Medical Research and Development (AMED) grants.

Title: Boosting glutamatergic tone in infralimbic -but not prelimbic- cortex evokes antidepressant-like effects in rats through AMPA receptor activation

Authors: J. GASULL-CAMÓS[1,2,3], F. ARTIGAS[1,2,3], *A. CASTAÑE[1,2,3];
[1]IIBB-CSIC, Barcelona, Spain; [2]IDIBAPS, Barcelona, Spain; [3]CIBERSAM, Barcelona, Spain

Abstract: Since the discovery of the antidepressant effects of ketamine, a growing number of clinical and preclinical studies have shown the capability of several drugs to induce rapid antidepressant responses. Ketamine is known to increase glutamate release in the medial

prefrontal cortex (mPFC) and an increased AMPA receptor (AMPA-R) signaling has been suggested to mediate the effects of several fast-acting antidepressant strategies. The dorsal (prelimbic, PrL) and ventral (infralimbic, IL) subdivisions of mPFC exert a differential control over emotional behavior. Thus, the main goal of the present study was to investigate the possible involvement of excitatory neurotransmission in the IL and PrL cortex on mood regulation. Hence, we examined the potential antidepressant responses of boosting glutamatergic function in these mPFC subdivisions and studied the involvement of AMPA receptors (AMPA-R). We characterized the rapid behavioral consequences evoked by the bilateral microinfusion of a depolarizing drug, veratridine (50 pmol); a selective inhibitor of the glutamate transporter 1 (GLT-1; mostly present in astrocytes and main responsible for synaptic glutamate reuptake), dihydrokainic acid (DHK; 0.15, 1.5 and 5 nmol); or an AMPA-R agonist, s-AMPA (50 pmol), either in the PrL or IL. Neurochemical effects of these drugs over glutamate and serotonin (5-HT) concentration were determined by *in vivo* microdialysis in freely-moving rats. Veratridine reduced immobility time on the forced-swim test (FST) when infused into IL but not PrL. Likewise, DHK (5 nmol) and s-AMPA reduced both immobility on the FST and latency to feed on the novelty-suppressed feeding test (NSFT) when infused into IL, but not PrL. Lower doses of DHK were without effect. Furthermore, the local blockade of AMPA-R with NBQX (10 nmol) previous to DHK microinfusion into IL prevented DHK-induced reduction in immobility, supporting the involvement of IL AMPA-R in mediating rapid antidepressant responses. Microdialysis studies showed that the inhibition of GLT-1 with DHK increased extracellular glutamate to the same extent in IL and PrL. However 5-HT output increased only after GLT-1 blockade in IL, suggesting a differential control of both mPFC areas on serotonergic activity. Accordingly, s-AMPA increased glutamate and serotonin concentration in IL. Overall, the present results indicate that an acute increase of glutamatergic neurotransmission in the IL mPFC triggers immediate antidepressant-like responses in rats, which are mediated by AMPA-R activation and likely involve a PFC-driven enhancement of serotonergic activity.

Title: Transcriptomic evidence for dematuration of the mouse hippocampus and frontal cortex by chronic antidepressant treatment

Authors: *H. HAGIHARA[1], K. OHIRA[1,2], T. MIYAKAWA[1,3];
[1]Fujita Hlth. Univ., Toyoake/Aichi, Japan; [2]Mukogawa Women's Univ., Nishinomiya, Japan; [3]Natl. Inst. for Physiological Sci., Okazaki, Japan

Abstract: Fluoxetine (FLX), a serotonergic antidepressant drug, has been widely used to treat depression and anxiety disorders, but mechanisms underlying its antidepressant effect remain unclear. Previous studies that evaluated several molecular and/or electrophysiological features of the maturation stages of each neuron type have demonstrated that FLX treatment can reverse the established maturation of certain types of neurons in the hippocampus and frontal cortex (FC). However, this dematuration effect of FLX in the adult brain has not been assessed with regard to genome-wide gene expression patterns. In this study, we compared gene expression patterns in the FLX-treated FC and hippocampus of adult mice with those of the corresponding brain regions of normal infant mice. The gene expression patterns of FLX-treated mice significantly resembled those of normal infant mice in the FC and, to a large extent, in the hippocampus. In addition, time-course analyses of the ages of infant mice used in the comparisons with FLX-treated mice indicated that the gene expression patterns of FLX-treated mice were most similar to those of the youngest infants examined (1-week-old hippocampus and 2-week-old FC). Our results suggest that FLX treatment induces dematuration of the FC and hippocampus of adult mice with respect to genome-wide gene expression patterns. The dematuration of these brain regions might be involved in the therapeutic mechanism of FLX and/or some of its adverse effects.

Abstract: Clinical and preclinical studies consistently demonstrate the rapid antidepressant effects of *N*-methyl-D-aspartate receptor (NMDAR) antagonists, although the underlying mechanisms are still unclear. Death-associated protein kinase 1 (DAPK1) couples NR2B subunits at extrasynaptic sites to regulate the NMDA receptor channel conductance. Here we found that chronic unpredictable stress (CUS) induces extracellular glutamate accumulation, accompanied by increased DAPK1-NMDA receptor interaction and high expression of DAPK1 and *p*-NR2B at Ser1303 and synaptic protein deficits in rat medial prefrontal cortex (mPFC). CUS also enhances NR2B-mediated NMDA currents and extrasynaptic responses induced by bursts of high-frequency stimulation, which may be associated with astrocyte loss and low expression of glutamate transporter-1 (GLT-1). Blockade of transporter GLT-1 in the mPFC is sufficient to induce depressive-like behaviors and causes similar molecular changes. Administration of selective NR2B antagonist, DAPK1 inhibitor or uncoupling DAPK1 from NMDA receptor NR2B subunit produced rapid antidepressant effects and reversed CUS-induced alterations in the mPFC. Moreover, selective NR2B antagonist did not have rewarding effect measured with conditioned place preference (CPP) paradigm. Altogether, our findings suggest that DAPK1 interaction with NMDA receptor NR2B subunit acts as a critical component in the pathophysiology of depression and is a potential target for new antidepressant treatments.

Title: Sex differences in the antidepressant effect of scopolamine in rats

Authors: *B. WICKS, M. SHORE, S. KHANTSIS, A. CERETTI, S. COHEN, A. FRITZ, Y. KAWASUMI, D. BANGASSER;
Psychology and Neuroscienc Program, Temple Univ., Philadelphia, PA

Abstract: Scopolamine, a non-selective muscarinic receptor antagonist, has recently been found to have rapid antidepressant effects, even in a subset of patients who are resistant to other treatments. Compellingly, women have a greater antidepressant response to scopolamine than men, an effect that suggests heightened female sensitivity to the drug. Most sex differences in drug efficacy are thought to be attributable to circulating ovarian hormones. To test whether scopolamine efficacy is regulated by ovarian hormones, we utilized rat models of antidepressant efficacy. First we found that in both the Forced Swim and the Novelty Suppressed Feeding (NSF) tests of antidepressant efficacy, scopolamine had a greater antidepressant effect in female rats than it had in male rats. Next using the NSF task we determined that the magnitude of scopolamine's efficacy changed across the estrous cycle. To further examine a role for circulating ovarian hormones we tested the effects of scopolamine in ovariectomized female rats utilizing NSF. Female sensitivity to scopolamine was reduced in ovariectomized compared to gonadally intact female rats. Collectively, these results indicate that circulating ovarian hormones contribute to the sex differences in scopolamine efficacy in rodents. Scopolamine has a narrow therapeutic index and can cause severe side effects (e.g. psychosis). These preclinical findings suggest that clinical studies into the efficacy and safety of scopolamine should consider hormonal status of women in case different dosing recommendations are needed for women during their reproductive years.

Title: Cell cycle regulation of the hippocampal progenitor cells in depression and by antidepressants

Authors: *P. PATRICIO[1,2], A. MATEUS-PINHEIRO[1,2], A. MACHADO-SANTOS[1,2], N. ALVES[1,2], M. MORAIS[1,2], J. BESSA[1,2], N. SOUSA[1,2], L. PINTO[1,2];

Abstract: Depression is a complex multidimensional disorder affecting around 20% of the world population. Nevertheless, its pathophysiology is still incompletely understood. Depression is thought to result from the interplay between genetic predisposition and environmental factors, such as stress. Plasticity impairments in the hippocampus, a brain region involved in memory and stress response, are involved in the pathophysiology of depression. Moreover, the hippocampus comprises one of the few brain regions in the adult brain where neurogenesis occurs, the dentate gyrus (hDG). Previous works showed that decreased cell genesis and dendritic morphology alterations are detected in the hippocampus of depressed individuals and animal models of depression, whereas antidepressant treatment prevents these changes.
We used a validated rat model of depression, the unpredictable chronic mild stress (uCMS), to explore the molecular underpinnings of neural plasticity in the hDG, in the context of depression and antidepressant treatment. The aim of this works was to assess the cell cycle mechanisms regulating hippocampal cell proliferation in the context of depression and antidepressant treatment. For that we used both *in vivo* - uCMS rat model -and *in vitro* - rat hippocampal-derived neurospheres - approaches. UCMS-exposed animals presented decreased proliferation and generation of newborn neurons that were reversed by fluoxetine. In our *in vivo* model, results suggest that uCMS-exposure produces a cell cycle arrest in the hDG progenitor cells that is accompanied by decreased levels of cyclins D1, E and A expression. Chronic fluoxetine treatment reversed the G1 phase arrest and increased cyclin E expression. Dexamethasone (DEX), used to mimic the elevation of glucocorticoids after chronic stress, decreased proliferation *in vitro,* whereas the administration of serotonin (5-HT), a neurotransmitter involved in the actions of fluoxetine, partly reversed this decrease. DEX also induced a G1-phase arrest, decreasing the expression of cyclins D1, cyclin D2 and Cdk6, while increasing p27 expression. 5-HT treatment partly reversed the G1-phase arrest and restored the expression of cyclin D1 and Cdk6. These results suggest that the anti-proliferative actions of chronic stress in the adult hDG result from a glucocorticoid-mediated G1-phase arrest in the progenitor cells that may be overcome by antidepressant treatment.
These findings contribute to the identification of novel molecular players and targets underlying neural plasticity phenomena in the hDG in the context of depression, thus opening new avenues for the development of novel antidepressant strategies.

Title: Effect of the antidepressant agomelatine on the IL-6 pathway in rats exposed to chronic mild stress: role of suppressor of cytokine signaling 3 (SOCS3)

Authors: *A. C. ROSSETTI[1], M. PALADINI[1], C. A. BRUNING[2], G. RACAGNI[1], M. PAPP[3], M. A. RIVA[1], R. MOLTENI[1];

Abstract: Major depression (MD) is a debilitating disorder whose treatment is being challenged by the high rate of failure and relapse of the pathology. Among the molecular systems thought to be involved in the MD etiology and in the mechanism of action of antidepressant drugs, inflammation has emerged as an important actor. In particular, increased levels of pro-inflammatory cytokines have been observed in the plasma and cerebrospinal fluid of depressed patients and, among these inflammatory mediators, interleukin (IL-) 6 has been recently proposed to play a crucial role (Fonseka et al., 2015). IL-6 triggers a peculiar pathway comprising the JAK/STAT signaling proteins and characterized by a specific negative feedback loop exerted by the cytoplasmic protein SOCS3 (Suppressor Of Cytokine Signalling-3). We have recently demonstrated that a seven weeks lasting chronic mild stress (CMS) paradigm, able to induce a depressive-like phenotype, up-regulates the expression of different pro-inflammatory cytokines in the rat brain. In this scenario, the pharmacological treatment with the antidepressant agomelatine during the last 5 weeks of stress (daily i.p., 40mg/kg) was able to normalize not only the pathologic phenotype but also the inflammatory state (Rossetti et al 2015). With these premises, the aim of the present work was to further investigate the mechanisms underpinning the anti-inflammatory activity of agomelatine by evaluating the impact of the drug on IL-6 pathway in the prefrontal cortex of rats exposed to CMS. As expected, stress was able to activate the IL-6 cascade, including SOCS3 gene and protein expression and JAK1/STAT3 phosphorylation, without any suppressive effect of SOCS3 on the feedback-loop inhibition. On the contrary, chronic treatment with agomelatine was able not only to normalize the stress-induced activation of IL-6 signaling, but also to induce SOCS3 transcription and translation under basal conditions. To better understand how agomelatine modulates IL-6 pathway, we deepened our analyses measuring the nuclear phosphorylation of STAT3 at Ser727, the activation of MAP-kinases, and STAT3-mediated gene expression of molecules involved in the control of apoptosis (i.e. Bcl-XL, Casp1, Casp3). The results show that in both non-stressed and stressed animals agomelatine is inducing SOCS3 expression by different mechanisms, but with a

common potential neuroprotective effect. Furthermore, given the potentiality of IL-6 signaling as target of antidepressant treatment and the key protective activity of agomelatine on this system, probably through SOCS3, this data suggest that SOCS3 modulation might be a valuable target for new drug development.

Title: Peripheral administration of Lactate produces antidepressant-like effects

Authors: A. CARRARD[1], M. ELSAYED[2], M. MARGINEANU[3], B. BOURY-JAMOT[1], L. FRAGNIÈRE[1], E. MEYLAN[1], J.-M. PETIT[1,2], H. FIUMELLI[3], P. J. MAGISTRETTI[3,2], *J.-L. MARTIN[1];
[1]Ctr. For Psychiatric Neurosci., Prilly-Lausanne, Switzerland; [2]Brain Mind Inst. Ecole Polytechnique de Lausanne, Lausanne, Switzerland; [3]King Abdullah Univ. of Sci. and Technol. (KAUST) BESE Div., Thuwal, Saudi Arabia

Abstract: In addition to its role as metabolic substrate that can sustain neuronal function and viability, emerging evidence supports a role for L-lactate as an intercellular signaling molecule involved in synaptic plasticity. Clinical and basic research studies have shown that major depression and chronic stress are associated with alterations in structural and functional plasticity. These findings led us to investigate the role of L-lactate as a potential novel antidepressant. We found that peripheral administration of L-lactate produced antidepressant-like effects in the forced swim test. These antidepressant effects of L-lactate were not reproduced by

the enantiomer D-lactate and did not result from changes in locomotor activity and muscle strength. The antidepressant response induced by acute L-lactate administration was accompanied by increases in hippocampal L-lactate concentration and by changes in GSK3α/β and CREB phosphorylation levels as well as by alterations of Arc, COX-2 and NOS1 mRNA expression. Further investigation revealed that chronic administration of L-lactate induced antidepressant-like effects in two animal models that respond to chronic but not acute antidepressant treatment, including the open-space forced swim test and the corticosterone model of depression. In particular, we found that chronic administration of L-lactate partially restored mobility in the open-space forced swim test and completely reversed the corticosterone-induced anhedonia-like behavior. The antidepressant-like effects induced by chronic L-lactate administration were accompanied by changes in the expression of target genes implicated in serotonin receptor trafficking (p11), astrocyte functions (S100β), neurogenesis (Hes5), nitric oxide synthesis (NOS1 and NOS1AP) and cAMP signaling (PDE4D). Collectively, these studies identify a previously unrecognized action of L-lactate by which acute and chronic peripheral administration of L-lactate produces antidepressant-like behavioral responses. Further elucidation of the mechanisms underlying the antidepressant effects of L-lactate may help to identify novel therapeutic targets for the treatment of depression.

Title: Role of medial prefrontal cortical Brain-Derived Neurotrophic Factor in the rapid antidepressant effects of scopolamine in mice

Authors: *M. RAMAKER[1], M. ZHANG[2], K. VU[1], M. HAWKINS[2], S. L. THOMPSON[1], S. C. DULAWA[1];
[1]Univ. of California-San Diego, San Diego, CA; [2]Univ. of Chicago, Chicago, IL

Abstract: Introduction: Classical antidepressants require 2-4 weeks of treatment to elicit a therapeutic response. On the other hand, recent clinical trials have shown fast-onset antidepressant effects within days of a single administration of scopolamine, a muscarinic acetylcholine antagonist. This rapid-onset of action has reignited interest in the neural changes that underlie this difference in time to onset between different classes of antidepressants. One common molecular marker of antidepressant onset is Brain Derived Neurotropic Factor (**BDNF**); virtually all known classical and fast-onset antidepressants increase BDNF levels in the hippocampus and medial prefrontal cortex (**mPFC**), concurrently with their behavioral effects. However, one potential deviation from this is scopolamine, which has been shown in multiple studies to decrease BDNF levels. The present study aimed to examine the necessity of BDNF induction in the mPFC for the fast-onset antidepressant effect of scopolamine. Methods: Adult male and female BDNF floxed mice on a BALB/cJ background were infused bilaterally into the mPFC with AAV-cre-GFP or AAV-GFP control. Four weeks later, mice were implanted with subcutaneous osmotic mini-pumps (0 or 20 mg/kg/day). A catheter was attached to the mini-pump allowing a 2-day saline delay prior to 24-hours of drug treatment. At the conclusion of treatment, mice were tested in the open field test (**OFT**), followed immediately by the chronic forced swim test (**cFST**). In the OFT, horizontal activity was collected via automated MedPC software. In the cFST, behavior was scored for time immobile, swimming, or climbing by an experimenter blind to condition. Results: There were no interactions with sex for any measures, so male and female data were collapsed. Scopolamine significantly decreased immobility and increased swimming in the cFST, but there were no virus by drug interactions for any measure. In the open field test, scopolamine significantly increased horizontal activity, but there were no drug by virus interactions. Additionally, horizontal activity in the OFT and immobility in the cFST were not correlated. Discussion: These data suggest that induction of BDNF in the mPFC is not necessary for the antidepressant effects of scopolamine as measured in the chronic forced swim test. While scopolamine did have a locomotor activating effect, consistent with previous reports, locomotor behavior did not predict immobility in the cFST. Future studies examining whether preventing mPFC BDNF induction prevents the antidepressant effect of other classes of antidepressants will enhance our understanding of this pathway.

Title: Antidepressant-like effects of the atypical antipsychotic amisulpride in the differential-reinforcement-of-low-rate (drl) 72 sec operant procedure and in the forced swim task

Authors: *M. KHAN[1], H. NANGUNURI[2], S. E. CARLAN[2], S. E. YOUNG[2], S. E. YOUNG[2], A. R. GRANT[2], D. SMITH[2], K. A. WEBSTER[2], T. M. HILLHOUSE[3,4], J. H. PORTER[2]; [1]Psychology, Virginia Commonwealth Univ., Glen Allen, VA; [2]Dept. of Psychology, Virginia Commonwealth Univ., Richmond, VA; [3]Dept. of Pharmacol., Univ. of Michigan, Ann Arbor, MI; [4]Psychology, Weber State Univ., Ogden, UT

Abstract: Amisulpride is an atypical antipsychotic antidepressant used in Europe that is clinically effective in the treatment of both positive and negative symptoms of schizophrenia with a low incidence of extrapyramidal motor side effects. At low doses, amisulpride is used for the treatment of depression (primarily dysthymia). Amisulpride has a high binding affinity at dopamine D_2 and D_3 and serotonin 5-HT_7 and 5-HT_{2B} receptors. More recent studies suggest that amisulpride's antidepressant activity is due to 5-HT_{7A} antagonism and not D2/D3 antagonism. However, the degree to which amisulpride produces antidepressant-like behavioral effects is poorly understood. The present study examined the antidepressant-like effects of amisulpride in a differential-reinforcement-of-low-rate (DRL) 72-sec task in mice and rats, which has been shown to effectively screen antidepressant drugs, and in a forced swim test in mice. Adult male C57BL/6 mice were tested in the DRL 72 sec task for sweet milk reward and were tested with the tricyclic antidepressant imipramine (3.2, 10.0, and 17.8 mg/kg) as a positive control and with the atypical antipsychotic amisulpride (1.0, 3.2, 10.0, 17.8, 32, and 56 mg/kg). Imipramine produced an antidepressant-like profile with a significant increase in number of reinforcers at 17.8 mg/kg and a significant decrease in responses at 17.8 mg/kg. Amisulpride produced significant increases in number of reinforcers at 17.8, 32, and 56 mg/kg; however, there were no significant changes in responses. In adult Sprague-Dawley rats tested in the DRL 72 sec task, imipramine (3 and 10 mg/kg) significantly increased reinforcers and decreased responses. Amisulpride also produced significant increases in reinforcers at 3 and 10 mg/kg doses; however, there were no significant changes in responses. Adult C57BL/6 mice also were tested in in a forced swim task. In contrast to results reported by Abbas et al. (2009), 0.1 mg/kg amisulpride did not significantly reduce immobility in the forced swim test. Future studies should examine higher doses of amisulpride to more fully characterize amisulpride's effects on immobility in the

forced swim task. Regardless, these findings suggest that amisulpride's antidepressant-like effects may have different efficacies in the DRL and forced swim task in mice.

Title: Evaluation of home-cage social behaviors in a mouse model of mood disorders by chronic treatment with imipramine

Authors: *G. KURATOMI, Y. ARIME, S. SUZUKI, K. AKIYAMA;
Dokkyo Med. Univ. Sch. of Med., Tochigi, Japan

Abstract: Mutant mitochondrial DNA polymerase (*Polg1*) transgenic (Tg) mice that express mutant *POLG1* with defective 3'-5' exonuclease activity under the promoter of calcium/calmodulin dependent protein kinase II α have forebrain specific accumulation of multiple deleted mitochondrial DNA. Female Tg mice were reported to demonstrate mood disorder-like phenotypes and periodic wheel-running activity pattern associated with estrous cycle (Kasahara et al., 2006, 2016). In this study, we evaluated the long-term home-cage social behaviors and anhedonia-like behavior of Tg mice chronically treated with tricyclic antidepressant imipramine (IMI).
Twenty- to twenty-two-week-old female Tg mice and control C57BL/6J mice were housed on a 12 h light/dark cycle and used for experiments. For behavioral observation, mice were administered ether saline (SAL) or IMI (30 mg/kg/day) subcutaneously via implanted osmotic pumps for 28 days (n = 6-8 for each group). The IMI- or SAL-administered mouse was paired with a female wild-type sibling (cagemate) and bred in a polycarbonate cage with a transparent lid for 24 days. Home cages were consecutively recorded using digital video cameras which were placed above the cage. The video files obtained by recording home-cage behaviors during the first hour of dark period every other day were analyzed. The total duration of behaviors were blind scored to rate aggressive behaviors (chase, food competition, boxing posture), non-aggressive behaviors (huddle, allogrooming, body contact), and non-social behaviors (feeding,

self-grooming). Social interaction test with unfamiliar female mouse was conducted the day after the end of the 24-day observation (day 25). Sucrose preference was tested using two-bottle choice procedure between bottle containing a 1% sucrose and water-containing bottle for 2 days (day 27, 28). The whole study was formally approved by the animal care and use committee of Dokkyo Medical University School of Medicine.
The behavioral observation in home cage revealed that IMI-treated Tg and non-Tg mice showed significantly shorter duration of nose-to-body contact with their cagemates as compared in SAL-treated Tg ($p = 0.001$, one-way ANOVA). A comparison between early (< 12 days) and late periods during administration demonstrated that IMI-treated Tg mice only displayed increases in duration of passive nose-to-genital contact and inactive state by a two-way repeated measures ANOVA (group × period effect; $p = 0.005$ and 0.035, respectively). These results indicate mutant *Polg1* Tg mice continuously administrated with imipramine show altered manifestation of activity and social interactions in the home-cage environment.

Title: Maternal-fetal transfer of the SSRI Citalopram: pharmacokinetics and effects on fetal brain development.

Authors: *J. C. VELASQUEZ[1,2,3], N. GOEDEN[1], L. GALINDO[1,4], S. HEROD[5], C. SIMASOTCHI[3], T. FOURNIER[2,3], S. GIL[2,3], A. BONNIN[1];

Abstract: Selective Serotonin Reuptake Inhibitors (SSRIs) antidepressants are increasingly prescribed during pregnancy. As a result, prenatal exposures to SSRIs are becoming more

common despite an unclear safety profile for the fetus and conflicting findings from epidemiological studies regarding neonatal outcomes. While few studies focus on the consequences on fetal neurodevelopment, our understanding is also limited by not delineating the effects of maternal depression from those that are pharmacologically induced. These observations raise questions about the developmental effects of SSRIs during pregnancy and the factors that affect fetal drug exposures. Using human and mouse models and the widely-prescribed SSRI Citalopram (CIT), this project aims to assess maternal-fetal drug disposition throughout pregnancy and examine the developmental effects of CIT exposures on the fetal brain.
In this study, we evaluated the pharmacokinetics of CIT transfer across the mouse and human placentas. We implemented *ex vivo* placental perfusion systems to assess maternal-fetal drug transfer independently of maternal and fetal metabolism in addition to the effects on placental physiology. *In vivo* experiments were also conducted to assess fetal drug disposition profiles to CIT and its primary metabolite at different developmental stages. Results revealed a rapid maternal-fetal CIT transfer, significant placental tissue drug accumulation and a pregnancy stage-dependent exposure of the fetal brain to bioactive CIT metabolites. Enzymatic activity assays showed that fetal drug metabolic capacity develops in late gestation, resulting in elevated circulating and brain concentrations of DCIT at embryonic day (E)18. Furthermore, we measured the effects of CIT exposures on fetal brain serotonin at multiple developmental time points. Results show that prenatal exposure to CIT differentially impacts fetal brain neurochemistry and that the effects are modulated by duration and developmental stage of exposure. In particular, CIT exposure significantly altered fetal brain tissue concentrations of serotonin and other biogenic amines with critical roles in various neurodevelopmental processes. Immunohistochemical analyses of serotonergic and thalamocortical axon pathways formation revealed differential impacts on fetal brain circuit formation. Taken together, the results suggest that the pharmacological inhibition of serotonin reuptake during fetal development alters axonal circuit formation. The effects of maternal depression on these outcomes, independently and combined with SSRI exposure, are under investigation.

Title: Altered sensitivity to the rewarding properties of cocaine in adult female c57bl/6 mice exposed to fluoxetine during adolescence

Authors: F. J. FLORES-RAMIREZ[1], D. O. SANCHEZ[1], I. GARCIA[1], C. GONZALEZ[1], A. R. ZAVALA[2], *S. D. INIGUEZ[1];
[1]Psychology, Univ. of Texas at El Paso, El Paso, TX; [2]California State Univ., Long Beach, CA

Abstract: Accumulating preclinical evidence indicates that early-life exposure to psychotropic medications results in long-lasting altered behavioral responses to drugs of abuse - suggesting a risk of enhanced drug liability, later in life. However, to date, these preclinical experimental approaches have been conducted primarily using male subjects. This is surprising given that females, when compared to males, are more likely to be diagnosed with mood-related disorders, and thus, to be prescribed with psychotropic drugs, such as antidepressants. Therefore, to examine whether long-lasting alterations to the rewarding properties of drugs of abuse are exhibited as a result of juvenile antidepressant exposure, we exposed adolescent female mice to the selective serotonin reuptake inhibitor (SSRI) fluoxetine (FLX). We selected FLX given that it is the only SSRI approved by the US Food and Drug Administration for the treatment of pediatric depression. Specifically, female c57bl/6 mice were exposed to FLX in their drinking water (250 mg/L) during adolescence (postnatal days [PD] 35-49), and were later assessed in adulthood (PD 70+) on behavioral responsivity to cocaine (0, 2.5, 5, and 7.5 mg/kg) place conditioning (CPP). Our results show that adult female mice pretreated with FLX during adolescence displayed a decreased preference for environments previously paired with cocaine, when compared to saline-pretreated controls. Collectively, our data suggest that adolescent exposure to the antidepressant FLX causes behavioral adaptations that endure into adulthood, and that are indicative of a decreased sensitivity to the rewarding properties of cocaine in female mice.

Title: Effect of amygdaloid kindling and the fluoxetine in the depressive behavior and the susceptibility tonic-clonic seizures in rats

Authors: *A. DÍAZ, A. VALDÉS-CRUZ, J. D. AYALA-RODRIGUÉZ, L. MARTÍNEZ-MOTA, B. A. GARAY-CORTÉS, S. ALMAZÁN-ALVARADO, R. FERNÁNDEZ-MAS; Inst. Nacional De Psiquiatría Ramón De La Fuen, Mexico, Mexico

Abstract: The fluoxetine (FLX) is a selective serotonin reuptake inhibitor used for the treatment of depression. Despite of the efficacy of FLX in depressive disorders, its effect on epilepsy remains controversial. Experimental models have shown that FLX affects excitability in short time scales which may lead to changes in epilepsy severity. Amygdaloid kindling (AK) is a model of epilepsy characterized by sustained increase in seizure susceptibility. Therefore, the goal of the present study was to examine AK epileptogenesis with behavioral correlates of depression in the rat forced swim test (FST) as well as the effects of FLX on seizure susceptibility and depressive behaviors. Male Wistar rats (280-320 g) were used. Tripolar electrodes were placed in the basolateral nucleus of left temporal lobe amygdala (P: 2.8, L: 5.0, H: 8.5) and both frontal cortices. AK was induced by daily electrical stimulation (1 s train, 1 ms pulses, 60 Hz, 250-500 μA) until AK stage V (tonic-clonic seizure) was achieved for three consecutive days. One hour after last seizure, FST sessions were conducted by placing rats in individual glass cylinders (46 cm height; 20 cm diameter). An initial FST of 15 min (termed pre-test) was performed and after 24 h, was performed a 5 min test. A 10 mg/kg of fluoxetine hydrochloride (2 ml/kg) dose was administered following a sub-acute schedule, three injections administered between pretest and test sessions (21 h, 5 h, and 1 h before test session). Rats were assigned to seven experimental groups: K-FLX (n = 7), in which AK, FST and FLX injections were applied; K-Vh (n = 7), AK, FST and vehicle (saline solution 0.9%); Sham-FLX (n = 7), FST and FLX; Sham-Vh (n = 7), FST and vehicle; Control-FST (C-FST) (n = 7) solely with FST and Control-K (C-K) (n = 7) solely with AK. Immobility time in FST and seizure susceptibility on test stimulations of post stage V were assessed. We found a decrement in immobility time in the FST on all groups compared with C-FST ($P < 0.001$) and between Sham-FLX and K-FLX ($P < 0.02$). Whereas also there were changes between initial kindling threshold and threshold postFST by susceptibility spike in the groups K-FLX ($P < 0.001$), K-Vh ($P < 0.017$) and C-K ($P < 0.01$), and only group K-FLX for susceptibility seizure tonic-clonic ($P < 0.005$). Our results suggest that the FLX has effects on seizure susceptibility, thus the neuronal plastic changes associated with limbic system, particularly with the amygdala, could be interfered by the development of depressive behavior.

Title: Behavioural and hippocampal changes across the pre- to postpartum transition within a postpartum depression model with and without the effects of a serotonin reuptake inhibitor in rats

Authors: *A. OVERGAARD[1,2], S. E. LIEBLICH[2], R. RICHARDSON[2], L. A. M. GALEA[2], V. G. FROKJAER[1,3];
[1]Neurobio. Res. Unit, Copenhagen Univ. Hosp. Rigshospitalet, Kobenhavn O, Denmark; [2]Dept. of Psychology, Univ. of British Columbia, Vancouver, BC, Canada; [3]Mental Hlth. Services, Copenhagen, Denmark

Abstract: Postpartum depression (PPD) affects ~13% of mothers, and maternal mood is coupled to peripartum changes in sex steroid hormones, potentially in a manner dependent on serotonergic dysfunctions and stress hormone biology.
AIMS: To determine behavioural and neurobiological changes across natural peripartum, as well as in a model of PPD.
METHODS: We examined changes in anhedonia- (sucrose preference), anxiety- (elevated plus maze (EPM) and open field test (OFT)), and coping behaviours (using the forced swim test (FST)) in nulliparous rats, pregnant rats, and early, mid, and late postpartum, and maternal behaviour of the dams. The effects of postpartum exposure to corticosterone (CORT; 40 mg/kg/d s.c; a model of postpartum stress/depression) with or without concurrent administration of the selective serotonin reuptake inhibitor (SSRI) paroxetine (5 mg/kg/d s.c.) were also evaluated.
RESULTS: We found decreased anxiety-like behaviour (OFT) in the early postpartum and increased anhedonia-like behaviour mid postpartum relative to nulliparous and pregnant rats. Both postpartum CORT and SSRI increased immobility in the FST. While postpartum CORT did not affect anxiety, SSRI treatment postpartum increased anxiety (OFT and EPM) in both CORT and control dams. Neither CORT nor SSRI affected anhedonia-like behaviour. Postpartum CORT increased the percent time spent off the nest and SSRI did not remediate this effect.
CONCLUSIONS: We find increased anxiety- and anhedonia-like behaviour, but unchanged coping behaviour during different times postpartum in control dams. In accordance with the

literature, our PPD model increased depression-like behaviour, decreased maternal care, and did not affect anxiety. SSRI treatment did not remediate the behavioural effects of PPD in this model, and triggered in itself anxiety-like behaviour and reduced coping. Hippocampal neurogenesis data measurements are ongoing. Taken together, our study will advance the understanding of the time course and nature of PPD and may provide a rationale for evaluating treatment strategies in the immediate postpartum period, which interestingly may benefit from including non-serotonergic targets.

Title: Depressive and anxiety-like behaviors in Akt3 KO mice are rescued by chronic lithium treatment

Authors: *Y. BERGERON, G. BUREAU, M.-É. LAURIER-LAURIN, E. ASSELIN, G. MASSICOTTE, M. CYR;
Med. biology, Univ. du Quebec a Trois-Rivieres, Trois-Rivieres, QC, Canada

Abstract: The protein kinase B (PKB/Akt) is found in three distinctive isoforms: PKBα/Akt1, PKBβ/Akt2, and PKBγ/Akt3. While Akt1 and Akt2 have been intensively investigated, less is known about the Akt3 isoform. Yet, Akt3 differs from Akt1 and Akt2, being the most highly expressed isoform in the brain and being critical for postnatal brain development. Then, we hypothesized that Akt3 could play a distinctive role in cerebral functions. To address this hypothesis, we have investigated the impact of Akt3 deletion on behaviors, synaptic plasticity and biochemical signaling. First, in the Morris water maze and the novel object recognition test, no difference was observed between WT and Akt3 KO mice, suggesting no effect of Akt3 deletion on cognitive functions. In addition, electrophysiology on Akt3 KO hippocampal slices showed that neither STP nor LTP levels were modified compared to WT hippocampal slices. However, Akt3 deletion induced several behavioral anomalies: reduced prepulse inhibition, social behavior deficits as well as high level of depressive and anxiety-like behaviors. Biochemical investigations revealed that levels of total Akt1 and Akt2 in the anterior cortex, striatum, hippocampus and cerebellum were not modulated by Akt3 deletion. However, levels of phosphorylated GSK3α/β at serine 21/9 were decreased in the anterior cortex, hippocampus,

striatum and cerebellum of Akt3 KO mice; no change in levels of total GSK3α/β was observed. To verify if the modulation of GSK3α/β levels could be related to the observed depressive and anxiety-like behaviors, a lithium diet was chronically administrated to WT and Akt3 KO mice. This treatment has increased levels of phosphorylated GSK3α/β and rescued the depressive and anxiety-like behaviors observed in Akt3 KO mice. Then, these results suggest that GSK3α/β may contribute to the depressive and anxiety-like behaviors found in the Akt3 KO mice and support that an isoform-specific mechanism may define the neuronal signaling of Akt in psychiatric illnesses-related behaviors.

Title: Prefrontal cortex and amygdala oscillatory and single-unit activity during escapable and inescapable stress in the learned helplessness model

Authors: ***M. T. ROSSIGNOLI**, D. B. MARQUES, R. N. RUGGIERO, L. S. BUENO-JUNIOR, J. P. LEITE;
Ribeirao Preto Med. Sch., Univ. of São Paulo, Ribeirão Preto, Brazil

Abstract: Both the learned helplessness (LH) model of induced depressive behavior and clinical major depression are associated with anatomical and functional impairments in the prefrontal cortex (PFC) and amygdala (AMY). To date, there are no electrophysiological data from these brain sites in the LH model, which motivated our study. Thus, we implanted chronic microwire bundles into the PFC and AMY of adult rats for the recording of local field potentials (LFP) and single-unit activity (SUA). Once recovered from surgery, rats were submitted to a single session (~100 min duration) with escapable shocks trials (ES), paired inescapable shock trials (IS) or none (1 min intertrial interval), as proposed in the triadic model of LH (Amat et al., 2005, Nat Neurosci, 8(3): 365-71). ES and IS-trials consisted of conditioned stimulus (light, 10 s) immediately followed by unconditioned stimulus (foot shock, 10 s, 0.6 mA, 40-60 s intertrial), however in ES trials foot shock can be avoided by crossing to the opposite side of the chamber during the unconditioned stimulus. On day two, the helplessness behavior was assessed using an

active avoidance task, similar to ES trials. Ongoing perievent analyses show that conditioned stimuli transiently decreased the PFC alpha band power (8-12 Hz) in all trial types, but this effect was stronger in IS compared to ES. In contrast, the same stimuli decreased and increased PFC theta power (4-8 Hz) in IS and ES trials, respectively. PFC neural activity was consistently modulated across trial events. Particularly, the post-shock period induced greater SUA changes in the PFC of helpless rats compared to escaping animals. Our preliminary findings suggest distinct effects of escapable and inescapable stress on the PFC activity. Analyses of AMY recordings will potentially provide additional insights on the amygdala-prefrontal interaction in the LH model.

Title: Taurine reduces oxidative stress and DNA damage in the frontal cortex and in the hippocampus of diabetic rats

Authors: *H. M. BARROS[1], G. CALETTI[2], S. BANDIERA, 90050-171[4], A. W. HANSEN[4], A. M. MORÁS[4], L. STEFFENS, 90050-171[1], D. J. MOURA[3], R. GOMEZ[4];
[2]Pharmacosciences, [3]Basic sciences in health, [1]UFCSPA, Porto Alegre, Brazil; [4]Pharmacol., UFRGS, Porto Alegre, Brazil

Abstract: Diabetes is a chronic metabolic disease and hyperglycemia is associated with unbalance between pro- and antioxidants parameters and DNA damage. Taurine is a non-essential amino acid, widespread in the brain and peripheral tissues, with antioxidant, osmoregulatory and neuromodulatory properties. It may postpone the tissue injury and DNA damage of diabetes. Our objective was to evaluate the effect of chronic taurine treatment on antioxidant parameters and DNA damage in the hippocampus and frontal cortex in diabetic rats. Forty male adult Wistar rats were divided into control (CTR) and streptozotocin-induced diabetic (STZ) group. Rats from each group were daily administered with saline or 100 mg/kg of taurine

(CTR0; CTR100; STZ0; STZ100, n = 10/group), i.p., for 28 days. After 1 hour from the last taurine/saline administration, rats were killed and the frontal cortex and hippocampus were dissected and stored to further DCFH-DA assay, SOD, and CAT activity analysis. DNA damage was analyzed with the alkaline comet assay. A two-way ANOVA showed that diabetes condition significantly increased the DCF values in both brain structures, evidencing a pro-oxidant effect of chronic hyperglycemia. STZ rats also increased SOD and CAT enzymes activity in both brain areas. Moreover, diabetes significantly increased DNA damage in hippocampus ($P = 0.003$) and frontal cortex ($P = 0.039$). Prolonged taurine treatment reduced the DCF oxidation with consequent reduction in the SOD and CAT enzymes activity in both brain areas of STZ100 rats. Additionally, taurine decreased DNA damage in both brain areas evaluated of the diabetic rats, showing a protective effects on genotoxic damage (Hippocampus = 0.022; frontal cortex: $P = 0.008$). Therefore, taurine reduces oxidative stress and DNA damage in the frontal cortex and in the hippocampus of STZ diabetic rats. Additional studies need to be conducted to better explore therapeutic properties of taurine in humans.

Title: Sex-dependent alterations in habenular endocannabinoid signaling following exposure to chronic unpredictable stress

Authors: ***A. L. BERGER**[1], A. M. HENRICKS[1], L. N. BAXTER-POTTER[2], J. M. LUGO[2], M. A. STITCH[3], M. N. HILL[3], R. J. MCLAUGHLIN[2];

[3]Departments of Cell Biol. & Anat. and Psychiatry, Hotchkiss Brain Inst., Univ. of Calgary, Calgary, AB, Canada

Abstract: Stress is a pervasive aspect of life and a significant risk factor for a multitude of mental, cardiovascular, metabolic, and immune diseases. As such, understanding the effects of stress on the brain may uncover novel therapeutic targets for the treatment of stress-related illnesses. The epithalamic habenular nuclei have recently been linked to the pathological development of stress-related neuropsychiatric disorders via modulation of downstream monoaminergic neurotransmission. Moreover, multiple lines of evidence from our laboratory and

others have implicated the endocannabinoid (eCB) system in the neuroendocrine and behavioral response to stress. However, the role of eCB signaling in the habenula, and more specifically, how this system may become perturbed following chronic stress exposure, has yet to be empirically evaluated. Thus, we sought to examine the extent to which chronic unpredictable stress (CUS) exposure alters eCB content and mRNA expression for the primary routes of eCB biosynthesis and metabolism in the habenula of male and female Sprague Dawley rats. Rats were exposed to six weeks of CUS and the habenula was rapidly dissected for determination of anandamide (AEA) and 2-arachidonoylglycerol (2-AG) concentrations and relative mRNA expression for biosynthetic (NAPE-PLD, DAGLα) and degradative (FAAH, MAGL) enzymes using LC/MS/MS and RT-qPCR, respectively. Preliminary results indicate that AEA content in habenular tissue was significantly higher in female rats compared to male rats under basal, non-stress conditions, with no significant differences in AEA content in either sex following CUS exposure. In contrast, 2-AG content was significantly elevated in the habenula only in female rats exposed to CUS compared to non-stressed female rats. Concentrations of AEA and 2-AG were also strongly correlated with adrenal gland weights and body weight gain. With respect to eCB mRNA in the habenula, we observed a trend (p=.06) for reduced NAPE-PLD expression in stress-exposed male rats compared to non-stressed controls while no other evaluated genes differed in male rats. Together, these results indicate that eCB signaling in the habenula is significantly altered by CUS exposure in a sex-dependent and ligand-specific manner. These findings contribute to the growing body of evidence suggesting an important role for the habenula in response to stress and argue that eCB signaling within the habenula may be fundamentally involved in stress-related perturbations within this nucleus, as well as its downstream targets, thereby increasing vulnerability for the development of stress-related psychopathology.

Abstract: Increased kynurenine (Kyn) within the central nervous system is associated with symptomologies of depression and other neurological disorders such as schizophrenia, multiple sclerosis, Parkinson's and Alzheimer's disease. In particular, depression behaviors correlate with an elevation of pro-inflammatory cytokines responsible for the induction of rate-limiting enzymes that generate Kyn from tryptophan: indoleamine-2,3-dioxgenases (Ido1 and Ido2). Galectins (Gals) are well-established inflammatory modifiers which may play significant roles in the pathogenesis of the aforementioned disorders. However, there are no reports describing the ability of Gals to modulate the Kyn Pathway, thus linking their expression to major depression. Lipopolysaccharide (LPS) is frequently used to induce cytokine expression, Ido expression and brain Kyn culminating in depression-like behaviors of rodents. Here, we show that intraperitoneal injection of mice with LPS induces Ido1, Ido2, interferon-gamma (IFNγ), Gal-3 and Gal-9 expression in the mouse brain, and that IFNγ and Gal-9 play a critical role for Ido1 and Ido2 induction within the hippocampus. Organotypic hippocampal slice cultures (OHSCs) were used to determine if in vivo surges of IFNγ and Gal-9 are responsive for elevated Ido1 and Ido2 expression and if Ido expression is sensitive to antidepressant therapy. OHSCs were treated with IFNγ plus Gal-1, Gal-3 or Gal-9 with or without desipramine (Desip); mRNA levels were quantified by qPCR. IFNγ was not expressed by OHSCs, but the addition of IFNγ increased Gal-9 expression. IFNγ also increased expression of two distinct Ido1 transcripts (Ido1-FL and Ido1-v1), and remarkably, the antidepressant Desip blocked this induction. Although not active alone, Gal-9 interacted with IFNγ to synergistically upregulate Ido1-FL, an effect also blocked by Desip. IFNγ also increased expression of Ido2 transcripts (Ido2-v1, Ido2-v2 and Ido2-v3), and similarly, IFNγ-induced Ido2 expression was decreased by Desip. Gal-9 further accentuated IFNγ-induced Ido2-v1 expression; this interaction was blocked by Desip. These effects are Gal-9 specific as Gal-1 and Gal-3 did not affect Ido expression. These data are the first to show that both IFNγ and Gal-9 are up-regulated in the hippocampus during LPS-induced neuroinflammation. Since IFNγ is not expressed by the OHSCs, our data suggest that IFNγ (probably derived from infiltrating peripheral cells in vivo) induces central Gal-9 to augment IFNγ-dependent Ido expression. The exciting discovery that desipramine blocks inflammation-dependent Ido1 and Ido2 expression expands the mechanism-of-action for antidepressants.

Abstract: The Nucleus accumbens (NAc) has recently emerged as a key reward brain region in the symptomatology of depression, including reduced motivation and anhedonia. It has been proved that BDNF signaling from the VTA to the NAc exerts a pro-depression-like effect in the social defeat stress. Apart from VTA, the NAc also receives dense glutamatergic innervation from basolateral amygdala (BLA). Despite previous studies demonstrate excitatory transmission from the amygdala to NAc facilitates reward seeking, the individual role of amygdala-NAc circuit in aversion affective behaviors and their contribution to the depressive behavior are poorly understand. Recently, we found a class of BLA cholecystokinin neurons projecting to the NAc, which release excitatory transmitter "glutamate". Social defeat stress can rapidly activate amygdala cholecystokinin neurons and their terminal in NAc in susceptible, but not resilient mice. Activation or silence of NAc-projecting BLA CCK neurons can bidirectionally regulate depression-like behavior.

Title: RNAseq on FACS-isolated medium spiny neurons reveals distinct roles for D1 and D2 cells at baseline and in response to chronic stress

Authors: *H. KRONMAN[1], B. LABONTÉ[1], E. RIBEIRO[1], I. PURUSHOTHAMAN[1], C. PEÑA[1], O. ENGMANN[1], M. CAHILL[1], O. ISSLER[1], D. FERGUSON[2], H. SUN[3], E. NESTLER[1];

Abstract: Stress induces many pathological changes in the brain's reward circuit. In particular, stress exerts potent effects on the nucleus accumbens (NAc), a largely GABAergic nucleus receiving dopaminergic input from the ventral tegmental area. The NAc contains several neuronal populations of distinct identity, the most abundant of which is the population of dopamine-responsive, GABAergic medium spiny neurons (MSNs). MSNs are subdivided by their response to dopamine, with one class expressing predominantly the dopamine receptor type 1 (D1) and the other expressing dopamine receptor type 2 (D2). While D1- and D2-expressing MSNs utilize different G protein signaling cascades and have been shown to play different – and often opposing – roles in stress responses, only a handful of D1- and D2-enriched genes are known. The purpose of the present study was to define transcriptional signatures for D1 and D2 MSNs at baseline and in response to stress, and to assess the relative contribution of D1- and D2-enriched genes in stress action. To this end, we used a cutting edge combination of techniques, performing RNA sequencing on whole cells and on nuclei sorted from D1 and D2 transgenic reporter mice using Fluorescence-Associated Cell Sorting (FACS). Bioinformatic analysis of the RNAseq data included differential expression, network, and clustering analyses to evaluate the transcriptional profiles of D1 and D2 MSNs. Ingenuity Pathway Analysis (IPA) of D1- and D2-enriched gene lists indicated that each cell type was enriched for its known signaling pathway at baseline, and that stress induced cell type-specific patterns in mice susceptible vs. resilient to stress. The importance of specific transcripts was assessed by manipulation of key genes selectively in D1 and D2 cells using cell type-specific viral-mediated gene transfer. Furthermore, we found global patterns in D1 and D2 responses to stress, with D2 MSNs altering their transcriptional landscape to more closely resemble D1 MSNs. The improved resolution of cell type-specific over whole-tissue RNAseq in NAc uncovered transcriptional effects previously masked by population averaging, and generated novel targets for genetic manipulation to promote stress resilience.

Title: Reversal of the durable consequences of adolescent social isolation

Authors: *E. A. HINTON[1,4], A. G. ALLEN[2,4], S. L. GOURLEY[1,2,4,3];
[1]Grad. Program in Neurosci., [2]Sch. of Med., [3]Dept. of Pediatrics, Emory Univ., Atlanta, GA;
[4]Yerkes Natl. Primate Res. Ctr., Atlanta, GA

Abstract: Adolescent-onset depression is associated with high rates of depression recurrence later in life, is frequently precipitated by social adversity, and is more prevalent in women. Therefore, identifying both the durable consequences of early-life social adversity in female populations and corrective interventions is of great importance. Here, female C57BL/6 mice were isolated or group-housed from postnatal days (P) 31-60. At P60, all mice were "re-socialized," with each cage containing 3-4 previously-isolated mice (n=6-8/pen). Expression levels of 2',3'-Cyclic-nucleotide 3'-phosphodiesterase (CNPase) were assessed throughout the prefrontal cortex (PFC), amygdala, and hippocampus. Circulating corticosterone (CORT) levels were analyzed via ELISA. Decision-making strategies were classified using response-outcome contingency degradation. Anhedonic-like behavior was assessed via the sucrose consumption test. Dendritic spines on deep-layer PFC neurons of *thy1*-YFP-expressing mice were imaged using confocal microscopy. Finally, CaMKIIa-controlled Gi-coupled Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) were expressed bilaterally in the ventromedial PFC (vmPFC), and activated by their ligand Clozapine-N-oxide via *i.p.* injection. We found that isolation during adolescence induced hypocortisolemia. Despite social re-integration and normalization of CORT, a history of social isolation also reduced CNPase expression, increased vmPFC spine densities, impaired goal-directed decision-making, and induced anhedonic-like behavior. Reversal of these behavioral outcomes via DREADD-mediated vmPFC inhibition provides a novel G protein-coupled receptor-based approach for mitigating neuropsychiatric outcomes related to social adversity in adolescence.

Title: Perineuronal nets in the medial prefrontal cortex regulate vulnerability to stress

Authors: *J. SHI[1], N. CHEN[1], D. HU[1], Y. HAN[1], L. LU[1,2,3];
[1]Natl. Inst. On Drug Dependence of Peking Un, Beijing, China; [2]Inst. of Mental Health, Natl. Clin. Res. Ctr. for Mental Disorders, Key Lab. of Mental Hlth. and Peking Univ. Sixth Hospital, Peking Univ., Beijing, China; [3]Peking-Tsinghua Ctr. for Life Sci. and PKU-IDG/McGovern Inst. for Brain Res., Beijing, China

Abstract: Introduction: Perineuronal nets (PNNs) are extracellular matrix structures enwrapping parvalbumin-positive γ-aminobutyric acid (GABA)-ergic interneurons. PNNs have recently been implicated in experience-dependent neuroplastic changes in central nervous system, but it is poorly understood that whether PNNs modulates the neural maladaptation after repeated exposure to stress.
Methods: First, we measured levels of PNNs and proteins constituting PNNs in the medial prefrontal cortex (mPFC) of adolescent and adult rats which exhibited different responses to 10-days chronic unpredictable mild stress (CUMS). Then we evaluated the effect of enzymatic degradation of PNNs in mPFC on stress vulnerability in adults, and the effect of elevating PNNs in adolescent rats through environment enrichment on CUMS-induced depressive and anxiety-like behaviors. And we also injected fluoxetine in adolescent rats and measured the stress vulnerability and PNNs levels. Finally we investigated the role of PNNs in regulating the expression of glutamic acid decarboxylase 67 (GAD 67) and frequency and amplitude of inhibitory postsynaptic current (IPSC) after CUMS in rat mPFC.
Results: We found that adolescent rats with lower level of PNNs, tenascin-R and aggrecan in the mPFC exhibited increased susceptibility to stress. Degradation of PNNs in mPFC promoted vulnerability to 10-days CUMS in adult rats. Elevating PNNs in the mPFC through environment enrichment prevented CUMS-induced depressive and anxiety-like behavior. Fluoxetine also reversed the stress vulnerability in adolescent rats. Lower level of PNNs rendered GABAergic neurons susceptible to CUMS, manifesting as decreases in expression of GAD 67 and frequency and amplitude of IPSC after CUMS.

Conclusion: The organization of PNNs coincided with the developmental switch in stress vulnerability to resilience. These findings indicate a role of PNNs in mPFC in predicting and modulating vulnerability to stress, and the effect may be produced though regulating GABAergic functions.

Title: Unfolded protein response activity in hippocampus of rodent models of depression

Authors: ***M. TIMBERLAKE**, Y. DWIVEDI;
Psychiatry, UAB, Birmingham, AL

Abstract: Background: Major Depressive Disorder (MDD) is a debilitating mental disorder that is characterized by low mood, self-esteem dips, and loss of interest/pleasure in otherwise pleasurable activities that can affect a person's work, family, and other relationships as well as sleeping, eating and general health quite adversely. One of the symptoms of MDD is a decline in memory aptitude as well structural changes in hippocampus - the part of the brain responsible for converting short-term memories to long-term ones; the underlying cause of this decline has yet to be detailed. Multiple lines of evidence suggest that a process known collectively as the unfolded protein response (UPR) may be responsible for some of the adverse, underlying physiology of the MDD phenotype. **Methods:** To examine whether UPR system plays a role in depression, we examined the expression of genes that are part of the three different pathways for UPR activation, namely GRP78, GRP94, ATF6, XBP-1, ATF4 and CHOP in the hippocampus of two animal models of depression: learned helplessness and restraint. **Results:** We have demonstrated that rats subjected to the stress paradigms of learned helplessness and restraint, show a significant increase in UPR activity in the hippocampus. **Conclusion:** Our data show strong evidence of altered UPR system in depressed rats, which could be associated with development of depressive behavior. We hypothesized that the cellular stress response could be responsible

for the initiation of some apoptotic pathways in conjunction with immune system activity in the depressed brain.

Title: Cell type and projection specific roles of ventral pallidal neurons in depression

Authors: *D. KNOWLAND, V. LILASCHAROEN, C. PACIA, S. SHIN, B. LIM;
UCSD, San Diego, CA

Abstract: Although nearly 10% of adults are diagnosed with Major Depressive Disorder (MDD) during their lifetime, positive patient response to existing treatments are highly variable and often treat symptoms rather than address the underlying cause. A significant hurdle in treating MDD is the wide and often variable spectrum of symptoms patients exhibit such as anhedonia, social withdrawal, and a lack of motivation. Although the behavioral symptoms are well described in MDD, much less is understood about the precise changes in neural circuitry that accompany MDD and if specific changes underlie separate behavioral symptoms. In particular, are there certain circuit adaptations that mark the transition from a healthy patient to one with MDD? To address this question, we anatomically and functionally dissect the circuitry of the ventral pallidum (VP), a largely overlooked area in the reward and motivational circuit. Using a novel retrograde viral system our lab has developed to outline the cell-type and projection-specific circuit of VP PV neurons we find that VP PV neurons send projections to the ventral tegmental area (VTA) and lateral habenula (LHb), two areas that have been previously implicated in depression. Furthermore, these cells represent distinct subpopulations that predominantly send their projections specifically to the LHb or VTA, but not both. Using optogenetic-mediated axon terminal stimulation we also find that these subpopulations mediate

separate behaviors. At basal levels, we find that LHb-, but not VTA-projecting cells mediate rewarding effects. To assess contributions to depressive behaviors, we use the chronic social defeat stress (SDS) model of depression which has shown to elicit a broad spectrum of phenotypes that parallel those seen in humans with MDD. Interestingly, we find that different subpopulations underlie distinct symptoms of depression in mice. Only LHb-, but not VTA-projecting neurons modulate helplessness or behavioral despair. Conversely, VTA- but not LHb-projecting neurons mediates social avoidance behaviors induced by SDS. These results suggest that ventral pallidal PV neurons are critical in mediating SDS-induced depressive phenotypes. Furthermore, separate subpopulations of VP PV neurons distinguished by their projection target modulate distinct and separate depressive behaviors and exhibit different stress-induced physiological changes. This data points to an increased need in specificity in cell-type specific circuit studies and the importance of considering projection-specific subpopulations when studying behaviors related to mental disorders.

Title: Beta-hydroxybutyrate, endogenic NLRP3 inflammasome inhibitor, ameliorates neuro inflammation caused by stress.

Authors: *T. YAMANASHI[1], M. IWATA[1], K. TSUNETOMI[1], N. KAJITANI[1], A. MIURA[1], R. S. DUMAN[2], K. KANEKO[1];
[1]Tottori Univ., Tottori, Japan; [2]Yale Univ. Sch. of Med., New Haven, CT

Abstract: Stress decreases neurogenesis and synaptogenesis in the adult hippocampus, contributing to depressive-like behaviors in rodent models, but the mechanisms by which stress causes neuronal damage remain unknown. It has been reported that interleukin-1beta (IL-1beta) decreases neurogenesis and causes depressive behavior. We had previously reported that stress increases ATP and activates Nucleotide-binding protein, Leucine-rich repeat, Pyrin domain containing 3 (NLRP3) inflammasome, which in turn increases IL-1beta in the adult rat hippocampus. We also reported that administration of purinergic type 2X7 receptor (P2X7R), a receptor for ATP, antagonist (A-804598) ameliorates both the increase of NLRP3 inflammasome and IL-1beta in the hippocampus, as well as decreased neurogenesis and depressive-like

behaviors caused by stress. P2X7R, when combined with ATP, triggers K^+ efflux and leads to the formation of a large multi-protein complex termed the NLRP3 inflammasome responsible for the processing of pro-IL-1beta to mature IL-1beta that is then released. These findings indicate that the NLRP3 inflammasome plays a critical role in the stress-induced inflammatory response and depressive-like behaviors. Recently, it was reported that beta-hydroxybutyrate (BHB), which is a ketone body that supports mammalian survival during states of energy deficiency in peripheral tissues and the brain, suppresses activation of the NLRP3 inflammasome in response to ATP by preventing K^+ efflux and reducing NLRP3 oligomerization. Thus, we hypothesized that BHB could produce antidepressant effects via inhibition of NLRP3 inflammasome activation and neuro-inflammation in the hippocampus, particularly in response to chronic psychological stress. In the present study, we found that peripheral BHB administration prevents depressive- and anxious-like behaviors induced by a rodent model of chronic unpredictable stress. We also confirmed that peripheral administration results in elevated BHB levels in the hippocampus, supporting the possibility that the antidepressant effects of BHB are mediated by direct actions in brain. Furthermore, we confirmed that peripheral administration of BHB inhibits the induction of mature IL-1beta elevation in the adult rat hippocampus in response to immobilization stress. These findings are consistent with the hypothesis that inhibition of the NLRP3 inflammasome represents a relevant and efficacious approach for the development of novel antidepressant treatments.

Title: Ryanodine receptor type 2, a potential therapeutic target for bipolar disorder & major depressive disorder

Authors: *J. YAO, F. HIESS, R. WANG, S. W. CHEN;
Dep.of Physiol. & Pharmacol., Univ. of Calgary, Calgary, AB, Canada

Abstract: Bipolar disorder (BD) and major depressive disorder (MDD) are mood disorders that impact approximately 10% of adults in the United States, which represent an enormous burden on our society. Despite years of intensive studies, the molecular basis of these disorders remains undefined, and there are no long-term effective treatments for BD and MDD. One emerging area

of investigation involves endoplasmic reticulum (ER) calcium homeostasis. Increased evidence indicates that the inositol 1,4,5-trisphosphate receptor type 1 (IP3R1), one of the Ca^{2+} releasing channels in the ER membrane, plays an important role in the pathogenesis of BD and MDD. However, the role of ryanodine receptor type 2 (RyR2), another member of the Ca^{2+} release channel family, in these mood disorders are unclear.By using GFP-tagged RyR2 mice, we found that RyR2 is highly expressed in brain regions that are involved in emotion control, including the prefrontal cortex (PFC), amygdala (AMYG), and hippocampus (HIPP). In open field (OF) test and elevated plus maze (EPM) test, we found that mice with RyR2 suppression-of-function (SOF) mutation show depression-like behavior, while mice with gain-of-function (GOF) RyR2 mutation exhibit mania-like activity. In order to see whether manipulating RyR2 function will affect neuron activity, we performed patch-clamp recording to measure the frequency of action potential (AP) firing, the threshold and latency of current injection-induced AP, and the frequency and amplitude of miniature excitatory postsynaptic current (mEPSC). Interestingly, we found that pyramidal neurons in layer II/III of PFC and CA1 region of HIPP brain slices from SOF-RyR2 mice are less active compared to WT, in contrast, GOF-RyR2 mutation renders the neurons hyperactive. Furthermore, recordings of long term potentiation (LTP) from the same regions showed that SOF-RyR2 mutant requires stronger stimulation than WT for triggering LTP. Interestingly, we were unable to induce LTP in the same region in the GOF-RyR2 mice. High frequency stimulation (HFS) may no longer potentiate the synaptic activity in already hyperactive neurons. Further studies are needed to determine whether SOF- and GOF-RyR2 mutations also alter intracellular Ca^{2+} homeostasis in an opposite manner. Together, these data suggest that RyR2 may play an important role in pathogenesis of BD and MDD. Thus, targeting RyR2 may represent a potential therapeutic approach for treating BD and MDD.

Title: Reduced Slc6a15 in nucleus accumbens D2 expressing neurons mediates depression susceptibility

Authors: *L. M. RIGGS[1], R. CHANDRA[1], T. C. FRANCIS[1], H. NAM[1], H. SUN[2], C. A. TAMMINGA[3], G. TURECKI[4], M. LOBO[1];
[1]Anat. and Neurobio., Univ. of Maryland Sch. of Med., Baltimore, MD; [2]Fishberg Dept. of Neurosci., Mount Sinai Sch. of Med., New York, NY; [3]Dept. of Psychiatry, Univ. of Texas Southwestern Med. Ctr., Dallas, TX; [4]Dept. of Psychiatry, McGill Group for Suicide Studies, McGill Univ., Montreal, QC, Canada

Abstract: Depression is a devastating illness whose complex etiology makes it difficult to treat. Transporters that are encoded by the solute carrier 6 (Slc6) gene family are ideal therapeutic targets for depression, given their regulation of neurotransmitter homeostasis. However, the development of novel therapeutics will depend on improving our understanding of how genetic factors promote depression susceptibility through cell-type specific molecular adaptions. Although previous research has shown that decreased expression of Slc6a15 (a neutral amino acid transporter) is associated with depression susceptibility, no study has examined this relationship within nucleus accumbens (NAc) medium spiny neuron (MSN) subtypes (D1 vs. D2). Given our previous characterization of Slc6a15 as being a D2-MSN enriched gene, we examined the role of D2-MSN Slc6a15 in mediating negative behavioral states (i.e., social avoidance). First, we show that mRNA expression of Slc6a15 is significantly reduced in the NAc of medicated and unmedicated depressed suicide victims. These results are consistent with our preclinical data showing significant reductions of Slc6a15 mRNA in the NAc of susceptible mice following chronic social defeat stress (CSDS) - a paradigm that produces behavioral and molecular adaptations that resemble clinical depression. In order to examine whether these observations are driven by reductions of Slc6a15 selectively within D2-MSNs, we isolated ribosome-associated mRNA Slc6a15 transcripts from D2-MSNs following the CSDS procedure. We show significant reductions in Slc6a15 mRNA in D2-MSNs of mice susceptible to CSDS, whereas no mRNA changes are detected in NAc D2-MSNs of resilient mice, relative to non-stressed controls. In order to determine the role of Slc6a15 in stress susceptibility, we selectively manipulated the expression of Slc6a15 in D2-MSNs by bilaterally injecting Cre-inducible double-floxed inverted open reading frame (DIO) adenoassociated viruses (AAV) into the NAc of D2-Cre mice. Virus-mediated Slc6a15 miRNA knockdown in D2-MSNs led to enhanced susceptibility to subchronic social defeat stress (SSDS), which supports the hypothesis that Slc6a15 cell-type specifically confers vulnerability to depression. Interestingly, we show enhanced resilience to CSDS when Slc6a15 is overexpressed in D2-MSNs, which resembles an antidepressant restoration of normal behavior. When taken together, our results show that reduced Slc6a15 expression within the NAc mediates susceptibility to depression, and that this effect occurs selectively within the D2-MSN population.

Abstract: The neurobiological mechanisms underlying affective disorders, i.e. major depressive disorder and bipolar disorder, are not fully elucidated yet. Genetic and environmental risk factors contribute critically to their etiology, but the exact pathophysiological pathways how these risk factors interact and influence brain structure and function remain to be uncovered. Important genetic factors include the gene *CACNA1C*. Here, we used the newly generated *Cacna1c* rat model to study its role in regulating phenotypes relevant to affective disorders. Firstly, behavioral phenotypes displayed by *Cacna1c* heterozygous (+/-) rats and wildtype littermate controls were compared in a sex-dependent manner. Secondly, to study environmental effects on inflammatory markers, *Cacna1c* +/- rats and wildtype littermate controls were exposed to post-weaning social isolation as a model for maltreatment or social plus physical enrichment modeling beneficial environments. Our results show that *Cacna1c* +/- rats are viable, yet the average number of rat pups born per litter is smaller for *Cacna1c* +/- than for wildtype females, with genotypes being evenly distributed. Interestingly, *Cacna1c* +/- females displayed less maternal licking/grooming, while nursing behavior did not differ. Consistent with the idea that reduced maternal licking/grooming results in an anxious phenotype, offspring of *Cacna1c* +/- females emitted more isolation-induced ultrasonic vocalizations (USV) in the first week of life, as compared to offspring of wildtype females. In addition, *Cacna1c* +/- pups emitted fewer isolation-induced USV than wildtype controls. No genotype differences were seen in body weight gain, temperature regulation and somatosensory reflexes, with both genotypes following normal early developmental patterns. In adulthood, exploratory behavior in the open field was reduced and anxiety-related behavior in the elevated plus maze was enhanced in both male and

female *Cacan1c* +/- rats. Finally, cytokine measurements revealed that post-weaning social isolation mostly increased proinflammatory markers, while social plus physical enrichment mainly led to opposite effects. Such changes were most prominently seen in wildtype controls, with relatively minor environmental effects being evident in *Cacna1c* +/- rats. Together, our findings indicate that *Cacna1c* is involved in the regulation of behavioral phenotypes relevant to neuropsychiatric disorders and that the responsivity to environmental changes at the level of inflammatory markers is reduced in *Cacna1c* +/- rats. Title: Effects of kappa-opioid receptor antagonist on depression-like behavior

Authors: *A. WILLIAMS, B. C. TRAINOR;
Psychology, Univ. of California Davis, Davis, CA

Abstract: Stressful experiences are a risk factor for the development of mood disorders such as depression and anxiety. Kappa opioid receptors (KOR) play an important role in mediating behavioral responses to stress and may represent a novel target for antidepressants. Social defeat activates KOR through the action of dynorphin, which in turn promotes aversion and depression-like behaviors. Previous research targeting KOR as a therapeutic option have focused on using long-acting antagonists such as norBNI. Although the use of these antagonists show promising antidepressant properties, the extremely long action of these compounds make them impractical for clinical use. Thus short-acting KOR antagonists may be a more viable option for the treatment of mood disorders. We examined the effect of the short-acting KOR antagonist AZ-MTAB on the development of depression-like phenotypes following social defeat stress in the monogamous California mouse (*Peromyscus californicus*). Mice underwent three episodes of

defeat or control conditions and were treated with either 10mg/kg dose of AZ-MTAB or vehicle prior to each episode. Autogrooming behavior was recorded immediately before the first and last episode of social defeat. Preliminary data indicate that AZ-MTAB immediately prior to defeat had short and long term effects. Mice exposed to defeat and vehicle showed significant increases in autogrooming behavior immediately prior to a third episode of defeat (indicating increased anxiety), and decreased sucrose preference two weeks after the last episode of defeat. Mice exposed to defeat and AZ-MTAB did not show these behavioral changes. These results show that temporary inhibition of KOR during stress blocks long lasting behavioral changes. Previous research shows that physiological effects of KOR differ between males and females, yet most of the research being done currently use only male rodents. We are currently repeating this experiment in female California mice to test for sex differences in behavior that may be mediated by KOR function.

Title: Reduced enkephalin signaling in the nucleus accumbens D2 - MSN circuit regulates depression-like phenotype in social defeat stress

Authors: *H. NAM, R. CHANDRA, T. C. FRANCIS, S. DAS, M. K. LOBO;
Dept. of Anat. and Neurobio., Univ. of Maryland, Baltimore, Baltimore, MD

Abstract: Enkephalins are primary endogenous ligands for delta opioid receptors (DORs) and are highly enriched in D2-medium spiny neurons (MSNs) in the nucleus accumbens (NAc) and dorsal striatum. Enkephalins are highly implicated in depression, as preproenkephalin knockout and DOR knockout mice display anxiety- and depression-like phenotypes. Further, enkephalinase inhibitors can act as antidepressants. However, the specific the role of enkephalins, selectively in the D2-MSN microcircuit in NAc - ventral pallidum (VP) pathway, in depression is not fully investigated. To provide insight into enkephalin function in this circuit we use an animal model of depression, the 10-day chronic social defeat stress paradigm. Following the defeat sessions, animals were either categorized as susceptible (displaying depression-like behavior) or resilient to social defeat stress according to their performance in a social interaction

test. Compared to the control and the resilient animals, the susceptible animals showed reduction in enkephalin levels in the VP. To determine if the reduced enkephalin levels cause depression-like behavior through disrupted Enk-DOR signaling, we treated the animals that experienced chronic social defeat stress with a DOR agonist SNC80. Preliminary studies demonstrate this treatment was able to reverse the depression-like conditions in susceptible animals. In order to investigate further into the mechanisms that reduce levels of enkephalins in the depressed conditions, we analyzed levels of different peptidases that can act as enkephalinases. Our qRT-PCR results demonstrate an increase in mRNA levels of peptidases angiotensin-converting enzyme (ACE) and analyl aminopeptidase (ANPEP) in susceptible animals compared to the controls, which may account for the decrease in enkephalin levels. Overall, our data implicate that depression-like behavior induced by social defeat stress is caused by reduced DOR signaling resulting from lowered level of enkephalins, which may be mediated through elevated expression of enkephalinases.

Title: Hippocampal α7 nAChR is a critical component for cholinergic regulation of anxiety and depression-like behaviors in C57BL/6J male and female mice.

Authors: ***T. MOSE**[1], Y. S. MINEUR[2], S. BLAKEMAN[2], S. A. NEWBOLD[2], M. R. PICCIOTTO[2], M. R. PICCIOTTO[2];
[1]Yale Univ., New Haven, CT; [2]Psychiatry, Yale Univ. Sch. of Med., New Haven, CT

Abstract: Evidence from pre-clinical and clinical studies has highlighted the link that exists between cholinergic signaling, anxiety and depression. We previously showed that blockade of

acetylcholinesterase (AChE; the enzyme responsible for hydrolyzing ACh) with physostigmine, can induce behaviors related to anxiety and depression in mice. This effect can be recapitulated by knocking down AChE only in the hippocampus and can be reversed by systemic injection of nicotinic antagonist and several partial agonists. Furthermore, knockdown of either the β2 or α7 subunit of the nicotinic acetylcholine receptor (nAChR) in the amygdala is sufficient to induce an antidepressant-like effect in mice. These results demonstrate that signaling at multiple nAChRs can mediate the effects of ACh on behaviors related to anxiety and depression. Previous studies have mainly focused on β2- and β4-containing nAChRs, and nicotinic compounds can also target α7 nAChRs. We therefore used more specific pharmacological agents to determine the contribution of α7 nAChRs to behaviors related to anxiety and depression. Administration of the α7 nAChR agonist GTS-21 increased anxiety-like behavior in male and female C57BL/6J mice in the light dark box, and increased immobility in the tail suspension and forced swim tests in male, but not female, mice. Conversely, the α7 nAChR antagonist methyllycaconitine (MLA) induced anxiolytic and antidepressant-like effects in male mice in the tail suspension and forced swim tests, but this effect was limited in female mice. Local knockdown of the α7 nAChR subunit in the hippocampus was confirmed by equilibrium binding using α-bungarotoxin, and was sufficient to prevent behavioral phenotypes induced by physostigmine in male and female mice. Interestingly, α7 nAChR knockdown in the hippocampus did not result in significant behavioral effects in the absence of pharmacological challenge. These results suggest that ACh can signal through α7 nAChRs in the hippocampus to regulate behaviors related to anxiety and depression. Further, these studies provide evidence for sex differences in signaling through these receptors that may be relevant for development of novel treatments for mood disorders.

Title: p11, a possible mood regulator, is essential for dopamine responses to reward in the nucleus accumbens.

Authors: *Y. HANADA[1], Y. KAWAHARA[1], Y. OHNISHI[1], T. SHUTO[1], M. KUROIWA[1], N. SOTOGAKU[1], Y. SAGI[2], P. GREENGARD[2], A. NISHI[1];

Abstract: p11, a member of the S100 protein family, regulates depression-like behaviors and responses to antidepressants. A recent study showed that the nucleus accumbens (NAc) is a key brain region of p11 action. Dopamine (DA) releasing neurons projecting to the NAc and prefrontal cortex (PFC) are responsible for aspects of reward- and cognition-related behaviors, respectively, and their functions are assumed to be impaired in depression. The present study investigated the role of p11 in the DA responses to rewarding stimuli. For this aim, the effects of rewarding stimuli (cocaine, palatable food and sexual interaction) on the extracellular DA levels in the NAc and PFC were evaluated in p11 knockout mice using in vivo microdialysis. All the rewarding stimuli induced an increase in DA levels in the NAc and PFC in wild-type mice. DA responses to rewarding stimuli in the NAc were attenuated (cocaine) or abolished (food and sexual interaction) in p11 knockout mice. DA responses in the PFC in p11 knockout mice were similar to those in wild-type mice. These results demonstrate that p11 is essential for the DA response in the NAc, but not in the PFC, to rewarding stimuli. The dysregulation of mesolimbic DA neurons might be involved in depression-like behaviors in p11 knockout mice.

Title: Depressive phenotype in N-acetylaspartate synthetase Shati/Nat8l-overexpressed mice

Authors: *Y. MIYAMOTO[1], K. FU[1], N. IEGAKI[1], K. SUMI[1], Y. FURUKAWA-HIBI[2], S.-I. MURAMATSU[3], T. NABESHIMA[4], K. UNO[1], A. NITTA[1];

Abstract: Both *N*-acetylaspartate (NAA) and *N*-acetylaspartylglutamate (NAAG) are present at high concentrations in mammalian brain, and are considered to serve for various neuronal actions. Recently, several reports demonstrated that the contents of those endogenous substances

alter in the postmortem brain of patients with mental disorders, such as depression and schizophrenia. We previously identified a molecule Shati/Nat8l, which is containing a well-conserved *N*-acetyltransferase sequence, from the brain of psychosis animal model. Shati/Nat8l synthesizes NAA from L-aspartate and acetyl-CoA, and NAA is subsequently condensed with glutamate to produce NAAG. In the present study, we investigated the roles of NAA and/or NAAG in depression-like behaviors using Shati/Nat8l-overexpressed mice. After exposing the forced swimming stress, the expression levels of Shati/Nat8l mRNA elevated in the dorsal striatum of wild-type mice. We therefore generated striatal Shati/Nat8l-overexpressed mice by microinjecting Shati/Nat8l gene-contained adeno-associated virus vectors into the dorsal striatum. The contents of NAA, but not NAAG, were elevated in the dorsal striatum of the Shati/Nat8l-overexpressed mice. On the other hand, the content ratio of NAAG/NAA was low, and the expression levels of NAAG synthetase were enhanced in the dorsal striatum of these mice compared with control mice. The Shati/Nat8l-overexpressed mice revealed prolonged immobility time in both the forced swimming and tail suspension tests. The Shati/Nat8l-overexpressed mice also exhibited decreased sociability in the three chambers social interaction test. These three emotional impairments in the Shati/Nat8l-overexpressed mice were ameliorated by treatment with antidepressant drug fluvoxamine, an inhibitor of selective serotonin reuptake. In addition, those emotional impairments were restored by treatment with LY341495, a potent antagonist of the group II metabotropic glutamate receptors including mGluR3 as the target of NAAG. These observations defined depressive phenotype in the Shati/Nat8l-overexpressed mice, suggesting that the NAA-NAAG-mGluR3 pathway regulated by Shati/Nat8l in the dorsal striatum serves for motivation and sociability via regulation of the serotonergic neuronal system.

Title: Transcriptional regulation of dendritic complexity mediates susceptibility to social stress

Authors: ***T. C. FRANCIS**[1], R. CHANDRA[1], P. KONKALMATT[2], L. M. RIGGS[1], A. SERAFINI[3], M. LOBO[1];

[1]Dept. of Anat. and Neurobio., Univ. of Maryland, Baltimore, Baltimore, MD; [2]George Washington Univ., Washington, DC; [3]Johns Hopkins Univ., Baltimore, MD

Abstract: The nucleus accumbens (NAc) integrates emotionally salient stimuli and is highly involved in behavioral deficits produced by chronic social defeat stress (CSDS). Current evidence suggests dopamine 1 (D1) receptor expressing medium spiny neurons (MSNs) of the NAc are central to these alterations. Previously, we established that repeated stimulation of D1-MSNs restores normal social interaction and sucrose preference in mice susceptible to CSDS. Using quantitative RT-PCR, we found this stimulation significantly reduces NAc expression of the transcription factor and neuronal plasticity regulator early growth response 3 (Egr3). Further, using transgenic D1-Cre mice crossed with RiboTag mice (D1-RiboTag) to isolate ribosome-associated mRNA specifically in D1-MSNs, we found increased Egr3 expression in mice susceptible to, but not resilient to CSDS. Egr3 expression remained unchanged in D2 receptor expressing MSNs. Cre-dependent adeno-associated virus (AAV) overexpression of Egr3 in the NAc of D1-Cre mice promoted susceptibility to subthreshold social defeat stress. In contrast, knock-down of Egr3 in D1-Cre mice utilizing a Cre-dependent AAV micro RNA (miR) construct promoted resilience to CSDS and prevented anhedonia outcomes. D1-MSNS of susceptible mice displayed reduction in frequency of mEPSCs, enhancement in intrinsic excitability and changes in dendritic arborization, an effect blocked by Egr3-miR mediated knockdown. These results suggest Egr3 regulates stress-induced dendritic morphology through structural molecules that regulate dendritic atrophy, such as RhoA. RhoA expression was significantly up-regulated in D1-MSNs of susceptible, but not resilient D1-RiboTag mice. Chromatin immunoprecipitation demonstrated enhanced Egr3 binding to the promoter of RhoA, revealing RhoA up-regulation is mediated by Egr3 in CSDS mice. RhoA inhibition by the specific inhibitor Rhosin, via systemic administration or specific infusion in to the NAc, blunted the behavioral and electrophysiological effects of CSDS. These results establish a novel role for social stress-induced transcriptional control of dendritic structure through Egr3 regulation of RhoA in NAc D1-MSNs.

Title: Anxiety and depression in Setdb1 histone H3K9 methyltransferase mutant mice

Authors: *Y. JIANG[1], E. LOH[2], B. KASSIM[1], I. MAGRO[1], B. JAVIDFAR[1], I. PURUSHOTHAMAN[2], L. SHEN[2], S. AKBARIAN[1];

Abstract: Histone methyltransferases specific for the histone H3-lysine 9 residue, including Setdb1 (Set domain, bifurcated 1)/Eset/Kmt1e are associated with repressive chromatin remodeling. Setdb1 is highly expressed in brain during early development and plays an important role in maintaining stem cell status, but potential effects on neuronal function and behavior remain largely unexplored. We previously reported that transgenic mice (*CK-Setdb1*) with increased Setdb1 expression in adult forebrain neurons show antidepressant-like phenotypes. Here, we explore Setdb1 in a loss-of-function model with conditional knockout mice. *Setdb1-CK-cKO* mice underwent ablation of Setdb1 specifically in CaMK II-alpha active postmitotic neurons. *Setdb1-CK-cKO* deficient mice, opposite to the behavioral phenotype previously reported for *CK-Setdb1* overexpressors, showed elevated level of anxiety and depression-like phenotype in multiple behavioral paradigms, including open filed, light dark and forced swim. Meanwhile, *Setdb1-CK-cKO* mice show decrease in brain weight, and cognitive deficits in radial-arm, object recognition and passive avoidance tests. To test whether such behaviors could be rescued by re-introducing Setdb1 to knockout neurons, we generated Setdb1-resuce mice by crossing *CK-setdb1* transgenic mice with *Setdb1-CK-cKO* mice. Strikingly, brain weight, anxiety, and depression-like phenotypes were fully reversed in Setdb1-rescue mice, indistinguishable from wildtype. Interestingly, *Setdb1-CK-cKO* brain showed loss of perforant path (PP) projection to hippocampus and additional subtle changes in connectivity. RNAseq from prefrontal cortex revealed differential transcriptome in *Setdb1-CK-cKO* as compare to littermate wildtype controls, showing 215 significantly unregulated and 106 downregulated genes (adjP<0.05). Experiments are in process to map epigenomic profiling in *Setdb1-CK-cKO* neurons using ChIPseq on FACS sorted neuronal nuclei from both native and fixed mouse cortical tissues. In conjunction with data from RNAseq, our goal is to identify a select set of target genes or functional genomic elements that contribute to the regulation affective and motivational behaviors through Setdb1-mediated repressive chromatin remodeling in mature brain.

Title: TNF-alpha antagonism restores deficits in neurogenesis and hippocampal and prefrontal cortex-dependent memory in an animal model of depression

Authors: *K. BRYMER[1], E. FENTON[1], H. J. CARUNCHO[2], L. E. KALYNCHUK[3];
[2]Pharm. and Nutr., [3]Med., [1]Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Chronic stress decreases neurogenesis within the hippocampus and impairs both hippocampal and prefrontal-cortex-dependent memory. Furthermore, chronic exposure to stress promotes the release of cytokines, which in turn exacerbate the stress response and disrupt cognition. Prominent among these is the cytokine TNF-alpha, which is preferentially expressed in the hippocampus and pre-frontal cortex. Importantly, the TNF-alpha antagonist etanercept is known to increase neurogenesis within the hippocampus. We hypothesized that treating chronically-stressed rats with etanercept could have antidepressant effects, and could reverse stress-induced deficits in cognition and neurogenesis. To test this hypothesis, we examined the effect of repeated corticosterone (CORT) treatment and concurrent TNF-alpha antagonism (i.e., with etanercept) on cross-modal memory and forced-swim test (FST) behavior. Additionally, we examined object-location and object-in-place memory--tasks that are dependent on the hippocampus and pre-frontal cortex, respectively. Finally, we examined hippocampal neurogenesis through doublecortin (DCX) immunohistochemistry. Rats received either 21 days of daily CORT injections (40 mg/kg) or vehicle injections. Rats also received semi-weekly injections of etanercept (0.8 mg/kg). Behavioral testing began on day 22. CORT increased depression-like behavior and impaired both object-location and object-in-place memory. Importantly, CORT rats treated with etanercept behaved like vehicle rats. CORT also decreased the number of DCX+ cells in the granule cell layer and dendritic complexity within surviving DCX+ cells, but etanercept restored both measures to control levels. These novel results clearly demonstrate that etanercept has antidepressant effects, which are accompanied by the restoration of normal levels of neurogenesis and both hippocampal-dependent and prefrontal-cortex-dependent memory. These results highlight an important role for the immune system in the pathogenesis of depression.

Abstract: Depression is a leading cause of disease burden, yet current therapies fully treat less than 50% of affected individuals. Increasing evidence implicates epigenetic mechanisms in depression and antidepressant action. Here, we examined a possible role for the DNA dioxygenase, ten eleven translocation protein 1 (TET1), in depression-related behavioral abnormalities. We show that chronic social defeat stress, an ethologically validated mouse model of depression, decreased *Tet1* expression in nucleus accumbens (NAc), a key brain reward region, in stress susceptible mice. Surprisingly, selective knockout of *Tet1* in NAc neurons of adult mice produced antidepressant-like effects in several behavioral assays. To identify *Tet1* targets that mediate these actions, we performed mRNAseq on NAc after conditional deletion of *Tet1* and found that immune-related genes are the most highly dysregulated. Interestingly, many of these genes are also upregulated in NAc of resilient mice after chronic social defeat stress. Together, these findings link *Tet1* to stress responses and identify novel targets for future antidepressant drug discovery efforts.

Title: Ablation of interferon inducible IFITM genes leads to anxiety- and depression- like behaviors

Authors: *S.-K. CHEN[1], W.-K. LIN[1], H.-C. CHANG[1], Y. WEE[3], P.-W. CHU[2];
[1]Inst. of Neurosci., [2]Dept. of Psychology, Natl. Chengchi Univ., Taipei, Taiwan; [3]Dept. of Pathology, Univ. of Utah, Salt Lake City, UT

Abstract: *Ifitm* genes are a group of interferon inducible genes. These genes are transcriptional activated upon interferon stimulation and play important roles in interferon meditated antiviral functions, including limiting viral entry and replication. However, the biochemical properties of these proteins are not fully understood. In addition to immune cell lineages, *Ifitm* genes are widely expressed in various tissues and cell type, including in central nervous system (CNS) in both embryonic stages and adult brains. Although the biological functions of these proteins besides immune system are still elusive, elevated IFITM proteins in schizophrenia patient brains, especially cerebral cortex, suggests a role of these proteins in modulating neural physiology. We recently revealed the behavioral abnormalities in *IfitmDel* mutants, in which 5 of the 6 *Ifitm* genes are deleted. These mutants exhibit anxiety- and depression- like phenotype in elevated plus maze and tail suspension test. The results of histological analyses, such as Nissl staining and immunohistochemical analysis of various neuron types, show no anatomical defects, detectable neuron count differences and morphological alterations of neurons in *IfitmDel* mutant brains, implying that these proteins are not crucial for the development of CNS. The expression levels of neuropeptides related to stress response and anxiety or depression status, such as corticotrophin releasing factor (CRF) and neuropeptide Y (NPY), are altered in mutant hypothalamus, suggesting hypothalamic influences on the behavioral phenotypes. Although no obvious differences in different types of neurons can be found, morphological changes of microglia and the trends of increased proinflammatory cytokines are detected in the hypothalamic regions in *IfitmDel* mutant brains, implying that hypothalamic inflammation and microglial activations might be involved in the abnormal behaviors. The cellular mechanisms underlying the behavioral phenotype induced by loss of IFITM proteins will be further determined in the future studies.

Title: Expression of inflammatory cytokine genes in the Disc1 mouse model of major mental illness

Authors: C. R. LAPSLEY[1], B. LANG[3], D. ST. CLAIR[3], C. MCCAIG[3], A. J. BJOURSON[1], *E. K. MURRAY[2];
[1]Northern Ireland Ctr. for Stratified Med., [2]Univ. of Ulster, L'Derry, United Kingdom; [3]Univ. of Aberdeen, Aberdeen, United Kingdom

Abstract: Disc1 is a balanced chromosomal translocation and a significant risk gene for major mental illness, including schizophrenia and depression. There is considerable overlap between the Disc1 interactome and the downstream signal transduction pathways involved in response to immune challenge, and a role for Disc1 as a mediator of neuro-immune interplay has been suggested. To date, the effect of mutations in the Disc1 gene on immune status has not been investigated. In the current study, we investigated the inflammatory profile in the brains and blood of adult wild type and Disc1tr mice to determine if baseline levels of immune markers altered in the Disc1tr mouse brain. Cortex and hippocampus samples were dissected from adult Disc1 mice (n=10 5M, 5F) and WT littermates (n=10 5M, 5F). Gene expression levels were then measured for four inflammatory genes (IL-6, TNF-a, INF-g and IL-1b) by qPCR using commercially available assays. Each cDNA sample was run in triplicate for each assay and relative gene expression was calculated using the ΔΔCT method. Cytokine levels will be examined using multiplex ELISA in hippocampus, cortex and blood. No significant effects of sex were detected in expression levels of any of the four inflammatory genes; data from males and females were therefore combined. No significant differences were detected in expression levels of any of the four genes in the hippocampus between wild type and Disc1tr mice. In the cortex, IL-1B, IL-6 and TNF-a were significantly decreased in Disc1tr compared to wild type mice ($p<0.05$). IFN-y expression was also lower in the cortex but this did not reach statistical significance. These findings suggest that baseline immune status in the brain is altered by the Disc1tr mutation. Future studies will examine the effect of immune challenge on cytokine expression levels in Disc1 and wild-type mice.

Title: Role of Heat shock protein 105 on depression-like behavior in mice

Authors: *Y. UTAKA, R. TANOUE, Y. MORITA, S. YAMAMOTO, N. HASHIKAWA-HOBARA, N. HASHIKAWA;
Okayama Univ. of Sci., Okayama-Shi, Japan

Abstract: Aim Changes in the Heat shock proteins (HSPs) are involved in neurological disease. However, the relationship between HSPs and depression-like behavior is still unclear. In the present study, we examined whether oral geranylgeranyl acetone (GGA), known as HSPs inducer, administration induced an anti-depressant effect in a social defeat stress model in mice. We also investigated the possible molecular mechanisms involved, particularly focusing on hippocampal neurogenesis and neurotrophic factor expression.
Methods C57B6/J male mice were submitted to social defeat stress for 15 consecutive days. Every day, each experimental mouse was introduced into the home cage of an aggressor male ICR mouse for 10 min, during which time the experimental animal was physically defeated. Following the 10 min defeat, each experimental mouse was separated from aggressor and placed across a plastic separator with holes, where they remained in sensory contact with the ICR aggressor for the remainder of the 24 hours. After the stress exposure, depression-like behaviors were assessed by the forced swim test, tail suspension test, social interaction test and sucrose preference test. *HSPs* (*Hsp60, 72, 90, 105*) and neurotrophic factor (*Bdnf*, *Cntf*, *Nt-3*, *Ngf*) mRNA levels in the hippocampus were analyzed by qRT-PCR. Furthermore, hippocampal neurogenesis was assessed by immunofluorescence staining using doublecortin antibody. Moreover, to clarify whether HSPs are involved in behavioral development, GGA (0.34%) was orally administered during stress exposure. In addition, to elucidate the effects of HSP105 knockdown on depression-like behavior, we injected *Hsp105*-siRNA into the mouse brain on day 1, 7 and 14 during 15-day stress exposure.
Results and Discussion After stress exposure, mice were exhibited depression-like behavior and decrease of *Hsp105* and *Bdnf* mRNA levels in the hippocampus when compared with control mice. GGA administration recovered the behavioral dysfunctions and hippocampal neurogenesis

and *Bdnf* mRNA level. Moreover, HSP105 knockdown inhibited the GGA-mediated anti-depressant effect. These results suggest that HSP105 in the mouse hippocampus is associated with depression-like behavior through hippocampal neurogenesis.

Abstract: Major depression is one of the most common mood disorder worldwide, being a serious public health problem in most countries. The biological study of depression has elucidated partly the development of this condition. Previous studies has been demonstrated that hippocampal neurons from depressive patients show a reduction in dendritic arborization and number of dendritic spines, nevertheless, the mechanisms responsible at the molecular level for these changes are still to be defined. $Ca_V1.2$ calcium channels are the principal pathway for calcium influx in neuronal soma, and have been associated to several cellular processes such as

changes in neuronal morphology, and excitation-transcriptional coupling. These processes involve changes in gene expression for at least three pathways: activation of Calmodulin, nuclear translocation of Nuclear Factor Activated T- cells (NFAT) and nuclear translocation of C-terminus region of the $Ca_V1.2$. Our working hypothesis is that changes in morphology and function in hippocampal neurons from animal models of depression are due to regulation in gene expression dependent on signaling through $Ca_V1.2$. In order to test this hypothesis we use chronic restraint stress (CRS) to generate a model of chronic stress-induced depression. Behavioral parameters such as anhedonia, change in social interaction and behavioral despair, demonstrate that these animals share characteristic of mayor depression, as has been reported for this model previously. By using electrophysiological and molecular biology techniques, we are currently studying changes in $Ca_V1.2$ calcium channel expression and subcellular localization that could be related to the described pathways that modulate gene expression. When comparing the expression level in control and CRS animals we have obtained a significant increase of $Ca_V1.2$ calcium channel in whole hippocampal samples and increase in expression of C-terminal region associated to the transcriptional factor. Our results support the idea that $Ca_V1.2$ is a key player in the development of depression in an animal.

Title: Neural cell adhesion molecule peptide mimetics modulate affective behavior

Authors: *C. A. TURNER[1], S. J. WATSON, Jr.[2], H. AKIL[2];
[1]Molec & Behav Neurosci Inst., [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Recent studies have highlighted the importance of the fibroblast growth factor (FGF) family in modulating emotionality. Moreover, ligands that activate FGF receptors, such as FGF2, have antidepressant and anxiolytic effects in animal models. Neural cell adhesion molecule (NCAM) is also known to bind to and activate FGF receptors. Therefore, this study assessed the ability of NCAM peptide mimetics to modulate anxiety-like and depression-like behavior in rodents. Anxiety-like behavior was measured on the elevated plus-maze and depression-like behavior was measured on the forced swim test. Specifically, we assessed the acute and chronic effects of three different NCAM peptide mimetics that have previously been shown to have effects on learning and memory in rodents. One peptide increased anxiety-like behavior in the EPM acutely. Chronically, it decreased depression-like behavior in the FST. The second peptide decreased depression-like behavior both acutely and chronically. The third peptide increased anxiety-like behavior acutely. Chronically, it decreased anxiety-like behavior. These findings lend support for the idea that NCAM peptides can modulate emotionality in animal models. Moreover, some peptides may be more beneficial in treating major depressive disorder, whereas others may be more beneficial in treating anxiety disorders.

Title: siRNA-mediated suppression of astroglial glutamate transporters GLT-1 and GLAST in infralimbic, but not prelimbic cortex, induces depressive-like behaviors in mice

Authors: N. FULLANA[1,2,3], A. FERRÉS-COY[1,2,3], E. RUIZ-BRONCHAL[3,1,2], A. BORTOLOZZI[3,1,2], *F. ARTIGAS[1,2,3];

Abstract: Major depression has been associated with alterations of the monoaminergic systems. However, recent evidence suggests that dysregulations of glutamatergic neurotransmission in the prefrontal cortex (PFC) are involved in the pathophysiology of depression. Previous studies showed that astrocytic glutamate transporter, GLT-1, blockade induces anhedonia, impaired memory and *c-fos* expression in rat PFC. Given the role of ventral cingulate areas in mood regulation, we hypothesized that reduced expression of GLAST and GLT-1 in the infralimbic cortex (IL) would induce depressive-like behaviors in mice due to dysfunctional glutamatergic neurotransmission. We knocked-down the expression of GLAST and GLT-1 to evoke an increase of excitatory neurotransmission in IL cortex. We microinjected small interfering RNA (siRNA) targeting GLAST or GLT-1 unilaterally into prelimbic (PrL) or IL cortices of mice and examined cellular and behavioral effects. Moreover, the extracellular levels of 5-HT in dorsal raphe nucleus (DRN) were determined by *in vivo* microdialysis. Local unilateral GLAST-siRNA microinfusion in the mouse IL (4.2 nmol) reduced selectively GLAST mRNA and protein levels to ~80% of control mice. GLAST knockdown mice exhibited depressive-like behaviors in the tail suspension test (TST, 125% of controls) and in the forced swim test (FST, 128% of controls) and anhedonia in the sucrose of preference test (SPT, 50% of controls). Likewise, intra-IL infusion of GLT-1-siRNA (4.2 nmol) reduced GLT-1 expression (~70% of controls), increased immobility time also in the TST (130% of controls) and in FST (118% of controls) and reduced preference for sucrose in SPT (56% of controls). In contrast, reduced GLAST or GLT-1 expression in the PrL cortex did not affect behavioral responses to stress. Moreover, GLAST- and GLT-1-siRNA administered animals showed a reduction in baseline 5-HT extracellular levels in the DRN (49% of controls), even if the responsiveness of the neurons to veratridine was not altered. The present results suggest that astroglial regulation of excitatory neurotransmission in the IL cortex plays a major role in mood control. GLAST and GLT-1 down-regulation impairs the normal clearance of synaptically released glutamate. Given the reciprocal connectivity between the ventral PFC and many cortical and subcortical areas, an increased excitatory function in IL likely translates into downstream alterations of other brain areas involved in major depression, such as the monoamine nuclei. Overall, these findings improve our understanding of the pathophysiology of major depression, and help to identify novel targets in antidepressant drug development.

Title: A cell-type specific role for nucleus accumbens neuroligin-2 in depression and stress susceptibility

Authors: *M. HESHMATI[1], H. ALEYASIN[1], C. MENARD[1], M. E. FLANIGAN[1], M. L. PFAU[1], P. H. GOFF[1], G. E. HODES[1], A. TAKAHASHI[1], A. LEPACK[1], L. BICKS[1], D. J. CHRISTOFFEL[2], R. Abstract: Neuroligin-2 (NLGN-2) is a postsynaptic cell adhesion protein that plays an integral role in the inhibitory synapse. Mutations in the neuroligin gene family have been associated with neuropsychiatric disorders like autism and schizophrenia; however, relatively little is known about NLGN-2. Transcriptional profiling of the neuroligin gene family in postmortem nucleus accumbens (NAc) of patients with major depressive disorder revealed a decrease in NLGN-2. Reverse translation of these findings in the chronic social defeat stress model in mice supported an overall decrease in NAc NLGN-2 in mice that are susceptible to stress. A cell-type specific analysis of NLGN-2 transcription in D1 receptor-positive (D1-MSNs) compared to D2 receptor-positive cells (D2-MSNs) revealed that NLGN-2 mRNA is reduced selectively in D1-MSNs of stress susceptible mice.
To further explore the cell-type specific contribution of NAc NLGN-2 to stress resiliency and coping behavior, we used a Cre-conditional RNA interference approach to knockdown NLGN-2 in either D1-MSNs or D2-MSNs of transgenic mice. Cell-type specific knockdown of NLGN-2 in NAc D1-MSNs results in decreased dominance behavior and promotes susceptibility to social defeat stress. NLGN-2 knockdown in NAc D2-MSNs causes anxiolysis, increased dominance behavior, and the engagement of coping strategies to mediate increased stress resiliency. Overall, we demonstrate a unique role for NAc NLGN-2 in major depressive disorder and the engagement of behavioral strategies to promote dominance and active stress resiliency. These findings establish a novel role for NAc NLGN-2 in stress susceptibility, providing a molecular basis for the development of cell-type specific depression therapies.

Title: Effects of norbinaltorphimine (nor-BNI) on depressive-like and habit formation behavior in the IFN-α-induced depression model

Authors: ***J. ROUINE**, C. K. CALLAGHAN, S. M. O'MARA;
Psychology, Trinity Col. Inst. of Neurosci., Dublin 2, Ireland

Abstract: Depression is a heterogeneous condition that affects approximately 350 million people worldwide. Current research is focussing on the development of novel antidepressant compounds with differing mechanisms of action to standard tricyclic or selective reuptake inhibitors. Kappa opioid receptor (KOR) antagonism has been reported to have antidepressant-like properties. The current study examined the effects of norbinaltorphimine (nor-BNI), a potent KOR antagonist, in a progressive ratio schedule and forced swim test (FST) in an IFN-α-induced depression model. Male Wistar rats (3mth, 350-400g, n=8 per group) were injected with recombinant human IFN-α (170,000 IU s.c., 3 times per week for 4 weeks). nor-BNI (10 mg/kg, s.c.) was tested in the progressive ratio schedule of reinforcement (operant responses required to dispense a sucrose pellet reward) at 30 min and 24 h. nor-BNI was tested in the FST, a measure of behavioral despair, at 24 h. The effects of acute administration of nor-BNI were measured on brain-derived neurotrophic factor (BDNF) levels in prefrontal cortex, hippocampus and nucleus accumbens. IFN-α treatment increased breaking point (maximum responses per reinforcement), while reducing nose-pokes in the progressive ratio schedule compared to saline treated controls, indicating habitual lever pressing behavior, and not goal-directed behavior, in this cohort. Immobility score in the FST was increased following IFN-α treatment in comparison to saline treated controls. nor-BNI administration reduced breaking point in IFN-α treated animals when tested at 24 h compared to saline treated controls. nor-BNI administration significantly reduced immobility score in IFN-α treated animals compared to saline treated controls, without affecting

locomotor activity. nor-BNI prevented IFN-α-induced reductions in BDNF levels in prefrontal cortex, hippocampus and nucleus accumbens. These data indicate kappa opioid receptors mediate, at least in-part, depressive-like behavior in the IFN-α-induced depression model and provide more evidence that KOR antagonists could potentially be used as novel antidepressants.

Title: Dissecting the contribution of intracellular estrogen receptor subtypes to chronic stress resilience in female mice

Authors: *R. MAHMOUD, J. A. CHAITON, C. CHOW, S. E. LIEBLICH, L. A. M. GALEA; Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Chronic stress has profound effects on the brain, is intimately linked to the development of cognitive deficits, and is associated with an increased vulnerability for neuropsychiatric disorders such as depression and anxiety. Prior research indicates that females may be more resilient to some of the deleterious effects of chronic stress, and that estradiol may at least partially afford this resilience. However, the molecular mechanisms through which estradiol may impart resilience against chronic stress are poorly understood, in part due to the complexity of estradiol signaling. The aim of this study was to investigate the contribution of estrogen receptor (ER) subtypes to estradiol-mediated resiliency, using the Chronic Unpredictable Stress (CUS) rodent model. Adult female mice (C57BL/6) were ovariectomized or sham operated, and chronically treated with the ERα-selective agonist propylpyrazole-triol (PPT), ERβ-selective agonist diarylpropionitrile (DPN), estradiol (E2), or vehicle (Oil). Mice from each treatment group were assigned to CUS or non-CUS conditions. All mice were assessed for depressive- and anxiety-like behaviour (forced swim test, tail suspension test, sucrose preference test, and novelty suppressed feeding), hippocampal neurogenesis, neuroinflammatory markers (cytokine levels and microglial activation), and neuroendocrine function (dexamethasone suppression test). Preliminary results suggest that the ERβ-selective agonist DPN may alleviate depressive-like behaviour in the tail suspension test. Thus, estrogen

receptor subtypes may differentially modulate the effects of estradiol in the context of chronic stress, shedding light on the potential cellular mechanisms of estradiol-mediated stress resilience.

Title: Esr1 is an upstream regulator of pro-resilient transcriptional changes in mouse models of depression

Authors: *Z. S. LORSCH, R. BAGOT, I. PURUSHOTHAMAN, D. WALKER, O. ISSLER, B. LABONTÉ, H. KRONMAN, P. J. HAMILTON, C. J. PEÑA, M. E. CAHILL, L. SHEN, E. J. NESTLER;
Neurosci. and Friedman Brain Inst., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Numerous studies have identified wide-ranging transcriptional changes associated with Major Depressive Disorder in humans and depression-like behavior in animal models. However, analysis of the mechanisms by which these multiple transcriptional changes occur has been limited. In this study, we performed upstream regulator analysis on RNA sequencing data from male mice following ten days of Chronic Social Defeat Stress (CSDS). We identified Esr1 as one of the strongest predicted upstream regulators of pro-resilient transcriptional changes in the nucleus accumbens (NAc). Accordingly, we found that Esr1 mRNA levels were decreased in the NAc of susceptible, but not resilient, mice. Esr1, which encodes the nuclear estrogen receptor-alpha, has been shown to play a role in development of the dopaminergic reward system but its specific involvement in depression is unknown. To test the putative role of Esr1 in depression, we overexpressed Esr1 in the NAc and exposed mice to established stress paradigms. Overexpression of Esr1 reduced depression-like behavior in both male and female mice. Further,

overexpression of Esr1 was associated with unique transcriptional changes in both stressed mice and unstressed controls. As a whole, these findings suggest that Esr1 is an upstream regulator of pro-resilient transcriptional changes in the NAc with significant implications for depression-like behavior.

Title: Loss of SIRT1 in hippocampal and cortical glutamatergic neurons leads to depressive-like behaviors and hypoexcitability of pyramidal neurons

Authors: *Y. LEI, J. J. YOU, J. G. WANG, X. Y. LU;
Dept. of Pharmacol., UT Hlth. Sci. Ctr. At San Antonio, San Antonio, TX

Abstract: SIRT1 is a key regulator of cellular metabolism. It has been recently identified as a genetic marker linked to major depressive disorder. However, the underlying neural mechanisms are largely unknown. In this study, we investigated the effects of SIRT1 in forebrain glutamatergic neurons on depression-related behaviors. Both male and female mice lacking SIRT1 in hippocampal and cortical glutamatergic neurons showed normal growth and locomotor activity. Male SIRT1 conditional knockout mice displayed behavioral despair in the forced swim test and anhedonia in the saccharin preference test without affecting anxiety behavior. In contrast, female SIRT1 conditional knockout mice didn't exhibit significant behavioral phenotype in the same behavioral tests. Whole-cell patch-clamp recordings were made from layer V pyramidal neurons located in the prelimbic and infralimbic areas of the medial prefrontal cortex (mPFC) and CA1 pyramidal neurons in the ventral hippocampus. We found that intrinsic excitability of pyramidal neurons were decreased in a region-specific manner in SIRT1 conditional knockout mice. These results suggest that SIRT1 in mPFC and hippocampal

glutamatergic neurons is involved in the modulation of depressive-like behaviors and is essential for normal neuronal excitability.

Title: Cell-type specific actions of SIRT1 in the nucleus accumbens mediate depression-like behaviors

Authors: ***H.-D. KIM**, J. HESTERMAN, T. CALL, S. CAROTENUTO, K. ARMENTA, D. FERGUSON;
Basic Med. Sci., The Univ. of Arizona Col. of Med., Phoenix, AZ

Abstract: Major depressive disorder (MDD) is a leading cause of disability and 20% of individuals will suffer from a major onset of clinical depression during their lifetime. The nucleus accumbens (NAc), a key region in the reward circuitry, integrates rewarding and aversive information from various brain regions, thus the NAc is thought to contribute to the pathophysiology and symptomatology of depression. A majority of the neurons in the NAc are GABAergic medium spiny neurons (MSNs) which are primarily composed of two subtypes enriched with dopaminergic D1- or D2-type receptors, but the distinct roles of these two populations in depression are still elusive. Recently, it has been demonstrated that *Sirt1*, a well-characterized deacetylase, is involved in addiction and depression-like symptoms and that *Sirt1* expression is increased in the NAc of depressed (susceptible) mice. To dissect cell-type specific functions of SIRT1 in the NAc, we used chronic social defeat stress to model depression, combined with a Cre-inducible viral vector system and SIRT1 conditional knock-out mice. We found that selective modulation of *Sirt1* expression in a specific subtype of MSNs differentially regulates anxiety- and depression-like behaviors. Indeed, overexpression of *Sirt1* in D1-MSNs, but not in D2, significantly promotes depression-like behaviors. Electrophysiological recordings also demonstrate that SIRT1 differentially modulates neurophysiological response of the MSNs subpopulations in the NAc. Based on our morphological analysis and cell-type specific transcriptomics using RiboTag mice, we believe that changes in neuronal structure and *Sirt1* downstream gene signaling network might be involved in this modulation mechanisms. Taken

together, we demonstrate that *Sirt1* signaling differentially regulates depression-like behaviors in a cell-type specific manner, implicating a novel candidate therapeutic target for antidepressants.

Title: TonEBP regulates psychotomimetic behaviors of mice through modulating brain dopaminergic neurotransmission

Authors: *S. KIM[1], H. PARK[2], S. PARK[1], Y. KIM[1], H. KWON[3];
[1]Dongguk Univ. Intl. Hosp., Ilsandong-Gu, Goyang-Si, Gyeonggi-Do, Korea, Republic of; [2]Seoul Natl. Univesity, Seoul, Korea, Republic of; [3]Ulsan Natl. Inst. of Sci. and Technol., Ulsan, Korea, Republic of

Abstract: Tonicity enhancer element binding protein (TonEBP), also known as nuclear factor of activated T-cells 5 (NFAT5), is the osmosensitive transcription factor, which plays a crucial role in protection of renal medullary cells against hyperosmotic stress, urinary concentration, the adaptive immune response. TonEBP is expressed abundantly in the brain, while the functions in nervous systems have not been understood yet. We examined the role of TonEBP on the behaviors in terms of mood and psychotomimetic domains and the behavios-related regulatory mechanisms. TonEBP heterozygote (+/-) mice did not show significant differences compared to wild type (WT) mice in forced swim test, sucrose preference test, and open field activity. When chronic unpredictable stress (CUS) has been applied, WT mice demonstrated depression-like behavioral phenotypes, while TonEBP (+/-) mice showed attenuated response to CUS compared to WT. The reponse to cocaine injection was also in TonEBP (+/-) mice compared to WT. While overexpression of TonEBP gene in mice striatum using adenovirus iuduced the increased behavioral response to cocaine. The dopamine level was reduced in the striatum of TonEBP (+/-) mice compare to WT. TonEBP gene knockdown using siRNA showed reduced expression of dopamine decarboxylase and tyrosine hydroxylase genes. The findings suggest the important role of TonEBP gene in dopamine neurotransmission and related psychotomimetic behaviors in the brain.

Abstract: Depression is a recurring and life threatening illness that affects up to 120 million people worldwide. In the present study we show that chronic social defeat stress, an ethologically validated model of depression in mice, increases SIRT1 levels in the nucleus accumbens (NAc), a key brain reward region. Increases in SIRT,1 a well-characterized class III histone deacetylase, after chronic social defeat suggest a role for this enzyme in mediating depression-like behaviors. When resveratrol, a pharmacological activator of SIRT1, was directly infused bilaterally into the NAc, we observed an increase in depression- and anxiety-like behaviors. Conversely, intra-NAc infusions of EX-527, a SIRT1 antagonist, reduced these behaviors; EX-527 also reduced despair-like behaviors in stress-naïve mice. Next, we directly increased SIRT1 levels in the NAc by use of viral-mediated gene transfer and observed an increase in depressive- and anxiety-like behaviors when mice were assessed in the open field, elevated plus maze, and forced swim tests. Using a Cre-inducible viral vector system to selectively overexpress SIRT1 in dopamine D1 or D2 subpopulations of medium spiny neurons (MSNs) in the NAc, we found that SIRT1 promotes depressive-like behaviors only when overexpressed in D1 MSNs, with no effect seen in D2 MSNs. Conversely, selective ablation of SIRT1 in the NAc, using viral-Cre in floxed *Sirt1* mice, resulted in decreased depression- and anxiety-like behaviors. Together, these results demonstrate that SIRT1 plays an essential role in the NAc in regulating mood-related behavioral abnormalities and identifies a novel-signaling pathway for the development of innovative antidepressants to treat major depressive disorders.

Title: Role of pde1b in depressive-like behavior: a mouse model

Authors: *J. R. HUFGARD[1], M. T. WILLIAMS[2], C. V. VORHEES[2];
[1]Univ. of Cincinnati Med. Ctr., Cincinnati, OH; [2]Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: Depression is one of the most prevalent mental disorders, yet the underlying mechanism remains unknown and current treatments are frequently ineffective. Secondary messengers, such as cAMP and cGMP, are implicated in depression and schizophrenia and are regulated by phosphodiesterases (PDE). There are 11 PDE families each with multiple isoforms. PDE4 inhibitors were efficacious for depression but had excessive side effects. Many of the other isoforms have never been explored for their role in neuropsychiatric disorders. PDE1b is highly expressed in the striatum and hippocampus, regions linked to depression, therefore, we created a Pde1b floxed mouse and bred it to a cytomegalovirus cre line mouse to make a global knockout (KO) mouse. This mouse shows a phenotype that is resistant to the induction of depressive-like behaviors in both the tail suspension test (TST) and the forced swim tests (FST). Immunohistochemistry for RNA and protein has shown that Pde1b is localized to post-synaptic serotonin and dopamine positive cells in the striatum and hippocampus. The cell specificity for the PDE1b phenotype was further explored using pre- and postsynaptic serotonin and dopamine Cre drivers to create serotonin transporter (SERT), dopamine transporter (DAT), and dopamine receptor 1a (Drd1a) specific Pde1b KO animals. The resistance to depressive phenotype was not observed in either the SERT or DAT KO animals; the Drd1a KO mice are being tested. To further explore the mechanism of Pde1b we are using D1 agonists and antagonists directly targeted to the striatum in conjunction to determine the regional specificity of the phenotype. FST and TST are the behavioral readouts along with and changes in cAMP, cGMP, and PKA. (Supported by NIH T32 ES07051)

Title: Morc1, a gene associated with early-life stress and depression, in the rodent brain.

Authors: *N. B. FREUND, A. MUNDORF, D. BEYER;
Universitaetsklinikum Tuebingen, Tuebingen, Germany

Abstract: Recent studies point to an important role of the MORC family CW-type zinc finger 1 (MORC1)-gene in early life stress and depression. A multidimensional, cross-species, epigenetic study revealed MORC1 DNA hypomethylation following early life stress[1]. MORC1 was also significantly associated with major depressive disorder in a gene-based association analysis[1]. This relation of MORC1 and depression was furthermore confirmed in an animal model[2]. Mice with a functional knock-out of MORC1 demonstrated a depressive-like phenotype in several behavioral tests[2]. Despite this clear evidence for a neurobiological function of MORC1, little is known about its function. MORC1 is involved in spermatogenesis and was found in cancer tissue, but its role in the brain is still unknown. In a first step to reveal the neurobiological influence of MORC1 on stress and depression, we started characterizing MORC1 in the rodent brain. Immunohistochemical staining revealed the distribution of MORC1 protein in motoric and somatosentoric areas but also regions involved in mood regulation like nucleus accumbens, hippocampus and amygdala. Quantitative PCR furthermore detected MORC1 mRNA in the medial prefrontal cortex, dorsal raphe nucleus and hippocampus. The distribution within the brain and its structure[3] indicate that MORC1 plays an important role in mood regulation by influencing transcription rates within mood pathways. This ability puts this gene in a position to predispose the brain for the development of major depressive disorder as a result of early life stress. A better understanding of this relationship between stress and MORC1 will improve our general understanding of the connection between stress and the development of major depressive disorder.

Title: Susceptibility and resilience to the effects of prolonged social defeat in adolescent male mice: a study of neuronal nitric oxide synthase

Authors: *S. CHIAVEGATTO, L. S. RESENDE, M. N. MUSCARA, S. A. TEIXEIRA, M. R. ARAUJO, P. E. N. S. VASCONCELOS, J. F. S. CARRILLO;
Biomed. Sci. Inst. - Univ. of Sao Paulo, Sao Paulo, Brazil

Abstract: The brain does not reach full maturity until adulthood making adolescents especially vulnerable to the effects of stressors. Exposure to bullying is a risk factor for major depression (MD), however, it is unclear why some individuals are more susceptible than others. Nitric oxide (NO), an important neurotransmitter in the SNC, is mainly synthetized by the neuronal NO synthase (nNOS). Recent studies have shown that paroxetine, a selective serotonin reuptake inhibitor, also inhibits nNOS implicating the NO in the pathophysiology of MD.Thus, our objective was to investigate the effects of chronic social defeat stress (SD) on emotional behaviors, on nNOS protein and gene expression in distinct brain areas, and on systemic metabolism of NO in adolescent male mice. C57BL/6 (30 day-old) were subjected to daily bouts of SD with an aggressive adult male CD-1 mouse for 10 days. Control mice were exposed to the same situation without the aggressive encounter. Twenty-four hours after the last defeat episode, mice were evaluated in the social interaction and sucrose preference (SP) tests. Approximately 60% of adolescents displayed social avoidance ($p<0.0001$) and reduced SP (anhedonia) ($p<0.001$; “susceptible”). The remaining 40% were similar to control group ($p>0.05$; “resilient”). Brain tissues [hippocampus (HC), prefrontal cortex (PFC), dorsal striatum (DS)] and trunk blood were collected for molecular and biochemical analyses. Western blot and RNA-seq tests showed an increase of nNOS protein levels ($p<0.05$) and mRNA ($p<0.01$, FDR=0.06), respectively, in the HC of susceptible mice. In the PFC and DS, no alterations were found ($p>0.05$). Additionally, resilient mice showed increased serum levels of total nitrite and nitrate (NOx) ($p<0.05$). Our data suggest that prolonged psychosocial stress induces depressive and anxiety like-behaviors in adolescent male mice. Moreover, susceptibility to depression, but not resilience, is associated with increase of nNOS gene and protein expression selectively in the HC. Our data indicate an interesting association between hippocampal nNOS and NO systemic metabolism with vulnerability and resilience to depression post-bullying in male adolescents.

Title: Social interaction rescued abnormal mood and attention behaviors caused by acute stress in adolescent mice through ERK1/2 modulation

Authors: ***J.-W. KIM**, M. KO, E. L. GONZALES;
Konkuk Univ., Seoul, Korea, Republic of

Abstract: Multiple stressors are intertwined with work, school and living conditions. Finding reasonable strategy to cope up with stresses has become an important issue to the current society. In the present study, we evaluated the stress-buffering effect of social interactions on a molecular signal related to abnormal behaviors induced by an hour of acute restraint stress in adolescent ICR mice. Interestingly, one hour of restraint stress induced the activation of ERK1/2, which was reduced in the stress group subjected to social interaction with conspecific mice. We also examined the effects of social interaction on behavioral changes induced by restraint stress, assessed through forced swimming test, and Y-maze test. The abnormal behaviors in the stress group were normalized by the addition of social interaction with conspecific mice. To specify the roles of ERK1/2 in these stress-induced abnormal behaviors, we investigated stress-induced behaviors and ERK1/2 level in prefrontal cortex using brain-penetrant ERK1/2 inhibitor, SL327. Fascinatingly, this ERK1/2 inhibitor rescued abnormal attention behavior and mood behavior. These results suggest that social interactions could alleviate the acute restraint stress-induced behavioral abnormalities in mice, as well as the overt ERK1/2 activation in the medial prefrontal cortex. Moreover, ERK1/2 might be an important target in social buffering effects against stress.

Title: Repetitive transcranial magnetic stimulation (rTMS) side effect characterization for treatment resistant depression. Non-inferiority rTMS trial

Authors: *C. DOBEK[1], J. THAM[1], C. NORTHCOTT[1], J. DOWNAR[2], Z. J. DASKALAKIS[3], A. DIPINTO[1], R. W. LAM[1], D. M. BLUMBERGER[3], F. VILA-RODRIGUEZ[1];
[1]Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada; [2]Psychiatry, Univ. Hlth. Network, Toronto, ON, Canada; [3]Psychiatry, Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

Abstract: Introduction rTMS is a non-invasive neurostimulation treatment used for Treatment Resistant Depression (TRD). Conventional 10 Hz treatment (HFL) takes 37 minutes to administer, however a newer 50 Hz intermittent theta burst stimulation (iTBS) takes 3 minutes. This pilot study compares the two excitatory protocols targeting the Left DLPFC, to determine if iTBS is just as effective, and has no difference in the tolerability and safety profile compared to HFL. This study provides an in depth characterization and accurate timing depiction of the side effect profiles for both treatments on a daily basis.**Method** 20 TRD patients were medically screened for history of seizures, neurological insult, among other exclusion criteria prior to entry. Participants received 20-30 treatment sessions and were randomly selected to receive either treatment course. Before each treatment, technicians inquired about hours of sleep, alcohol/substance use, and medications as additional screening for seizure risk factors. Technicians also systematically recorded side effects and adverse events (AE) reported.A daily questionnaire of the following 10-items (pain, tingling, burning, fatigue, nervousness, headache, disturbed visual perception/ sleep/ concentration, visual flash) was completed 1) immediately post-treatment and 2) emailed home to be completed before the next treatment. **Results** Out of 541 treatments, common side effects include headache (5.2%) and fatigue (0.74%) with majority reporting mild severity. Of 20 participants, 12 reported at least 1 incidence of headache, fatigue (3), or sleep issues (3). Only 2.4% of treatments required an analgesic for headache. Side effects were reported more frequently within the first 10 treatments with a steady decrease over time, and were comparable between treatment conditions. Most side effects reported were self-limited and lasted < 24hrs.Both treatment conditions have similar side effect and AE reporting trajectories with HFL treatment reporting slightly higher rates of disturbed concentration, fatigue, and nervousness (1-2.5 points out of 9 point likert scale). No treatment-related serious

AE or seizure was reported during either treatment. **Conclusion** If iTBS treatment is as effective and safe as the HFL, it will drastically reduce treatment time, increase rTMS clinic capacity, and significantly reduce associated cost. A more cost-effective treatment option is a compelling argument to include rTMS in health insurance coverage. A thorough medical screening process in combination with a standardized pre-treatment risk assessment for rTMS-induced seizures may decrease the risk of seizures and other side effects.

Title: Magnetic seizure therapy in geriatric depression: neurophysiological characteristics

Authors: *M. LY[1], S. B. ROWNY[2], L. CASAL-ROSCUM[2], J. GOWATSKY[2], P. SEHATPOUR[2], J. PRUDIC[3], D. C. JAVITT[2], C.-M. A. CHEN[1];
[1]Dept. of Psychological Sci., Univ. of Connecticut, Storrs, CT; [2]Div. of Exptl. Therapeutics, Dept. of Psychiatry, [3]Dept. of Psychiatry, Columbia Univ. Med. Ctr., New York, NY

Abstract: Magnetic seizure therapy (MST) is under development as an alternative to conventional electroconvulsive therapy (ECT) for the treatment of severe depression. ECT has long been established as an efficacious treatment for severe depression, but is known for its adverse cognitive effects. Both its efficacy and side effects are influenced by the site of seizure induction and the extent of stimulation, which are difficult to control. MST uses high frequency repetitive transcranial magnetic stimulation (rTMS) to induce seizures, offering better control over the spatial distribution of stimulation and reduced side effects. The neurophysiological characteristics of MST have been studied with two-channel electroencephalogram (EEG) in non-human primates, where the ictal period showed significantly greater power than the two subsequent post-ictal periods for four frequency bands (delta, theta, alpha, beta). Our ongoing trial of MST uses 64-channel EEG recordings of geriatric patients with severe depression who received treatment three times per week for six to 18 sessions. EEG recordings were collected during and immediately after the ictal period for the second and penultimate treatment sessions. Power within delta, theta, alpha, beta, and gamma frequency bands was calculated for ten frontal channels. Preliminary results are consistent with past research in non-human primates. Global power was higher during the ictal period compared to both of the post-ictal periods. This pattern was significant within the theta, alpha, beta, and gamma frequency bands but not for delta, as delta power was highly variable across sessions. Preliminary results also suggest a difference in response over the course of MST treatment, where all frequency bands showed increased power during the ictal period of the penultimate session compared to the second treatment session. To date, this is the first simultaneous high-density EEG-MST study in humans. Our findings of the neurophysiological characteristics of the seizures induced by MST provide insight into mechanisms by which MST may be a safer and more favorable treatment for severe depression in geriatric patients.

Title: Improved outcomes in treatment-resistant depression with concurrent rTMS and CBT

Authors: *A. D. SNYDER, M. SPIVEY, C. BLEDOWSKI, A. PANDURANGI;
Dept. of Psychiatry, Virginia Commonwealth Univ., Richmond, VA

Abstract: The STAR*D trial demonstrated that only about half of patients suffering from depression are expected to remit entirely with adherence to medication. While perhaps more effective, electroconvulsive therapy (ECT) is not as well-tolerated as repetitive transcranial magnetic stimulation (rTMS). Though cognitive behavioral therapy (CBT) has been demonstrated an effective adjunct therapy with medication, relatively few data have been published on the effectiveness of concurrent rTMS and CBT. The present study investigates the viability this combination.Only patients with treatment-resistant unipolar depression who had failed 4 or more different antidepressant medications were recruited for this open label adjunct TMS study. At this time, 49 patients (35 female, 14 male; 44 Caucasian, 4 African American, 1 Hispanic) were recruited for the study; 34 patients participated in the full 9-week course of 36 rTMS sessions. CBT was offered to all and administered for the vast majority of patients. MADRS, HAM-D, and PHQ-9 scores were recorded during each week as well as during a final follow-up visit 2-4 weeks later. Mental status examination was conducted during each visit. CBT and rTMS treatment modalities were administered by the same mental health nurse practitioner. A Neuronetics NeuroStar TMS machine was utilized to administer left prefrontal rTMS. CBT methods included introduction of the cognitive model, psychoeducation, identification of cognitive distortions and core beliefs, and assistance with dysfunctional thought record worksheets. Preliminary analyses were conducted with Microsoft Excel. Depression scale scores with improvement of < 50% were recorded as “no response”; 50-60% as “response”; and > 60% as “remission.” When results were normalized to the number of participants who successfully followed-up, 26 patients (~75%) were responders and 8 (~25%) were non-responders. Of the responders, 14 patients (42%) demonstrated remission, 12 (34%) met criteria for response only. Since the non-CBT group is small, formal statistics have not been conducted at this time. Limitations of this study include that it is a retrospective analysis of an open-label clinical

treatment sample and there was variability in the length of time that CBT was administered during each treatment session. However, when compared with other results in the literature, which shows average remission/response rates in the 20-30/40-50% range, rTMS + CBT appears to demonstrate greater efficacy than rTMS or CBT alone. Also, this combination therapy may demonstrate efficacy similar to ECT with higher tolerability. Ongoing side-by-side comparisons with other modalities seems merited.

Abstract: Major Depression is a debilitating disorder and resistance to pharmacotherapy is common and leads to treatment resistant depression (TRD). The most effective treatment for TRD, 'Electroconvulsive Therapy' (ECT), involves applying a direct electrical current to the brain in order to elicit a therapeutic seizure. The underlying mechanism of how this seizure leads to clinical improvement is not fully understood, but prevailing theories involve mechanisms of neural plasticity. Because of the adverse cognitive side effects of ECT, an alternative convulsive therapy, Magnetic Seizure Therapy (MST), is currently under investigation. Electrophysiological (EEG) recordings of the treatment seizures in ECT have been previously used to predict response to treatment. However, these characteristics have yet to be examined in MST to determine whether they can predict who will respond to treatment. Moreover, the effects of MST frequency on the seizure characteristics have yet to be investigated. We examined EEG seizure characteristics in a sample of depressed subject receiving MST at three separate frequencies: 25

(n=10), 50 (n=10) and 100 (n=10) Hz. The polyspike phase amplitude and duration, slow wave phase amplitude and duration, post-ictal suppression, global seizure strength and symmetry were evaluated across a course of treatment in all subjects. Using a binary logistic regression to predict response, none of the EEG seizure variables were significant $p>.05$. Overall, the average EEG seizure duration significantly decreased from baseline (M=71.54 seconds) to the last treatment (M=36.20 seconds) $t(22)=4.068$, $p<.001$. Slow wave duration also significantly decrease over time from the baseline (M=57.32 seconds) to the final treatment (M=19.23 seconds) $t(18)=2.741$,$p=.013$, likely driving the total decreased duration effect. When analyzing the data by frequency, a non-significant trend in the average polyspike amplitude increased with treatment frequency for the 25 Hz (M=57.69 μV, SD=26.82), 50 (M=65.56 μV, SD=25.72) and 100 Hz (M=64.17 μV, SD=35.02) groups $F(1)=7.332$, $p=.073$. Moreover, suppression ratings showed trend increases with increased frequency $F(1)= 6.795$, $p=.080$. Although none of the variables were significant predictors of response we observed changes in the quality and duration of seizures during a course and across frequencies. Polyspike amplitude and suppression ratings may be significant predictors of response. Future research with a larger sample size is needed to elucidate the role of seizure adequacy in informing treatment decisions with MST.

Title: Next-generation sequencing of the rat hippocampal miRNome following chronic electroconvulsive stimulation

Authors: *K. M. RYAN[1,2], P. SMYTH[3], G. BLACKSHIELDS[3], O. SHEILS[3], D. M. MCLOUGHLIN[1,2];
[1]Trinity Col. Inst. of Neurosci., Dublin, Ireland; [2]Dept. of Psychiatry, Trinity Col. Dublin, St. Patrick's Univ. Hosp., Dublin, Ireland; [3]Dept. of Histopathology, Sir Patrick Dun Res. Laboratory, Trinity Col. Dublin, St. James's Hosp., Dublin, Ireland

Abstract: Background: MicroRNAs (miRNAs), a class of endogenous small RNA species, may contribute to the development of depression and its treatment. MiRNAs control about half of all

protein-coding genes in mammals and are found in abundance in the brain where they play a role in a variety of functions such as neurogenesis, cell specification, apoptosis and synaptic plasticity. We previously reported that chronic treatment with electroconvulsive stimulation (ECS), the animal model equivalent of electroconvulsive therapy (ECT), alters expression of miRNAs associated with the neurotrophin BDNF in rat brain and blood. To gain further understanding of the effects of chronic ECS on hippocampal miRNAs, we used the hypothesis-neutral approach of Next-Generation Sequencing here. **Methods:** Male Sprague-Dawley rats (*n*=8 per group) received either "sham" or "real" ECS (100pulses/s; pulse-width=0.5ms; duration=0.7s; 75mA) daily for 10 days. Hippocampal RNA was run on a SOLiD^{TM} sequencing platform. Differential expression analysis was performed using DESeq2. Confirmation and specificity studies were carried out using individual stem-loop primers and quantitative real-time polymerase chain reaction (qRT-PCR). Drosha and Dicer1 mRNA levels were assessed using qRT-PCR. mRNA target and pathway analyses were performed using miRWalk and DAVID. **Results:** DESeq2 analysis identified significant differential expression ($p<0.001$) in six miRNAs in the hippocampus following ECS after correcting for multiple comparisons. qRT-PCR confirmed significant changes in four of the six miRNAs, including miR-212 which we previously reported to be altered by ECS. These changes were confirmed to be hippocampal specific. Hippocampal levels of Drosha and Dicer1, which regulate production of mature miRNAs, were unaltered. Preliminary miRWalk and DAVID analyses predict that these miRNAs target mRNA species involved in inflammatory, glutamatergic, neurotrophic and intracellular signalling pathways, cytoskeletal regulation, axon guidance and long-term potentiation. **Conclusions:** Alterations in miRNA expression may be informative about the mechanism of action of ECS/ECT and in turn may give insight into the neurobiology of depression. MiRNAs have already shown tremendous promise in treating other diseases such as Hepatitis C. Ultimately, a better understanding of the role of miRNAs in depression and its treatments may also lead to novel therapeutic targets.

Title: An open pilot study of non-pharmacological augmentation therapy in major depressive patients using inaudible high-frequency sounds

Authors: ***M. HONDA**[1], R. YAGI[2], N. KAWAI[3], O. UENO[1], Y. YAMASHITA[1], T. OOHASHI[3];
[1]Dept. Functional Brain Research, Natl. Ctr. of Neurol. and Psychiatry, Tokyo, Japan; [2]Dept. of Early Childhood Educ., Tokyo Seitoku Col., Tokyo, Japan; [3]Dept. of Res. and Development, Fndn. for Advancement of Intl. Sci., Tsukuba, Japan

Abstract: Due to the fact that major depressive disorder (MDD) patients often fail to achieve remission with the initial treatment of antidepressants, in order to improve outcome, a number of augmentation options including non-pharmacological treatments have been used. The aim of the current study is to explore a potential non-pharmacological augmentation option using high-frequency sounds above the human audible range (max. 20 kHz). In the previous studies, we have found that sounds containing inaudible high-frequency components activate the midbrain and diencephalon and evoke various physiological, psychological and behavioral responses, which referred to as hypersonic effect. To test the safety and efficacy of inaudible high-frequency sound on MDD, an open pilot trial was conducted.Ten MDD outpatients diagnosed with the Diagnostic and Statistical Manual for Mental Disorders, fourth edition (DSM-IV) criteria entered an open trial receiving the inaudible high-frequency sound stimulation therapy. Participants received 3-28 sessions of sound stimulation therapy. In each session, during participants sat on a comfortable seat and watched a movie showing natural environment, the tropical rain forest sounds including inaudible high-frequency components were presented for 20-minute. At the same time, spontaneous fluctuations of alpha power in electro encephalogram (EEG) was measured from the occipital regions, which is recognized as an index of the emergence of the hypersonic effect. Efficacy and tolerability were assessed using the State-Trait Anxiety Inventory (STAI), EEG, patients' subjective reports of side effects.Throughout the trial, there was no reports of side effects and a rejection of attribution for any reason, indicating the safety of the inaudible high-frequency sound stimulation. Remarkably, the anxiety scores of STAI were significantly decreased after the sessions. In addition, spontaneous fluctuations of alpha power in EEG was significantly increased, indicating the emergence of the hypersonic effect in MDD patients. Moreover, there was a significant negative correlation between the alpha power and the scores of STAI.These results suggest that the fluctuations of alpha power may be a useful biomarker reflecting anxiety states of MDD patients. Moreover, the current results suggest that the inaudible high-frequency sound stimulation may be a potential non-pharmacological augmentation option for some depressed patients with anxiety. In order to show clinical effect, further controlled trials will be necessary.

Neurosci., Karolinska Institutet, Stockholm, Sweden

Abstract: Deep brain stimulation (DBS) of limbic targets has been advanced as a treatment for otherwise therapy-resistant major depression with initial reports showing promising results. Recently however, major randomized controlled trials fail to replicate these findings, demonstrating a need for refined DBS protocols. While the challenges involved in this line of research must eventually be met at a clinical level, model rodents meeting criteria for construct, face and predictive validity may aid in redefining issues at the proof-of-concept level.
Using the Flinders sensitive line (FSL) and congenital learned helpless (cLH) rats and their respective controls, we investigated the anti-depressant-like effects of DBS to the ventromedial prefrontal cortex (vmPFC, rodent equivalent to the Cg25 region) and the nucleus accumbens (Nacc) applying chronic-intermittent or chronic-continuous stimulation protocols. We found vmPFC-DBS to outperform Nacc-DBS in anti-depressant efficacy. Chronic continuous stimulation did not add further benefit compared to chronic-intermittent DBS, suggesting that continuous stimulation overrides the involved neural network. Further, the otherwise therapy-resistant cLH rats did not benefit from DBS at all.
These data reflect the current clinical literature and are still unsatisfactory. A way to advance from this point could be to focus on individual patient's symptom profiles. This would give guidance as to where, when and how to stimulate most efficiently. Further, in Parkinson research, it has already been shown that adaptive DBS is more effective than conventional continuous DBS. In order to apply adaptive stimulation protocols also in depression, we now need to systematically investigate into neurophysiological and neurochemical biomarkers of the

disorder.
For that purpose, we study electrophysiological and biochemical characteristics of several brain areas in FSL rats using in-vivo local field potential recordings and microdialysis. We are comparing data for baseline pathological states versus conditions under therapeutic doses of fluoxetine. That way identifying specific biomarkers that go along with depressive symptomatology, we will eventually be able to redefine DBS protocols.

Title: Cellular mechanisms of simulated deep brain stimulation (sDBS) in rat infralimbic cortex

Authors: ***F. LUO**[1], Z. H. T. KISS[2];
[1]Dept. of Clin. Neuroscience, Hotchkiss Brain Inst., [2]Univ. of Calgary, Calgary, AB, Canada

Abstract: Chronic, high frequency (>100 Hz) electrical stimulation, known as deep brain stimulation (DBS), of the subcallosal cingulate gyrus (SCG) including Brodmann area 25 (BA25) may be a promising therapy for treatment-resistant depression. However the neural mechanisms underlying the clinical benefit are unknown. The ventral division of the medial prefrontal cortex (vmPFC), particularly infralimbic cortex (IL), is the homologous region in rat based on anatomical connections and cytoarchitectural features. vmPFC DBS in rats shows antidepressant-like effects in the forced swim test and is used as a model to study mechanisms involved in SCG DBS. Therefore we investigated the cellular mechanisms of simulated DBS (sDBS) in layer 5 IL pyramidal neurons, using *in vitro* whole-cell patch clamp recordings. Single pulse stimulation was used to ensure the synaptic connection between the two sites of electrical stimulation and recording. sDBS applied inside the IL layer 5 induced a prolonged afterdepolarization that was dependent on stimulation frequency and current amplitude (n=14). The high frequencies (>100 Hz) used clinically for SCG DBS and a minimum current intensity of 222.7 ± 13.8 μA could reliably induce these afterdepolarizations. In contrast, sDBS applied in the subcortical white matter, although delivered at a higher intensity of 500.0 ± 42.7 μA, failed to induce any persisting membrane potential changes in layer 5 IL pyramidal neurons (n=5)

using similar parameters. Based on our previous work indicating that sDBS-induced afterdepolarization in basal ganglia involved cholinergic activation of muscarinic receptors, we next tested cholinergic involvement in IL neurons by application of atropine (2.4 μM, non-selective muscarinic receptor antagonist, n=6). Despite significant cholinergic projections from basal forebrain as well as the presence of cholinergic interneurons in IL, cholinergic blockade only abolished the afterdepolarization in 1 neuron, partially blocked it in another neuron, and did not affect afterdepolarization in the 4 remaining neurons. Therefore these preliminary data suggest that (i) sDBS in grey and white matter produce different cellular effects, and (ii) sDBS-induced afterdepolarizations must be mediated by different neuromodulators, in addition to acetylcholine. Key words: DBS, infralimbic cortex, patch clamp, rat. Funding: AIHS CRIO project

Title: Mechanical stimulation at PC6 acupoint suppresses stress-induced depressive behavior in rats

Authors: *J.-Y. MOON, S.-Y. KANG, O. KWON, Y.-H. RYU;
Korea Inst. of Oriental Med., Daejeon, Korea, Republic of

Abstract: Acupunture is widely used for treating many psychological disorders such as depression. Previous studies reported that repeated restraint stress induces depressive behavior in rats. Here we examine the effect of mechanical stimulation of PC6 or GV20 acupoint using mechanical acupuncture instrument (MAI) in stress induced depression model. Our results showed that repeated restriantstress (2hr/day, for 14 days) caused significant depressive-like behaviors, such as reduced body weight gain, prolonged duration of immobility in forced swimming test (FST) and decrease in the number of entries into open arms during the elevated pluse maze (EPM) compared to normal rats. In addition, corticosterone levels in plasma were increased and expression of BDNF and phosphorylated CREB (pCREB) were downregulated in hippocampus. After confirming the depressive behavior on 14 days after restraint, we treated machanical stimulation at PC6, GV20 or non-acupoint with MAI 30min prior to repeated restraint stress for 7 days. Daily mechanical stimulation at PC6 acupoint significantly reduced the duration of immobility in the FST and attenuated a decrese in the number of entries into open

arms during the EPM compared to GV20 or non-acupoint stimulation on day21. In addition, acupoint stimulation at PC6 reduced increased corticosterone level in plasma. However, the treatment did not affect decreased BDNF expression or pCREB in hippocampus. These results indicate that repeated stress induces depressive behavior and the acupuncture at PC6 is more effective than GV20 or non-acupont. However, the antidepressive effects are not related to BDNF or pCREB downregulation in hippocampus. Our study supports clinical use of acupuncture depending on the acupoint in depression.

Title: The potential protective role of communal nesting on the behavioral consequences of prenatal infection in adult mouse offspring

Authors: ***M. CHAVEZ**[1], H. NORRIS[1], K. L. D'ANNA-HERNANADEZ[2];
[2]Psychology, [1]California State Univ. San Marcos, San Marcos, CA

Abstract: Proper formation of the fetal brain during the prenatal period is important for mental health outcomes in adulthood. In rodent models, prenatal insults such as infection during the second trimester have been linked to the disruption of neural development and alterations in depression and anxiety-like behaviors as well as impaired cognitive function in offspring in a sex-dependent manner. While the prenatal environment can alter fetal development, the postnatal environment has also been observed to affect offspring development and behavior. Communal nesting (CN) is an enriched perinatal environment that increases neurogenesis and promotes sociability in both male and female offspring, but this rearing style differentially affects anxiety- and depression-like behaviors between males and females. Currently, the effect that an enriched perinatal environment has on offspring prenatally exposed to LPS is unknown. The current study was designed assess the potential protective role of CN on male and female offspring prenatally exposed to LPS when tested on measures of anxiety, depression, and memory performance. Prenatal LPS administration was found to alter the number of self-grooming and on nest bouts with LPS exposed pregnant dams self-grooming more and spending more time on nest than saline treated dams. However, total time retrieving pups and the latency to first approach pups was not altered suggesting that prenatal LPS administration on PND 9 does not negatively affect these maternal behaviors in the postnatal period. Offspring behavioral data is forthcoming.

Title: The effects of mild chronic variable stress and hypocretin in lactating dams during the postpartum period

Authors: ***A. J. CASTANEDA**, E. LANE, M. CHAVEZ, H. NORRIS, M. HAMLIN, K. L. D'ANNA-HERNANDEZ;
Psychology, California State Univ. San Marcos, San Marcos, CA

Abstract: Postpartum depression is disruptive to maternal care and has negative health consequences for both mothers and infants, but the underlying neuromechanisms of the disorder are not well understood. Hypocretin (HCRT), a hypothalamic excitatory neuropeptide, has been shown to have direct influence separately on stress regulation, maternal care, and depressive-like symptoms in rodents. However, the potential role of hypocretin in postpartum depression and regulation of maternal behavior is not clear. The current study addressed the role of HCRT in the postpartum period in three ways: 1) creation of a chronic variable stress model (CVS) of postpartum depression, 2) antagonism of the HCRT system in the postpartum period and 3) labeling of HCRT-active cells in brain regions related to maternal behavior in response to pup-related stimuli. Results show that dams exposed to CVS postnatal days 1-3 reduced latencies to retrieve pups in a T-maze ($p = 0.041$), and show reduced immobility on the forced swim test ($p = 0.002$) compared to relative controls. However, intraperitoneal injections of a HCRT receptor 1 antagonsist (15 and 30 mg/kg) do not alter depressive-like behaviors on a forced swim test. Lastly, a separate cohort of dams was exposed to pups, pup bedding, no pups or a pup-like item. Brains were then processed for cells double-labeled for cFos and prepro-HCRT and analysis is ongoing. This study will provide information on the potential role of HCRT associated with depressive-like symptoms and maternal care during lactation.

Title: Contingency training influences neurobiological responses to environmental threats and cognitive uncertainty in male and female rats: a potential rat model of behavioral therapy

Authors: *M. H. KENT[1], S. SCOTT[3], S. LAMBERT[4], E. KIRK[2], B. TERHUNE-COTTER[2], B. THOMPSON[2], S. NEAL[2], B. DOZIER[2], M. BARDI[2], K. LAMBERT[2];
[1]Neurosci., [2]Psychology - behavioral Neurosci., Randolph Macon Col., Ashland, VA;
[3]Psychology, Arizona State Univ., Tempe, AZ; [4]Biol., Furman Univ., Greenville, SC

Abstract: Despite the availability of multiple modes of treatment strategies, depression remains one of the most prevalent disorders in the world (Ledford, 2014). The use of cognitive-behavioral therapies produce outcome effectiveness scores ranging from 42-66%, a higher rate than pharmacological approaches (i.e, 22-40% Anthes, 2014). Research with a rat model of behavioral therapy [i.e, effort-based reward (EBR) contingency training] suggests that training focused on building associations between physical effort and desired outcomes enhances neurobiological indices of resilience in male rats (Lambert, 2006; Lambert et al., 2014). In the current study, both male and female Long-Evans rats were exposed to either six weeks of EBR training or non-contingent training prior to 10 days of exposure to chronic unpredictable stress (CUS; n=8 or 9 for each of the four groups). Subsequently, all animals were exposed to a problem-solving task and then trained in a spatial learning/foraging task, the dry land maze (DLM). Following habituation training and test trials, rats experienced a probe trial in which the expected reward was removed to create a prediction error (cognitive uncertainty). Results indicated that, during CUS exposure, contingency-trained males exhibited higher Dehydroepiandrosterone/Corticosterone ratios (indicative of healthier stress responses); an effect not observed in females. Additionally, contingency training increased exploratory and information seeking in the probe trial whereas a *sex x contingency* interaction indicated that contingency training differentially influenced on-task problem-solving performance in males and females. Following the probe trial, brains were exposed to immunocytochemistry to determine the effects of sex and contingency training on fos-, BDNF-, glucocorticoid receptor- and NPY-immunoreactivity in limbic and cortical areas involved in emotional and cognitive responses. Contingency training decreased BDNF-ir in the hippocampus CA1 and lateral habenula, implicating differential neuroplasticity responses in the training groups. Further, coordinated fos-ir between the retrosplenial cortex and several limbic areas (e.g, amygdala) corroborates past

research implicating this area as a modulating area in spatial tasks—emphasizing the value of the DLM probe task (Alexander & Nitz, 2015). In sum, the current findings confirm that behavioral training is associated with sex-specific neurobiological effects; however, further assessments are necessary to more accurately determine the therapeutic potential for the EBR behavioral training/therapy model. Title: Under watchful eyes: social observation modulates feedback processing in social anxiety disorder

Authors: ***J. PETERBURS**[1], R. VOEGLER[1], C. BELLEBAUM[2], T. STRAUBE[1];
[1]Univ. of Muenster, Muenster, Germany; [2]Univ. of Duesseldorf, Duesseldorf, Germany

Abstract: Intense fear of (social) performance situations and negative evaluation is a core symptom of social anxiety disorder (SAD). Evidence for altered feedback processing in SAD has recently been accumulating, yet little is known about the impact of contextual factors. The present study investigated processing of feedback during probabilistic learning in SAD patients (N = 22) and healthy controls (N = 20) using electroencephalography (EEG) and event-related potentials (ERPs). Crucially, subjects performed the task in two contextual conditions, A) under social observation (with an observer present and a camera running), and B) in a control condition with no observation (and the camera switched off).
Results showed no group differences in overall learning rates. Social observation differentially affected patients and controls: social observation increased avoidance learning in controls but not in patients, while patients showed increased avoidance learning in the control condition.
The feedback-related negativity (FRN), an ERP components linked to fast processing of performance feedback, was increased to negative feedback under social observation in patients, and to negative feedback in the control condition for controls. This finding is in line with hypersensitivity to social negative evaluative information in SAD. Interestingly, behavioral

results appear to suggest that social observation may suppress manifestation of this hypersensitivity in overt behavior.
Amplitudes of the P300, an ERP component associated with cognitive appraisal, attention and evaluation, were generally decreased under social observation and increased in response to negative feedback, the latter result likely reflecting more frequent occurrence of positive feedback due to successful learning. Interestingly, patients as compared to controls showed increased P300 amplitudes under social observation only, possibly indicating increased attentional orientation towards and salience of feedback in the presence of an observer in SAD, a notion that is in accordance with SAD psychopathology.
Overall, the present study adds to a growing body of evidence for altered performance monitoring in SAD.

Title: Impact of anxiety on neural and behavioral responses to incentives

Authors: *B. FUCHS, C. GRILLON, M. ERNST, A. GORKA;
Natl. Inst. of Mental Hlth., NIH, Bethesda, MD

Abstract: Background: Potential rewards and losses motivate behavior and activate reward processing brain regions, including the striatum. Exposure to threat has been shown to reduce neural responses to gain in the striatum (Choi et al., 2014). However, it is unclear how anxiety impacts neural processing of loss. Therefore, this study aims to examine the impact of state anxiety, induced by threat of shock, on neural and behavioral responses to anticipation of gain and loss.
Methods: In an MRI scanner, healthy adults (N=34) performed a timed task. Participants were instructed to respond to a target, presented after either an incentive cue, to gain or avoid losing money, or a neutral cue devoid of monetary incentive. Correct responses depended on the response speed. The task was completed under alternating blocks of threat and safe conditions, where threat was instantiated by administration of an unpredictable mild electric shock to the wrist. Effects of threat and incentive type were assessed using 2x3 repeated measures ANOVAs.

Results: Behaviorally, responses to targets were significantly faster on incentive than neutral trials. Across incentive and neutral trials, reaction times were longer under threat of shock than safety. Neurally, whole brain analyses revealed that, compared to neutral trials, incentive trials were associated with greater BOLD responses in bilateral ventral striatum (VS), ventral tegmental area, and bilateral insula during target anticipation. Threat of shock increased BOLD responses during target anticipation in left caudate and right dorsolateral prefrontal cortex. A priori ROI analyses revealed enhanced left VS activation under threat during gain trials, and to a lesser extent, loss trials.
Conclusions: Threat increased VS responses during all types of trials. This finding is in contrast to prior work (Choi et al., 2014) reporting that threat decreased VS activation to gain. This discrepancy may reflect methodological differences between the two paradigms, such as (1) the inclusion of loss trials in our paradigm; or (2) that the threat in our paradigm was unpredictable rather than predictable. Notably, a priori ROI analyses suggest that unpredictable threat impacts neural responses to the anticipation of gain and loss. Increased activity during the threat condition may reflect the conflict between anxious anticipation and the processing of gains and losses. These interpretations will need to be explored in future work.

Title: Susceptibility to 7.5% CO_2-evoked panic is associated with hypersensitivity to unpredictable threat

Authors: ***J. Y.-T. LIU**, N. L. BALDERSTON, M. ERNST, C. GRILLON;
Section on Neurobio. of Anxiety and Fear, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: A core feature of panic disorder (PD) is a heightened anticipatory anxiety, as indexed by anxiety-potentiated startle. However, it is unknown whether this abnormality is specific to the diagnosis of PD or would manifest along a continuum of panic sensitivity (PS). This study examines this question using exposure to carbon dioxide (CO_2) shown in preclinical studies to induce panic symptoms.
The present study investigated associations among PS, as assessed with behavioral and

autonomic responses to CO_2, psychophysiological (startle potentiation) and brain measures of anticipatory anxiety in healthy individuals. We hypothesize that PS is associated with startle potentiation to threat of shock and brain measures of anticipatory anxiety in healthy individuals. Healthy individuals completed a CO_2 challenge consisting of 5 minutes baseline (room air), 8 minutes challenge (7.5% CO_2), and 5 minutes recovery (room air). PS was quantified using physiological measures (N=49) and item-optimized scores of subjective panic symptoms (N=60) during the challenge period. Participants also completed the "NPU threat" task consisting of alternating blocks of safe conditions (no (N) shock) and two threat conditions -predictable (P) shock signaled by a cue and unpredictable (U) shock. Anticipatory anxiety during the threat of predictable (P) and unpredictable (U) shock was compared to safe periods when no (N) shock could be administered in two separate sessions, one to assess startle potentiation (N=60) and the other to investigate brain activity (fMRI: N=46).
Behaviorally, participants displayed increased physiological and subjective symptoms of panic under CO_2 inhalation, as well as increased startle and subjective distress during both threat conditions. Subjects also showed a pattern of brain activity commonly observed in studies of fear and anxiety, including significant threat-evoked activation in the dorsal anterior cingulate cortex, dorsolateral prefrontal cortex, and anterior insula. Importantly, subjective awareness of panic symptoms under CO_2 significantly correlated with subjective anxiety and fear in threat conditions. In addition, fear-potentiated startle significantly correlated with subjective reports of palpitations under CO_2.
Although preliminary, these results suggest a potential link between panic sensitivity and anxious arousal. These results highlight utility of CO_2 inhalation in inducing panic symptoms, and future analyses will explore the link between panic sensitivity and the network underlying fear and anxiety.

Title: Threat of shock engages the dlPFC during a wide variety of cognitive paradigms.

Authors: ***N. L. BALDERSTON**, A. HSIUNG, J. LIU, M. ERNST, C. GRILLON;
Natl. Inst. of Mental Hlth., NIH, Bethesda, MD

Abstract: Threat of shock (TOS) is a well validated, translational procedure that reliably increases anxious arousal, causes worry, and affects cognition. In a typical TOS experiment, subjects are exposed to alternating blocks where they are safe or at risk for receiving an unpleasant electrical stimulation. Because the shock can be delivered infrequently, it is possible to conduct a wide variety of tasks during TOS, making it an ideal paradigm to experimentally test the effects of elevated state anxiety on cognitive processes and their underlying neural mechanisms. Resting state studies have shown that TOS changes functional connectivity, in particular by increasing coupling between the amygdala and dmPFC. However, it is unclear how subjects recruit the resources necessary to overcome these network changes when faced with task demands. One possibility is that they recruit prefrontal cognitive control resources when they encounter task-based stimuli under TOS.

We tested this hypothesis across several TOS studies with independent cohorts from ongoing studies. In Study 1 (n = 37), subjects were exposed to blocks of no threat (N), predictable threat (P), and unpredictable threat (U) in the standard NPU task. Simple geometric shapes served as cues, and predicted the shock only in the predictable condition. In Study 2 (n = 36), subjects viewed pictures of common household items during blocks of safety and (unpredictable) threat, and made a simple perceptual judgement. In Study 3 (n = 21), subjects completed a Sternberg working memory (WM) paradigm. On each trial, subjects were presented with a series of letters, and were required to maintain these letters for a brief interval.

During all tasks, we collected multi-echo fMRI data, and processed the data using standard practices. At the single subject level, we conducted the general linear model using the onsets and durations for trials in the individual conditions. We conducted group level ANOVAs to examine the effect of threat on stimulus evoked BOLD activity.

In all studies we found a significant cluster of activity over the right dlPFC as a function of threat. Across studies this region showed increased cue evoked activity during threat blocks relative to safe blocks. Importantly, this region has been repeatedly shown to be involved in both cognitive control, and WM. Taken together, these results suggest that cognitive control processes are engaged by even low load tasks during periods of elevated state anxiety. Additionally, in a previous study we found that anxiety patients show reduced WM-related activity in this region, suggesting that these individuals may have a reduced capacity for engaging these mechanisms.

Title: Anxiety enhances right dorsolateral prefrontal cortex activity during retrieval in behavioral pattern separation paradigm

Authors: *A. HSIUNG, N. BALDERSTON, M. ERNST, C. GRILLON;
Natl. Inst. of Mental Hlth., NIH, Bethesda, MD

Abstract: Forming distinct representations for items, places, and events is crucial for everyday life. This function is commonly impaired in individuals with anxiety disorders, who often overgeneralize details of a fearful situation to a non-fearful situation. Behavioral pattern separation (BPS), the ability to discriminate among items or experiences in episodic memory based on subtle differences, could elucidate possible mechanisms underlying this fear overgeneralization. Previously, we showed that BPS was impaired when items were retrieved under threat of shock, suggesting that fear overgeneralization in anxiety disorders may be linked to impaired BPS; however the neural underpinnings mediating this effect remain unclear. The current study explored changes in neural activity as participants performed BPS under periods of threat and safety. We hypothesized that differences in activation of the hippocampus, particularly in the dentate gyrus, could help explain the effect of anxiety on BPS.

Subjects (n = 36) viewed images of common household items at encoding and retrieval in blocks of safety and threat in a 2 x 2 factorial design during fMRI. In retrieval, participants judged whether the items they saw were new, old, or altered. New items were images not presented during encoding, old items were identical in encoding and retrieval, and altered items were images that had been rotated slightly from encoding to retrieval. To assess BPS and brain activity, we analyzed responses in retrieval as a function of encoding block (threat or safe), retrieval block (threat or safe), and image type (old or altered).

Participants reported greater feelings of anxiety in threat blocks compared to safe for both blocks. Additionally, threat during retrieval increased activity in the left anterior insula and the dorsal anterior cingulate cortex (dACC), across all stimuli. Threat also increased activation in the right dorsolateral prefrontal cortex (dlPFC), in response to altered (but not old) images. No behavioral differences were found across conditions.

Activation of the left anterior insula and dACC as a function of threat replicate previous work suggesting these regions play a vital role in emotional expression. Although we did not see our hypothesized differences in the hippocampus, we saw robust activation in the dlPFC, an area important for cognitive control that is impaired in anxiety patients. This elevated dlPFC activity to altered images may reflect cognitive control processes needed to perform a difficult task during periods of elevated state anxiety. Accordingly, impairment in this skill may explain the fear overgeneralization in anxiety patients.

Title: Investigation of grey matter volume in Social Anxiety Disorder: an independent replication

Authors: *M. R. STEFANESCU[1], S. BOEHME[1], T. STRAUBE[2], U. LUEKEN[1];
[1]Dept. of Psychiatry, Psychosomatics and Psychotherapy, Univ. Hosp. Wuerzburg, Wuerzburg, Germany; [2]Inst. of Med. Psychology and Systems Neurosci., Univ. Hosp. Muenster, Muenster, Germany

Abstract: Due to its prevalence, early onset and in its precursor function for subsequent comorbid disorders, social anxiety disorder (SAD) is associated with a high individual burden and socioeconomic costs. Evidence is accumulating on altered frontolimbic circuity function. Compared to functional neuroanatomy, however, brain morphometric alterations are relatively understudied. Moreover, independent replications are missing. The purpose of this study was to investigate gray matter volume changes in two independent German samples. Matched SAD patients and healthy comparison (HC) subjects (Jena group: n = 33 SAD and n = 33 HC; Muenster group: n = 33 SAD and n = 33 HC; 19 women and 15 men in each group) were compared regarding gray matter volumes (GMV) using Voxel-Based Morphometry (VBM12). In the Jena group, SAD patients compared to controls showed a reduction in GMV in the left middle parts of frontal gyrus, precuneus, middle occipital gyrus, parahippocampal and lingual gyrus, inferior parietal lobule and in the right middle temporal gyrus. In the Muenster group, SAD patients compared to controls showed a reduction in GMV in the left superior frontal gyrus, supramarginal gyrus, left middle and superior temporal gyrus, bilateral parts of insula, the right cuneus and medial part of the superior frontal gyrus. Present results point towards reduced gray matter volumes in SAD patients as replicated by an independent site encompassing the left middle and superior frontal gyrus, regions of insula and middle temporal gyrus. In conclusion, findings illustrate gray matter volume reductions in fear circuitry and object processing brain regions as a correlate of SAD that was partly replicated in a second, independent sample.

Title: Not everything that looks like change is change: anxious individuals show over-reactivity to uncertainty in a change point detection task

Authors: *H. HUANG, M. PAULUS;
Laureate Inst. for Brain Res., Tulsa, OK

Abstract: Differentiating between fluctuations that occur by chance or by an underlying statistical regularity that signals environment change is an important task that profoundly affects adaptive behavior. It has been shown that anxious individuals may not appropriately differentiate between those situations (Browning et al. 2015). This study examined whether anxiety leads to a non-adaptively increased reactivity by manipulating environmental volatility in a visual search task. 181 subjects (0<= Overall Anxiety Severity and Impairment Scale <=20) participated this study and were divided into Non-anxious group (N = 90, OASIS<9) and Anxious group (N = 91, OASIS>=9). Anxious subjects showed significantly higher lose-shift rate regardless of the underlying probability, i.e. higher lose-shift rate even at the most likely location, while no significant difference in their first choices was found, i.e., percentage of trials that started the searching at the most likely location. Using a dynamic R-W model with a base learning rate and a value-based sensitivity rate, we found that anxious individuals had significantly higher base learning rate and lower sensitivity rate. In addition, base-learning rate positively correlates with lose-shift rate, but not the optimality of the first choices (inverted U shape). Taken together, this indicates anxious subjects are not optimal in two aspects: 1) higher base learning rate caused by over-reactivity to uncertainty, 2) lower sensitivity to true changes in the environment. Thus, clinically anxious individuals non-adaptively respond to random fluctuations and are less able to detect changes in the environmental condition when they - in fact - have occurred.

Title: Relationship between cholesterol & number of suicide attempts

Authors: *O. H. HERNANDEZ[1,2], B. CARMONA-RUIZ[3], F. A. LEON-CRUZ[3];
[1]UNIVERSIDAD AUTONOMA DE CAMPECHE, CAMPECHE, Mexico; [2]Jefatura de investigacion, HOSPITAL GENERAL DE ESPECIALIDADES "DR. JAVIER BUENFIL OSORIO". SSA, Campeche, Mexico; [3]HOSPITAL PSIQUIATRICO DE CAMPECHE, CAMPECHE, Mexico

Abstract: Background: Suicidal behavior remains a major challenge for psychiatrists. The WHO estimates that approximately 900,000 people die each year by suicide worldwide. The role of lipids in mental health has aroused the interest of the scientific community, due to its association with the oligomerisation kinetics of synaptic membrane proteins (G protein-coupled receptors) in some psychiatric disorders (depression, schizophrenia). Together with sphingolipids and gangliosides, cholesterol is concentrated in detergent-resistant microdomains of the membrane called lipid rafts, which have been implicated in signal transduction. It has been reported that glutamatergic, gabaergic, dopaminergic, serotoninergic, cholinergic and purinergic neurotransmissions are affected by cholesterol depletion in lipids rafts. Many studies support the association between low serum cholesterol and higher risk of suicidal behavior; however, other studies have found no relationship. In this controversy, the number of suicide attempts has never been considered.
Objective: The aims of this study were to determine whether serum cholesterol and triglycerides are related to the number of suicide attempts; to explore whether the type of attempt (violent, non-violent) affects such association and analyze lipid levels as risk factors for multiple attempts.
Method: This is an observational, transversal, prospective, and analytical study. 81 patients with one or more suicide attempts were included. Socio-demographic, clinical and biochemical variables (cholesterol, triglycerides) were measured. Data were analyzed using descriptive, X^2, odds ratio and Spearman correlations tests. Results: The number of suicide attempts was negatively correlated with levels of cholesterol and triglycerides, but not with BMI, alcoholism, depression, type of attempt or gender. The use of poisoning substances was prevalent in women, but hanging was more common in men. There is a high risk of having multiple attempts in patients with low lipid levels.
Discussion and conclusion: The results support the use of cholesterol and triglycerides as

biological markers of suicidal behavior. It is important to categorize the number of suicide attempts. We are running experiments to test if electrophysiological parameters of brain waves (P100, P200) are related to lipid levels and number of suicide attempts.

Title: Increased prefrontal activation to negative stimuli associated with clinical improvement following emotion regulation therapy for generalized anxiety disorder

Authors: *H. A. RAAB[1], C. F. SANDMAN[2], S. H. SEELEY[3], E. GARCÍA-LESY[2,4], D. M. FRESCO[5], D. S. MENNIN[2,4], C. LISTON[6,7,8];
[1]Weill Cornell Grad. Sch. of Med. Sci., New York, NY; [2]Hunter College, City Univ. of New York, New York, NY; [3]Univ. of Arizona, Tucson, AZ; [4]The Grad. Ctr., City Univ. of New York, New York, NY; [5]Kent State Univ., Kent, OH; [6]Psychiatry, [7]Brain and Mind Res. Inst., [8]Sackler Inst. for Developmental Psychobiology, Weill Cornell Med. Col., New York, NY

Abstract: Generalized anxiety disorder (GAD) is characterized by excessive worry, which may result from deficits in adaptively regulating emotions. Emotion regulation therapy (ERT) may be an effective treatment for GAD as it trains the use of cognitive control strategies to modulate emotions. The prefrontal cortex (PFC) plays a critical role in mediating these cognitive processes to down-regulate negative emotion. We aim to elucidate behavioral and neural changes associated with ERT in patients with GAD. Eighteen young adults with GAD (mean age=21.96 years, 15 females) were recruited from the NYC area and participated in 16 weekly sessions of ERT. We assessed neural activity (fMRI), clinician severity, and self-report measures pre- and post-ERT. Functional neuroimaging data was acquired on a Siemens 3T MRI scanner while patients performed an emotion regulation task. During the task they viewed aversive or neutral

images. For each trial, patients were instructed to either “LOOK” at the image as they normally would or “DECREASE” their negative emotion (only for aversive images). Following each image, patients rated the strength of their negative emotion. There was no difference in the emotional intensity ratings for aversive images on “DECREASE” versus “LOOK” trials. This was true both pre- and post-ERT. There was a main effect of treatment for aversive but not neutral images. Following ERT, patients reported significantly lower ratings of negative emotion to aversive images compared to pre-treatment. Accordingly, our fMRI analyses focused on the contrast of aversive versus neutral images. Prior to ERT patients had increased activation for aversive as compared to neutral images in posterior visual processing regions of the brain but no difference in PFC. Following ERT, PFC regions, implicated in emotion regulation, including the inferior frontal gyrus (BA 45 and 46) and middle frontal gyrus (BA 6, 8, 9), as well as fusiform gyrus (all $p<.05$, corrected) had increased activation for aversive as compared to neutral images. Increases in neural activity in BA 9 and 45 from pre- to post-treatment correlated with lower ratings of self-reported anxious arousal and improved attentional control ($p<.05$). These results suggest increased activity in PFC regions following ERT is associated with improvements in clinical severity and emotion regulation abilities in GAD patients. Future research will investigate how changes in brain activity during emotion regulation relate to improvements in clinical severity during a 3-month follow-up period.

Title: Effects of benzodiazepine receptor agonists on pentobarbital-induced sleep latency in lipopolysaccharide-treated mice

Authors: *Y. KITAMURA[1], S. HONGO[1], K. OTSUKI[1], Y. YAMASHITA[1], A. MACHIDA[1], H. KANZAKI[1], I. MIYAZAKI[2], M. ASANUMA[2], T. SENDO[1];
[1]Okayama Univ. Hosp., Okayama, Japan; [2]Okayama Univ. Grad. Sch. of Medicine, Dent. and Pharmaceut. Sci., Okayama, Japan

Abstract: Benzodiazepine receptor agonists are the most frequently administered type of drug for insomnia. The prevalence of insomnia has recently increased. Accordingly, the prescription rate of benzodiazepine receptor agonists has risen. However, benzodiazepine receptor agonists

are known to induce postoperative delirium in surgical patients. Delirium involves an acute change in cognition and psychiatric symptoms. Namely, it can change benzodiazepine receptor function under inflammatory conditions. In this study, we sought to investigate whether benzodiazepine receptor agonists influence pentobarbital-induced sleep latency using a mouse model of lipopolysaccharide (LPS)-induced inflammation. [METHODS] Male ICR mice were administered LPS (300 μg/kg, i.p.). We assessed pentobarbital-induced sleep latency at 24 hours after the LPS treatment. [RESULTS] LPS administration resulted in increased serum levels of tumor necrosis factor-α and interleukin 6 at 1 and 2 hours, but not 24 hours. Benzodiazepine receptor agonists (diazepam and brotizolam) and a gamma-aminobutyric acid $(GABA)_A$ receptor agonist (muscimol) produced significantly greater increases in pentobarbital-induced sleep latency in LPS-treated mice than in saline-treated mice. These effects were blocked by bicuculline, a $GABA_A$ receptor antagonist. Hippocampal $GABA_A$ receptor α3 mRNA expression was significantly increased at 24 hours after the administration of LPS. [DISCUSSION and CONCLUSION] The findings of the current study suggest that benzodiazepine receptor agonists enhance pentobarbital-induced sleep latency to a greater extent in inflammatory conditions than in normal conditions, and these effects might be related to $GABA_A$ receptor expression.

Title: Are gulf war illness related symptoms unique to gulf war i veterans?

Authors: ***K. LEI**[1], V. METZGER-SMITH[2], J. JAVORS[3], S. GOLSHAN[4], A. LEUNG[5]; [1]Univ. of California San Diego, La Jolla, CA; [2]Veterans Med. Res. Fndn., San Diego, CA; [3]Occup. Med., Veterans Admin. San Diego Healthcare, San Diego, CA; [4]Biostatistics Core, Veteran Admin. San Diego Healthcare Syst., La Jolla, CA; [5]Dept. of Anesthesiol., Univ. of California, Sch. of Medicine, San Diego, San Diego, CA

Abstract: Background: Public interest in Gulf War Veterans (GWV) has continued to rise due to their specific range of neurological and other health related complaints following their return. Now termed Gulf War Illness (GWI), many of these veterans experience pain, fatigue, neurological symptoms, gastrointestinal and skin problems, and respiratory issues. Past studies have suggested that this chronic multi-symptom illness is linked to certain chemical and

environmental exposures (White et al., 2016). Unfortunately, these studies have mainly focused on Gulf War I (GW-I) Veterans even though deployed military personnel from other GW periods exhibit very similar symptoms.
Objective: This study aims to assess the prevalence of GWI symptoms based on different periods of the war and durations of the deployment.
Methods: Information was extracted from physicians' intake note of who applied for the GW Registry at the Veteran Administration San Diego Healthcare System over a period of 24 months. This information was systematically extracted from the computerized patient record system and inputted into a categorized Excel spreadsheet for analysis. Chi-square was used for categorical data and Analysis of Variance was conducted for the continuous outcomes. All analyses were two-tailed, where applicable, with $\alpha = .05$ and Bonferroni for pairwise group comparisons using the SPSS v23.
Results: There were three groups created based on periods of war: Group One (n=164) served from 1990-1991 (GW-I), Group Two (n=156) served after 1991 (GW-II) and Group Three (n=47) served in both GW-I and GW-II. Group One was uniquely (8.5%) exposed to pyridostigmine ($P<0.001$), yet exhibited significantly less pain ($P=0.005$, 70.1% vs. 83.3%) and neurological symptoms ($P=0.013$, 64.0% vs.76.8%) than their counterparts from Group Two.
As the average tour length for GWV is 7 months, they were then categorized based on duration into Group A (≤7 months, n=138), Group B (8-11 months, n=55) and Group C (≥12 months, n=171) of deployment. Significantly ($P<0.001$) more pain symptoms were presented in Group C (86.5%) compared to Group A (68.8%). Group C (36.3%) was also more likely ($P=0.006$) to take nonsteroidal anti-inflammatory drugs (NSAIDs) to manage their pain than Group A (21.7%), as well as take more non-pain or mood related medications overall.
In addition, GWV who had been exposed to toxic exposures (n=40) had more significant ($P=0.042$) memory and attention problems (20.0%) than those who were not exposed (n=327, 9.5%).
Conclusion: The results of this study suggest that the range of symptoms constituting GWI may not be due to the chemical or environmental exposures, but rather the length of their duty.

Title: Investigation of brain oscillation under academic stress in the classroom setting

Authors: ***S. LIU**[1], L.-W. KO[2], O. KOMAROV[3], C.-T. LIN[4], T.-P. JUNG[5];
[2]Dept. of Biol. Sci. and Technol., [3]Inst. of Mol. Med. and Bioengineering, [4]Dept. of Electrical and Computer Engin., [1]Natl. Chiao Tung Univ., Hsinchu, Taiwan; [5]Swartz Ctr. for Computat. Neurosci., UCSD, San Diego, CA

Abstract: Academic stress is considered as a source of negative emotions and commonly affects both students' behavior and cognitive abilities. Several studies have shown that different academic examinations, for example, unexpected or scheduled quizzes, midterms and final exams, can cause psychological consequences, such as an increase in the level of stress-related anxiety. Behavioral studies revealed that anxiety is a common consequence of stress that can lead to the loss of the attention, inefficient time management and lack of productivity. However, there are very few studies that use electroencephalography (EEG) to investigate physiological activities related to the effect of academic stress. This study implements the method of EEG to explore how students perceive and experience academic stress. The aim of this study is to investigate the phenomenon of brain oscillatory correlates of students' stress under naturalistic classroom settings. We recruited 26 college students and collected multiple physiological signals including synchronized recording of EEG, video monitoring, presentation of visual stimuli and collection of the participants' responses. Also the participants were asked to fill in the Depression Anxiety Stress Scales (DASS21) before each experimental session to evaluate their levels of long-term stress and stress-related anxiety. Based on the collected information, we observed correlations between the student's different stress levels, and changes in their EEG recordings. The experiments were performed under two conditions. All 26 students participated in experimental sessions under "non-stress" condition, and then 8 of them volunteered to participate in the "stress" part. The opened-eye resting state EEG data of the "stress" group were recorded during real academic examinations. The "non-stress" condition means that the participants didn't have any examinations during EEG recording. Emphasis were on the changes in brain activity as reaction to specific, real-life stressors. In this study, we processed the opened-eye resting state EEG data and obtained channel-based EEG topography for both "stress" and "non-stress" groups. The results show significant differences between "stress" and "non-stress" conditions. These changes in frontal region are associated with an increase of the theta and beta powers. In conclusion, we finding that frontal area may be predictive of stress hormonal responses.

Title: Translational evidence for dysregulation of acid-sensing TDAG8 receptor evoked inflammation in panic disorder

Authors: *L. L. VOLLMER, R. AHLBRAND, J. R. STRAWN, R. SAH;
Psychiatry and Behavioral Neurosci., Univ. Of Cincinnati, Cincinnati, OH

Abstract: Panic Disorder (PD) is a prevalent anxiety disorder characterized by repeated, unexpected attacks of intense fear as well as overwhelming respiratory and cardiovascular symptoms. Despite having a high prevalence and debilitating effects, the neurobiology of PD is still largely unknown. Several lines of evidence suggest that "acidosis" may relate pathoetiologically to panic disorder. CO_2 inhalation, a well-studied panicogen, causes brain acidosis. Recent evidence also shows significant comorbidity of panic disorder with chronic inflammatory conditions, such as arthritis, suggesting a potential role of inflammation in the pathophysiology of PD. Thus, converging homeostatic mechanisms involving acidosis and inflammation may underlie panic pathophysiology. Recently, using a rodent model we reported a role of microglial acid sensing receptor TDAG8 and pro-inflammatory cytokine IL-1β in CO_2-evoked fear (Vollmer et al, *Biological Psychiatry* 2016). Our studies suggest a primary role of innate immune cells in transducing acidosis to panic-associated behavior and physiology. However, the translational relevance of these "bench" findings to humans is not known. Given the potential association of panic disorder with inflammatory conditions we hypothesized that elevated inflammatory tone may be present in panic disorder patients, represented as increased TDAG8 expression as well as sensitized macrophage inflammatory responses. This pilot study evaluated: a) variance in acid sensor TDAG8 expression and acidosis-evoked cytokine release in monocytes from healthy volunteers, b) TDAG8 expression in monocytes collected from PD patients and healthy volunteers, and c) acidosis-evoked release of pro-inflammatory cytokines from macrophages cultured from these individuals. Baseline variance in TDAG8 expression was observed in macrophages from human volunteers without PD. Furthermore, selective acidosis-evoked release of IL-1β in cultured human macrophages was observed in agreement with our rodent data. This underscores the relevance of IL-1β in acidosis-evoked responses in innate immune cells. Ongoing studies are quantifying TDAG8 expression and macrophage pro-

inflammatory responses in patients with PD. Preliminary data indicate a potential age and gender specific changes in TDAG8 expression that is currently being replicated in a larger sample. Collectively, our studies support convergent acidosis-inflammatory mechanisms in panic disorder. TDAG8 associated inflammation may represent a potential marker of prognosis or risk in patients with PD or those at risk for the condition, and may inform novel treatment interventions.

Title: Neurological predictors of treatment outcome in social anxiety disorder: a Neurosynth-aided review

Authors: ***J. CURTISS**[1], S. M. NOBLE[2];
[1]Clin. Psychology, Boston Univ., Boston, MA; [2]Interdepartmental Neurosci. Program, Yale Univ., New Haven, CT

Abstract: Social anxiety disorder (SAD) is among the most prevalent and debilitating psychiatric disorders (Kessler et al., 2005). Several efficacious treatments exist for SAD, including cognitive behavioral therapy and pharmacological interventions; however, such interventions are only modestly effective (Davidson et al., 2004). As such, there have been recent initiatives to enhance treatment for SAD by leveraging neuroimaging techniques to determine whether neurological markers predict successful remission (Hofmann, 2013). It is particularly important to identify neural predictors of treatment outcome in SAD to improve upon behavioral measures. Extant literature reveals an increase in the use of fMRI to predict treatment outcome for SAD; however, no systematic review has yet been conducted on this bourgeoning body of literature. To address this, we perform the first review of the literature with the aim of pooling evidence of markers of SAD outcome after three commonly-employed interventions: cognitive behavioral therapy (CBT), pharmacotherapy, and mindfulness-based therapies. Using PubMed, a search from the database inception until May 1st 2016 yielded 49 potential studies. Overall, we identified 10 studies relevant to the purpose of the current review. Our results suggest that activity and connectivity in frontal regions and the amygdala are crucial neurological

mechanisms underlying responsivity to the treatment of SAD. Specifically, successful treatment response for SAD was most commonly predicted by decreased activity and connectivity in the salience network (i.e., ACC and insula) and amygdala, as well as increased connectivity between the default mode network (e.g., ventromedial prefrontal cortex) and the amygdala. Several studies also suggest that the occipitotemporal regions may predict treatment response for SAD. We also used Neurosynth, an online aggregator of fMRI studies and coordinate-based meta-analysis tool, to further investigate the role of these regions in SAD. Results of the Neurosynth meta-analysis on 33 studies confirm that functional abnormalities in the amygdala, insula, and ventromedial prefrontal cortex are neural signatures of SAD. These studies attest to the utility of incorporating neuroimaging in the treatment of SAD and afford good impetus to extend this research to other disorders. Furthermore, the incorporation of neuroimaging can refine and optimize decisions about which treatment is most appropriate for a specific individual, which would complement recent initiatives toward personalized medicine.

Title: Compulsive behavior of sapap3 mutants in the signal attenuation task

Authors: *I. EHMER[1,2], L. CROWN[1], W. VAN LEEUWEN[1,2], I. WILLUHN[1,2], M. FEENSTRA[1,2], D. DENYS[1,2];
[1]Neuromodulation and Behavior, Netherlands Inst. For Neurosci., Amsterdam, Netherlands;
[2]Psychiatry, Academic Med. Ctr., Amsterdam, Netherlands

Abstract: The neurobiological mechanism of compulsivity in obsessive-compulsive disorder (OCD) is unknown. Various hypotheses have been put forward, one of which is based on the idea that compulsive behavior results from impaired feedback processing (Joel and Avisar, 2001). The signal attenuation (SA) task for rats models this processing deficit by attenuating a feedback stimulus associated with the performance of a normal goal-directed response. Compulsive-like responding following SA is well characterized in normal rats, but has not yet been tested in genetic models of OCD-like behavior, such as the Sapap3 mutant mouse that presents with excessive grooming behavior (Welch et al., 2007). Here, we first demonstrate that the SA task can be implemented in mice. Subsequently, we tested the hypothesis that Sapap3 mutants show enhanced compulsive-like behavior in the SA model. Mice (24 wild-type (WT)

mice; 25 Sapap3 mutants; males, 3-6 months of age) learned that nose pokes lead to the presentation of a food reward and an audiovisual signal providing feedback. To simulate feedback deficiency experimentally, the signal was attenuated by presenting it without the corresponding outcome in half of the animals. Finally, operant responding of mice with and without feedback deficiency was compared in an extinction test. WT mice that underwent SA displayed significantly more uncompleted trials (UCT), extra nose pokes (ENP), and extra nose pokes per uncompleted trials (ENP-UCT) than WT mice that had experienced extinction only, and thus, were considered more compulsive-like. Analysis of Sapap3 mutant responses revealed a significantly higher number of ENP for animals that underwent SA, however, UCT and ENP-UCT did not differ from the regular extinction group. Comparison of the ENP-UCT between WT mice and Sapap3 mutants did not yield significant differences. Instead, Sapap3 mutants displayed significantly fewer completed trials (CT) and more no-poke trials compared to normal WT mice, indicative of enhanced extinction of the operant response. We show that the SA task produce similar behavior in mice as in rats, thereby introducing the opportunity to assess compulsive-like behavior due to defective feedback processing in various genetic mouse models. Contrary to our hypothesis, we found no evidence for increased compulsive-like responding or impaired extinction learning in Sapap3 mutants. This suggests that feedback processing during operant conditioning is not impaired in Sapap3 mice.

Title: Identifying mechanisms underlying behavioral effects of putative OCD risk gene BTBD3

Authors: *S. L. THOMPSON[1,2], E. V. HO[1], M. E. KLINGER[2], M. J. RAMAKER[1], A. HAJEISSA[3], W. R. KATZKA[1], J. A. KNOWLES[4], S. C. DULAWA[1];
[1]UC San Diego, San Diego, CA; [2]Univ. of Chicago, Chicago, IL; [3]Univ. of Michigan, Ann Arbor, MI; [4]USC, Los Angeles, CA

Abstract: The first genome-wide association study for Obsessive-Compulsive Disorder (OCD) identified one genome-wide significant single nucleotide polymorphism (SNP), rs6131295, in the trio subset of the sample. This SNP regulates expression of the BTBD3 gene, which encodes a transcription factor implicated in activity-dependent dendritic patterning during development. However, nothing is known about the role of BTBD3 in regulating behavior. We have identified several behavioral deficits in BTBD3 KO mice that may be relevant to OCD and work toward identifying the mechanisms underlying these behaviors. Male and female BTBD3 wild-type (WT), heterozygous (HT) and knockout (KO) mice were assessed in the open field, dig test, and splash test. In addition, mice were assessed weekly for barbering. Behavioral deficits were found in all of these paradigms. Together, these phenotypes indicate hyperactivity, reduced exploratory drive, and perseverative/impulsive behavior. BTBD3 mice were next assessed for effects of OCD-effective and OCD-ineffective treatment on these behavioral deficits. Mice were pretreated with 10 mg/kg/day fluoxetine (OCD-effective), 20 mg/kg/day desipramine (OCD-ineffective), or vehicle in the drinking water for fourteen weeks. After four weeks of drug treatment, mice were assessed in the same tests as above. Barbering was assessed weekly throughout treatment. Fluoxetine reduced barbering in WT and HT but not KO mice starting at four weeks of treatment, whereas desipramine had no effect. This data indicate an interaction between BTBD3 expression and serotonin signaling and provides predictive validity for barbering as an OCD-like behavior. BTBD3 mice were then assessed for basic sensory and motor function. BTBD3 KO mice had no impairments in olfactory dis/habituation, olfactory memory, grip strength, or gait, but did exhibit excessive wheel-running in the home cage and impaired nest building. These data indicate that BTBD3 KO mice do not exhibit gross sensory or motor impairments that may confer the other behavioral deficits identified. To identify brain regions requiring BTBD3 expression for normal behavior, BTBD3 expression was knocked down in juvenile mouse hippocampus using an adeno-associated virus expressing shRNA against BTBD3. Knockdown mice were assessed in the open field and nest building test during adulthood. Knockdown mice built worse nests and trended toward hyperactivity in the open field, recapitulating two phenotypes found in the global knockout. These data indicate that BTBD3 expression in hippocampus may play a role in the mechanism underlying effects of BTBD3 on behavior.

Title: Juvenile onset of stereotypy with loss of BDNF signaling in D1R expressing striatal neurons

Authors: *M. ENGELN[1], R. CHANDRA[1], A. LA[2], S. HAIDER[3], T.-C. FRANCIS[1], M.-K. LOBO[1];
[1]Anat. and Neurobio., Univ. of Maryland Baltimore, Baltimore, MD; [2]Univ. of Maryland, Col. Park, College Park, MD; [3]Johns Hopkins Univ., Baltimore, MD

Abstract: Imbalance between D1- vs. D2-receptor containing medium spiny neuron (MSN) basal ganglia output-pathways is implicated in stereotyped disorders including Tourette Syndrome (TS). Surprisingly, there is little information on the molecular role of MSN subtypes in TS or other stereotypy disorders. We have a mouse model with a deletion of TrkB (the BDNF receptor) in D1-MSNs (D1-Cre-flTrkB mice), in which a subset of mice display involuntary stereotypic behaviors beginning around 3 weeks of age. Consistent with an impaired GABAergic system in TS, these mice display a decrease in striatal GABA-A subunits accompanied by reduced inhibition in striatal D1-MSNs. We first characterized repetitive behaviors in D1-Cre-flTrkB mice with stereotypy (S), or with no stereotypy (NS), and D1-Cre control mice. Complete turns, head tics, rearing, and grooming are assessed weekly from ages 3 to 8 weeks. We found that D1-Cre-flTrkB-S mice display more complete turns at all ages compared to D1-Cre-flTrkB-NS and control mice. D1-Cre-flTrkB-S mice exclusively display head tics, which decline from juvenile to adult ages. We then selectively inhibited dorsal striatum D1-MSNs using Designer Receptors Exclusively Activated by Designer Drugs (DREADDs; AAV-DIO-HM4(Gi)-mCherry) to evaluate if abnormal D1-MSN activity is responsible for stereotypic behaviors. Our preliminary data suggests that selective inhibition of D1-MSNs with DREADDs reduces circling behavior. Finally, since the transcription factor, early growth response 3 (Egr3) is regulated by BDNF and Egr3 transcriptionally regulates a subset of GABA-A subunits, we are examining Egr3 mRNA in all groups. We find that both Egr3 mRNA and protein levels are decreased in the striatum of D1-Cre-flTrkB mice. To investigate if this change is specific to D1-Cre-flTrkB-S mice we are using D1-Cre-flTrkB-RiboTag mice to measure Egr3 levels selectively in D1-MSNs. We also performed chromatin immunoprecipitation to examine Egr3 transcriptional regulation of GABA-A subunits in these mice. Finally, to determine if restoring Egr3 levels to D1-MSNs can rescue the stereotypy behaviors we injected AAV-DIO-Egr3-eYFP into the dorsal striatum of D1-Cre-flTrkB mice. Our findings demonstrate that D1-MSNs, through dysfunctional BDNF signaling, play a role in juvenile onset of stereotypy behaviors. The enhanced stereotypy behaviors potentially occur through reduced inhibition in D1-MSNs via altered Egr3 regulation of GABA-A subunits. Our ongoing studies can provide novel insight into the cell subtypes and molecular mechanisms underlying stereotypy disorders.

Abstract: A major limitation in treating Parkinson's disease (PD) is the development of L-Dopa-induced dyskinesias (LID), which are disruptive involuntary movements that lead to a decreased quality of life in PD patients. Prior research demonstrates that mice lacking the D1-dopamine receptor (D1DR) do not develop LID. Here, we injected the D1DR antagonist SCH23390 (1 mg/kg, ip) and investigated changes in activity of medium spiny neurons (MSN) in the striatum of a 6-OHDA PD mouse model following LID development. We found that administration of SCH23390 modulated striatal activity and decreased some subtypes of dyskinesias. We studied this issue using computer-assisted tracking of LID. We further studied the role of the striatal D1DRs in D1-Cre mice by optogenetically inhibiting or stimulating D1DR expressing MSN in the striatum while simultaneously recording striatal activity during LID. We also investigated how activity of MSN related to striatal field potentials. These results may elucidate how D1DR expressing neurons in the striatum dysfunction during LID and further the understanding of the mechanism underlying LID.

Title: Functional shift in noradrenergic control over behaviour between the development and the expression of compulsivity

Authors: *A. BELIN-RAUSCENT[1], S. A. TORRISI[1], B. J. EVERITT[2], D. BELIN[1];
[1]Pharmacol., [2]Psychology, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: The neural basis of individual vulnerability to compulsive disorders remains largely unknown. Whereas most research on compulsivity has hitherto focused on dopaminergic or serotoninergic mechanisms, there is increasing evidence that noradrenergic processes influence impulse control and contribute to the development of impulsive/compulsive behaviours. Thus, in rats, atomoxetine, a selective noradrenergic reuptake inhibitor, decreases trait high impulsivity and the associated vulnerability compulsively to relapse to cocaine seeking. Atomoxetine also prevents, in highly impulsive rats, the development of an excessive, maladaptive and compulsive adjunctive behaviour as measured under a schedule-induced polydipsia procedure (SIP).
While the effect of atomoxetine on high impulsivity has been shown to depend upon noradrenergic mechanisms in the shell of the nucleus accumbens (AcbS), the precise neural locus of this noradrenergic control over the development, and expression of compulsive behaviour remains unknown.
Having demonstrated that chronic atomoxetine treatment prevents the development of compulsivity in the SIP procedure in highly impulsive rats known to be more vulnerable to develop compulsivity than low impulsive rats, we investigated whether atomoxetine could also influence the well-established expression of compulsivity.
Sprague Dawley rats were characterized as high or low compulsive based upon their water intake after 21 days of training under SIP. Rats then received daily intraperitoneal injections of either vehicle or atomoxetine for 3 weeks. In marked contrast to its influence on the development of compulsivity, atomoxetine potentiated the well-established expression of SIP in high compulsive rats only.
These results show that atomoxetine exerts opposite influence on the development and the expression of compulsivity, preventing the former while enhancing the later. This suggests that a shift in the nature of the noradrenergic control over behaviour occurs over the course of the development of compulsivity. Noradrenaline may therefore be involved in the switch from impulsivity to compulsivity.

Title: Evidence of maladaptive goal-directed system in obsessive-compulsive disorder (OCD) as indexed by abnormal instrumental contingency

Authors: *M. M. VAGHI[1,2], A. M. APERGIS-SCHOUTE[3,2], A. SULE[4], N. A. FINEBERG[5], R. N. CARDINAL[3,2], T. W. ROBBINS[1,2];

Trust, Penrith, Cumbria, United Kingdom; [5]Hertfordshire Partnership Univ. NHS Fndn. Trust and Univ. of Hertfordshire, Hertfordshire, United Kingdom

Abstract: Obsessive-compulsive disorder (OCD) is regarded as a prototypical disorder of compulsivity in which actions persist despite being inappropriate to the situation and without relationship to the overall goal. To test this hypothesis formally, we used contingency degradation, a procedure devised to test whether instrumental behavior is guided by knowledge of the relationship between an action and its consequences. In this classic free-operant behavioral assay, the relationship between the action and its associated outcome is weakened by the additional delivery of non-contingent outcomes. Across species, action response rate declines selectively under contingency degradation when the outcome is no longer associated with that action. In humans a similar effect has been shown not only for action response rate by also for causal judgements. Moreover, the influence of contingency degradation is mediated by a cortico-striatal brain system, including the caudate nucleus, that has been shown to be abnormal in patients with OCD. We tested a sample of healthy volunteers and patients with OCD using a contingency degradation task in which we manipulated P (outcome | action) and P (outcome | no action) to produce different levels of positive, degraded, and negative contingency (when action is disadvantageous as it prevents the outcome from occurring). Both response rates and explicit causal judgements showed a systematic decline as objective contingency decreased. There was a significant interaction between contingency and group in the extent to which explicit causal judgements predicted response rates, suggesting that OCD patients were less aware of whether an action was advantageous or disadvantageous. In addition, for positive contingencies, there

was a trend for response rate to be less sensitive to contingency degradation in OCD patients. These data lend further support to the hypothesis that abnormal goal-directed regulation and more specifically altered instrumental contingency learning play a role in sustaining maladaptive OCD psychopathology.

Title: Disruption of cognitive flexibility in models with disturbances in cortico-striatal circuit function: relevance to OCD

Authors: *E. E. MANNING[1], J. SHEN[1,2], B. BIZUP[1], M. TORREGROSSA[1], S. E. AHMARI[1]; [1]Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA; [2]Tsinghua Univ., Beijing, China

Abstract: Background: Obsessive Compulsive Disorder (OCD) is a chronic, severe mental illness, but despite its severity and prevalence, the pathophysiology remains unclear. Functional imaging studies in patients demonstrate increased activity in cortico-striato-thalamo-cortical (CSTC) circuits after symptom provocation; and we recently demonstrated that brief but repeated orbitofrontal cortex (OFC)-ventromedial striatum (VMS) optogenetic hyperstimulation can induce OCD-like increased grooming in mice (Ahmari et al., *Science* 2013). Studies in transgenic models [such as the SAPAP3 knockout (KO) mouse] also support the role of CSTC disturbances in the emergence of compulsive grooming. Disruption of flexible cognition plays a critical role in the symptoms observed in OCD, and yet the effects of OCD-relevant changes in CSTC function have not been addressed in relevant animal models. The current study characterizes cognitive flexibility in an operant reversal learning task in two independent animal models of OCD-relevant CSTC dysfunction; OFC-VMS hyperstimulation and SAPAP3 KO mice.
Methods: To generate OFC-VMS hyperstimulation, mice were injected with AAV-channelrhodopsin-EYFP or AAV-EYFP in the OFC, and implanted with fiberoptics in the VMS. Following at least 7 days of daily stimulation [5 minutes, 473nm, 1-10mW, 10Hz, 10msec pulse width], food restricted mice were tested on discrimination and reversal learning. Testing

occurred in operant chambers with two levers, and mice were first trained to press one lever to receive a food reward; after several days of training the contingency was reversed. Separate cohorts of SAPAP3 KO and wild-type (WT) littermates were tested in operant chambers under similar conditions. Data were analyzed using repeated-measures ANOVAs and post-hoc tests ($\alpha = 0.05$).
Results: mOFC-VMS stimulated mice and SAPAP3 KO mice showed a similar preference for the active lever to control groups during the discrimination phase. In contrast, both models showed impairments in cognitive flexibility following contingency reversal.
Conclusions: CSTC disruption is associated with impairments in flexible behaviour in a reversal learning paradigm. Further comparison of the neural mechanisms underlying impaired reversal in these two models may shed light on neural mechanisms underlying perseverative behavior and disruption of flexible cognition in OCD. Improved understanding of the neural mechanisms underlying disruption of cognition in OCD, using circuit-specific tools, may provide insight regarding new treatment targets for the disorder.

Title: Voxel-wise predictors of response to stereotactic capsulotomy for OCD

Authors: *P. NANDA[1], G. P. BANKS[2], Y. PATHAK[2], D. L. PAULO[2], G. HORGA[2], M. Q. HOEXTER[3], Z. XU[4], A. C. LOPES[3], N. C. MCLAUGHLIN[5], B. GREENBERG[5], J. P. SHEEHAN[4], E. C. MIGUEL[3], A. A. GORGULHO[3], A. A. DE SALLES[3], E. T. FONOFF[3], S. A. RASMUSSEN[5], S. A. SHETH[2];
[1]Neurolog. Surgery, [2]Columbia Univ., New York, NY; [3]Univ. of Sao Paulo, Sao Paulo, Brazil; [4]Univ. of Virginia, Charlottesville, VA; [5]Brown Univ., Providence, RI

Abstract: Introduction: Whereas most patients with obsessive-compulsive disorder (OCD) are well controlled with pharmacological and behavioral therapy, 10-20% remain severe and refractory. Lesions in the anterior limb of the internal capsule (ALIC) have been used for decades to treat these patients. Recent stereotactic radiosurgical (SRS) studies have demonstrated significant symptom response in 30-70% of patients. One factor in response variability may be differences in brain networks affected by lesions. We used voxel-based statistics and diffusion

tensor imaging to identify successful targets and examine involved networks.
Methods: We analyzed postoperative volumetric T1 MRIs from 21 patients with refractory OCD who underwent SRS capsulotomy at 2 institutions. Data were analyzed using a voxel-based generalized linear model to identify an area predicting clinical response. Using an atlas from diffusion data of 842 Human Connectome Project controls, we identified fiber-tracts crossing this significantly predictive area ("predictive ROI").
Results: The statistical model identified right and left ALIC regions significantly differentiating responders from non-responders. The predictive ROI exhibited connections with orbitofrontal cortex (OFC) and thalamus.
Conclusions: SRS capsulotomy remains attractive for severe, refractory OCD. This analysis shows that lesions in right and left ALIC will more likely produce clinical response. Lesions here modulate a network connecting OFC and thalamus, supporting the hypothesis that aberrant frontal cortico-basal-thalamo-cortical positive feedback loops may underlie OCD. Prospective longitudinal imaging collection will help validate our understanding of affected networks, permit individualized analyses, and improve this approach's efficacy.

Title: Acquisition and extinction of avoidance behaviors: The role of context

Authors: *T. K. JACOBSON[1], J. R. PHILLIPS[1], R. D. BURWELL[1,2];
[1]CLPS, [2]Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: Avoidance is a hallmark feature of many syndromes of pathological anxiety, including obsessive-compulsive disorder (OCD) and post-traumatic stress disorder (PTSD). Animal models of these syndromes typically use classical conditioning paradigms (i.e. fear conditioning in rats), but there are limitations to these approaches. Notably, most fear-conditioning studies focus on passive and reflexive defensive behaviors, such as freezing, and ignore active defensive behaviors, (i.e. active avoidance) evident in OCD and PTSD. Also, few studies attempt to model the role of context in the pathology and treatment of these disorders. The use of context to guide cognition and behavior is disrupted in PTSD and OCD, and the primary treatments for OCD and PTSD are forms of exposure therapy that are highly context dependent. Exposure to trigger stimuli outside the therapy context results in relapse and the return of pathological avoidance behaviors. Available evidence suggests that different neural circuits modulate active and passive defensive behaviors. Both circuits involve prefrontal regions and the periaqueductal gray. Passive behaviors (freezing) are supported by a prefrontal->amygdala->ventrolateral PAG pathway, whereas active behaviors (avoidance) are supported by a prefrontal->ventral striatum->dorsolateral PAG (dlPAG) pathway. Importantly, both pathways include connections with parahippocampal cortex (PHC), which is critical for representing spatial context. PHC and its rodent homolog, the postrhinal cortex (POR), have reciprocal connections with prefrontal regions and project to both striatum and the central nucleus of the amygdala. We have developed a novel paradigm, the Contextual Approach/Avoidance Task (CAAT), which is motivated by this circuitry and addresses limitations of existing models. CAAT models conditioning to anxiety-provoking stimuli, active avoidance, relapse (both renewal and reinstatement), and the context-dependency of extinction. Briefly, rats are implanted with stimulation electrodes in the dlPAG. Stimulation of the dlPAG causes unpleasant, anxiety-provoking sensations. After recovery rats are shaped on the CAAT. Unpleasant anxiety-like sensations are conditioned to the tone with several Tone->dlPAG stimulation pairings. Next rats are trained in avoidance learning. During a trial, the tone and a visual cue on the floor are presented simultaneously. Rats learn to avoid

dlPAG stimulation by approaching the cue. We will present data on acquisition, extinction, and renewal in the CAAT task. Strategies for minimizing the context-dependency of extinction in this model of anxiety disorders will be discussed.

Title: Exploring activation-connectivity relationships in Obsessive-Compulsive Disorder: Conjoint assessment of task-based activation profiles and resting state functional connectivity

Authors: *H. PAREKH[1], K. RAMASESHAN[2], A. BURGESS[2], G. HANNA[3], P. ARNOLD[4], D. ROSENBERG[2], V. DIWADKAR[2];
[1]Wayne State Univ., Sterling Heights, MI; [2]Wayne State Univ., Detroit, MI; [3]Univ. of Michigan, Ann Arbor, MI; [4]Univ. of Calgary, Calgary, AB, Canada

Abstract: Background: OCD are characterized by dysfunctional activation profiles in frontal, striatal and thalamic regions when basic working memory-related processing is induced (Diwadkar et al., 2015). The dynamic properties of regional activations stand distinctly from independent assessment of resting state signals (e.g., Anticevic et al., 2014). These latter studies suggest that OCD patients are characterized by a mix of hypo- and hyper-connectivity in cortical, striatal and cerebellar networks. The relationship between task-based activation profiles and resting state functional connectivity (rsFC) within subjects is unclear. Exploring these relationships within subjects may illuminate understanding of the mechanisms of pathology in both the task-active and task-free states.
Methods: 17 healthy controls and 22 OCD subjects underwent fMRI (3T Siemens Verio) during which they performed a standard verbal working memory paradigm (0-back and 1-back conditions: 30s epochs, Rest: 20s epochs). In the same imaging session, resting state (rs) fMRI data were collected in the same subjects (eyes closed). Task based data were processed using typical methods (SPM8). First level activation maps (1-Back > 0-Back) were submitted to second level random effects analysis to identify group differences in activation (HC ≠ OCD). rsfMRI images were separately preprocessed (Whitfield-Gabrieli & Nieto-Castanon, 2012) using

typical methods.
Results: Activation analyses identified regions of hyper- and hypo-activity in OCD. Hyper-activity was observed in the parietal lobe and dorsal anterior cingulate cortex (dACC); hypo-activity in the parietal lobe, basal ganglia, middle frontal gyrus (middle FG), dorsal prefrontal cortex (dPFC), and thalamus. Significance peaks ($p < .05$) for each contrast were identified as separate networks of inquiry for rsfMRI connectivity. Within network pairs, we assessed significant differences between groups (HC ≠ OCD, $p<.05$, FDR). Notably, for each of the task-based networks assessed (hyper- and hypo-active), no differences in rsFC were observed.
Conclusion: Activity differences that exist between OCD and HC may index dynamic pathology in brain function. However, our results indicate that the relationship between task-induced activation and rsFC between the identified pathological nodes is at best uncertain. More assessment will be needed to elucidate relationships between task-active and resting FC (Deco et al., 2013), and their relevance for OCD associated brain network dysfunction.

Title: Influence of Tourette Syndrome associated SNP on cortical thickness and behavior in children and young adults

Authors: *T. K. HSU, A. KRAFNICK, A. TOGA, K. CLARK;
USC Mark and Mary Stevens Neuroimaging and Informatics Inst., Keck USC Sch. of Med., Los Angeles, CA

Abstract: Background: Tourette syndrome (TS) is a neurologic developmental disorder with one of the highest familial recurrence rates among neuropsychiatric diseases with complex

inheritance pattern. A genome-wide association study (GWAS) study found multiple genetic markers with increased susceptibility to developing TS. The single nucleotide polymorphism (SNP) with the highest signal was rs7868992 which occurs in COL27A1, a fibrillary collagen gene located on chromosome 9q32-33. We undertook the current study to find correlations between the genetics, neuroanatomy and behavior. **Method**: Using neuroimaging and genetic data from the Pediatric Imaging, Neurocognition and Genetics Study (PING) from 409 subjects (209 M/ 200 F; ages 8-21), cortical thickness variations with genotype for SNP rs7868992 (COL27A1) was investigated using FreeSurfer with group analysis. Post-hoc correlation with cognitive abilities as measured by the NIH toolbox Flanker and Dimensional Change Card Sort (DCCS) test were used to examine relevant behavior within regions identified by the genotype analysis. **Results**: Significant variations with genotype was found for rs7868992 (COL27A1) within females in both the left and right hemispheres. In the left lingual and parsorbitalis regions significant differences were found between GA and AA genotypes ($p<0.01$, cluster extent corrected). In the right superiorparietal and lateraloccipital regions significant differences were found for GG and AA ($p<0.01$). In the right post central gyrus regions significant differences were noted for GG and GA as well ($p<0.01$). Significant correlation between cortical thickness and behavioral scores within the female population, specifically, an inverse relationship between lingual and pars orbitalis cortical thickness and behavioral scores. **Conclusion**: The data show that genetic variation in COL27A1 are related to significant changes in cortical thickness and behavioral scores in regions that may be relevant to the development of Tourette Syndrome. The effect was specific to females and further investigations are warranted to ascertain the cause.

Title: Attenuation of compulsivelike behavior through positive allosteric modulation of alpha4beta2 nicotinic acetylcholine receptors in noninduced compulsive-like mice.

Authors: *S. MITRA[1], M. MUCHA[2], S. N. KHATRI[4], R. GLENNON[6], M. K. SCHULTE[5], A. BULT-ITO[3];
[1]Dept. of Chem. Biochem., [2]Dept. of chemistry Biochem., [3]Biol. and Wild life, Univ. of Alaska Fairbanks, Fairbanks, AK; [4]Dept. of Pharmaceut. Sci., [5]Univ. of the Sci. Philadelphia, Philadelphia, PA; [6]Dept. of Medicinal Chem., Virginia Commonwealth Univ., Richmond, VA

Abstract: *Rationale:* Nicotinic *alpha4beta2* receptors are the most abundant subtypes of nicotinic acetylcholine receptors (nAChRs) expressed in brain regions implicated in OCD. These receptors are known to modify normal and addictive behaviors by modulating neuronal excitability. Desformylflustrabromine (dFBr) is a novel, positive allosteric modulator (PAM) of HS (high acetylcholine sensitivity) and LS (low acetylcholine sensitivity) alpha4beta2 nAChRs. The present study tested the hypothesis that positive allosteric modulation of alpha4beta2 receptors by dFBr will attenuate compulsive-like behavior in a non-induced compulsive-like mouse model. *Methods:* Male mice (*Mus musculus*) selected for compulsivelike nesting behavior (48 animals; 12 per group) received a subcutaneous injection of dFBr at 2, 4 and 6 mg/kg doses. Saline was used as a control (0 mg/kg). Compulsive-like nesting behavior was assessed after 1, 2, 3, 4, 5 and 24 hours, while marble burying was performed 2 hours after dFBr administration. Anxietylike behaviors were determined by the open field test 2 hours after dFBr administration.*Results:* dFBr dose dependently attenuated compulsive-like nesting and marble burying behavior. No effects of dFBr were observed for anxietylike open field behaviors. *Conclusions:* This research demonstrates a novel therapeutic target for OCD and OCD spectrum disorders through positive allosteric modulation of alpha4beta2 nicotinic receptors.

Topic: G.08. Drugs of Abuse and Addiction

Title: Consideration of hemispheric asymmetry in addiction research

Authors: *H. W. GORDON;
Clin. Neurosci. Br., Natl. Inst. Drug Abuse, Bethesda, MD

Abstract: In a previously-published report (Gordon, 2016), it was demonstrated that two risk factors for addiction differentially activated the right and left hemispheres of the brain: impulsivity (assessed by response inhibition) activated areas in the right hemisphere; craving activated the left. This report extends these observations by demonstrating differential structural or activation effects on the right or left hemisphere by prenatal exposure to drugs of abuse or by ingestion by individuals themselves. Data were extracted from journal articles compiled from PubMed searches by pairing each drug of abuse with key words such as MRI or laterality. Then the brain structures and locations (i.e., right, left, bilateral) were tabulated. For prenatal exposure

across all substances (cocaine, nicotine, alcohol, cannabis, opiates), there were nearly 3 times as many unilateral (right or left) structures specifically mentioned than for (presumably equivalent) bilateral structures. There were nearly 4 times as many mentioned in individuals who were taking these drugs. However, contrary to the activation studies of impulsivity and craving, and in spite of the fact that unilateral structures were mentioned, the effects do not appear to favor one hemisphere more than the other. The most common anatomical effect for both prenatal exposure and/or adolescent or adult drug use was reduced gray matter volume or reduced cortical thickness, although for a few studies of prenatal alcohol exposure, thicker cortices were reported. Among individuals taking drugs, thinning or reduced volume seemed to affect the left cingulate and superior frontal gyrus more than the right, but affected the right orbital and medial frontal cortices more than the left. Functional imaging (BOLD signals) was also affected by prenatal exposure usually in either right or, more often, left sites. For the most part, there was increased activation, though reduced activation was also reported. The significance of these observations is that drugs of abuse affecting individuals exposed either prenatally or as adolescents or adults seem to target individual structures in either the right or left hemisphere. Why this is the case is unknown. Perhaps there is differential brain development or neurotransmitter activity. Up to now, not much attention has been paid to these asymmetries. Consideration of them may give clues as to the basis of drug abuse and its effect on the brain. [Gordon, HW, Laterality of brain activation for risk factors of addiction. Title: Repeated administration of ketamine in adolescence produces affective changes that last into adulthood.

Authors: *T. ZAFAR, A. ROCHA, T. TOWNER, K. A. TRUJILLO;
Psychology, California State Univ. San Marcos, San Marcos, CA

Abstract: Ketamine (KET) was originally developed for clinical use as an anesthetic. Known as a 'dissociative drug,' it is popularly abused, especially by teens and young adults in club and rave settings. Ketamine produces out of body experience, cognitive disorganization, and hallucinations, as well as transient symptoms that mimic both positive and negative symptoms of schizophrenia. Moreover, because of its rewarding effects and broad availability, KET is often used by teens for recreational purposes. Behavioral sensitization is an increase in an effect of a drug after repeated adminstration. Also referred to as "reverse tolerance," sensitization is thought to be involved in the development of addiction. While there are reports of behavioral sensitization to ketamine in adult rats, little has been done to elucidate sensitization in adolescents, and potential differences in sensitization between adults and adolescents. The present study examined the locomotor effects of KET following repeated administration to adolescent and adult Sprague-Dawley rats. We hypothesized that ketamine would induce an increase in locomotor activity across days reflective of behavioral sensitization and that adolescent rats would differ in sensitization when compared to adults. Furthermore, we sought to determine if sensitization would persist into adulthood across two different behavioral paradigms. Animals received saline or KET (10 mg/kg s.c), once daily for seven days and locomotor activity was assessed each day to follow the development of locomotor sensitization. After a washout period in which the adolescent rats developed into adulthood, animals were given an injection of ketamine and ultrasonic vocalizations (USVs) were measured to assess the impact of early exposure on the rewarding effects of the drug. On day 1 of treatment, ketamine (10.0 mg/kg) induced a short-lived stimulant effect that was considerably greater in adolescents than adults. In addition, although both groups showed evidence of sensitization, the increase in response to ketamine across days was greater in adolescents than adults. After the washout period, the group that received repeated ketamine as adolescents showed the greatest number of USVs in response to ketamine, reflective of sensitization to the rewarding effect of the drug. Thus, while repeat administration of KET leads to behavioral sensitization, we found that this sensitization differs in adults and adolescents. Further research will help to determine the factors involved in KET sensitization in adults and adolescents, and may lead to better prevention and treatment for KET abuse and addiction in teenagers.

Title: Oxycodone reward in male and female adolescent rats: effects of dose

Authors: *N. SOLLENBERGER[1], A. MANOOGIAN[2], H. K. PARK[2], A. R. ZAVALA[2]; [1]Psychology, California State University, Long Beach, Lakewood, CA; [2]Psychology, California State University, Long Beach, Long Beach, CA

Abstract: Oxycodone abuse among adolescents has increased in recent years. Surprisingly, little preclinical research has examined the rewarding effects of oxycodone in male and female adolescent rats. To this end, we examined the rewarding effects of oxycodone in adolescent rats using the established conditioned place preference (CPP) paradigm. Male and female rats were assessed for oxycodone-induced CPP using an 11-day CPP procedure beginning on postnatal day (PD) 40. During pre-conditioning and post-conditioning sessions, rats were tested for their baseline and final place preference, respectively, in 15-min sessions. During conditioning (PD 42-47), rats underwent daily 30-min sessions, during which they received alternating oxycodone (0, .033, 0.1, 0.3, 0.9 mg/kg) and saline injections in distinct compartments. Results indicated that regardless of sex, rats showed a significant shift towards the oxycodone-paired compartment at the higher doses, suggesting that the CPP model may be useful for understanding the neurobiology of oxycodone abuse in adolescence.

Title: Early-life experience decreases opioid self-administration in adulthood through anti-inflammatory IL-10 signaling in nucleus accumbens

Authors: *M. J. LACAGNINA[1], A. M. KOPEC[1], S. S. COX[1], C. WELLS[2], S. SLADE[2], P. M. GRACE[3], L. R. WATKINS[3], E. D. LEVIN[2], S. D. BILBO[1];

Abstract: Opioid drug abuse is a serious public health concern with few effective therapeutic strategies. There is evidence that opioids can activate glial cells within the nucleus accumbens (NAc), and the subsequent pro-inflammatory cytokine and chemokine response may contribute to drug reward and relapse. We have previously shown that a neonatal handling procedure in rats (which promotes enriched maternal care) reduces glial activation in response to an acute morphine challenge and attenuates morphine conditioned place preference. We hypothesize that these responses may be driven in part by increased expression of the anti-inflammatory cytokine interleukin-10 (IL-10). Here, we employed a model of opioid self-administration to interrogate the effects of early-life experience on later-life drug taking for male Sprague-Dawley rats. Neonatal handling attenuated intravenous self-administration of remifentanil (a short-acting synthetic opioid) in a dose-dependent manner, as handled rats self-administered less remifentanil by the final day of drug acquisition. Transcriptional profiling revealed a unique suppression of chemokine signaling molecules in the NAc of handled rats. To determine if anti-inflammatory IL-10 could explain this effect, we delivered bilateral intracranial injections of naked plasmid DNA encoding IL-10 (pDNA-IL-10) or a control plasmid along with the transgene adjuvant D-mannose into the NAc of naïve rats. Treatment with pDNA-IL-10 reduced the number of remifentanil infusions acquired in a dose-dependent fashion, an effect similar to handled rats. Importantly, neither handling nor pDNA-IL-10 treatment altered operant responding for food or sucrose pellets compared to controls. These collective observations suggest that neuroimmune signaling in the NAc can be influenced by early-life experience, and these signaling mechanisms may be important in the development of self-motivated opioid drug acquisition. In addition, these results demonstrate that *in vivo* manipulation of anti-inflammatory IL-10 represents a promising target for future investigations.

Title: The effects of prenatal stress on cocaine reward, cocaine locomotion and sensorimotor processing are heritable in the BXD recombinant inbred strain panel

Authors: *J. R. BAGLEY, R. BOZADJIAN, L. BUBALO, K. L. PLOENSE, P. A. VIEIRA, T. E. KIPPIN;
UC Santa Barbara, Santa Barbara, CA

Abstract: Early life stress has been implicated in a number of psychiatric conditions, including addiction and schizophrenia, and appears to be involved in complex gene X environment interaction leading to pathology. To dissect this interaction, we have been examining the impact of prenatal stress (PNS) on cocaine-seeking/locomotion and sensorimotor processing in mice with different genetic backgrounds. Previously, we found that PNS in C57BL/6 (B6) but not DBA/2 (D2) increased the magnitude of cocaine-induced conditioned place preference (CPP) and cocaine induced locomotion whereas PNS in D2, but not B6, impaired pre-pulse inhibition (PPI) of acoustic startle. Identification of the alleles mediating these interactions is an important step in understanding the underlying neurobiology. In pursuit of this goal, we have characterized the effects of PNS on BXD recombinant inbred strains. These strains possess unique combinations of B6 and D2 alleles and may allow for identification of quantitative trait loci (QTLs) that mediate the effects of PNS. **Methods.** BXD strains were subject to timed mating followed by assignment to PNS and control groups. PNS dams were placed in a restraint stress protocol (1 hour restraint, 3 times daily) starting between embryonic day (E) 11 and 14 and continued until parturition. PNS may affect developmental outcomes by altering maternal behavior in the post-natal period. Accordingly, the frequency of pup-dam contact was measured in the first 10 post-natal days. Adult control and PNS offspring (8 to 9 weeks) were tested in a PPI procedure (110 dB startle, 74 and 90 dB PPI) followed by cocaine (10 mg/kg, I.P.) CPP. **Results.** We have found PNS by strain interactions, indicating the effects of PNS are heritable in the BXD panel. Specifically, PNS interacts with strain to alter cocaine acute locomotion, locomotion sensitization and CPP, acoustic startle response and PPI. PNS interacts with strain to alter pup-dam contact, with the most frequent effect being a reduction in contact. Interestingly, the PNS strain effect on maternal behavior correlates with the PNS strain effects on cocaine reward/locomotion, but not with startle or PPI, indicating the effects of PNS on cocaine related behaviors may be mediated by changes in maternal behavior in the post-natal period. Overall, these results suggest that the effects of PNS on cocaine reward/locomotion, sensorimotor processing and maternal stress response are heritable in the BXD panel. Future work will seek to identify QTLs, and ultimately polymorphisms, that mediate the effects of PNS. This research may serve to elucidate gene X environment interactions that lead to the development of psychiatric disorders.

Title: One-trial methamphetamine-induced locomotor sensitization in male and female adolescent rats

Authors: *B. SALINAS, E. BATES, B. SCHUESSLER, A. SU, L. TRAN, A. R. ZAVALA; California State University, Long Beach, Long Beach, CA

Abstract: One-trial locomotor sensitization is the process by which a single exposure to a drug leads to a progressively higher locomotor behavioral response during a subsequent drug exposure. In adult rats, the context, or the environment where the initial drug administration took place, plays a key role in the development of this phenomenon. One-trial sensitization in young rats (postnatal days (PD) 21 or younger) is characteristically different. For instance, young rats typically demonstrate one-trial sensitization to cocaine and methamphetamine (METH), but the sensitization is context-independent (i.e., rats exhibit sensitization regardless of where the drug was given). Few studies have examined one-trial sensitization in adolescent rats. Thus the present study examined one-trial sensitization in adolescent rats to determine the ontogeny of context-dependent METH sensitization. Adolescent (PD 48) male and female rats were pretreated with saline or 3.0 mg/kg METH (IP) and immediately placed in a novel test chamber where locomotor activity was measured for 60 min. To assess for context-dependent sensitization, rats that were previously given saline in the novel chamber were injected with saline or 3.0 mg/kg METH (IP) in their home cage 45 min after being returned from the novel chamber. In contrast, rats given METH in the novel chamber were injected with saline in the home cage. The next day (i.e., PD 49), rats from each group were given a challenge injection of METH (0, 0.15, or 0.3 mg/kg, IP) in the novel test chamber and their locomotor activity was assessed for 90 min. Results show that adolescent female rats largely exhibited a weaker sensitized behavioral response after administration of METH that was primarily expressed during the first 30 min of testing. In contrast, adolescent male rats pretreated with 3.0 mg/kg METH showed drug-induced context-dependent locomotor activity relative to control conditions.

This indicates that in adolescent males, one-trial sensitization is similar to adult one-trial sensitization in that they are both context-dependent, unlike younger rats (PD 21) who exhibit context-independent one-trial sensitization.

Title: Developmental methamphetamine exposure causes lasting changes to mesolimbic dopamine signaling.

Authors: ***D. TORRES**[1], S. BARAYUGA[1], R. RUELI[1], J. YORGASON[2], M. ANDRES[3], S. STEFFENSEN[4], F. BELLINGER[1];
[1]Cell and Mol. Biol., Univ. of Hawai'i at Manoa Dept. of Cell and Mol. Biol., Honolulu, HI; [2]Vollum Inst., Oregon Hlth. and Sci. Univ., Portland, OR; [3]Pacific Biosci. Res. Ctr., Univ. of Hawaii at Manoa, Honolulu, HI; [4]Dept. of Psychology, Brigham Young Univ., Provo, UT

Abstract: Abuse of Methamphetamine (METH), a neurotoxic psychostimulant that affects the dopaminergic system, has become a serious public health issue in the United States and is of particular concern regarding pregnant women who are users. While the teratogenic effects of drugs such as alcohol and cocaine have been extensively investigated, much less is known about the effects of prenatal methamphetamine exposure (PME). Recent findings show that PME can produce lasting deficits in attention, arousal and memory. Exposure during the third trimester of pregnancy can have particularly harmful consequences as it is during this period that the brain growth spurt begins and neurons are especially vulnerable to insult. In this study, we investigated the long-term consequences of early methamphetamine exposure using a mouse model of human third-trimester exposure. METH increases dopamine (DA) signaling by inhibiting DA reuptake and triggering reverse transport of DA through its transporters. DA neurons can release DA through action-potential dependent and independent mechanisms. We used fast-scan cyclic

voltammetry (FSCV) to measure DA responses to METH in adult mouse nucleus accumbens (NAc) brain slices following developmental METH exposure. PME model mice exhibited impaired basal DA reuptake kinetics compared to control mice. The reduced rate of DA reuptake indicates reduced levels of the dopamine active transporter (DAT). Developmental METH exposure did not alter peak evoked DA release either prior to or following acute METH application. METH-induced impairments of DA reuptake were attenuated, however, in comparison to controls. In contrast to evoked DA release, non-evoked DA release in response to acute Meth application was increased by developmental Meth exposure. Behavioral tests revealed increased hyperactivity in adulthood of PME model mice. This data suggests that METH exposure during this period of development causes long-lasting changes within the mesolimbic system. These changes alter behavior and physiological responses to METH in adulthood.

Title: The influence of prenatal buprenorphine exposure on the nociceptin/orphan FQ system in the locus coeruleus of offspring rats

Authors: *Y.-C. CHIANG[1,2], J. WU[1], C.-W. LEE[3,4], I.-K. HO[1,2];
[1]Ctr. for Drug Abuse and Addiction, China Med. Univ. Hosp., Taichung, Taiwan; [2]China Med. Univ., Taichung, Taiwan; [3]Div. of Basic Med. Sci., [4]Dept. of Nursing, and Chronic Dis. and Hlth. Promotion Res. Ctr., Chang Gung Inst. of Technol., Chiayi, Taiwan

Abstract: Abuse of addictive substances is a serious problem, which has significant impact on health, economy, public safety and society. Buprenorphine is a new maintenance agent for treating heroin addicts, that has benefits on less addictive liability and respiratory depression when compared to methadone. Buprenorphine has also been used to treat opioid addictive

pregnant women, yet the intrauterine effects of buprenorphine on the offspring are still unclear. This indicates that investigating the prenatal effects of buprenorphine on the offspring is an important and urgent issue. Buprenorphine is an agonist-antagonist mixed agent acting on both μ-opioid receptor and nociceptin/orphan FQ receptor (NOPR) at high doses (detoxification doses). Our previous studies showed that prenatally higher dose of buprenorphine (3 mg/kg/day)-exposed rats exhibited a marked change in the postnatally morphine-induced tolerance, and dopaminergic-mediated cellular pathways in the nucleus accumbens. In the current study, we showed that when treated only with vehicle, higher frequencies of withdrawal signs precipitated by NOPR antagonist J113397 (4 mg/kg) were exhibited in the prenatally buprenorphine-exposed offspring as compared with the prenatal vehicle-exposed subjects. The precipitated withdrawal symptoms could also be observed after postnatal treatment of buprenorphine in a dose dependent manner. The levels of mRNA and protein of NOPR in the locus coeruleus were also changed after prenatal or postnatal exposure to buprenorphine, but the nociceptin mRNA (precursor) and protein expressions were only changed in postnatal buprenorphine exposure condition. Since the protein kinase C (PKC) and beta-arrestin systems have been reported to play an important regulatory role in opioid receptors internalization, the PKC and arrestin expressions were also investigated in this study. Different protein expression patterns of beta-arrestin 1 and 2, and PKC δ and γ were obtained after buprenorphine re-exposure on prenatally buprenorphine-exposed rats. The study reveals that prenatal exposure to buprenorphine caused long-term and complex effects on postnatal buprenorphine-induced withdrawal and dependence on the offspring.

Title: Effects of late gestational cannabinoid exposure on behavioral development in rats

Authors: *B. ZAMUDIO[1], K. R. BREIT[2], J. D. THOMAS[3];
[1]Psychology, San Diego State Univ., Chula Vista, CA; [2]Psychology, [3]San Diego State Univ., San Diego, CA

Abstract: Given the recent legalization of marijuana for both recreational and medical use in several states, cannabis use has increased, even among pregnant women. The most psychoactive

constituent in cannabis, delta-9- tetrahydrocannabinol (Δ9-THC), crosses the placenta during maternal consumption and can directly affect the fetal brain. Some prospective clinical studies indicate that developmental cannabinoid exposure may alter long-term behavior in emotional and cognitive functioning domains. However, given the increasing potency in cannabinoid products available today and the novel "synthetic marijuana" market, fetal consequences may be more severe. The goal of this study was to investigate the effects of cannabinoid exposure on behavioral development. Using an animal model, the present study examined the effects of cannabinoid exposure during the brain growth spurt, a period of brain development during which there is a rapid increase in the number of CB1 cannabinoid receptors in multiple brain areas. Sprague-Dawley rats were randomly assigned to one of 3 groups receiving varying doses of the cannabinoid receptor agonist CP 55,940 (CP; 0.10, 0.25, 0.40 mg/kg/day), an agonist that activates both CB1 and CB2 cannabinoid receptors. Subjects received i.p. injections of CP or vehicle from postnatal day (PD) 4 through 9, a period of brain development equivalent to the human third trimester; control subjects were injected with DSMO or saline vehicle. From PD 12-20, motor development was assessed with a hindlimb coordination task, on PD 25, anxiety was measured with an elevated plus- maze, and on PD 40-46, spatial learning was assessed with the Morris water maze. Cannabinoid exposure altered the trajectory of motor development. Subjects exposed to CP were more successful in hindlimb coordination at an earlier age compared to controls. In contrast, there were no significant effects of CP on open arm entries within the elevated plus maze, although CP increased grooming behavior, suggesting that perinatal CP exposure has little effect on later anxiety. Finally, the highest dose of CP significantly impaired spatial memory, but only among the female subjects. These data suggest that cannabis exposure late in gestation alters brain and behavioral development, but in a domain- and sex-dependent manner. These data have important implications for children of women who consume cannabis during pregnancy. Further elucidation of the effects of prenatal cannabinoid exposure has important implications for public health that may guide public policy on cannabis, particularly for use during pregnancy.

Title: Adolescent THC exposure following stress induces synaptic changes in adult rats

Authors: E. REPO, N. LANDRY, T. BENT, A. STILLAR, M. SAARI, *A. C. WEEKS; Nipissing Univ., North Bay, ON, ON, Canada

Abstract: The legalization and increased use of cannabis and its main constituent Δ9-tetrahydrocannabinol (THC), as a recreational and medicinal drug, has enhanced research interest related to the potential interactions of cannabis use and other psychological conditions. For example, adults and adolescents often report using cannabis as a way of coping with stress and anxiety. While the effects of marijuana use on the adult brain are fairly well understood, less is known about chronic use during adolescence. This study assessed anxiety levels and social interaction in adult rats after chronic THC was given following an isolation stressor event during the adolescent phase of development. Four experimental groups included: isolation/THC, no isolation/THC, isolation/vehicle, and no isolation/vehicle. Following one week in the housing condition (isolation or social housing), daily THC or vehicle injections were carried out for 15 days starting at post-natal day 43 (see Fig. 1). An open field test was completed after the isolation period, but before injections, to assess pre-THC anxiety levels. Following the injections, a withdrawal period, and a maturation delay, an elevated zero maze and a social interaction task were used to assess anxiety/fear related behavioural changes. The behavioural results from the zero maze indicated that chronic adolescent THC administration following isolation-induced stress caused adult rats to spend less time in the closed regions during the first minute in the maze. For the social interaction task, there was a main effect of the drug where animals treated with THC were found to groom other rats significantly less often. Following the behavioural tests, the rats were perfused for confocal microscopy. Pilot data from this analysis related to changes in synaptic protein levels in the nucleus accumbens suggests that THC leads to a decrease in synaptic compliment in this brain region. Full synaptic results from the nucleus accumbens and other brain areas such as the amygdala, will be presented. Figure 1

Title: Permanent disruptions of hippocampal GABAergic neurotransmission in adult rats following perinatal Δ^9-THC exposure.

Authors: *S. BEGGIATO[1,2], M. C. TOMASINI[3], A. C. BORELLI[3], T. ANTONELLI[3], L. FERRARO[3], S. TANGANELLI[3];
[1]Psychiatry, Univ. of Maryland Baltimore, Baltimore, MD; [2]Life Sci. and Biotech., [3]Univ. of Ferrara, Ferrara, Italy

Abstract: Cannabis or its psychoactive component delta^9-tetrahydrocannabinol (Δ^9-THC) is the most commonly abused illicit drug by pregnant women. Despite its wide use, at present, the long-lasting effects on the adult brain of the offspring are still unclear. It has already been showed that prenatal cannabinoids exposure induces learning and memory disruption in rat adult offspring, associated with permanent alterations of cortical glutamatergic neurotransmission (1) and cognitive deficits (2). In the present study, the risk of long-term consequences induced by perinatal exposure to cannabinoids (CBs) on hippocampal GABAergic system of the male offspring, has been explored. To this purpose, pregnant rats were treated daily with Δ^9-THC (5 mg/kg by gavage) or its vehicle. Litters from both groups were then assigned to non-exposed mothers whose pups were born on the same day. Perinatal exposure to Δ^9-THC induced a significant reduction ($p < 0.05$) in basal and K^+-evoked [^{3}H]-GABA outflow from 90-day old rat hippocampal slices. Furthermore, by using this preparation, we observed that the pharmacological challenge with either Δ^9-THC (0.1 μM) or WIN 55,212-2 (2 μM), significantly reduced K^+-evoked [^{3}H]-GABA outflow ($p < 0.05$). The reduction was significantly blocked by adding the CB_1 antagonist SR141716A. Perinatal exposure to Δ^9-THC induced a significant reduction on CB_1 receptor binding in hippocampus of rats and a significant reduction on CB_1 receptor mRNA expression ($p < 0.01$). Finally, in adult rats born from Δ^9-THC exposed dams were observed a significant decrease of hippocampal [^{3}H]-GABA uptake compared to vehicle exposed groups and a significant reduction of GAT-1 mRNA expression ($p < 0.01$). These findings suggest that perinatal exposure to Δ^9-THC induces long-term alterations of hippocampal GABAergic system. Interestingly, previous behavioural studies demonstrated that, under the same experimental conditions as in the present study, perinatal CBs exposure induced cognitive impairments in adult rats (1,3) Thus, although it is difficult and sometimes misleading to extrapolate findings obtained from animal models to humans, the possibility that an alteration of hippocampus aminoacidergic transmission might underlie, at least in part, some of the cognitive deficits affecting the offspring of marijuana users, is supported. *References* 1) Ferraro et al., J

Abstract: The use of anabolic androgenic steroids (AAS) by adolescents is rising. Adolescents seek AAS because of their anabolic properties unaware of the effects these might have on the developing reproductive and nervous system. Previous studies show that AAS cross-sensitize with other drugs of abuse such as cocaine. Whether these effects persist through adulthood remains unknown. For 10 consecutive days, starting on day 28, adolescence male rats received daily injections of nandrolone decanoate (20mg/kg/sc) or of vehicle. When they reached 64 days of age, Starting on day 64, they were tested for locomotor sensitization to cocaine. From days 1-5 and at days 13 and 23 rats received an injection of cocaine (15 mg/kg/ip). Their locomotor response to cocaine was measured at days 1, 5, 13 and 23. Nandrolone increased the locomotor response to cocaine on day 1, but did not affect the response thereafter. In addition, spermatogenesis, as well as testes and seminiferus tubule size, was decreased. These data show that AAS have long lasting effects on cocaine-induced locomotor activity and the reproductive system.

Title: Fluoxetine exposure during adolescence, in female C57bl/6 mice, does not influence Morris water maze performance in adulthood

Authors: *J. B. ALIPIO[1], L. M. RIGGS[1], S. D. IÑIGUEZ[2];
[1]Neurosci., Univ. of Maryland Baltimore, Baltimore, MD; [2]Psychology, Univ. of Texas at El Paso, El Paso, TX

Abstract: Mood-related disorders such as major depression are commonly diagnosed in children and adolescents, with a higher occurrence among females. The increasing prevalence of adolescent depression has resulted in parallel increases in the prescription rate of fluoxetine (FLX), the only antidepressant currently approved by the FDA for treatment of clinical depression within the juvenile population. Although treatment can last for years, very little is known about the consequences of antidepressant exposure during early developmental periods on memory performance in adulthood. Recently, in male rodents, it has been reported that juvenile FLX exposure results in a long-lasting altered memory-related behavioral phenotype - however, whether such memory-related alterations are observed in female mice has not been examined. Thus, we exposed adolescent (postnatal day [PD]35) c57bl/6 female mice to FLX (0 or 20 mg/kg/day) for 15 consecutive days. We then assessed animals' behavioral performance on the Morris water maze spatial memory task, three weeks after antidepressant exposure (PD70+). Specifically, mice were trained to find the location of a submerged escape platform on a single day task of 8 training trials, and memory for the platform location was tested after a 24 hour delay (distance traveled and velocity). To increase the demands of the spatial task, the mice returned to the maze, 48 hours after training, and completed a probe trial (escape platform absent). We found that adolescent FLX exposure did not influence spatial memory acquisition on the training day. Additionally, no differences between the groups were observed when spatial memory was examined 24 hours (test day) or 48 hours after training (probe trial). Together, our results suggest no long-lasting spatial memory deficiencies become apparent in female c57bl/6 mice exposed to FLX during adolescence.

Title: Effects of chronic caffeine exposure on rat brain serotonergic systems

Authors: *M. ARNOLD[1], T. M. SMITH[1], S. R. ARCHULETA[2], P. H. WILLIAMS[1], J. A. MCARTHUR[1], C. E. O'NEILL[2], C. A. LOWRY[1], R. K. BACHTELL[2];

Abstract: Chronic caffeine exposure during adolescence has been shown to induce persistent maladaptive anxiety-like behavioral responses that are evident during adulthood in rats. It is possible that these maladaptive responses are mediated by the serotonergic system. In this study, we investigated the effects of chronic adolescent caffeine exposure on rat brain serotonin (5-hydroxytryptamine; 5-HT) systems. Specifically, we analyzed serotonergic neuron gene expression and activation in subregions of the dorsal raphe nucleus (DRN), a brainstem region with abundant serotonergic neurons. After a week of acclimatization, rats were randomly divided into four groups in a two-by-two experimental design. Two groups received chronic caffeine (CC) administration in drinking water (0.3 g/L) from postnatal day 28 to postnatal day 56 while the other two groups received drinking water (NC) alone during the same developmental time period. After 28 days of caffeine or control treatment and a 24-hour washout period, rats received an i.p. injection of either 30 mg/kg caffeine (C) or 0.9% sterile saline (S) vehicle, were then replaced in their home cages, and were euthanized 90 minutes following treatment for immunohistochemistry experiments and 4 hours following treatment for in situ hybridization histochemistry experiments. This was a 2 x 2 design with four treatment groups, NCS, NCC, CCS, and CCC. In situ hybridization histochemistry analysis revealed that acute caffeine injection, in rats that chronically consumed either drinking water or caffeinated drinking water, induced widespread decreases in the expression of *tph2*, encoding tryptophan hydroxylase 2, the rate-limiting enzyme in neuronal serotonin biosynthesis. Similar effects of acute caffeine treatment were observed on *slc22a3* mRNA expression, encoding organic cation transporter 3 (OCT3). Rats that received chronic caffeine, relative to controls, and were subsequently treated with saline, also responded with decreased *tph2* and *slc22a3* mRNA expression, indicating persistent effects of caffeine on serotonergic systems. Using a double immunostaining technique we quantified the immunoreactivity for the acute activation marker c-Fos and tryptophan hydroxylase 2 (Tph2) as a marker of serotonergic neurons. NCC rats, relative to NCS and CCC groups, had higher activation of 5-HT neurons in a number of DRN subregions, supporting

persistent effects of caffeine exposure on anxiety-related serotonergic systems These data are consistent with the hypothesis that the DRN is a key structure in promoting the adult pro-anxiety behavioral phenotype following adolescent caffeine exposure.

Title: Cannabidiol mediated regulation of alcohol consumption

Authors: *M. GARCÍA-GUTIÉRREZ, SR[1], A. VIUDEZ-MARTÍNEZ[2], C. NAVARRON[2], M. MORALES-CALERO[3], F. NAVARRETE[2], A. TORRES-SUÁREZ[3], J. MANZANARES[2]; [1]Inst. De Neurociencias, Univ. Miguel Her, San Juan De Alicante, Spain; [2]Inst. de Neurociencias, Univ. Miguel Hernandez, San Juan de Alicante, Spain; [3]Facultad de Farmacia, Univ. Complutense, Madrid, Spain

Abstract: The aim of this study was to evaluate the effects of cannabidiol (CBD) in alcohol reinforcement, motivation and relapse in C57BL/6J mice. To this purpose, the effects of CBD (60 mg/kg i.p.) and ethanol on rectal temperature (3 g/kg p.o.), ethanol-handling-induced convulsions (HIC) (4 g/kg i.p.) and blood ethanol concentration (BEC) (3 g/kg p.o.) were studied. The two-bottle choice test was performed to evaluate the effect of CBD (30, 60 and 120 mg/kg/day, i.p.) on ethanol intake and preference. In addition, an oral ethanol self-administration experiment was carried out to evaluate the effect of CBD (poly-ε-caprolactone spherical microparticles with small pores which provided a CBD continuous controlled release (30 mg/kg, s.c.)) on the reinforcement and motivation for ethanol. A further oral ethanol self-administration was performed to evaluate the effects of CBD (60 and 120 mg/kg/day, i.p.) on ethanol-induced relapse. Gene expression analyses of tyrosine hydroxylase (TH) in ventral tegmental area (VTA) and μ-opioid receptor in nucleus accumbens (NAcc) were carried out by Rt-PCR.
The results revealed that a single dose of CBD (60 mg/kg, i.p.) reduced the ethanol-induced hypothermia and handling-induced convulsions (Two-way RM ANOVA; $p<0.001$). CBD failed to modify blood ethanol levels. In addition, CBD (30, 60 and 120 mg/kg/day, i.p.) reduced ethanol consumption (Two-way RM ANOVA; $p<0.001$) and ethanol preference (Two-way RM

ANOVA; $p<0.001$) in the two-bottle choice experiment. Interestingly, CBD (microparticle formulation (30 mg/kg, s.c.)) significantly decreased the ethanol intake and the number of active lever presses in the ethanol oral self-administration (Two-way RM ANOVA; $p<0.05$). Furthermore, CBD (60 and 120 mg/kg/day, i.p.) significantly reduced ethanol-induced relapse (Two-way RM ANOVA; $p<0.05$). In the ethanol self-administration study, CBD significantly reduced TH gene expression in the VTA (40%) (Student's t-test, $p<0.05$) and μ-opioid receptor gene expression (35%) in the NAcc (Student's t-test, $p< 0.05$).
In conclusion, these results reveal that the administration of CBD reduced the reinforcing properties, motivation and relapse for ethanol. These findings strongly suggest that CBD may result useful for the treatment of alcohol use disorders.

Title: Cannabidiol a drug lacking reinforcing activity

Authors: ***J. MANZANARES**, J. MEDRANO-RELINQUE, A. VIUDEZ-MARTÍNEZ, C. NAVARRÓN, A. ARACIL-FERNÁNDEZ, F. NAVARRETE, M. GARCÍA-GUTIÉRREZ; Inst. De Neurociencias, Univ. Miguel Hernandez-Csic, San Juan de Alicante, Spain

Abstract: Cannabidiol, one of the main compounds present in the plant Cannabis sativa, has recently emerged as a potential drug for the treatment of different psychiatric disorders, based on its anxiolytic, antidepressant and antipsychotic properties. However, some controversy regarding its non-psychoactive properties significantly hampers the development of basic and clinical studies. Indeed, CBD is currently classified in the Schedule 1 according to the Drug Enforcement Administration (DEA) suggesting high potential for abuse.
In order to shed light on this subject, the aim of this study was to evaluate the potential reinforcing properties of CBD. Hence, three behavioral assays were performed using C57BL/6J male mice. Reinforcing properties of CBD (15, 30 and 60 mg/kg, i.p.) were evaluated in the conditioned place preference (CPP). Spontaneous withdrawal symptoms and motor activity were

evaluated in the open field (OF) on day 8 after the administration of CBD (30 mg/kg/12h, i.p., 7 days). In addition, the CBD consumption was evaluated using an oral self-administration paradigm (60 mg/kg; CBD water soluble).
The results revealed that CBD failed to produce CPP (Student t-test, p= 0.31). Furthermore, the administration of CBD did not alter motor behavior (Student t-test, p= 0.12) nor induced withdrawal symptoms after cessation of treatment. Interestingly, there was no differences between CBD and water in the oral self-administration paradigm.
In conclusion, these results demonstrate that CBD did not present reinforcing activity in any of the different evaluated behavioral assays (CPP, spontaneous withdrawal and self-administration) suggesting that the inclusion of CBD in the Schedule I should be questioned.

Title: Social environment prevents alcohol intake and modifies dopaminergic and endocannabinoid systems in maternal care deprived rats

Authors: *O. AMANCIO-BELMONT[1], A. BECERRIL-MELÉNDEZ[1], M. MÉNDEZ-DÍAZ[1], A. E. RUIZ-CONTRERAS[2], Ó. PROSPÉRO-GARCÍA[1];
[2]Neurogenómica Cognitiva, [1]UNAM, Mexico, DF, Mexico

Abstract: Experimental evidence suggests that natural rewards, such as a social interaction, enriched environment or physical exercise devaluate drugs of abuse, therefore the practice of these activities prevent from drug abuse and drug addiction. On the other hand, a considerable amount of experimental studies have shown that maternal care deprivation (MCD) is associated with drug abuse and drug addiction. Dopaminergic and endocannabinoid system have been implicated in reward processes, including drug intake and drug addiction. MCD causes changes

in the dopaminergic and endocannabinoid system in the prefrontal cortex (PFC) and nucleus accumbens (NAcc) that seem to facilitate alcohol consumption. This study used a rodent model to test whether exposure to a social environment could protect MCD and non-MCD adult rats from alcohol intake. Also to evaluate dopaminergic and endocannabinoid system potential changes in the PFC and NAcc.
Pregnant Wistar rats were obtained at gestational day 14-17 from our facilities (Facultad de Medicina, UNAM). The day of birth was designated as PND 0. MCD was performed from PND 2 to PND 16, between 9:00 and 12:00 h daily. Rats were weaned on PND 21. From PND 24 to PND 60 male rats were reared into two housing conditions: a social condition (10 rats/cage) and a nonsocial condition (singly housed). Once the rats became adults (PND 60), all groups (n = 10 each group) were submitted to a voluntary alcohol (10% v/v) protocol for 10 days. Different groups of rats (n = 10 each group) were sacrificed when adult but with no exposition to alcohol whatsoever to dissect PFC, NAcc and hippocampus to analyze the expression of cannabinoid (CB1R and CB2R) and dopaminergic (D1R, D2R and D3R) receptors.
Social environment reduces alcohol intake in non-MCD and MCD rats and modifies the expression of these receptors. These results indicate that socialization prevents rats from drinking alcohol and induces changes in the expression of these receptors

Title: Behavioral and neural markers of craving regulation in marijuana-dependent adolescents

Authors: *D. G. GHAHREMANI[1], A. ELIAZ[3], K. KATO[2], A. DEAN[2], M. HUESTIS[4], E. LONDON[2];
[1]Dept. of Psychiatry and Biobehavioral Sci., [2]UCLA, Los Angeles, CA; [3]UCSF, San Francisco, CA; [4]NIDA NIH, Bethesda, MD

Abstract: Adolescence is a neurodevelopmental period in which cortico-limbic circuitry has not yet reached maturation, likely resulting in greater difficulty with regulation of appetitive behavior. Marijuana use is increasing among adolescents, and behavioral strategies that help with

regulation of craving for marijuana may be helpful for reducing its use yet remain underexplored. The current fMRI study uses behavioral and brain measures to examine craving regulation in adolescent heavy marijuana users (smoking at least 5 times per week, >1 gram per day). Adolescents (13-19 years old) abstinent from marijuana for 48 hours underwent fMRI scanning while performing a reappraisal-based craving regulation task, which involved proximal/distal perspective taking while viewing images containing content reflecting marijuana use (e.g., pipes, buds) or matched neutral images. Prior to viewing images, participants were instructed to either imagine themselves immersed in the scene depicted in the image, allowing themselves to experience any sensations that arose ("close", i.e., reactivity), or to imagine themselves at a distance from the scene ("far", i.e., regulation), making factual, objective observations of the content of the scene (e.g., indoors/outdoors). Participants rated their craving after each image presentation. Behavioral results indicated a main effect of cue-type, with marijuana images eliciting greater craving than neutral images, and an interaction of proximity (close/far), and image type (marijuana/neutral images) on craving - lower craving ratings were given following the "far" versus "close" instructions, and no effect of proximity was found for the neutral cues. The contrast of marijuana vs. neutral images (index of cue-reactivity) showed activation in ventromedial prefrontal cortex and ventral striatum; where as, for the far vs. close contrast (index of regulation), fMRI activation was found in fronto-parietal regions. Whole-brain correlation analyses of craving ratings and the fMRI index of regulation revealed that degree of "regulation success" in behavior (difference in craving ratings after "close" and "far" instructions) was positively correlated with rostral anterior cingulate and mid-insula. These preliminary results suggest that reappraisal strategies have an impact on cue-elicited self-reported craving for marijuana and recruit brain regions important for cognitive control among adolescents.

Title: Preclinical evaluation of the potential utility of neutral cb1 receptor antagonists and negative allosteric cb1 receptor modulators in treatment of drug abuse and addiction

Authors: *Z. XI[1], G.-H. BI[1], X.-H. HE[1], G. THAKUR[2], A. MAKRIYANNIS[3], H. H. SELTZMAN[4], E. GARDNER[1];
[1]Natl. Inst. on Drug Abuse Intramural Res. Program, Baltimore, MD; [2]Dept. of Pharmaceut. Sciences, Bouvé Col. of Hlth. Sci., [3]Ctr. for Drug Discovery, Col. of Sci., Northeastern Univ., Boston, MA; [4]Ctr. for Organic and Medicinal Chem., Res. Triangle Inst., Research Triangle Park, NC

Abstract: Recent studies show that cannabinoid CB1 receptors are importantly involved in drug reward and addiction. Accordingly, brain CB1 receptors have been thought to be potential targets in medication development for treatment of drug abuse and addiction. However, rimonabent-based medication development was terminated in 2008 worldwide due to significantly unwanted side-effects such as depression and suicide intendancy. Since rimonaben is a CB1 receptor antagonist and also an inverse CB1 receptor agonist, it has been proposed and demonstrated that the inverse agonist property of rimonabent may contribute to those unwanted side-effects. Based on these findings, it has been recently proposed that neutral CB1 receptor antagonists (i.e., the drugs themselves have no intrinsic activity) or negative allosteric modulators (which bind to transmembrane allosteric bindings sites, not extracellular orthesteric ligand binding domain) may have therapeutic anti-addiction potential without such unwanted effects as rimonabent does. To test this hypothesis, we systemically evaluate the effects of these three types of CB1 receptor ligands in animal models of drug addiction. We found that 1) the inverse CB1R agonist rimobent (0, 3, 10 mg/kg, i.p.) significantly inhibited cocaine (or heroin, nicotine) self-administration and cocaine-enhanced electrical brain-stimulation reward, while rimonabent itself produced significant aversive effects in electrical brain-stimulation reward; 2) the CB1 neutral antagonists AM4113 and PIMSR1 (0, 3, 10 mg/kg) are similarly effective in attenuation of cocaine (nicotine, heroin) self-administration and cocaine-enhanced brain-stimulation reward, while both compounds themselves have no effect in brain reward function as assessed by electrical brain-stimulation reward; 3) In contrast, the negative allosteric modulators (NAMs) GAT358 and GAT369 (0, 10, 20 mg/kg) neither altered nicotine-enhanced brain-stimulation reward nor altered brain reward function by themselves. Taken together, all these (preliminary) findings suggest that neutral CB1R antagonists appear to be more promising than CB1R NAMs in medication development for treatment of drug abuse and addiction.

Title: Adolescent cannabinoid agonist exposure impairs learned timing in adult rats

Authors: *J. H. FREEMAN[1], M. ELKIN[2], B. DE CORTE[2];
[1]Psychological and Brain Sci., [2]Univ. of Iowa, Iowa City, IA

Abstract: Cannabinoid receptors are highly expressed within the cerebellar cortex and systemic administration of cannabinoid agonists impairs cerebellum-dependent eyeblink conditioning in adult animals and humans. Eyeblink conditioning is an associative learning task that includes a conditional stimulus (CS) that is followed after 400 ms by an unconditional stimulus (US) which causes eyelid closure before training. With repeated training trials the subject will produce an eyelid closure conditional response (CR) that is timed to the onset time of the US. Recent findings indicate that learned timing at longer intervals (12 s) may also depend on the cerebellum. Although there have been several studies of cannabinoid effects on cerebellar learning in adults, the effects of cannabinoid exposure during adolescence on subsequent cerebellar learning in adults have not been examined. The current study examined the effects of systemic injections of the cannabinoid agonist WIN55,212-2 or vehicle during adolescence in rats (postnatal days 35-45) on eyeblink conditioning and interval timing tasks on PD65. Rats given adolescent exposure to WIN55,212-2 showed deficits in the amplitude, area, and timing of the CR. During CS-alone extinction testing, the group given WIN55,212-2 showed deficits in the frequency, amplitude, area, and timing of the CR. Interval timing was examined in a 12 s fixed interval task using a touchscreen apparatus. The rats were trained to touch a stimulus presented on a touchscreen after a 12 s interval to obtain a food reward. Rats given WIN55,212-2 showed slower acquisition of temporal modulation of response rate across sessions and their responses were less precisely timed to the end of the interval within sessions. The results indicate that adolescent exposure to cannabinoid agonists has persistent effects on learned timing mechanisms.

Title: A comparison between delta-9-tetrahydrocannabinol and a Jamaican marijuana tea extract in an animal model of addiction

Authors: *L. E. YOUNG, K. P. CHIN-QUEE;
The Univ. of the West Indies, Kingston 7, Jamaica

Abstract: Marijuana is the most widely used illicit drug world-wide because of its psychoactive compound, Δ^9-tetrahydrocannabinol (THC). The plant, *Cannabis sativa,* however contains a myriad of other non-psychoactive cannabinoids. In Jamaica, it is smoked, drank or eaten for recreational and medicinal purposes. Rodents do not voluntarily consume or self-administer cannabis due to the anhedonic properties associated with THC and often exhibit conditioned place aversion (CPA), inconsistent with many known addictive drugs. Like ethanol and phencyclidine, modifications of classic animal models of addiction to show reward have been demonstrated. We hypothesize that drug-seeking behavior or reward to cannabis can be achieved at a low dose by modifications to the conditioned place preference (CPP) paradigm that involves a decrease or elimination of the dysphoria associated with the THC, which could significantly impact cue-associated reward. Sprague-Dawley rats were taken through a biased CPP paradigm utilizing an 8-day schedule. The pre-conditioning phase consisted of 3 trials of 15 mins each and the conditioning phase lasted either 40 or 18 mins. A decrease in the spontaneous motor activity was assessed to determine the 18 min confinement period and dosage of the marijuana tea extract (MTE) that was compared with THC (0.05 - 2 mg/kg). Time spent in the non-preferred (white) chamber on the test day over a 15 mins period was compared with the pre-conditioning time. The MTE was prepared by boiling the dried leaves and stems of the marijuana plant under reflux for 6 hours followed by vacuum filtering, freeze-drying and reconstituting with saline for intra-peritoneal injection (*i.p*). The effect of sensitization to a low dose (3 mg/kg, *i.p.)* of amphetamine (AMP) given 14 days prior to conditioning was also assessed. Data were analyzed using Student's paired t-test. The 40-min confinement period resulted in significant CPA to the drug-paired chamber (MTE, $p<0.01$); whereas the 18-min confinement period did not (MTE, $p>0.05$). AMP sensitization also increased MTE place preference for the drug-paired chamber ($p = 0.09$). Significant CPP ($p<0.001$) was achieved with the low dose of 0.05 mg/kg THC using an 18-min confinement period in the conditioning phase. CPP can thus be achieved at very low doses of THC if attention is paid to decreasing the dysphoric or anhedonic cue-associated effects due mainly to the psychoactive cannabinoid, THC, either separately or when part of the bio-material of an extract of the whole cannabis plant.

Title: Delta^9-THC withdrawal induces somatic and emotionality-related behaviors in mice

Authors: *S. G. KINSEY, K. R. TREXLER, S. R. NASS, M. S. CROWE, A. W. MCKITRICK;
Psychology, West Virginia Univ., Morgantown, WV

Abstract: Cannabis dependence can be inferred from tolerance and withdrawal symptoms following repeated exposure. In rodents, cannabinoid withdrawal is commonly quantified using somatic signs, for example frequency of paw tremors and head twitches. Two critiques of the validity of these models are (1) these symptoms are absent during human cannabis use disorder, which is characterized by drug craving, sleep disturbances, and altered emotional processing; and (2) the reliance of a CB_1 selective antagonist to precipitate withdrawal symptoms. Thus, behavioral assays that exploit emotionality-related measures of withdrawal may more closely mimic symptoms experienced in humans. In the present study, two models of anxiety-like behavior, marble burying test and light/dark box, and a model of depressive-like behavior, the tail suspension test, were used to evaluate withdrawal induced by 5.5 days of tetrahydrocannabinol(THC; 10 or 50 mg/kg, s.c.) administration compared to vehicle-treated control animals. Withdrawal was precipitated using rimonabant (3 mg/kg, i.p.) in some instances, however, spontaneous withdrawal was also evaluated to address critiques associated with precipitated withdrawal. We hypothesized that THC withdrawal-induced increases and anxiety-like and depressive-like behaviors would be attenuated by pretreatment with a FAAH or MAGL inhibitor. Surprisingly, precipitated THC withdrawal significantly suppressed both marble burying and immobility in the tail suspension test. Neither effect was altered by pretreatment with the FAAH inhibitor PF-3845 (10 mg/kg, i.p.), the MAGL inhibitor JZL184 (8 or 40 mg/kg, i.p.), or propranolol (10 mg/kg, i.p.). However, as published previously, JZL184 did significantly attenuate paw tremors and head twitches induced by precipitated THC withdrawal, indicating differential effects of MAGL inhibition on withdrawal behaviors. Of particular interest, spontaneous THC withdrawal also significantly altered marble burying behavior. The results of these experiments suggest that marble burying and tail suspension may be appropriate to include

in test batteries of cannabinoid withdrawal with traditional tests of somatic withdrawal signs in order to increase the overall predictive validity of potential pharmacological treatments for cannabis dependence.

Title: Diacylglycerol lipase-α expression increases in the coeruleo-cortical pathway in dopamine-β-hydroxylase knockout mice as well as rats treated with DSP-4

Authors: *M. URQUHART[1], B. A. S. REYES[1], S. A. THOMAS[2], K. MACKIE[3], E. J. VAN BOCKSTAELE[1];
[1]Pharmacol. and Physiol., Col. of Medicine, Drexel Univ., Philadelphia, PA; [2]Pharmacol., Perelman Sch. of Medicine, Univ. of Pennsylvania, Philadelphia, PA; [3]Psychological and Brain Sciences,, Indiana Univ., Bloomington, IN

Abstract: Endocannabinoids are involved in the regulation of many physiological processes including behavioral responses to stress. Endocannabinoids modulate norepinephrine (NE) signaling primarily via involvement of CB1 cannabinoid receptors (CB1r). Our previous studies have shown that acute and repeated administration of a CB1r agonist increases multiple indices of noradrenergic activity involving the locus coeruleus (LC)-frontal cortex (FC) pathway. Diacylglycerol lipase-α (DGL-α), a key enzyme in the biosynthesis of the endocannabinoid 2-arachidonoylglycerol (2-AG) is localized to both the FC and the LC. Using electron microscopy, we have recently shown that in the rat FC DGL-α is localized in postsynaptic profiles that are targeted by dopamine-β-hydroxylase (DβH), the enzyme that converts dopamine to norepinephrine and represents a marker of noradrenergic neurons (Hartman et al., 1972). In this study, we also described interactions between DGL-α, CB1r and DβH in the FC using confocal microscopy. In the present study, we investigated expression levels of DGL-α under two conditions of NE deletion: in a rat model using a systemic injection of saporin conjugated with antibody against DβH (DSP-4) and in a genetically engineered mouse that lacked the enzyme DβH (DβH-knockout, KO). We compared expression levels of DGL-α to either control rats or

wild type (WT) mice using Western blot analysis. Protein extracts from micropunches of FC and LC were obtained and probed for DGL-α. Results showed that DGL-α expression was significantly increased in FC ($P < 0.05$) of both DSP-4 treated rats and DβHKO mice when compared to WT mice. DGL-α expression was also significantly increased in the LC ($P < 0.05$) of DβHKO when compared to WT mice. These data add to the accumulating evidence that dysregulation of NE transmission results in significant adaptations in the brain endocannabinoid system.

Title: Sex differences in delta-9-Tetrahydrocannabinol-induced hypothermia and hypolocomotion in rats

Authors: *M. JAVADI PAYDAR[1], J. D. NGUYEN[1], Y. GRANT[1], S. A. VANDEWATER[1], M. COLE[2], M. A. TAFFE[1];
[1]Committee on the Neurobio. of Addictive Disorders, The Scripps Res. Inst., San Diego, CA; [2]La Jolla Alcohol Res. Inc,, La Jolla, CA

Abstract: Backgrounds:
Previous studies suggest that there are sex differences in response to exogenous cannabinoids. Unfortunately data from animal and clinical studies comparing cannabinoid effects between males and females, under controlled laboratory conditions, are limited. This study was undertaken to determine any sex differences in thermoregulatory and locomotor responses to the inhalation of THC in rats.
Methods:
Male and female Sprague-Dawley rats were exposed to vapor of either a propylene glycol vehicle (PG) or THC (12.5-100 mg/mL in PG, 4 puffs every 5 minutes) for a duration of 30 minutes. Body temperature and locomotor responses were evaluated post-inhalation using a

radiotelemetry system.
Results:
Experiments determined that THC reduced the body temperature of both sexes in a dose-dependent manner. Temperature was reduced following 50 and 100 mg/ml THC inhalation with significant effects observed up to 90 min post-exposure for males and up to 120 min post-exposure for females. THC-treated male rats showed a significant dose-dependent reduction of locomotor activity for the first 30 min after THC exposure, but female locomotor activity did not change significantly. Additional experiments show that the inhalation of THC vapor attenuates nociception using a tail-flick assay.
Discussion:
THC vapor produced a robust and lasting decrement in the body temperature of both sexes. Unlike the males, female rats did not show hypolocomotion following exposure to THC vapor. THC inhalation also decreased tail-flick latency, demonstrating anti-nociceptive efficacy. The vapor inhalation model is therefore validated for use in both sexes of rat.

Title: EEG resting state analysis of cannabis users with and without rTMS

Authors: *S. PRASHAD, E. DEDRICK, T. RHINEHARDT, W. T. TO, J. EROH, S. VANNESTE, J. HART, Jr., F. FILBEY;
Ctr. for BrainHealth, Univ. of Texas at Dallas, Dallas, TX

Abstract: Cannabis is the most widely used illicit drug in the United States. With recent policy changes towards cannabis, it is important to investigate deficits associated with cannabis use. Although various therapies and medications have been used to treat and manage addiction, many individuals are left untreated, revealing a need for novel interventions and strategies. Repetitive transcranial magnetic stimulation (rTMS) has a neuromodulatory effect on cortical networks and has been used to relieve symptoms for many neurological and psychiatric disorders. Previous studies investigating rTMS in addiction suggest that active stimulation reduces craving; however,

it is still not known how rTMS affects the resting state of individuals that are regular cannabis users. In the current study, we analyzed resting state EEG (eyes closed condition) in ten users of cannabis compared to ten non-using controls in the theta (4-7Hz), alpha (8-12Hz), beta (13-30Hz), and gamma (30-50Hz) frequency bands. All participants attended two data collection sessions and underwent rTMS targeting the posterior cingulate cortex using a double cone coil prior to the EEG data collection. Half of the participants received rTMS at 1Hz (Low frequency; LF) in the first session and the other half received rTMS at 10Hz (High frequency; HF). These stimulation frequencies were reversed in the second session. We found that users of cannabis exhibited lower theta, alpha, and beta power, but higher gamma power compared to non-using controls in the LF condition. All participants exhibited greater power for all frequency bands after the HF rTMS condition compared to the LF rTMS condition, except for the gamma band in cannabis users in which power did not change after HF rTMS. However, non-using controls continued to exhibit greater power across the frequency bands compared to cannabis users after HF rTMS. These results are consistent with previous studies that have reported impaired memory, attention, and cognitive processing in users of cannabis as well as neuroimaging studies that suggest changes in brain networks. The increase in power after HF rTMS could suggest its potential effectiveness in reducing the impairments in cognition and that rTMS may be viable for intervention and treatment strategies for cannabis addiction.

Title: Endocannabinoid signaling as a modifier of zebrafish stress responses

Authors: *R. G. KRUG, M. O. PETERSEN, K. J. CLARK;
Mayo Clin., Rochester, MN

Abstract: The number of annual cannabis users exceeds 100,000,000 globally and an estimated 9% of these individuals will suffer from dependency, but a dearth of knowledge exists about the potential consequences on public health. However, the psychoactive constituents of cannabis are known to affect the endocannabinoid (eCB) system, and disrupt features of vertebrate physiology and behavior. Our central hypothesis is that disruptions in the eCB signaling system have pathological consequences on vertebrate behavior and physiology, including dysregulation of the stress response system. Herein, we use a preclinical zebrafish model to clarify the ramifications of disturbances in the eCB signaling system. Using qRT-PCR and *in situ* hybridization we show that the genes encoding enzymes that synthesize (*abhd4*, *gde1*, *napepld)*, enzymes that degrade (*faah*, *faah2a*, *faah2b*), and receptors that bind (*cnr1*, *cnr2*, *gpr55-like*) eCBs are expressed throughout development. We show that disruptions of this system via exogenous cannabinoid administration results in altered behavior and physiology, including increased secretion of glucocorticoids in our stress response reporter line. We are developing a zebrafish eCB signaling mutant library using TALENs and show that disruption of *faah2a* alters stress-associated behavior. Collectively, these results establish zebrafish as a viable model for studying eCB signaling, and lay a foundation for informing a better understanding of the toxicological and therapeutic potential of the eCB system.

Title: Colocalization of estrogen receptor alpha and cannabinoid receptor type 1 in the medial prefrontal cortex of female rats

Authors: *J. ZHANG, B. A. S. REYES, R. D. SHADE, E. J. VAN BOCKSTAELE;
Pharmacol. and Physiol., Col. of Medicine, Drexel Univ., Philadelphia, PA

Abstract: Mood disorders including anxiety and depression are the most common mental illnesses in the United States. Women are twice as likely as men to suffer from these psychopathologies. Estrogen has been reported to be strongly involved in the observed sex differences associated with these disorders. However, the underlying mechanism regarding how estrogen affects these non-reproductive brain functions remains unclear. Estrogen exerts its actions via binding to the estrogen receptor alpha (ERα), beta (ERβ), and GPR30. The endocannabinoid (eCB) system functions as "stress buffer" ubiquitously distributed throughout the brain and, modulates neurotransmitter release via the activation of CB type 1 (CB1r) and type 2 (CB2r) receptors. The eCB system may influence the development of anxiety and other stress related psychiatric disorders via dysregulation in stress-integrative neural circuits. Sex differences exist in the expression levels of CB receptors in many different brain regions including the prefrontal cortex, which is has been strongly implicated in the etiology of mood disorders. While functional sex differences in the eCB system have been reported, it is still not clear how these sex differences manifest physiologically. Recent studies have shown that estrogen is able to modulate eCB tone and consequently suppress gamma amino butyric acid (GABA) release in a sex specific manner, via involvement of ERα. Multiple studies have reported that ERα is mainly localized to axons and axon terminals in the medial prefrontal cortex (mPFC) where CB1r is predominantly localized. Taken together, we hypothesize that CB1 and ERα may colocalize in the same neuronal profiles in the mPFC and functionally interact, which may contribute to the observed sex differences in the eCB system. The present study utilized dual immunogold electron microscopy to investigate the cellular substrates for interactions between ERα and CB1r. Forty-micron thick tissue sections of female Sprague Dawley rats were collected from mPFC and processed for immunocytochemical detection of ERα and CB1r. Our preliminary data show that CB1r is predominantly located in axon terminals that also express ERα. CB1r was also found colocalized with ERα-labeled cell bodies and dendrites. Occasionally, CB1r-labeled axon terminals contacted ERα-labeled dendrites. These results indicate that CB1r may affect the neuronal activity of ERα-responsive neurons in the mPFC. ERα may also affect the neurotransmitter release via interacting with CB1r in the mPFC.

Title: Acute delta-9-tetrahydrocannabinol reduces loss sensitivity in a binary choice task.

Authors: *S. WONG, S. R. RANDOLPH, V. E. IVAN, A. J. GRUBER;
Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: We have previously shown that lose-shift responding, wherein animals tend to switch actions following reward omission, is disrupted in rats by infusion of D-amphetamine into the dorsolateral striatum or by systemic injection of D-amphetamine. If this behavioral effect is due to the drug's ability to elevate the level of dopamine in the striatum, then other drugs that elevate tonic brain dopamine levels should also reduce lose-shift responding. Here we tested if intraperitoneal injection of Δ^9-Tetrahydrocannabinol (THC; 0.5-2 mg/kg) prior to the task would reduce lose-shift responding. THC did evoke a dose-dependent reduction of lose-shift responding, providing further evidence that lose-shift responding is driven by the brief pauses in activity of dopaminergic neurons proposed to signal negative reward prediction error.

Title: On the role of TRPV1 receptors within the brain in anxiety elicited by cocaine cues

Authors: *W. NORZE[1], A. LOYOLA[2], E. TORRES[2], C. MALDONADO-VLAAR[2];
[1]Biol., Univ. of Porto Rico, San Juan, PR; [2]Biol., Univ. of Puerto Rico-Rio Piedras, San Juan, Puerto Rico

Abstract: Transient Receptor potential Vanilloid (TRPV1) is activated in peripheral terminals of nociceptive fibers by noxious heat, low pH and natural product such as capsaicin, and is expressed also in the brain where it seems to be involved in antinociception, locomotor control and regulation of affective behaviors. Capsazepine is a competitive antagonist of the vanilloid receptor. We investigated the effects of blockade of TRPV1 receptors in eliciting anxiolytic responses following exposure to cocaine related cues in rats. Male Sprague Dawley rats received daily intraperitoneal injections of cocaine (10 mg/kg) for five consecutive (D1-D5) prior to being placed in activity chambers. During the daily 90 min sessions, rats paired visual and olfactory cues with the cocaine treatment. Following one day of abstinence, animals were divided into two groups which received either vehicle or capsazepine (10 ug/kg, ip) and returned to the activity

chambers followed by Elevated Plus Maze (EPM) testing. Results showed that cocaine significantly increased locomotor activity and produced behavioral sensitization within the first five days. Animals treated with capsazepine showed no significant difference in locomotor behavior on Day 7 when compared to vehicle treated group ($p<0.05$, T-test). In the EPM, the capsazepine dose had no effect on the total time spent on open and close arms during 5 minutes of testing. Future studies are needed to test several doses of capsazepine in other to characterize a possible therapeutical profile of the drug.

Title: Cocaine-induced endocannabinoid mobilization disinhibits mouse midbrain dopamine neurons

Authors: *D. I. DRYANOVSKI, C. R. LUPICA;
Electrophysiology Res. Section, Natl. Inst. On Drug Abuse, NIH, Baltimore, MD

Abstract: Endogenous cannabinoids (eCB) are lipid molecules released from postsynaptic neurons to activate cannabinoid CB1 receptors (CB1R) on presynaptic axon terminals to inhibit neurotransmitter release. 2-arachidonoylglycerol (2-AG) is an eCB closely associated with activity dependent modulation of synapses, and its synthesis can be triggered by activation of $G\alpha_{/11}$-coupled GPCRs via their coupling to phospholipase C-β (PLCβ). PLCβ can hydrolyze phosphatidylinositol 4,5-bisphosphate to form 1,2-dacylglycerol (DAG) and inositol triphosphate. DAG is then hydrolyzed to form 2-AG via diacylglycerol lipase-α (DGLα). 2-AG can then be degraded to inactive metabolites by monoacylglycerol lipase (MAGL). We found that retrograde eCB signaling plays a crucial role in modulating synapses on midbrain dopamine (DA) neurons located in the mouse ventral tegmental area (VTA), using electrophysiological recordings of synaptic GABA release ($GABA_B$ IPSCs). Antagonism of CB1Rs with AM251 increased GABAergic inhibition of VTA DA neurons, and this was not observed in transgenic mice lacking CB1. We also found that cocaine mobilized 2-AG in mouse VTA, causing inhibition of $GABA_B$ IPSCs via activation of presynaptic CB1Rs. Extracellular bath application

of THL, a DGLα inhibitor, significantly reduced cocaine inhibition of $GABA_B$ IPSCs. JZL184, an inhibitor of MAGL, increased inhibition of $GABA_B$ IPSCs by cocaine. The disinhibition of DA neurons by cocaine represents a plausible mechanism to explain interactions between this drug and the eCB system observed in reward and addiction studies. The establishment of this interaction in the mouse VTA permits a more thorough molecular dissection of the relevant pathways using transgenic approaches.

Title: From LTD to LTP and back again - Changes in synaptic metaplasticity after extinction from THC self-administration and cue induced relapse

Authors: *D. NEUHOFER, S. SPENCER, P. KALIVAS;
Neurosci., MUSC, Charleston, SC

Abstract: Synaptic metaplasticity is a form of higher order plasticity that is not necessarily expressed as a change in the efficacy of synaptic transmission but as a change in the direction or degree of synaptic plasticity that will be induced by a distinct stimulation pattern. While there is ample evidence that drug induced alternations of glutamatergic synaptic transmission in the nucleus accumbens (NAc) might be a cellular substrate for drug seeking, the mechanisms and consequences of changes in metaplasticity after drug abuse have been less well studied, and this especially holds true for neuroadaptations induced by the chronic use of the psychoactive ingredient of marijuana, delta-9-tetrahydrocannabidiol (THC). To evaluate THC-induced metaplasticity, we trained rats to self-administer THC and cannabidiol (CBD) in a 10:1 ratio. Synaptic metaplasticity after drug extinction and cue induced reinstatement was evaluated via whole cell patch clamp recordings in the NAc core, using a pairing protocol that induces

NMDA-dependent LTD in control animals. After extinction from THC+CBD self-administration we observed a switch in the valence of synaptic plasticity from LTD to LTP. Surprisingly these distinct changes in metaplasticity were fully reversed and LTD reestablished when slices were made from animals that underwent 15 min of cue-induced reinstatement. We will discuss experiments underway to target the molecular substrates that might mediate these drug-seeking induced changes in metaplasticity.

Title: Alterations in glutamatergic transmission after cannabinoid self-administration: parallels and distinctions with cocaine

Authors: *S. M. SPENCER, D. NEUHOFER, C. GARCIA-KELLER, M. D. SCOFIELD, D. SCHWARTZ, P. W. KALIVAS;
Neurosci., Med. Univ. of South Carolina, Charleston, SC

Abstract: A preponderance of evidence indicates that addiction to drugs of abuse produces enduring changes in brain synaptic physiology that contribute to the vulnerability to relapse. Chief among these, it has been shown that chronic cocaine, nicotine, heroin, and ethanol administration leads to dysregulated glutamatergic transmission in the nucleus accumbens core (NAcore). For example, following self-administration and extinction of each of these drugs there is a decrease in the expression and activity of GLT-1 (glial glutamate transporter). However, it was unknown whether chronic THC administration produces similar effects. Here we performed a glutamate uptake assay to assess GLT-1 function after THC self-administration and extinction,

but were surprised to discover that there was no difference in sodium-dependent glutamate uptake between vehicle and THC self-administering rats. Next we went on to assess whether there might be alterations in glutamatergic transmission measurable at the electrophysiological level using the whole-cell patch clamp techniques to assess the ratio of AMPA to NMDA currents (A/N), measure glutamate spillover via NMDA current decay, and evaluate NMDA-dependent LTD. In contrast to cocaine that produces a potentiation of A/N, after THC self-administration and extinction there was no change in AMPA/NMDA ratio. However, akin to cocaine we observed a loss of LTD in NAcore suggesting drug-induced metaplasticity. Moreover, preliminary data suggests that there is an increase in glutamate spillover in THC-extinguished rats, implying alterations in the elimination of glutamate although undetected by the glutamate uptake assay. In summary, these data illustrate that THC self-administration and extinction results in enduring changes in glutamatergic transmission in the NAcore and suggests both distinct and overlapping mechanisms between marijuana and cocaine may prime glutamate transmission to support relapse.

Title: The phytocannabinoid THC mimics effects of chronic mild stress to reduce dendritic spine density in the vocal learning-essential brain region Area X of zebra finch striatum

Authors: *T. L. HOLLAND, K. SODERSTROM;
East Carolina Univ., Greenville, NC

Abstract: Zebra finches learn a complex song during a developmental sensitive period through a process of sensorimotor integration and auditory feedback, which shares features with language development in humans. Chronic treatment with the synthetic cannabinoid full agonist WIN 55,212-2 during this developmental period persistently alters song quality, suggesting that exogenous cannabinoid agonist exposure alters normal late-postnatal brain development. Presently, we are studying the persistent effects of psychological stress on vocal development and adult song patterns. An acute stressor activates the hypothalamic-pituitary-adrenal (HPA) axis, causing increased release of the stress hormone corticosterone. This stimulates endocannabinoid release as part of a mechanism of feedback inhibition on HPA activity. We

hypothesize that enhanced endocannabinoid signaling following psychological stress may alter song learning in a manner similar to that caused by exogenous agonist exposure.
Developing (50 days old) and adult (>100 days old) male zebra finches (n=4) were administered vehicle or THC (3 mg/kg) treatments under concurrent no stress or stress conditions daily for 25 days. Injections occurred at 11 AM, and stress treatments were administered at 2-7 PM using a chronic mild unpredictable stress paradigm. 2-3 stressors were randomly chosen per day, and possible stressors included restraint stress (30 min), white noise (1 h), rubber snake (1 h), bright light (1 h), or food and water deprivation (1 h). Following the 25 day treatment period, zebra finches received no treatment for >25 days, until developing animals had matured. Vocalizations were recorded for 24 hours, and brains were collected for Golgi-Cox staining.
Area X is a striatal song region that is necessary for vocal learning as part of a basal ganglia-thalamocortical circuit. Both THC + No stress and Vehicle + Stress groups had similarly reduced dendritic spine densities relative to Vehicle + No stress controls ($p<0.05$, two-way ANOVA, Student-Newman-Keuls post-test). In contrast, spine densities following adult treatments with THC or Vehicle + Stress did not differ.
In light of the significance of Area X to vocal learning, we hypothesize that chronic THC treatment or stress during development, but not during adulthood, will persistently alter song quality. This is currently being tested via analyses of song recordings. Results will illuminate persistent effects of chronic THC or stress exposure on late postnatal brain development and may suggest mechanistic commonalties.

Title: Identification of cannabinoid CB_1 receptors in midbrain dopamine neurons

Authors: *H. ZHANG[1], X. HAN[1], G.-H. BI[1], Q.-R. LIU[1], E. S. ONAIVI[2], E. L. GARNDER[1], Z.-X. XI[1];
[1]Natl. Inst. on Drug Abuse Intramural Res. Program, Baltimore, MD; [2]Dept. of Biol., William Paterson Univ., Wayne, NY

Abstract: Δ^9-tetrahydrocannabinol (THC) is the principal psychoactive constituent of marijuana or cannabis. The major effect of THC is mainly mediated by cannabinoid CB_1 receptors (CB_1Rs). THC produces both rewarding and aversive effects in experimental animals. However, the receptor mechanisms underlying such opposite effects are unknown. It is generally believed that CB_1Rs are mainly expressed in brain glutamate and GABA terminals, but not in ventral tegmental area (VTA) dopamine (DA) neurons. However, conclusive evidence regarding the cellular distributions of CB_1Rs in the VTA is lacking. It is also unclear how CB_1Rs located in different cell populations modulate striatal DA release. In this study, we first used classical immunohistochemistry (IHC) assay to detect CB_1 expression in rat midbrain slices. We found, under low magnification, high densities of CB_1R immunostaining in the substantia nigra pars reticulata (SNr) and low densities of CB_1R in the VTA and substantia nigra pars compacta (SNc). Under high magnification, CB_1R immunostaining was found mainly in nerve fibers or terminals within the VTA and no clear CB_1R immunostaining was found in the cell bodies of VTA DA neurons. Due to the limitation of IHC in distinguishing CB_1R expression in VTA DA neurons and the fibers or projection terminals, we next used highly sensitive RNAscope *in situ* hybridization assays to detect CB_1 mRNA expression in rat midbrain slices. We found clear CB_1 mRNA expression in ~ 20% VTA DA neurons and ~40% SNc DA neurons. To confirm the CB_1 mRNA signal specificity, we crossed CB_1-floxed mice and DAT-cre mice to generate conditional CB_1-knockout mice (CB_1-cKO) in brain DA neurons. We detected similar CB_1 mRNA signaling in midbrain DA neurons only in WT mice, but not in CB_1-cKO mice. We also used similar strategies to detect CB_2 mRNA expression in midbrain DA neurons. We detected low densities of CB_2 mRNA in almost all VTA DA neurons in WT mice, but not in CB_2-cKO mice. In addition, we found CB_1 and CB_2 mRNA co-localization in VTA/SNc DA neurons. CB_1 mRNAs were also found in VTA glutamate neurons ($vGluT2^+$), and VTA glutamate-DA dual neurons ($vGluT2^+/TH^+$), and VTA GABA neurons ($GAD1^+$). Taken together, these findings, for the first time, provide convincing evidence that CB_1Rs are expressed in a small subpopulation of midbrain DA neurons. The functional significance of CB_1Rs in DA neurons is unknown. Further studies are needed to address this issue.

Title: Activation of GPR55 receptor attenuates nicotine self-administration in rodents

Authors: Y. HE[1], H.-Y. ZHANG[1], J.-T. GAO[2], G.-H. BI[1], *E. L. GARDNER[1], Z.-X. XI[1]; [1]NIDA/IRP, Baltimore, MD; [2]Jilin Med. Collage, Jilin, China

Abstract: Cannabinoid CB1 and CB2 receptors are involved in drug reward and addiction, and therefore, have been considered as important potential therapeutic targets for treatment of substance dependence. Interestingly, growing evidence indicates that many CB1 and CB2 receptor agonists or antagonists, such as Δ9-tetrahydrocannabinol, AM251, rimonabant, anandamide and CP55940 exhibit affinity for the GPR55 receptor, a potential cannabinoid-related orphan receptor. However, little is known as to whether the GPR55 receptor is also involved in drug reward and addiction and in other pharmacological actions produced by cannabinoids. Recent studies suggest that brain GPR55 receptors may modulate excitatory synaptic transmission, in a manner opposite to the CB1 receptor. Thus, we hypothesized that the GPR55 receptor may be involved in drug reward and dependence in a manner similar to the CB2 receptors. To test this hypothesis, we used a pharmacological approach for evaluating the role of the GPR55 receptor in a rodent self-administration paradigm. Specifically, O-1602, a potent GPR55-selective agonist, and CID 16020046, a selective GPR55 antagonist, were used as pharmacological. We found that: 1) O-1602 (10, 20mg/kg, i.p.) dose-dependently reduced intravenous nicotine self-administration in alcohol-preferring P rats under fixed-ratio 1 and progressive-ratio reinforcement schedules, and that these effects can be blocked by CID 16020046; 2) mice receiving the same doses of O-1602 displayed a similar reduction in nicotine self-administration, but not oral sucrose self-administration, suggesting a specific effect on nicotine self-administration, not due to non-specific sedation or locomotor impairment after O-1602 administration; 3) in vivo microdialysis demonstrated that systemic or local administration of O-1602 into the nucleus accumbens (NAc) had no effect on extracellular dopamine in the NAc, suggesting that non-dopaminergic mechanisms involved; finally, 4) immunohistochemistry assay detected significant GRP55 receptor expression in the prefrontal cortex (PFC), but not in the ventral tegmental area (VTA) in wild-type mice, but not in GPR55-KO mice, suggesting that the GPR55 receptor in the PFC may be the target of O-1602. Taken together, the present findings suggest that GPR55 may be involved in nicotine reward and addiction, and therefore deserves further studies as a promising therapeutic target for treatment of nicotine dependence.

Title: Darylureas as allosteric modulators of the cannabinoid CB1 receptor

Authors: *Y. ZHANG[1], T. NGUYEN[1], A. DECKER[1], J.-X. LI[2], B. THOMAS[1], J. WILEY[1], T. KEN AKIN[3];
[1]Res. Triangle Inst., Research Triangle Park, NC; [2]Univ. at Buffalo, Buffalo, NY; [3]Univ. of North Carolina, Chapel Hill, NC

Abstract: Several classes of allosteric modulators of the CB1 receptor have recently been discovered which display unique pharmacological properties than the orthosteric ligands and may offer a much needed alternative strategy to modulate CB1 signaling for therapeutic benefits. We recently reported the first structure-activity relationship studies on one such modulator PSNCBAM-1. Here we will describe a series of diarylureas based on this scaffold with high CB1 potency and binding affinities.
All the compounds were characterized by MS, NMR and HPLC, and then evaluated in calcium-dependent functional assays in RD-HGA16 (Molecular Devices) cell lines stably expressing the CB1 receptor. These modulators reduced the Emax of CB1 receptor agonists (e.g. CP55940), as expected with negative allosteric modulators (NAMs), with low nanomolar IC50 values. In the binding assays, they increased the binding affinity of CB1 agonist CP55940, consistent with PSNCBAM-1 and other CB1 allosteric modulators such as Org27569. SAR studies suggest that the urea functionality is required for CB1 receptor activity. These compounds showed high selectivity against the CB2 receptor. These results will facilitate the development of potent and selective CB1 receptor modulators as potential medications for the treatment of drug addiction and related conditions.

Title: Cannabinoid type 2 receptors in brain dopamine neurons modulates anxiety-like and psychostimulant behaviors in floxed DAT-Cnr2 mouse model

Authors: *E. S. ONAIVI[1,1], H. ZHANG[2], E. L. GARDNER[2], H. ISHIGURO[3], Z.-X. XI[2], Q.-R. LIU[1];
[1]William Paterson Univ., Wayne, NJ; [2]NIDA-IRP/NIH, Baltimore, MD; [3]Univ. of Yamanashi, Yamanashi, Japan

Abstract: The functional neuronal expression of CB2 cannabinoid receptors has been a subject of controversy and debate and had been referred to as a "sphinx" wrapped in a mystery with "identity crisis", but no more. This is because research activities from our lab and those of others have found and reported that CB_2Rs are expressed in the mammalian brain and functionally involved in several dopamine (DA)-related and other CNS disorders including drug addiction in rodent models. Therefore, manipulation of CB_2R in mouse models is of critical importance in characterizing the molecular basis of CB_2R neuronal signaling mechanisms. The two available CB2R gene knockout mice contain partial *Cnr2* gene deletion at C- and N- terminal amino acid sequences and residues of CB2R activities might remain. Furthermore, these germline knockout mice in which the CB_2R function could be compromised by developmental compensation are not suitable for tissue- and cell-type specific studies at molecular, pharmacological and behavioral levels. Therefore, we have generated *Cnr2*-floxed mice that were crossed with DAT-*Cre* mice, in which the Cre recombinase expression is under DAT (dopamine transporter) gene promoter control, to generate conditional CB2-KO mice in midbrain DA neurons in DAT-*Cre*-*Cnr2*-Lox transgenic mice. By using a novel highly-sensitive RNAscope *in situ* hybridization method, we detected clear CB2 mRNA expression in VTA DA neurons in Dat-heterozygous and wildtype control mice, but not in conditional CB2-KO mice, suggesting neuronal CB2 gene expression in VTA DA neurons. The performance of the conditional DAT-*Cnr2* mutant mice were determined in motor function and emotionality tests in comparison to wild type controls. We report that in the motor function test using the spontaneous wheel running monitors, DAT-*Cre*-*Cnr2* homozygous mice were more responsive to cocaine induced motor activity than heterozygous

and wild type mice. In the plus maze test of aversive behavior, DAT-*Cre-Cnr2* homozygous mice were less aversive to the open arms of the maze than the heterozygous and the wild type mice. We conclude that CB2R in dopaminergic neurons plays a role in modulating anxiety-like and psychostimulant motor behaviors in mice.

Title: Distinctive sufficiency of cannabinoid CB1 receptor functions: contributions of GABAergic and glutamatergic components of the endocannabinoid system

Authors: *F. REMMERS[1], V. ENK[1], M. HÄRING[1], M. D. LANGE[2], S. RUEHLE[1], G. MARSICANO[3,4], H.-C. PAPE[2], B. LUTZ[1];
[1]Inst. of Physiological Chemistry, UMC Mainz, Mainz, Germany; [2]Inst. of Physiol. I, Westfaelische Wilhelms-University, Muenster, Germany; [3]Neurocentre Magendie INSERM U1215, Bordeaux, France; [4]Univ. of Bordeaux, Bordeaux, France

Abstract: The cannabinoid CB1 receptor is expressed in different neuronal subpopulations, including glutamatergic and GABAergic neurons. Via retrograde suppression of neurotransmission, it modulates a plethora of functions. The extent to which the CB1 receptor in these neurons is *necessary* for these functions has been addressed in studies using conditional knockout mice lacking the receptor in these neurons. However, little is known about the *sufficient role* of different CB1 receptor subpopulations.
To address *sufficiency* of the CB1 receptor subpopulations expressed in glutamatergic and GABAergic neurons, we used a conditional Cre-mediated cell-type-specific CB1 rescue strategy in a CB1-null background. Several behavioral domains that are modulated by the endocannabinoid system were analyzed: exploration, social behavior, fear and anxiety, metabolism, and seizure susceptibility.
Sufficiency of the dorsal telencephalic glutamatergic CB1 receptor subpopulation was found in the domains of social behavior, exploration, anxiety, metabolism, and seizure susceptibility, whereas the forebrain GABAergic subpopulation showed sufficient effects in the domains of

social behavior, exploration, seizures, and fear and anxiety. No sufficiency could be detected for the CB1 receptor in either neuronal population for the analgesic and cataleptic effects of exogenous stimulation of the endocannabinoid system. Although more sufficient effects were found after a glutamatergic rescue, on a few occasions GABAergic rescue resulted in additional effects that were opposite to normal endocannabinoid action. Including these opposite effects, both subsets of the CB1 receptor seem to have similar degrees of importance in the behavioral domains investigated.
This study revealed cell-type specificity of the actions of the endocannabinoid system and underlined the relevance of assessing not only necessary but also sufficient CB1 receptor functions, in order to understand the roles of this receptor in the context of the complexity of the brain.

Title: Macro extracellular vesicles, a novel transport system in the human brain

Authors: *H. PANTAZOPOULOS[1], M. ARDELT[2], A. BOYER-BOITEAU[2], S. A. MAUNEY[3], T.-U. W. WOO[1], M. MARKOTA[2], C. BERCIU[2], S. BERRETTA[1];
[1]Psychiatry, Harvard Med. School, McLean Hosp., Belmont, MA; [2]Translational Neurosci. Lab., [3]Lab. of Cell. Neuropathology, Mclean Hosp., Belmont, MA

Abstract: Growing evidence indicates molecules such growth and transcription factors, and miRNAs can travel long distances across the brain parenchyma, and from the choroid plexus (ChP) to specific regions deep into the brain. How can these molecules reach their targets across the dense and tortuous brain parenchyma without being diluted and/or catabolized? To answer this question we focused on OTX2, a non-cell autonomous transcription factor involved in developmental and adult brain functions. In adult rodents, OTX2 is detectable, but not synthesized in several brain regions, while the ChP may represent a main source of OTX2. Thus, OTX2 travels unidirectionally from the ChP to deep brain targets, transported by a yet unidentified mechanism. On the basis of preliminary findings of large OTX2-positive vesicles in

proximity of the lateral ventricles in the human brain, we tested the hypothesis that OTX2 is secreted by the ChP into vesicles that transport OTX2 through the cerebrospinal fluid (CSF) into the brain.
To test this hypothesis, we used a combination of in situ hybridization, immunohistochemistry, laser-capture micro-dissection, QRT-PCR, dual-fluorescence confocal and electron microscopy on human postmortem brain tissue and cerebrospinal fluid (CSF). Human ChP epithelial cell cultures were used to support observations made in postmortem tissue.
OTX2 protein was detected in all regions examined, amygdala, entorhinal cortex, prefrontal cortex, superior temporal gyrus, and visual cortex. Distinct populations of neurons and glia were immunoreactive (IR) for OTX2. In addition, we observed OTX2-IR, DAPI negative vesicles, ranging in size from 1-20 μm in diameter, which we termed 'macro extracellular vesicles' (MEVs). The largest MEVs were concentrated in areas corresponding to CSF flow, around the lateral ventricles and pial surfaces, and decreased in size deeper in the brain parenchyma. MEVs were detected in CSF and conditioned media from human ChP epithelial cells. Similarly, the human ChP contained labeled OTX2-IR epithelial cells and OTX2-IR MEVs. In contrast, none of the brain regions containing OTX2 protein expressed OTX2 mRNA. Analysis of specific cell populations confirmed that OTX2 mRNA is not expressed in pyramidal cells, PVB-IR neurons, or glia. Notably, OTX2 mRNA was detected robustly in the ChP.
Our result show a novel extracellular transport system, MEVs, that may carry molecules across long distances, in this case from the ChP, via CSF flow, to specific cell targets in the brain. This system has the potential to systemically administer factors that target specific cell populations in the brain, for therapeutic and research purposes.

Title: Context-induced relapse to the prescription opioid oxycodone in rats

Authors: *J. M. BOSSERT[1], S. ADHIKARY[1], H.-L. WANG[2], M. MORALES[2], Y. SHAHAM[1];
[1]Behavioral Neurosci., [2]Integrative Neurosci., NIH, NIDA, IRP, Baltimore, MD

Abstract: Background and objective: High relapse rates are a core feature in prescription opioid addiction, which drives the current drug overdose epidemic in the US. This public health problem is not the focus of current basic research on drug relapse, which primarily focuses on illicit drugs like heroin and cocaine. Here, we present a rat model, based on our previous studies with illicit drugs, to study context-induced reinstatement to oxycodone seeking after repeated cycles of drug self-administration and extinction.
Methods: We trained rats to self-administer oxycodone (0.1 and 0.05 mg/kg/infusion; 8-10 days per dose, 6-h/d) in Context A; lever pressing was paired with a discrete cue. Next, we extinguished lever pressing in the presence of the discrete cue in Context B for 9-11 days (6-h/d). We then tested them in both Contexts A and B under extinction conditions (1-h/day). Following this, we retrained the rats to self-administer oxycodone in Context A, re-extinguished lever pressing in Context B, and retested rats in Contexts A and B. We also tested the effect of the preferential mu opioid receptor antagonist, naltrexone (0, 0.5 or 1.0 mg/kg, s.c.) on context-induced reinstatement.
Results: Rats re-exposed to the oxycodone (Context A), but not the extinction (Context B) context, reinstated lever pressing; pretreatment with 1.0, but not 0.05 mg/kg naltrexone, decreased this reinstatement.
Conclusions: We modified an established rat model of relapse to illicit drugs to study relapse to oxycodone seeking after repeated cycles of drug self-administration and abstinence. We also showed a role of mu opioid receptors in context-induced relapse to oxycodone seeking.

Title: Attenuated conditioned place preference for buprenorphine in stress-exposed mice.

Authors: *C. A. BROWNE[1,2], R. NUSSBAUM[2], W. PALMER[2], I. LUCKI[1,2];
[1]Pharmacol. and Mol. Therapeut., Uniformed Services Univ. of Hlth. Sci., Bethesda, MD;
[2]Psychiatry, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Ongoing clinical and preclinical trials have highlighted the considerable antidepressant potential for low doses of the mixed opioid analgesic buprenorphine (BPN), an FDA approved medication for opioid addiction and chronic pain. Despite these promising results, the abuse liability associated with the potent partial agonist activity of BPN at mu opioid receptors (μ-ORs) may impede repurposing BPN as a therapeutic for major depressive disorder (MDD). Utilizing a rodent model of depression, unpredictable chronic mild stress (UCMS), to induce a robust depressive phenotype, these studies evaluated the effects of BPN (0.25 mg/kg) in stressed and non-stressed (NS) mice in a condition place preference (CPP) paradigm. UCMS consisted of exposure to three unpredictable mild stressors per day for 14 days and resulted in diminished bodyweight gain ($p<0.001$) and significant anhedonia, as measured by reductions in sucrose preference compared to NS controls ($p<0.001$). Mice were randomized into four unbiased experimental groups for CPP based on pretest scores established on day 0: NS/Vehicle, NS/BPN, UCMS/Vehicle and UCMS/BPN. All mice received 8 conditioning days of 30 min exposures, alternating vehicle (day 1, 3, 5 and 7) and drug (day 2, 4, 6 and 8). On day 12, the time spent by each mouse in both chambers of the apparatus was recorded. NS mice exhibited robust preference for BPN ($p<0.001$) compared to vehicle-paired NS mice. This effect was significantly attenuated in UCMS-exposed mice ($p<0.01$). In addition, sucrose preference tested on day 13, revealed that BPN normalized the anhedonia in UCMS mice compared to the UCMS/Vehicle treated group ($p<0.05$). These results indicate that the rewarding effects of BPN are blunted in mice exposed to chronic stress, just as chronic stress has been shown to blunt other forms of reward. Moreover, BPN administration reversed the behavioral deficits induced by UCMS in these animals, possibly due to its antidepressant effects. These data in animals support the need for clinical studies to evaluate the abuse potential of low doses of BPN in depressed patients separately from populations of opioid abusers or normal volunteers.

Title: Modulating remifentanil choice

Authors: *J. J. CHOW, J. S. BECKMANN;
Psychology, Univ. of Kentucky, Lexington, KY

Abstract: Drugs of abuse, such as opioids, are a significant public health problem. However, the mechanisms that drive opioid-associated choice are unknown. Alternative reinforcers have been shown to compete with drugs of abuse. Herein, we assessed how an alternative reinforcer (palatable food pellet) can modulate the choice for an opioid reward (remifentanil), using a dependent schedule and free choice procedure. Male Sprague Dawley rats were first magazine shaped and then trained to lever press for sucrose pellets on a FR1 to FR5 schedule. Following FR5 lever training, an orienting response was trained into the response chain, where the onset of the houselight signaled a contingent head entry (orienting response) into the magazine, which turned off the houselight and extended the response levers. Rats were then catheterized. Following catheterization recovery, rats were then trained on an FR1 to FR5 schedule for 10 μg/kg/infusion of remifentanil on a single lever. Next, rats were allowed to earn five sucrose pellet reinforcers and five remifentanil reinforcers (10 μg/kg/infusion) on a FR5, where presentation of the associated lever (remifentanil or food) was randomly presented alone. Finally, rats were placed on a dependent schedule or free choice procedure. Both choice procedures consisted of 5 blocks, where remifentanil dose increased as a function of block (0, 0.32, 1.0, 3.2, and 10 μg/kg/infusion) on one alternative, while the other alternative consistently offered a single 45-mg palatable food pellet across all blocks. The free choice procedure consisted of 2 sample trials per reinforcer and 6 choice trials per block, where choice of one option forwent the other option. The dependent schedule consisted of 6 trials (3 remifentanil and 3 food) per block, where allocation of reinforcement across alternatives was randomized on each trial to maintain equal experience with each option across blocks. Upon stability, food restriction, removal of drug infusion cues, and removal of the orienting response were manipulated to determine the effects on remifentanil versus food choice. Moreover, a matching analysis was used to compare changes to relative magnitude sensitivity and choice bias. Overall, the results indicate that remifentanil preference is dose-dependent. Additionally, food restriction and removal of drug infusion cues shifted preference towards food, while removal of the head entry shifted preference towards remifentanil. Collectively, the results herein indicate that remifentanil value is relative and can be modulated by an alternative. Future use of drug choice procedures will help to isolate variables of importance in drug-associated decision making.

Title: Modulation of traumatic memory acquisition and recall via prefrontal cortical dopamine d4 and d1 receptor transmission differentially controls opiate reward sensitivity: implications for addiction comorbidity in post traumatic stress disorder

Authors: ***J. LI**, J. RENARD, H. SZKUDLAREK, S. LAVIOLETTE;
Neurosci., Univ. Of Western Ontario, London, ON, Canada

Abstract: PTSD and opiate addiction share strong co-morbidity and the inability to suppress obtrusive memory recall related to either stressful or rewarding experiences may be an underlying neuropsychological feature triggering PTSD and/or addiction. Our previous research has shown that dopamine (DA) transmission in the prefrontal cortex (PFC) strongly modulates emotional memory formation: activation of the DA D4 receptor (D4R) strongly potentiates the emotional salience of normally non-salient fear memories whereas DA D1 receptor (D1R) activation blocks the behavioural recall of fear memory. Thus, while intra-PFC D4 transmission strongly controls the acquisition of emotional memory, D1 transmission is selectively involved in the recall phase of emotional memory processing. Using a pre-clinical model of PTSD in rats, we examined if recall of associative fear memory would increase subjects' sensitivity and vulnerability to morphine addiction. We also examined if blocking traumatic memory recall with PFC D1R stimulation may block this effect and if artificially creating a fear memory with PFC D4R stimulation would increase morphine reward sensitivity. Using an olfactory fear conditioning paradigm, we conditioned salient or non-salient associative fear memories by delivering supra-threshold (0.8 mA) vs. sub-threshold (0.4 mA) foot shock conditioning cues, and tested if recalling these memories increased sensitivity to morphine's rewarding properties, measured in a conditioned place preference (CPP) paradigm. We then examined the effects of intra-PFC DA D1R/D4R activation on expression and acquisition phases of associative fear memories and the subsequent influence on morphine reward sensitivity. Rats receiving supra-threshold fear conditioning showed strong associative fear memories and strongly potentiated morphine reward sensitivity. PFC activation of D1 receptor transmission with SKF 81297 (10-100 ng), dose-dependently blocked the recall of fear memory and similarly blocked the potentiation of morphine reward CPP through a cyclic AMP-dependent molecular pathway. In contrast, PFC D4 activation with PD-168077 (50 ng) during memory acquisition, created false fear memories in rats receiving sub-threshold foot shock. Remarkably, D4-mediated potentiation of normally non-salient fear memories also caused a dramatic potentiation in morphine reward sensitivity. Our findings have important implications for the role of the PFC DA receptor transmission in PTSD-related traumatic memory acquisition and recall and suggest that dysregulation of PFC DA transmission may underlie co-morbidity between PTSD and opiate addiction.

Title: The effects of orexin-1 receptor antagonist into the ventral tegmental area on forced swim stress-induced reinstatement of morphine in rats

Authors: *R. AZIZBEIGI[1], M. MORADI[2], A. HAGHPARAST[2];
[1]Dept. Of Physiol., Islamic Azad University, Sanandaj Br., Sanandaj, Iran, Islamic Republic of;
[2]Neurosci. Res. Center, Shahid Beheshti Univ. of Med. Sciences, P.O. Box 19615-1178, Tehran, Iran, Islamic Republic of

Abstract: It has been shown that the hypothalamic neuropeptide orexin (hypocretin) is not only involved in conditioned reward processes, but also in cue induced reinstatement of morphine. Regarding the effect of stress on reinstatement of morphine, it is shown that the ventral tegmental area (VTA) is one of the most important area involved which receive massive orexinergic inputs. Thus, in the present study, we investigated the role of orexin-1 receptor in the VTA in stress-induced reinstatement of morphine. The conditioned place preference (CPP) paradigm was done in adult male Wistar rats weighing 220 - 280 g, and conditioning score and locomotor activities were recorded by Ethovision software. After pre-test (day1), animals received morphine (5 mg/kg) during the 3-day conditioning phase and the next day (post-test; day 5) tested for CPP scores. In the extinction phase, rats were daily put in the CPP box for 30 min until the CPP score in two continuous days become similar to those on the pre-test; extinction happened on day13. On reinstatement day (day14), animals were microinjected bilaterally into the VTA by different doses of orexine-1 receptor antagonist, SB334867 (0.3, 1 , 3 nM/0.3 µl DMSO per side), then exposed to forced swim stress (FSS) for 6 min before subcutaneous injection of ineffective dose of morphine (0.5 mg/kg) to facilitate the reinstatement of extinguished morphine-CPP. The results revealed that FSS induced reinstatement of extinguished morphine-CPP and SB334867 deceased the FSS-induced reinstatement at the higher doses (1 and 3 nM/0.3 µl DMSO per side). Findings shows that intra-VTA orexin receptors have a role in reinstatement of morphine and it seems that stress partially exerts its effects on the reinstatement of morphine via orexin receptors in the VTA.

Title: Relationship between locomotor activity and individual differences in morphine self-administration in rats

Authors: *A. C. HARRIS[1], P. MUELKEN[1], M. G. LESAGE[1], J. C. GEWIRTZ[2];
[1]Med., Minneapolis Med. Res. Fndn., Minneapolis, MN; [2]Psychology, Univ. of Minnesota, Minneapolis, MN

Abstract: Understanding factors contributing to individual differences in opioid addiction vulnerability is essential for developing more effective preventions and treatments. Locomotor activity in a novel environment predicts individual differences in self-administration (SA) of several drugs of abuse (e.g., cocaine, amphetamine) in rodents, but the relationship between this variable and individual vulnerability in opiate SA has not been well established. The goal of the current study was to evaluate the ability of locomotor activity to predict individual differences in morphine SA in rats. The reinforcing efficacy of morphine was evaluated using a behavioral economic approach. This framework has been useful for studying individual differences in addiction vulnerability in both humans and animals, but has not previously been applied to morphine SA in rodents. Following an initial locomotor activity screen, animals were allowed to acquire morphine SA at a unit dose of 0.5 mg/kg/infusion in 4 hour/day sessions (Experiment 1) or 0.2 mg/kg/infusion in 2 hour/day sessions (Experiment 2) until infusion rates were stable. Unit price was subsequently manipulated via progressive reductions in unit dose (Experiment 1) or increases in response requirement per infusion (Experiment 2). Activity levels were not associated with acquisition of MSA or elasticity of demand (reinforcing efficacy) in either Experiment. Our findings indicate that locomotor activity in a novel environment did not predict individual differences in morphine SA in rats. These data contrast with findings using other drugs of abuse, and suggest that unique factors may contribute to individual differences in opioid addiction vulnerability.

Title: Inhibitory effects of SB366791, a selective TRPV1 antagonist, on morphine self-administration and anxiety-like behavior in rats after withdrawal of morphine

Authors: ***S. MA**[1], S.-Y. LEE[2], C.-G. JANG[2];
[1]Sungkyunkwan Univ., Suwon City, Korea, Republic of; [2]Sch. of Pharm., Sungkyunkwan Univ., Suwon city, Korea, Republic of

Abstract: TRPV1, the archetypal member of the vanilloid TRP family, was initially identified as the receptor for capsaicin, the pungent ingredient in hot chili peppers. We previously demonstrated that TRPV1 in the dorsal striatum significantly contributes to morphine reward using the conditioned place preference (CPP) paradigm in mice, but it is unknown whether TRPV1 has the same effect in other reward models. In this study, we investigated the role of TRPV1 in morphine reward using a self-administration paradigm in rats. We found that treatment with a selective TRPV1 antagonist, SB366791, significantly decreased morphine self-administration on a fixed-ratio 1 schedule or a progressive ratio schedule of reinforcement. Furthermore, administration of SB366791 decreased an anxiolytic-like effect during the morphine abstinence period. Moreover, treatment with SB366791 significantly decreased morphine-priming reinstatement. Taken together, our findings suggest that blockade of TRPV1 receptors could provide an approach to limiting morphine addiction.

Abstract: Biological mechanisms by which opioid drugs impair brain energy utilization, and thus contribute to opiate addiction, remain unclear. Using computed tomography (CT), ^{18}fluoro-deoxyglucose positron emission tomography (^{18}F-FDG-PET), and intravenous morphine self-administration (MSA), we investigated the effects of voluntary morphine intake and different ^{18}F-FDG uptake conditions on cerebral glucose utilization in rodents. Jugular vein cannulated male Sprague-Dawley rats self-administered intravenous saline or morphine (0.5 mg/kg/infusion, 4hrs/day) for 12 days. The animals were scanned at a baseline (pre-MSA) and 2 days after chronic MSA. One batch of animals (morphine and saline group) was anesthetized with isoflurane and the other (morphine and saline group) was kept awake during the ^{18}F-FDG uptake period. PET/CT images were analyzed using a 3D rat brain atlas for volume of interest and a statistical parametric mapping (SPM) for voxel-based analysis. The MSA group exhibited locomotor hyperactivity, constipation, and delayed weight gain during the self-administration period as compared with the saline controls. Isoflurane anesthesia reduced glucose utilization mainly in the cortical regions while increasing glucose utilization in the subcortical regions including midbrain and hypothalamus. Spontaneous withdrawal from chronic morphine increased glucose utilization in the basal ganglia only in isoflurane anesthetized ^{18}F-FDG uptake. This suggests that *in vivo* regional glucose utilization is different between isoflurane anesthetized and awake ^{18}F-FDG uptake conditions. Increased glucose utilization in the basal ganglia following chronic MSA may be associated with the development of opiate addiction. This study demonstrates the utility of combining a non-invasive brain imaging technology with an intravenous drug self-administration paradigm to enhance our understanding of the biological mechanisms of opiate addiction.

Title: Oxycodone self-administration in male and female rats

Authors: ***M. MAVRIKAKI**[1], M. PRAVETONI[2], S. PAGE[1], D. POTTER[1], E. CHARTOFF[1]; [1]Harvard Med. School, McLean Hosp., Belmont, MA; [2]Departments of Med. and Pharmacology, Univ. of Minnesota, Minneapolis, MN

Abstract: The prescription opioid oxycodone is one of the most widely prescribed painkillers in the US. However, its use is complicated by high abuse potential. Since sex differences have been described in most stages of drug addiction, the present study tests if there are sex differences in oxycodone intravenous self-administration, a rodent model of drug addiction. Male and female Sprague-Dawley rats were implanted with jugular vein catheters and trained to self-administer oxycodone (0.03mg/kg/infusion). Rate of acquisition and maintenance of self-administration behavior on fixed ratio 1 (FR1), FR2, and FR5 schedules of reinforcement were measured. In addition, sensitivity to the reinforcing effects of oxycodone (dose response), and motivation to work for oxycodone (progressive ratio) were measured. In a separate cohort of rats, distribution of oxycodone to serum and brain were measured after intravenous delivery. On an FR1 schedule of reinforcement, male rats self-administered more oxycodone than females. On FR2 and FR5 schedules, no significant sex differences in drug intake were observed, although females had significantly more inactive lever presses than males. In the dose response experiment, females tended to self-administer more oxycodone across doses, but this effect was not significant. Similarly, there was a trend for females to work harder for oxycodone in the progressive ratio experiment. No significant sex differences were observed in plasma or brain oxycodone levels, suggesting that sex differences in oxycodone self-administration behavior are not due to pharmacokinetics. Taken together, our results suggest that there are sex differences in abuse liability of oxycodone, which has ramifications for the treatment of oxycodone dependence and abuse.

Educ., London, United Kingdom

Abstract: The mu opioid receptor (MOR), widely expressed throughout the nervous system, mediates analgesic and addictive opiates effects. Several brain areas responsible for MOR-mediated reward have been identified by intracranial pharmacological manipulations; however underlying circuit mechanisms are unclear. In this study, we investigated whether MORs expressed in striatal medium spiny neurons (MSNs) contribute to central effects of opiates, with particular emphasis on addiction-related behaviors.
We developed a conditional knockout line (Dlx-MOR) by crossing floxed mice for the MOR gene *Oprm1* with transgenic mice expressing Cre recombinase in GABAergic forebrain neurons (Dlx5/6-Cre). First, we determined MORs distribution in these animals using qRT-PCR and autoradiographic binding. MOR mRNA expression analysis reveals inactivation of *Oprm1* in the striatum (nucleus accumbens, NAc, and dorsal striatum) only. Ventral tegmental area (VTA) slice electrophysiological recordings indicate a MOR-mediated inhibitory control over Dlx-MOR

dopamine (DA) but no GABA neurons, demonstrating that within VTA, presynaptic MSN-MORs are lacking, while MORs expressed by interneurons or other regions are intact. Second, we examined opiate effects on dopamine release and behavior. In Dlx-MOR mice, heroin fails to increase locomotor activity. Heroin reward in the conditioned place preference test (CPP), as well as heroin-induced NAc DA release measured in microdialysis experiment, is preserved in mutant mice, concordant with intact MOR expression in the VTA. We further studied heroin and palatable food self-administration (SA). In both experiments, Dlx-MOR mice improve operant performance in both fixed and progressive ratio sessions, which contrasts with CPP and microdialysis results. After extinction phase, they reinstate heroin SA upon cue exposure while control mice do not, revealing seeking behavior.
In conclusion, our targeted inactivation of *Oprm1* first demonstrates that MSN-MORs mediate locomotor effects of opiates. Second, the study shows that heroin rewarding effects are not mediated by striatal MORs, in agreement with the 2-neuron VTA model. Third, our data reveal a novel, yet unreported role of MSN-MORs in seeking behaviors for both drug and natural rewards. MORs therefore exert multiple functions throughout brain circuits of reward, which extend beyond hedonic control, and our study opens the way to circuit mapping of opioid mechanisms underlying motivation and decision-making.

Title: Mu opioid receptors in the habenula: dissecting reward and aversion in addiction

Authors: *L.-J. BOULOS[1], E. DARCQ[2], C. GAVÉRIAUX-RUFF[3], B. L. KIEFFER[2];
[1]Fac. of Med. - Integrated Program in Neurosci., McGill - Douglas Inst., Montreal, QC, Canada; [2]Douglas Mental Hlth. Inst., Montreal, QC, Canada; [3]Univ. de Strasbourg, Inst. de Génétique et de Biologie Moléculaire et Cellulaire, Ctr. Natl. de la Recherche Scientifique, Illkirch, France

Abstract: It is well-established that mu-opioid receptors (MORs) mediate the potent analgesic and rewarding effects of opiates (Matthes et al., Nature, 1996). Further, these receptors are central to reward processing for both drugs of abuse (Contet et al., Current opinion in neurobiology, 2004) and natural stimuli (Moles et al., Science, 2004), and largely contribute to the initiation of addictive behaviors. Finally, chronic MOR activation induces neuroadaptations that contribute to drug withdrawal symptoms and the negative and aversive emotional states associated to protracted abstinence (Goeldner et al., Biological Psychiatry, 2011; Lutz et al., Neuropsychopharmacology, 2014). Traditionally, the positive rewarding effects of opioids have been attributed to opioid receptors in the mesolimbic tract. Intriguingly, the medial habenula (MHb), a small epithalamic brain structure that shows the highest MOR density, has been shown to be implicated in both reward and aversive processes. Here, we created and characterized a conditional knockout mouse model that lacks MORs specifically in the MHb -using the nicotine receptor subunit ChrnB4 as a promoter- (B4-MOR mice) to dissect the role of MHb MORs in reward. Our cellular characterization of B4-MOR mice using PCR, qPCR, RNAscope and immunohistochemistry techniques proved that the conditional knockout mouse successfully shows a reduction of Hb MORs. In addition, our RNAscope results indicate that MORs are mainly expressed in glutamatergic substance P positive neurons in the MHb but they also colocalize with acetylcholine transferase in a smaller population of habenular neurons, consistent with protein distribution (Gardon et al., Neuroscience, 2014). Our first behavioral results show a reduction of withdrawal symptoms upon chronic morphine exposure in B4-MOR mice, thus indicating a role of Hb MORs in aversive processes associated to abstinence.

Title: Pretreatment with low dose naltrexone prevents death due to heroin overdose in rats

Authors: *P. S. GRIGSON, C. B. JENNEY, P. J. MCLAUGHLIN, I. S. ZAGON, M. VARVARIS;
Dept Neural/Behav Sci., Pennsylvania State Univ. Col. of Med., Hershey, PA

Abstract: Addiction is a growing problem worldwide, with an estimated 187,000 drug-related deaths in 2013 alone. Opioids are said to account for about three quarters of these cases. In the United States, opiate overdose is now recognized as an 'epidemic' in many states and overdose has surpassed car accidents as the leading cause of accidental death. The number of opiate overdose deaths more than quadrupled in a single decade nationwide, increasing from 4,030 in 1999 to 16,651 in 2010. These numbers soared to 43,982 in 2013. Unfortunately, such deaths continue to occur despite recent approval of the opiate blocker, naloxone, for use by caregivers and first responders. Here, rather than rescue one from opiate overdose with an opiate blocker, we tested whether opiate overdose could be prevented, altogether, in rats by daily administration of a relatively inexpensive opiate blocker, low dose naltrexone (LDN). The results showed that while 53.8% of the saline pretreated rats died following infusion of the high dose of heroin, only 14.3% and 13.3% of the rats died of heroin overdose when pretreated daily with a 1.0 or a 3.0 mg/kg dose of naltrexone, respectively. This constitutes a 74.4% reduction in heroin overdose death in LDN vs. saline pretreated rats. If these findings translate to humans, thousands of opiate deaths may be prevented yearly in the United States and around the world.

Title: VK4-116, a highly selective and metabolically stable D3R antagonist, inhibits oxycodone addiction-like behaviors in rodents.

Authors: *Z.-B. YOU, G.-H. BI, V. KUMAR, E. L. GARDNER, Z.-X. XI, A. H. NEWMAN;
Mol. Targets and Medications Discovery Br., NIDA-IRP/NIH/DHHS, Baltimore, MD

Abstract: Prescription opiates such as oxycodone are highly effective analgesics used in clinical pain management. One of the adverse effects that limits opiate analgesic use is the tendency of some patients to develop dependence. Therefore, development of effective pharmacotherapeutic agents to reduce the addictive potential of opiate analgesics, facilitate detoxification in opiate

dependence and prevent drug relapse from opiate abstinence has been a major focus of opiate addiction research. In the present study, we investigated the potential utility of VK4-116, a novel highly selective and metabolically stable dopamine D3 receptor (D3R) antagonist in the treatment of oxycodone abuse and dependence in rodents. In mice, pretreatment with VK4-116 (5-15 mg/kg, i.p.) showed no effect on basal levels of locomotor activity, but dose-dependently inhibited oxycodone-induced (4 mg/kg, i.p.) locomotor activation. Repeated treatment of mice with oxycodone (4 mg/kg for 5 days) progressively increased oxycodone-induced locomotor activation while pretreatment with VK4-116 (5-15 mg/kg) dose-dependently blocked this effect. In order to evaluate the effects of VK4-116 on opiate reward, male Long-Evans rats were first allowed to self-administer oxycodone at 0.1 mg/kg/infusion (3 h per daily session) for 2 weeks under an FR-1 schedule of reinforcement, followed by 0.05 mg/kg/infusion for an additional week, and subsequently tested following pretreatment with VK4-116 (5-25 mg/kg, i.p; 15 min before testing). We found that pretreatment with VK4-116 dose-dependently inhibited oxycodone self-administration. Furthermore, pretreatment with VK4-116 (5-15 mg/kg) dose-dependently inhibited drug-seeking tested in trained rats given an extinction session in which oxycodone was replaced by saline, and blocked oxycodone-induced (1 mg/kg, i.p.) reinstatement of drug-seeking after the drug-seeking behavior was extinguished. Importantly, in oxycodone treated rats (3 mg/kg, i.p; twice daily for 7 days), VK4-116 (5-15 mg/kg) dose-dependently blocked naloxone (1 mg/kg s.c.) precipitated conditioned place aversion. Taken together, these findings suggest an important role for brain D3R in opiate reward and dependence. The novel D3R antagonist VK4-116 is effective not only in diminishing the rewarding effects of oxycodone, but also the aversive responses precipitated by blockade of opiate receptors in dependent animals. Thus, VK4-116 may serve as an effective agent for mitigating the development of opiate addiction, reducing the severity of withdrawal and preventing relapse. (*Supported by NIDA IRP*)

Title: Environmental enrichment reduces heroin seeking; a novel approach to treat heroin relapse.

Authors: *E. J. GALAJ[1], M. MANUSZAK[2], R. RANALDI[3];
[1]City Univ. of New York, New York, NY; [3]Psychology, [2]Queens College/CUNY, Flushing, NY

Abstract: Heroin-related cues can trigger craving and relapse in addicts or heroin seeking in rats. In the present study we investigated whether environmental enrichment (EE) implemented after heroin exposure can reduce cue-induced reinstatement of heroin seeking and the expression of heroin conditioned place preference. In experiment 1, male Long Evans rats that already acquired a heroin self-administration habit, were housed in an enriched or non-enriched environment, underwent extinction and later were tested for cue-induced reinstatement of heroin seeking. In experiment 2, rats were conditioned with heroin in one compartment of a CPP apparatus and saline in the other, exposed to 30 days of enrichment/no enrichment and were later tested for heroin CPP. The results showed that exposure to EE significantly reduced responding during the reinstatement test (experiment 1) and prevented the expression of heroin CPP (experiment 2). Our findings suggest that EE can be an effective behavioral approach to diminish the effects of conditioned cues on heroin seeking.

Abstract: Opioid addiction is heritable, yet its genetic basis remains poorly understood. Mice are valuable for identifying novel genes that contribute to variation in addiction-associated phenotypes including acute psychomotor stimulation and conditioned reward. The closely related C57BL/6J and C57BL/6NJ strains exhibit limited genetic diversity, yet show significant strain differences in several addiction-associated traits, including oxycodone-induced (OXY) locomotor activity and naloxone conditioned place aversion. Quantitative Trait Locus (QTL) mapping in these substrains drastically reduces the number of segregating genetic variants from millions to thousands, accelerating the identification of the causal genetic factors. We conducted QTL mapping for oxycodone conditioned place preference (CPP, N=212), and naloxone conditioned place aversion (CPA, N=209), along with saline-treated mice as controls (SAL, N=213). We utilized a 9 day (D) CPP/CPA protocol. Mice received drug (1.25 mg/kg OXY, 4 mg/kg NAL, or SAL, i.p., suspended in SAL) on D2 and D4, and SAL on D3 and D5. Mice were assessed for drug-free CPP/CPA (D8) and drug state-dependent CPP/CPA (D9). Mice were genotyped at 96 informative markers and QTL mapping was performed in R/qtl (scanone, 1000 permutations). We identified a major genome-wide significant QTL for D2 and D4 locomotor (Chr. 1 72.43 cM, LOD= 9.79) that co-mapped to the same region as a QTL for anxiety-like opioid withdrawal behavior in the elevated plus maze (chr. 1 77.33 cM; LOD=5.33). High priority candidate genes within this locus include Rgs7 and Akt. We are currently conducting striatal transcriptome analysis via RNA-seq to aid in candidate gene identification and neurobiological mechanisms

Title: Choice between delayed food and immediate oxycodone in rats.

Authors: *M. SECCI, J. FACTOR, C. W. SCHINDLER, L. V. PANLILIO;
Preclinical Pharmacol., Natl. Inst. on Drug Abuse Intramural Res. Program, Baltimore, MD

Abstract: The choice to seek immediate drug effects instead of more meaningful but delayed rewards is a defining feature of addiction. To develop a rodent model of this behavior, we

allowed rats to choose between immediate intravenous delivery of the prescription opioid oxycodone (50 μg/kg) and delayed delivery of palatable food pellets. Food was preferred at delays up to 30 s, but food and oxycodone were chosen equally at 60-s delay, and oxycodone was preferred at 120-s delay. Comparison of food-drug choice, food-only and drug-only conditions indicated that food availability decreased drug intake, but drug availability increased food intake. In the food-only condition, food was a highly effective reinforcer even when delayed by 120 s. Pre-session feeding with chow slowed acquisition of food and drug self-administration, but did not affect choice. To establish procedures for testing potential medications, noncontingent pretreatment with oxycodone or naltrexone (analogous to substitution and antagonist therapies, respectively) was tested on a baseline in which oxycodone was preferred over delayed food. Naltrexone decreased drug intake and increased food intake. Noncontingent oxycodone decreased drug intake, but also produced extended periods with no food or drug responding. Overall, our findings show that the contingencies that induce preference for drugs over more meaningful but less immediate rewards in humans can be modeled in rodents, and they suggest that the model could be useful for assessing the effects of potential therapeutic treatments and exploring the underlying behavioral and neural mechanisms.

Title: Using ipsc derived human dopamine neurons from opioid dependent subjects to study dopamine dynamics

Authors: Y. LUO[1], P. TESAR[2], K. L. PRESTON[3], K. A. PHILLIPS[4], Z. LIN[5], Y. SHENG[1], *B. J. HOFFER[6];
[1]Neurolog. Surgery, [2]Genet., Case Western Reserve Univ., Cleveland, OH; [3]Intramural Res. Program, [4]Intrammural Res. Program, Natl. Inst. on Drug Abuse, Baltimore, MD; [5]Psychiatry, Harvard Univ. Mclean Hosp., Belmont, MA; [6]Scientist Emeritus, NIDA/NIH, Lyndhurst, OH

Abstract: The dopaminergic (DA) system plays an important role in addiction. However, human DA neurons from drug-dependent subjects were not available for study until recent development in inducible pluripotent stem cells (iPSCs) technology. In this study, we produced DA neurons

differentiated using iPSCs derived from opioid-dependent and control subjects carrying different 3' VNTR (variable number tandem repeat) polymorphisms in the human dopamine transporter (DAT, SLC6A3). We successfully generated midbrain dopamine neurons that expressed forkhead box protein A2, LIM homeobox transcription factor 1 alpha, tyrosine hydroxylase, the dopamine D_2 receptor, Nurr 1, the vesicular monoamine transporter 2, and the dopamine transporter. All iPSC lines generated dopamine neurons that released dopamine detectable by high-performance liquid chromatography. There was no apparent difference in dopamine differentiation efficiency between cell lines derived from control and opioid-dependent subjects with regard to the percentage of cells positive for tyrosine hydroxylase. We present the first evidence suggesting that the 3' VNTR polymorphism in the hDAT gene affects DAT expression level in iPSC-derived human DA neurons. There were also different expression levels of D_2 receptors in the control group's iPSC-derived dopamine neurons compared with the opioid-dependent group's iPSC-derived dopamine neurons. Specifically, our results showed lower expression levels of D_2 receptors in both opioid-dependent iPSC lines. We also examined the expression of different classes of opioid receptors. Our data showed that mu opioid receptors were not detected in our differentiated human dopamine neurons derived from iPS cells. In contrast, kappa and delta opioid receptors were detected in our human dopamine neuronal cultures from all four iPSC lines. In addition, the effects of valproic acid (VPA) exposure on iPSC-derived human DA neurons were also examined. In human DA neurons, VPA treatment altered the expression of several genes important for dopaminergic neuron function including DAT, Nurr1, and TH; this might partly explain its action in regulating addictive behaviors. VPA treatment also significantly increased DA D2 receptor (Drd2) expression, especially in the opioid-dependent iPSC cell lines. Our data suggest that human iPSC-derived DA neurons may be a useful in vitro experimental model to examine the effects of genetic variation in gene regulation, to examine the underlying mechanisms in neurological disorders including drug addiction, and to serve as a platform for therapeutic development.

Title: Determination of kappa opioid receptor contributions to re-escalation of oxycodone self-administration under extended access conditions

Authors: *J. D. NGUYEN, D. KIRSON, F. P. VARODAYAN, S. KHOM, M. ROBERTO, M. A. TAFFE;
Scripps Res. Inst., La Jolla, CA

Abstract: Prescription opioid abuse is a significant global problem, and opioid addiction is well-characterized by compulsive drug seeking, motivational withdrawal and chronic relapse. The goal of this study was to investigate escalation of opioid intake with extended access to intravenous oxycodone self-administration and re-engagement of drug seeking (re-escalation) following detoxification. Male Wistar rats were randomly assigned to short-access (ShA, 2-h) and long-access (LgA, 12-h) groups and trained to self-administer oxycodone (0.15 mg/kg/infusion) using a fixed-ratio 1 (FR1) response contingency and evaluated on a progressive-ratio (PR) procedure incorporating dose-substitution of oxycodone (0.06-0.3 mg/kg/infusion). Both groups underwent an abstinence period (4 weeks) and were tested for re-escalation. Rats given LgA to oxycodone earned more infusions than rats trained with ShA during acquisition. PR test results demonstrated an increase in drug-intake and breakpoints in rats assigned to LgA training relative to rats assigned to ShA training. All rats exhibited high levels of drug seeking upon re-engagement; however, LgA rats failed to de-escalate drug intake following the abstinence period. Previous findings show kappa opioid receptor (KOR) mediated disruption in GABAergic signaling in the central nucleus of the amygdala (CeA) is observed after acute (24-h) withdrawal from escalated cocaine self-administration. To investigate KOR dysregulation following acute oxycodone withdrawal, electrophysiological recordings were performed in CeA slices. The selective KOR agonist U-50488 decreased GABAergic signaling in both ShA and LgA rats, and this effect was blocked by KOR antagonist nor-binaltorphimine (nor-BNI). Applied alone, norBNI increased GABAergic signaling, suggesting tonic KOR activity. These findings further support the conclusion that access duration differentially impacts the acquisition and maintenance of the self-administration of oxycodone, and suggest that KOR-mediated signaling during oxycodone dependence may be distinct from that of other drugs of abuse.

Title: Evaluation of a novel "e-vape" system as a model of opioid self-administration in rats

Authors: J. C. M. VENDRUSCOLO[1], *L. F. VENDRUSCOLO[1], B. J. TUNSTALL[2], S. A. CARMACK[2], M. COLE[3], S. VANDEWATER[3], M. TAFFE[3], O. GEORGE[3], G. F. KOOB[4]; [1]Integrative Neurosci. Res. Br., [2]NIH - NIDA - IRP, Baltimore, MD; [3]TSRI, La Jolla, CA; [4]NIH - NIAAA, Rockville, MD

Abstract: Opioid misuse is a major public health issue. Rodent models have been critical for the understanding of the biological factors underlying opioid consumption and dependence. Among them, intravenous self-administration has been the “gold standard” in the drug addiction field. In this model, rodents readily learn to perform an operant response for a drug infusion and, depending on the procedure (e.g., extended drug access), exhibit somatic and motivational signs of opioid dependence. However, the use of intravenous self-administration imposes some difficulties, such as maintenance of catheter patency. Thus, the goal of the present study was to develop a model of opioid operant self-administration that does not require surgeries and can be used for long periods of time. We used an electronic vaporizer (e-vape) similar to what is used by humans for electronic cigarette smoking to vaporize the potent opioid sufentanil. Sufentanil was dissolved in distilled water and mixed with vegetable glycerin and propylene glycol. Wistar rats were trained to nosepoke the active hole to receive a 10-sec delivery of vaporized sufentanil solution in 2-h daily sessions. Each reinforced nosepoke also initiated a 60-sec timeout period signaled by cue light. Nosepokes in the inactive hole had no programmed consequences. The results indicate that rats rapidly acquired and maintained vaporized sufentanil self-administration and that responding level on the active but not the inactive lever was dose-dependent. Rats significantly increased responding after a decrease in sufentanil concentration and decreased responding after an increase in sufentanil concentration. Thus, rats partially titrate their intake to maintain an optimal level of intoxication in a manner similar to intravenous self-administration. Moreover, the rats exhibited clear visible signs of opioid intoxication following sufentanil vapor delivery (e.g., tail stiffness, abnormal ‘frozen’ posture and startle to noise). Furthermore, injection with a low dose of the preferential u-opioid receptor antagonist naloxone prior to self-administration caused a remarkable increase in responding for sufentanil. Together, the present results demonstrate that operant self-administration of vaporized sulfentanil reliably produces opioid intoxication and suggest the potential of this model as an alternative to intravenous self-administration. This model may be a useful tool for studies in some stages of development where catheterization is difficult (e.g., adolescence), longitudinal studies and drug interaction studies.

Title: Examination of potential sex differences in the behavior of Rictor knockout mice

Authors: ***S. KASKA**[1], R. BRUNK[2], M. S. MAZEI-ROBISON[3];
[1]Pharmacol. and Toxicology, [2]Neurosci. Program, Michigan State Univ., East Lansing, MI;
[3]Physiol. and Neurosci. Program, Michigan Stat Univ., East Lansing, MI

Abstract: Drug addiction is a disease that poses a significant health and financial burden on society. Dysregulation of the mesolimbic dopamine reward pathway is known to play a role in drug addiction and a more complete understanding of the molecular mechanisms underlying this dysregulation may lead to improved treatment. We have previously observed that chronic opiate exposure alters ventral tegmental area (VTA) dopamine (DA) neuron morphology and activity and that these changes are dependent on mammalian target of rapamycin complex 2 (TORC2) signaling. However, since previous studies examining TORC2 effects on behavior have utilized only male mice, here we sought to characterize the effect of decreased VTA or catecholaminergic TORC2 signaling in a battery of behavioral tests in both male and female mice. Since TORC2 signaling cannot be specifically manipulated pharmacologically, we have utilized a genetic approach. Rictor is core protein of TORC2 and knockout of Rictor eliminates TORC2 signaling. We utilized two models: 1) a developmental catecholaminergic Rictor knockout through crossing floxed Rictor and tyrosine hydroxylase (TH)-Cre mice (TH-Rictor-KO) and 2) an adult VTA Rictor knockout through stereotaxic injection of AAV-Cre into the VTA of floxed Rictor mice (VTA-Rictor-KO). Consistent with prior data (Dadalko et al., 2015), we see that male TH-Rictor-KO mice have increased locomotor activity in a novel environment,

but interestingly this phenotype is absent in female TH-Rictor-KO mice. However, there were no differences between the sexes, or from littermate controls, in anxiety-like measures (center time in open field, elevated plus mice) or social interaction. Additionally, we observe an increase in consummatory behavior in male TH-Rictor-KO mice, as they drink more water, sucrose, and morphine in a voluntary two-bottle choice assay compared to littermates, but with no difference in sucrose or morphine preference. In contrast, female TH-Rictor-KO mice have normal water consumption, but exhibit significantly increased morphine intake and a trend for increased sucrose intake. We are currently examining these same behaviors in VTA-Rictor-KO mice to determine whether these effects are driven by changes in the VTA or other catecholaminergic brain regions. We also plan to examine morphine conditioned place preference in both male and female TH-Rictor-KO mice and female VTA-Rictor-KO mice, as we previously found that male VTA-Rictor-KO mice exhibit decreased morphine CPP. Together, these data may suggest a difference in the role of catecholaminergic TORC2 signaling in baseline activity and consummatory behavior of male and female mice.

Title: Chronic heroin use in humans alters striatal histone H3 hyperacetylation that regulates glutamatergic synaptic plasticity and addiction behavior

Authors: *G. EGERVARI[1,2], J. LANDRY[2], J. CALLENS[2], J. FULLARD[2], P. ROUSSOS[2], Y. L. HURD[1,2];
[1]Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Opiate overdose is now the leading cause of death among drug users, and the economic costs to society are estimated to be in the billions. Heroin in particular is one of the most addictive drugs, with nearly a third of all users progressing to dependence, emphasizing the critical need for greater efforts to expand the neurobiological underpinnings of heroin use disorder. Despite a significant body of research in animal and *in vitro* models, little knowledge has directly been accrued about the molecular neurobiology of the heroin-addicted human brain.

In addition to shedding novel light about neural systems relevant to the human condition, such knowledge would provide critical 'reverse translation' perspectives to improve targeted future mechanistic studies in animal models.
In this study, we adopted a transcriptome strategy to examine gene expression in the human striatum and used biological pathway analyses to identify candidate genes relevant to heroin use disorder. The results revealed marked impairments of genes related to glutamatergic neurotransmission and chromatin remodeling in heroin abusers. These findings served to drive further molecular studies in order to dissect epigenetic mechanisms mediating drug-related changes at glutamatergic synapses. On the protein level, we found that epigenetic marks predictive of gene activation—global histone H3 acetylation (pan-AcH3) and acetylation of lysine 27 of histone H3 (H3K27ac)—correlated with history of drug use and heroin toxicology. Using chromatin immunoprecipitation, we observed a significant increase in the enrichment of pan-AcH3 and H3K27ac directly at the *GRIA1* glutamate AMPA receptor gene which was paralleled with greater open chromatin accessibility in this region as shown by the assay for transposase accessible chromatin (ATAC-seq). Importantly, we found analogous epigenetic and transcriptional impairments in heroin self-administering Long-Evans rats. Using this translational model, we showed that the small molecule bromodomain inhibitor JQ1 potently inhibits heroin self-administration as well as cue-induced drug seeking behavior.
Overall, our data suggest that heroin-related histone acetylation impairments play a crucial role in establishing glutamatergic transcriptional changes that underlie striatal synaptic plasticity and addiction behavior. The results indicate that JQ1 or other bromodomain inhibitors are promising candidates for targeted clinical interventions in heroin and potentially other substance use disorders.

Title: Zolmotriptan, a serotonin-1B receptor agonist, modulates the rewarding properties of nicotine in female and male adolescent rats

Authors: *K. HERNANDEZ[1,1], B. J. SALINAS[1], A. V. ABELLA[1], S. D. IÑIGUEZ[2], N. S. PENTKOWSKI[3], A. R. ZAVALA[1];
[1]Psychology, California State University, Long Beach, Long Beach, CA; [2]Psychology, The Univ. of Texas at El Paso, El Paso, TX; [3]Psychology, Univ. of New Mexico, New Mexico, NM

Abstract: Activation of serotonin-1B (5-HT_{1B}) receptors has been shown to modulate the rewarding effects of cocaine and alcohol. To date, the role of 5-HT_{1B} receptors in the rewarding effects of nicotine has not been investigated. To identify if these receptors play a role in nicotine reward, the nonselective FDA approved 5-HT_{1B} agonist, Zolmitriptan, was administered to adolescent rats prior to conditioning with nicotine using the conditioned place preference (CPP) paradigm-a validated animal model of drug reward. Specifically, female and male adolescent rats were conditioned on postnatal day 29-36 with saline or nicotine (0.0, 0.0022, 0.067, or 0.2 mg/kg, subcutaneously) on alternating days over an 8-day CPP conditioning procedure. During nicotine conditioning days, rats were administered Zolmitriptan (0, 3, or 10 mg/kg, subcutaneously) 15 min prior to nicotine injections. Results indicate that activation of 5-HT_{1B} receptors with Zolmitriptan decreased the rewarding properties of nicotine in both female and male rats in a dose dependent manner. As the dose of the agonist was increased, a decrease in nicotine-induced CPP was evident. Altogether these results indicate that 5-HT_{1B} receptors play a critical role in the rewarding properties of nicotine and further suggest that 5-HT_{1B} receptors are a novel target for nicotine dependence.

Title: Chronic exposure to nicotine during adolescence not adulthood triggers long term changes in mesolimbic expression of stress related genes

Authors: *L. F. ALCANTARA, C. BOLAÑOS-GUZMAN;
Psychology:BCN, Texas AM Univ., College Station, TX

Abstract: Individuals who smoke cigarettes often report having their initial nicotine (NIC) experience as an adolescent, escalating their use overtime. Long-term smokers have higher incidence of mood-disorders and initiation of smoking at earlier ages increases the likelihood of developing major depression later in life. This phenomenon is less pronounced in individuals whom begin smoking during adulthood suggesting that NIC exposure during different developmental stages can induce distinct biological consequences. For example, we have previously shown that adolescent, but not adult, rats exposed to chronic NIC show deficits when tested in depression- and anxiety- related tasks later in life. After 15 days of NIC exposure rats exhibit long-term decreases in latency to immobility and increased total immobility in the forced swim test (FST), suggesting increased learned helplessness. NIC pre-treated adolescents also show increased time spent in the closed arm of the elevated plus maze (EPM), indicating greater anxiety-like behavior. This effect is not seen in adult-treated rats, indicating a different NIC-induced behavioral profile. Additionally, given that these alterations are seen long after cessation of drug use and indicate more persistent biological regulation. One of the major brain circuits involved in both drug- and mood-related behaviors is the mesolimbic dopamine pathway. As one of the primary dopaminergic output sources, the ventral tegmental area (VTA) stands as the hub of this pathway, projecting mainly to the nucleus accumbens (NAc), prefrontal cortex and hippocampus. It is possible that NIC acts on this pathway to mediate depressive-like symptomology. Recent studies have implicated various signaling pathways as mediators of mood-related behaviors in the NAc and VTA. Specifically, genes related to the extra cellular-regulated kinase (Erk ½) and AKT/P13k pathways, have shown great promise in elucidating the mechanisms mediating depression. Therefore it is plausible that chronic exposure to NIC modulates these pathways differently based on age of exposure leading to divergent behavioral outcomes. To this end, Adolescent and adult male rats were injected with NIC for 15d and left undisturbed for one month. Tissue was collected from the VTA and NAc and gene expression was measured using rtPCR. We found that *Erk2, Creb, Akt* and *GSK3b* expression differed between adult and adolescent rats in both the VTA and NAc. This data demonstrates that chronic exposure to NIC alters long-term gene expression in an age-dependent manner and provides insight into the possible long-term mediators of depression-like symptoms induced by early life smoking.

Title: Altered gene expression (RNA-Seq) and response to nicotine in F1 offspring of paternal stress exposure

Authors: *N. L. YOHN[1], M. S. BARTOLOMEI[2], J. A. BLENDY[1];
[1]Dept. of Systems Pharmacol. and Translational Therapeut., [2]Dept. of Cell and Developmental Biol., Univ. of Pennsylvania, Perelman Sch. of Med., Philadelphia, PA

Abstract: Objective: Evidence suggests that parental stress exposure is inherited by future generations in both humans and animals. However, no work has identified if parental stress exposure influences offspring response to drugs of abuse, including nicotine. Thus, the goal of this work is to determine if stress administered to F0 animals alters response to nicotine in future generations.
Methods: Male C57BL/6 mice underwent chronic unpredictable stress (CUS) for 2 weeks starting at 4 weeks of age. Following CUS, mice were mated with naïve partners to produce F1 offspring. A second generation of mice was created by mating F1 offspring with naïve partners. Anxiety, startle response, and response to nicotine was characterized in F1 and F2 mice between 10-14 weeks of age. Gene expression changes in the amygdala of F1 male offspring were analyzed using RNA-Seq.
Results: F1 male mice derived from fathers exposed to CUS showed blunted sensitization to chronic nicotine administration. Interestingly, this phenotype was also found in their male offspring (F2). RNA-Seq of the amygdala of F1 male offspring identified 240 genes with altered expression in mice derived from fathers exposed to CUS (log2 fold change > 0.8, FDR < 0.05, and $P < 0.05$). Of those genes, 41 had increased expression while 199 were decreased. Gene ontology (GO) functional annotation clustering (DAVIDv6.7) revealed significant enrichment of extracellular matrix and plasma membrane gene sets. Driving the gene clustering was the altered expression of collagen and metabolic signaling genes as well as genes implicated in cellular response to stess and drugs of abuse.
Summary: Multi- and trans-generational inheritance of paternal stress exposure produces blunted response to chronic nicotine exposure in male mice. In addition, differential expression of genes found in offspring may contribute to these phenotypes.

Title: A second update on susceptibility genes for nicotine dependence identified by genome-wide linkage, candidate gene association, genome-wide association, and targeted sequencing approaches

Authors: ***M. D. LI**[1,2], J. YANG[1], T. J. PAYNE[3], J. Z. MA[4];

Abstract: Tobacco smoking is a severe health hazard worldwide, as nearly one-third of the global adult population smokes tobacco products, and these have been associated with numerous serious health problems. This high prevalence of tobacco use highlights the importance of studying the genetic determinants of nicotine dependence (ND). To identify genetic factors for ND, various approaches have been used, including genome-wide linkage, candidate gene-based association, genome-wide association (GWAS), and targeted sequencing analysis. In this study, we systematically analysed the findings from all the abovementioned approaches according to rigorous selection criteria for each included study such as sample size, statistical significance, and independent replication. Our analysis revealed 14 regions nominated by genome-wide linkage analysis and 34 significantly associated loci in 43 genes by candidate gene-based association. The GWAS and meta-GWAS revealed 11 genome-wide significant loci; however, only the loci on chromosomes 8, 15, and 19 have received independent replication. Although it is still in early stages, limited targeted sequencing studies using next-generation techniques have implicated 18 variants in the aetiology of ND. Together, we identified 14 linkage regions and 47 unique loci in 60 genes involved in the development of ND, which forms our current understanding of the susceptibility map for ND. Because almost all of these loci and genes have received replication by independent approaches in different samples, they should be considered high priorities for future functional study of ND.

Title: Adolescent and adult nicotine exposure: Precipitated withdrawal and conditioned place aversion

Authors: ***R. J. KEELEY**[1,2], T. E. MAYER[2], L.-M. HSU[2], H. LU[2], Y. YANG[2], E. A. STEIN[2]; [1]NIDA, Baltimore, MD; [2]Neuroimaging Res. Br., NIDA IRP, Baltimore, MD

Abstract: Smoking remains an economic and public health problem, with an estimated 20% of the world population engaging in regular cigarette use. Approximately 90% of smokers initiate first use before the age of 18, identifying adolescence as a development epoch sensitive to nicotine, the main addictive component of cigarettes. Preclinical studies have identified adolescents to be particularly sensitive to the rewarding effects of nicotine and less sensitive to its aversive properties. Indeed, precipitated and spontaneous withdrawal paradigms have demonstrated limited nicotine dose-dependent effect on withdrawal behavior in adolescents. Previous work from our group has observed, in adult smokers and rats exposed to nicotine, that the severity of withdrawal is negatively correlated with the strength of a resting-state functional connectivity (rsFC) between ventral striatum and dorsal anterior cingulate cortex. Here, we extend this cross-species work by first establishing a behavioral paradigm demonstrating dose-dependent withdrawal behavior in adolescent and adult Sprague-Dawley rats. In adolescents, nicotine exposure was initiated at postnatal day 33 (p33), p47 or p61 and was maintained for either 6, 4 or 2 weeks, respectively, corresponding to early, mid or late adolescence. Nicotine doses were 0, 1.2mg/kg/d or 4.8mg/kg/d delivered via osmotic minipumps, with pump replacement every 2 weeks. Adult rats were exposed to a similar paradigm for 2, 4 or 6 weeks. We trained rats to pair a precipitated withdrawal experience, through a single injection of 1.5mg/kg of mecamylamine, with a distinct context and a saline injection with another context. Precipitated withdrawal behaviors were recorded during the training. On the second day, rats were given the choice to freely explore both contexts to assess conditioned place aversion to the precipitated withdrawal. Training and testing was conducted every 2 weeks. We observed

nicotine-dependent withdrawal behaviors in adolescent rats, which persisted in rats continuously exposed to nicotine for 6 weeks. This model of nicotine withdrawal in adolescent and adult rats will next be applied in experiments examining how changes in rsFC correlate with differences in behavior in adolescent and adult rats. Determining how brain circuitry in adolescent and adult rats is differentially altered given similar exposure paradigms to nicotine will help to identify circuits in adolescence that are particularly vulnerable to the effects of nicotine, which may then serve as treatment target outcomes.

Title: Potential interactive effects of prenatal alcohol exposure combined with adolescent nicotine and/or ethanol exposure on ethanol and nicotine reward during adulthood.

Authors: K. DIXON, J. L. WAGNER, S. DAVIES, D. D. SAVAGE, *N. PENTKOWSKI; Univ. of New Mexico, Albuquerque, NM

Abstract: The use of nicotine and alcohol during adulthood is linked with drug exposure at different life stages, particularly during critical periods of prenatal and adolescent development. Prenatal alcohol exposure (PAE) is associated with birth defects, as well as cognitive, social and behavioral deficits, while adolescent drug exposure (ADE) has been associated with increased vulnerability for substance abuse during adulthood. The purpose of the present study was to examine the potential interactive effects of PAE and ADE (alcohol and/or nicotine) on drug reward for a cocktail of nicotine and alcohol during adulthood. Long-Evans dams were given daily 4-hour access to either an alcohol (5% v/v) solution or a saccharine solution starting after breeding and continuing throughout gestation. Male and female offspring from each prenatal group were aged to postnatal day (PND) 31 and then exposed to saline, alcohol (0.75 g/kg, i.p.), nicotine (0.6 mg/kg/s.c.), or a cocktail of nicotine and alcohol for 10 days. Beginning on PND 75, adult reward for the cocktail was evaluated using the conditioned place preference (CPP) procedure. Following baseline preference testing, rats were exposed to the cocktail for 10 min in their initially non-preferred side, and saline in their initially preferred side; saline and drug

sessions occurred 5 hours apart and were counterbalanced for order of presentation. The day following the last conditioning session each rat was placed into the apparatus for a 10-min test session without drug administration. We found a significant three-way interaction of sex, PAE, and ADE on adult cocktail preference (i.e., drug reward). In male rats, PAE enhanced adult preference for the cocktail, which depended on whether they were also exposed to alcohol during adolescence. A similar pattern was found in female PAE rats, although the change in preference depended on nicotine exposure in adolescence but not alcohol exposure. These results indicate that exposure to either nicotine or alcohol at critical developmental stages interacts to modulate vulnerability to drug reward during adulthood.

Title: Genetic variations of nicotinic receptor genes as predictors of nicotine dependence: a machine-learning approach

Authors: *S. LEE[1], W.-Y. AHN[2,1], E. S. BARRIE[1], K. HARTMANN[1], J. FRATER[1], W. SADEE[1];
[1]Ctr. for Pharmacogenomics, Col. of Med., [2]Dept. of Psychology, The Ohio State Univ., Columbus, OH

Abstract: Nicotinic acetylcholine receptors (nAChRs) are primary targets for nicotine, the pharmacological ingredient of tobacco, and play a major role in nicotine dependence (ND). Neuronal nAChRs are composed of five subunits that are encoded by eight alpha (CHRNA2-CHRNA9) and three beta (CHRNB2-CHRNB4) genes. Genome-wide association studies (GWAS) have yielded numerous variants implicated in ND, with the CHRNA5-CHRNA3-CHRNB4 gene cluster containing the most robust signals for ND. Evidence from transgenic animal studies and neuropharmacological studies indicate that additional nAChR subtypes also contribute to ND but fail to be significantly detected by genetic association studies. To overcome this gap, this study investigates the overall genetic effects on ND of multiple genetic variants from 11 nicotinic receptor genes. Using a data-driven approach, a machine learning method

called elastic net was used to identify multivariate data patterns and to make predictions that can be generalized across different study cohorts. Using smoking-related GWAS, single nucleotide polymorphism (SNP) up or downstream (± 100kb) of 11 nicotine genes were selected to predict ND measured by the Fagerstrom Test For Nicotine Dependence (FTND). Furthermore, we validated biological relevance of each classifier variant (significant predictors) using genomics databases including GTEx (Getnotype-Tissue Expression) and Braineac (Brain eQTL Almanac). The machine learning approach not only identified major signals in the CHRNA5-CHRNA3-CHRNB4 cluster including rs578776 and rs16969968 but also enabled us to detect significant genetic variations around the CHRNA9, CHRNA4 and CHRNB3 subunits, increasing the accuracy of classification predictions when assessed in combination. Taken together, our machine learning approach complements single SNP association studies to explain complex human disease conditions such as drug addiction.

Title: Modulation of kappa opioid receptor activity by nicotine and ethanol in adolescent and adult male rats

Authors: *S. J. CROSS[1], J. VAN[1], A. HO[1], D. BE[1], F. M. LESLIE[1,2];
[1]Anat. & Neurobio., [2]Pharmacol., Univ. of California Irvine, Irvine, CA

Abstract: Concurrent use of nicotine and alcohol represents a major public health concern, and use of both substances typically begins during adolescence. Adolescence is a sensitive developmental period marked by major reorganization of brain regions involved in executive function, learning and memory, and reward processing. Previous work from our lab has demonstrated that the combination of nicotine and alcohol is reinforcing and anxiolytic in adolescent, but not in adult, male rats. A potential mediator of these age differences is the kappa opioid receptor (KOR), as pretreatment with the KOR antagonist, norbinaltorphimine (norBNI), enhances nicotine and ethanol reinforcement in adults. Adolescents, on the other hand, are not affected by norBNI pretreatment, suggesting that they do not experience the same type of KOR

activation as do adults. The current study examines whether there are age differences in KOR activation and nicotine-ethanol modulation of KOR activity, particularly in brain regions involved in reward and motivated behavior. Brain tissue from drug naïve adult and adolescent male rats was processed for agonist stimulation of [^{35}S]GTPγS binding, with or without nicotine and ethanol, to determine KOR activity. Preliminary data suggest that adolescents may be more sensitive to KOR stimulation than adults. Further, agonist-stimulated activity of KORs may be blunted by nicotine and ethanol in the nucleus accumbens and caudate putamen of both adults and adolescents. These results provide age- and region-specific understanding of kappa opioid receptor activation and the influence of combinations of nicotine and alcohol on KOR activity.

Res. Unit, Worldwide Res. and Develop., Pfizer, Cambridge, MA; [5]Discovery Safety and Metabolism, AstraZeneca, Cambridge, United Kingdom

Abstract: Dysregulation of the brain-reward system has been associated with numerous psychiatric and neurological disorders and co-morbidity exists between mood disorders and addiction. Exposure to stress is associated with drug addiction in humans and can induce relapse and craving. Similarly, a variety of stressful stimuli can reinstate drug-seeking in animal models. Converging evidence have demonstrated that the kappa-opioid receptor (KOR) pathway plays a critical role in regulating dopamine release in areas of the brain highly associated with reward-related learning and are implicated in reward, stress and mechanisms underlying stimulus-controlled drug-seeking behavior. The objective of these studies was to investigate the dynorphin-KOR system and its involvement in stress-induced drug relapse using the novel selective KOR-antagonist, PF-04455242, and the prototype KOR-antagonist LY-2456302 in a

reinstatement model of drug-seeking. Male Sprague-Dawley rats were initially trained to self-administer nicotine or fentanyl, I.V., under a fixed ratio schedule of reinforcement using a standard 2-lever choice design, with infusion-paired cues. Following acquisition, an extinction period commenced to dissociate the act of lever pressing from delivery of the drug. Reinstatement tests were then conducted using a within-subjects design, with reinstatement induced by the pharmacological stressor, yohimbine administered alone and in combination with drug-paired (nicotine or fentanyl) cues. For reinstatement tests, animals were treated with PF-04455242 or LY-2456302, S.C., prior to each session. Congruent with the literature implicating KORs with the rewarding/reinforcing effects of drugs, and specifically the association between relapse to drugs of abuse and exposure to stress-inducing stimuli, the present findings suggest KOR-antagonists attenuate reinstatement of drug-seeking in rats and this effect appears specific to seeking induced by stress. The effect of these antagonists in blocking reinstatement of drug-seeking behavior was compared to their affinity to bind to, and occupy, the KOR. Taken together, these observations support the potential benefit of KOR-antagonism in relapse prevention.

Abstract: Several psychiatric symptoms such as depression, anxiety, hyperactivity and cognitive impairment appears a result of chronic stress and model PTSD symptoms. These symptoms are accompanied by hormonal changes, such as excessive activation hypothalamus pituitary- adrenal axis and the deregulation of several neurotransmitter signaling pathways, such as the sympathetic and serotonergic systems. Chronic or traumatic stress induces pathological changes in several brain regions of the fear network, including medial prefrontal cortex, medial temporal lobe system, the amygdala and hippocampus. Cotinine, considered a positive allosteric modulator of the alpha 7 nicotinic acetylcholine receptor (nAChR), when infused directly into the hippocampus, enhanced fear extinction in rats in a manner dependent on the activity of the nAChRs. Cotinine also stimulated downstream effectors of the alpha 7nAChR including the protein kinase B-Glycogen synthase kinase 3beta pathway and the extracellular signal-regulated kinases. Our hypothesis is that cotinine by these mechanisms can relieve these symptoms as a posttreatment. Thus, the positive effects of cotinine as a post-treatment on anxiety, visual recognition memory, depressive-like behavior that resulted from prolonged restrain stress. Mice were restrained 6 hours/day for 21 days. Treatment started after immobilization and extended for 14 days. Cotinine was administered via gavage (0.5 mg/kg in PBS). The impact of immobilization stress on mice´s behavior was evaluated with battery of behavioral tests (open field, Porsolt´s test, novel object recognition, light-dark box test,and elevated plus maze). Our findings suggest that cotinine can be used as a treatment option to alleviate symptoms derived of chronic stress.

Title: Nicotine induces change in estrus cycle phase

Authors: *L. WENNING[1], R. PHILLIP[2], P. BRODERICK[1];
[1]City Col. of New York, New York, NY; [2]Bronx High Sch. of Sci., Bronx, NY

Abstract: We hypothesized that females are more likely to become affected by nicotine than males as studied by startle response, estrus cycle, NMI, and neurotransmitter studies in our laboratory in female versus male mammals (Broderick and Malave, 2014). In order to address these sex differences in nicotine, estrogen and progesterone levels of 6 female Sprague Dawley

rats were monitored by post-intraperitoneal nicotine injection at the following time intervals: pre-injection, 30 minutes post-injection, and one hour post-injection. Exfoliate cytology of the vaginal mucosa was concurrently sampled at these three interim periods, stained, and analyzed via microscopy. Nicotine was administered daily for 6 days. The number of nucleated epithelial cells, anucleated cornified cells, and leukocytes was estimated to determine estrus cycle phase: proestrus, estrus, metestrus, or diestrus. Animals injected with saline were used as a control. Before the injection, the animals were in various stages of the estrus cycle with no significant differences in the number of animals in each stage. Thirty minutes post-injection, a significantly greater number of non-prescient mammals transitioned into estrus from their original stage rather than transitioning into the subsequent stage of the cycle ($p<0.001$). One hour post-injection, these values remained significant as more animals transitioned into estrus at this time interval ($p<0.001$). Correspondingly, an overwhelming majority of the nucleated epithelial cells became anucleated cornified cells at both 30 minutes and one hour post-injection. Animals injected with saline remained in the same stage throughout administration.
Our results demonstrate that nicotine induces estrus in non-prescient mammals, regardless of cycle phase before nicotine administration. During the estrus stage, both estrogen and progesterone levels were low as confirmed by an increase in nucleated cells on vaginal smear. Since nicotine administration caused this decrease in ovarian hormone levels, a lack of estrogen and progesterone could be paramount to elucidating the sexual dimorphism of addiction.

Title: Oxytocin flattens social order and enhances behavioral reciprocity via anterior cingulate cortex

Authors: *Y. JIANG, M. L. PLATT;
Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: The neuropeptide oxytocin (OT) is known to influence social functions in a wide array of mammals. In humans and non-human primates demonstrating complex social behaviors, OT delivered intranasally enhances trust, relaxes social vigilance, and promotes prosocial behavior.

The precise neural mechanisms underlying these effects, however, remain unclear. Here we show that treating one male macaque monkey with intranasal OT relaxed his social interaction with another male. OT treatment simultaneously suppressed the threatening behavior of dominant males and increased the boldness of submissive males, effectively flattening the pre-existing social hierarchy. Additionally, OT also enhanced the effectiveness of social communication by increasing the behavioral synchrony between the pair. Notably, OT altered the behavior of not only the treated monkey but also his non-treated partner, consistent with the idea of enhanced feedback through reciprocal social interactions. These effects were largely recapitulated when OT was injected focally into the anterior cingulate gyrus (ACCg), a brain area previously linked to empathy, self-control, and other-regarding behavior. ACCg lacks post-synaptic OT receptors, but is rich in post-synaptic vasopressin (AVP) receptors, indicating that exogenous OT shapes social behavior, in part, via nonspecific binding. These findings bear potentially important implications for the use of OT in both basic research and as a therapy for social impairments in autism, schizophrenia, and other disorders.

Title: A rodent model of negative urgency predicts acquisition of amphetamine self-administration

Authors: *V. WEISS[1], M. T. BARDO[2];
[2]Psychology, [1]Univ. of Kentucky, Lexington, KY

Abstract: Negative urgency is a facet of impulsivity that can be defined as engaging in a maladaptive impulsive behavior following a negative emotional event. In humans, negative urgency predicts problematic substance use. Our laboratory has developed a rodent model of negative urgency that is a modified version of the reward omission task published by Gipson et al., 2011. The task consists of two alternating components (one Pavlovian and one operant), each component being 10 sec and 2 min long, respectively. During the Pavlovian component, a light

predicts the delivery of a food reward, whereas during the operant component, rats are required to respond for food reward on a differential reinforcement of low rate 5 sec (DRL-5) schedule. After stable performance on the task is achieved, food reward is omitted in the Pavlovian component on rare occasions and the change in responding during the subsequent operant component is measured. “Negative urgency” is defined by an increase in responding during the operant sessions immediately following omission trials compared to reward trials, which is maladaptive because impulsive responding on the DRL reduces the number of reinforcers earned. The current study investigated whether individual differences in performance on this reward omission task would predict acquisition, maintenance, and/or escalation of amphetamine (AMPH) self-administration (SA). Adult male rats were trained to SA AMPH during 1 hr daily sessions. Experiment 1 started with a 0.3 mg/kg training dose, which was then decreased 0.03 mg/kg. Experiments 2 and 3 used 0.03 mg/kg during all SA sessions; Experiment 2 examined acquisition and maintenance only, whereas Experiment 3 included extended access (6 hr) sessions to determine if individual differences in reward omission performance predicted escalation of drug intake. Results revealed that impulsive rats acquired AMPH SA more rapidly than low impulsive rats at both doses. However, there were no significant differences during maintenance or escalation. Thus, individuals showing high impulsivity in the reward omission task were more sensitive to the initial reinforcing effect of AMPH. However, after reaching stable rates of AMPH SA, these individual differences did not predict escalated use. To the extent that the reward omission task used here models negative urgency in humans, these results suggest that preventive interventions that target mood-based rash action (negative urgency) as a risk factor would be most effective during the early phase of the addiction cycle.

Title: Voluntary alcohol consumption can impair reversal learning in rats in a go/no-go task that allows for multiple responses/trial

Authors: L. AURAND, M. RAY, H. FISHER, C. HARMON, *C. L. PICKENS;
Kansas State Univ., Manhattan, KS

Abstract: There is mixed evidence for an effect of alcohol exposure to impair reversal learning. In addition, previous research from our lab has shown that voluntary alcohol access may not

have an effect on reversal learning. In the current experiment, we determined whether chronic intermittent access to ethanol would cause impairments in go/no-go reversal learning in male rats if the task was made more difficult by giving more extensive discrimination training and lengthening the S- trials to make withholding responding more difficult. Rats were given 4 sessions of discrimination training with 2 levers to the right or left of the chamber. Each lever was available in alternating order with presses on one lever reinforced with food pellets ("active lever") and presses on the other lever never reinforced ("inactive lever"). Each lever-light was available for 50-sec regardless of whether lever presses were made, and presses on the active lever could earn up to 2 food pellets/trial. The rats then received 6 weeks of chronic intermittent access to 20% ethanol (24-h access, 3 times/week with water always available), or 6 weeks of access to water alone. In addition, half of each group was also given 9.1 ml/kg injections of saline at the end of each alcohol access period to determine whether injection stress would interact with alcohol to affect learning. The groups given access to alcohol with or without saline injections drank an average of ~10 g/kg/24-h of the alcohol across the 6-week alcohol access with no difference in the average drinking in the injection and no injection groups. The rats then received one discrimination reminder session 3 days after the final day of ethanol access, and then received 2 days with the lever-light contingencies switched and the previously non-reinforced lever-light compound reinforced and the previously reinforced lever-light compound non-reinforced. We found that the groups given alcohol access exhibited impaired reversal learning, specifically due to a delay in learning to press the newly reinforced lever. We found no evidence that injection stress had any effect on behavior in either the water or alcohol group. Our future research will examine the behavioral factors and neurobiological changes that occur to make our task sensitive to alcohol access.

Title: Foxp2 disruption during development but not adulthood causes deficits in model-based decision-making

Authors: *C. A. FRENCH[1], T. AKAM[1,2], M. CORREIA[1], S. E. FISHER[3,4], R. M. COSTA[1]; [1]Champalimaud Neurosci. Programme, Champalimaud Ctr. for the Unknown, Lisboa, Portugal; [2]Dept. of Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom; [3]Language and Genet. Dept., Max Planck Inst. for Psycholinguistics, Nijmegen, Netherlands; [4]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ., Nijmegen, Netherlands

Abstract: Disruptions of the *FOXP2* gene cause a rare neurodevelopmental speech and language disorder. In the KE family a heterozygous *FOXP2* mutation is dominantly inherited and affected individuals have difficulty producing the sequences of orofacial movements necessary for fluent speech. This core deficit is accompanied by other expressive and receptive language problems. Humans and other animals use multiple strategies to learn instrumental actions, which may extend to vocal communication. Model-based control learns the specific consequences of actions and evaluates choices through a process akin to search in a decision tree, while model-free control learns direct mappings from states to actions through reward prediction errors. These systems are rooted in cortico basal-ganglia circuits, where Foxp2 is expressed both during development and in adulthood. Imaging studies of the KE family have also shown changes in striatal grey-matter density as well as altered striatal activation during language-based tasks. Here we investigate whether Foxp2 modulates the balance between model-based and model-free control, which has been proposed to be disrupted in other neurodevelopmental and psychiatric disorders, including autism and obsessive compulsive disorder. A novel 'two-step' decision-making task was used to assess the learning strategies employed by mice with Foxp2 disruptions. Mice chose between two actions which led probabilistically to one of two second-step states. In each state a further action offered a possibility of reward. Both reward and state transition probabilities changed over time in blocks. We investigated developmental Foxp2 functions using the *Foxp2-S321X* line, which carries a premature stop codon and is effectively a knockout. Heterozygous *Foxp2-S321X* animals showed a reduction in both the fraction of correct choices at the end of blocks and the speed with which they adapted to reversals. Furthermore, a reinforcement learning model showed that model-based action values had a reduced influenced on the choice of *Foxp2-S321X/+* animals relative to controls and that *Foxp2-S321X/+* mice had lower learning rates in the model-based component. *Foxp2* floxed mice were crossed with a tamoxifen-inducible Cre line to disrupt *Foxp2* in adulthood. This resulted in the death of around one third of Foxp2 knockdown animals. However, surviving animals were healthy and did not show impaired performance on the two-step task. Together these data indicate that developmental Foxp2 expression is required to establish the circuits required for model-based learning.

Title: Neural basis of ovipositional preference in fruit fly, *Drosophila melanogaster*

Authors: *L. MUSKETT[1], D. SITARAMAN[2];
[2]Dept. of Psychological Sci., [1]Univ. of San Diego, San Diego, CA

Abstract: The long-term goal of our project involves finding evolutionarily conserved neurotransmitter systems and circuits that underlie decision-making processes. Decision-making is a complex behavior that depends on organism's environment, internal state (e.g. hunger, sleep etc.) and motivation.Layers of cognitive and emotional processes make it difficult to narrow down what factors cause organisms to make the decisions that they do. In order to find true cause and effect relationships, it's necessary to study simple organisms that have simple decision-making behaviors and fewer neurons. To this end, we chose Drosophila melanogaster, fruit fly, a widely used genetic model organism because of its experimental manipulability, ease of rearing, short life cycle and ability to make simple decisions in light of competing choices.Of the many decision-making processes, we chose to study egg-laying preference of the female fly. The decision to lay eggs in specific locations depends on texture, temperature, humidity and nutrient value of the substrates to ensure the success of the progeny. For example, female flies show a strong preference for food containing ethanol. The fly integrates multiple sensory stimuli (vision, smell, touch and taste) and lays eggs in highly specialized locations but it is unclear how internal behavioral states like hunger and sleep affect this decision. We have developed a novel assay design to test the oviposition preference and will present data showing a role for conserved neurotransmitters like dopamine, serotonin and octopamine in this behavioral assay.

Title: Identification of an amygdala-cortical circuit for cue-directed action.

Authors: *N. T. LICHTENBERG, V. Y. GREENFIELD, Z. T. PENNINGTON, K. M. WASSUM;
UCLA, Los Angeles, CA

Abstract: Environmental reward-predictive stimuli have the ability to trigger the recall of precise memories of their predicted reward and in doing so motivate action and guide choice. This process requires the basolateral amygdala (BLA), but little is known about how the amygdala contributes to this function within the broader circuit. The BLA shares dense and reciprocal excitatory connections with several cortical areas, including the orbitofrontal cortex (OFC), which is itself implicated in cue-directed choice. Here we examined the function of the BLA-OFC circuit in cue-directed action using the outcome-specific Pavlovian-instrumental transfer (PIT) task. Pharmacological disconnection of the two structures by contralateral transient inactivation impaired the ability of reward-predictive cues to, in a choice test, selectively invigorate the performance of actions that earned the same unique expected reward (i.e., to express outcome-specific PIT). Direction-specific manipulations of monosynaptic projections clarified this effect. Designer receptor-mediated transient inactivation of projections from the BLA to the OFC similarly disrupted the expression of outcome-specific PIT, while inactivation of OFC projections to the BLA were without effect. These data suggest that bottom-up signaling from the BLA to OFC is vital for the cued recall of precise reward memories and the use of this information to motivate specific action plans.

Title: Glutamate released into the basolateral amygdala tracks reward value encoding and the use of this information to guide reward seeking

Authors: *M. MALVAEZ[1], H. G. MONBOUQUETTE, 90095[2], K. M. WASSUM[1]; [1]Psychology, [2]Chem. Engin., UCLA, Los Angeles, CA

Abstract: Reward-seeking decisions are heavily controlled by the value of the specific reward they attain. This value is acquired and updated through the incentive learning process that occurs when the reward is experienced in a relevant motivational state (e.g., experience with a specific food in a novel hungry state). The basolateral amygdala (BLA) participates in this learning process, but precisely how is unknown. Because the BLA is densely innervated by both cortical and thalamic glutamatergic projections, we hypothesized that glutamate released into the BLA would track changes in reward value important for value-guided reward seeking. To test this, we used electroenzymatic biosensors to make near-real time measurements of BLA glutamate concentration changes during an incentive learning experience and during a subsequent reward-seeking test. First, rats were trained mildly-food deprived to lever press for a food reward. When rats were then allowed to experience the food reward hungry for the first time, we detected transient elevations in BLA glutamate concentration that tracked the incentive learning process. Interestingly, we also detected transient glutamate elevations immediately preceding bouts of reward-seeking activity following incentive learning, but only in those rats who had been given the opportunity to learn the food reward's higher value when hungry. These data suggest that transient BLA glutamate release tracks the reward evaluation process and use of this value information for guiding reward-seeking decisions. Ongoing experiments are evaluating the source of these signals to provide information on how the BLA functions within a broader circuit to coordinate reward-seeking actions.

Title: Frontalstriatal BDNF overflow and cognitive control deficits following spontaneous nicotine withdrawal

Authors: *R. COLE, M. ZIMMERMAN, M. G. KUTLU, A. MATCHANOVA, T. J. GOULD, V. PARIKH;
Psychology and Neurosci., Temple Univ., Philadelphia, PA

Abstract: Nicotine addiction continues to be a leading cause of preventable death worldwide. Despite the plethora of available treatments for smoking cessation, smoking relapse after attempts to quit remains high. Loss of cognitive control may be the linchpin in the inability to maintain long-term nicotine sobriety. The present study was designed to examine the effects of nicotine withdrawal on cognitive control processes in mice using an operant strategy set-shifting task that required the animals to switch from a spatial response-driven strategy to a visual cue-based strategy to achieve rewards. Because the integrity of frontostriatal circuits is critical for executive processes, and brain-derived neurotrophic factor (BDNF) exert modulatory effects on cognitive processes and is known to play an important role in drug addiction, we also assessed the effects of nicotine withdrawal on BDNF expression in the prefrontal cortex (PFC) and striatum. Male adult C57BL/6J mice were either exposed to chronic nicotine (6.3 mg/kg/d or 18mg/kg/d) or saline using subcutaneous mini-osmotic pumps for 14 days. During the treatment duration, the animals remained on the spatial lever discrimination phase of the task. Spontaneous nicotine withdrawal was induced by removing the pumps and the animals were tested on the strategy set-shifting phase until criterion is attained. Following behavioral testing, brains were extracted for q-PCR and immunoblot analysis of BDNF mRNA and protein expression. Mice undergoing nicotine withdrawal required more trials to attain strategy switching criterion as compared to the controls. Error analysis show that animals withdrawn from both nicotine doses committed higher perseverative errors. However, animals treated with the higher nicotine dose also displayed more strategy maintenance errors. We also uncovered that both total BDNF and transcript IV BDNF mRNA expression increased in the PFC following nicotine withdrawal. Surprisingly, the levels of the mature form of BDNF protein declined in the PFC but were elevated in the striatal synaptosomes of these animals indicating that perhaps nicotine withdrawal altered the trafficking of BDNF between the PFC and striatal brain regions. Taken together, our data illustrate that loss of cognitive control during nicotine withdrawal occurs in a dose-

dependent fashion and that robust impairments in strategy switching noted in mice chronically exposed with a higher nicotine dose resulted from a generalized behavioral disinhibition. Further studies are required to determine whether nicotine withdrawal-related deficits in executive functions are causally linked to frontostriatal BDNF overflow.

Title: A sex-specific role for glutamate trafficking in reversal learning

Authors: *M. M. WICKENS, J. D. LENZ, R. D. COLE, V. PARIKH, L. A. BRIAND; Psychology, Temple Univ., Philadelphia, PA

Abstract: Cognitive deficits are a core feature of many psychiatric disorders such as schizophrenia, ADHD, Alzheimer's disease, autism, depression, and substance use disorder. Accumulating evidence point to glutamatergic dysfunction in these disorders. Much of the preclinical work in this area has focused on the role of NMDA receptors. However, the contribution of AMPA receptors in relation to cognitive deficits associated with these disorders has not been systematically studied. Therefore, the current studies aimed to examine the role of AMPA receptor trafficking in two measures of cognitive flexibility: strategy shifting and reversal learning. Further, as many of these psychiatric disorders exhibit a sex bias in prevalence, we examined both male and female mice to determine how sex might interact with glutamate trafficking to influence cognitive flexibility. To do this we utilized a transgenic mouse with a point mutation preventing PKC-dependent phosphorylation of GluA2 subunits. As this phosphorylation event leads to activity-dependent internalization of AMPA receptors containing the GluA2 subunit, this mouse model exhibits blunted AMPA receptor trafficking. In the first study, mice performed an operant analog of the Wisconsin Card Sorting Test in which they underwent a strategy shift followed by a reversal. Although no differences were seen in strategy shift performance, we found that disrupting AMPA trafficking led to enhanced reversal learning

in female mice but not male mice. Next, we examined whether these effects would be more prominent in a pure reversal task without a prior strategy shift. In contrast to our findings in the first study, we found that in the absence of the strategy shift, disrupting AMPA trafficking led to a reversal deficit in male mice without affecting female mice. Additional studies are underway to further parse apart these sex differences. Taken together, these results suggest that sex influences the role of glutamate receptor trafficking on reversal learning. The results of these studies could inform future clinical studies on glutamatergic modulators in treating psychiatric diseases and how gender might influence the treatment outcome of these disorders.

Title: Adult neurogenesis regulates delay-based decision-making

Authors: *J. S. SNYDER, R. Q. YU, D. ESPINUEVA, O. PRINCZ-LEBEL, E. CHAHLEY, S. B. FLORESCO, D. R. SEIB;
Dept. of Psychology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Neural progenitors in the hippocampus generate new neurons throughout life. In several neurological disorders the production of new neurons is interrupted, for example in depression. Behavioral traits that are altered in depression include assigning less value to future outcomes, decreased motivation to obtain rewards and increased sensitivity towards negative feedback. Previous studies have investigated the effects of reduced neurogenesis on mood but the exact nature of these disturbances is unknown. To address this we have used a novel transgenic rat (GFAP-TK) in which neurogenesis can be specifically inhibited in adulthood, and operant decision-making tests of behaviors that are commonly disrupted in depression. We first tested rats on a delay-based decision-making task, where they must choose between a low reward lever that delivers 1 sugar pellet immediately and a high reward lever that delivers 4 pellets after a

delay. Compared to intact wild types (WT), GFAP-TK rats showed a decreased preference for the high reward option with increasing delay times, indicating that adult neurogenesis increases the subjective value of future rewards.
Second, we employed a probabilistic reversal learning task where rats have to show optimal behavior in the face of an uncertain reward. Here, correct (80% rewarded) and incorrect (20% rewarded) levers switch after 8 correct consecutive trials, and the number of reversals indicates behavioral flexibility. WT and GFAP-TK rats achieved a similar number of reversals. Moreover, win-stay and lose-shift behavior was also similar, indicating that neurogenesis does not regulate reward feedback sensitivity or negative feedback sensitivity, respectively. Third, we are performing an effort-based decision-making task where the number of lever presses required to receive the high reward option increases across blocks. Since depression is often associated with reduced energy and motivation, we may expect that neurogenesis-deficient GFAP-TK rats are less willing to choose the large reward option when additional work is required. This project combines a novel rat model with complex behavioral tasks to study the role of new neurons in decision-making behaviors that are disrupted in depression. Ongoing experiments will investigate the cellular mechanisms by which new neurons promote valuation of future rewards. Identifying these mechanisms may be helpful for developing treatments for depression and other disorders characterized by impulsivity and devaluation of future rewards, such as schizophrenia, Alzheimer's disease and addiction.

Title: Discriminative signaling of outcomes using stimuli attributed with incentive value promotes suboptimal risky choice

Authors: *A. P. SMITH, T. R. ZENTALL, J. S. BECKMANN;
Psychology, Univ. of Kentucky Dept. of Psychology, Lexington, KY

Abstract: Animal models of gambling often use risky choice tasks between probabilistic and certain alternatives where, following a response to an uncertain stimulus, the reward either occurs or is absent. With this procedure, animals generally choose adaptively to maximize reinforcement and do not tend to incur losses of reinforcement as human gamblers often do.

However, recent research has found that when discriminative conditioned stimuli (CS) attributed with incentive salience signal the outcomes (wins vs. losses), suboptimal increases in risk taking occur and have implications for other choice behavior. The present experiments tested the effects of using discriminative vs. uncertain cues in the widely used probability discounting procedure. Rats and pigeons chose between two initial link stimuli. Choice of the uncertain large (UL) alternative initially always led to a CS followed by 4 pellets of food while choice of the certain small (CS) alternative always led to a different CS and then 1 pellet. After an established preference for the UL, the UL became probabilistic across within-session blocks delivering reward only 50% of the time, then 25%, 12.5%, and 6.25%. The rate at which an individual decreases choice of the UL (or discounts its value) is the primary measure of risk taking. Importantly, for animals in the discriminative condition, choice of the UL only produced the CS when reward was to be delivered. In the nondiscriminative condition, a CS always appeared but was only sometimes followed by food making it an uncertain cue similar to traditionally used procedures. Relative to the nondiscriminative condition, the discriminative groups showed markedly reduced discounting indicative of increased risk taking. Reversing the conditions with pigeons showed the risk tendencies of individuals also reversed indicating the experimental conditions exerted strong control over individuals' level of risk taking. Additionally, increasing the ratio requirement to the UL initial link for pigeons from 1 to 2, 4, 8, 16, and 32 across blocks showed those in the discriminative condition still preferred the UL relative to the nondiscriminative group. For rats, subcutaneous administration of selective D1 and D2 dopaminergic agonists and antagonists revealed generally increased risk aversion in the nondiscriminative condition similar to previous reports but had little to no effect on the discriminative condition. Thus, the present experiments show a behavioral mechanism across species that promotes risk taking via predictive stimuli with incentive value outcompeting primary reinforcement and dissociates dopaminergic signaling between the two conditions in risky choice.

Title: Structural and functional connectivity associated with weight loss and omega-3 fatty acid supplementation in women at high-risk for breast cancer

Authors: *L. MARTIN[1], R. J. LEPPING[1], W. M. BROOKS[1], C. R. SAVAGE[3], I.-Y. CHOI[1], P. LEE[1], B. C. MCPHERSON[4,1], V. B. PAPA[1], M. G. BRUCKS[1], A. T. FOX[1], J. L. NYDEGGER[2], B. F. KIMLER[2], C. J. FABIAN[2];

Abstract: Post-menopausal obesity is associated with increased risk of developing breast cancer Weight loss has been shown to reduce this risk by reducing inflammation. Omega-3 fatty acids have been shown to reduce inflammation and are involved in cognitive factors such as attention, learning and memory. Little is known about the association between the role of omega-3 fatty acids to enhance weight loss and the related effects on brain function. The current study examined brain function related to weight loss among individuals enrolled in a randomized clinical trial examining the effects of omega-3 fatty acid supplementation on weight loss (6-months), weight loss maintenance (12-months) and breast cancer risk factors.
Twenty-five post-menopausal obese women who were participating in the parent weight loss study enrolled in the optional magnetic resonance imaging (MRI) study. Following a 6-month weight loss intervention participants completed an MRI session including structural MRI, diffusion tensor imaging (DTI), magnetic resonance spectroscopy (MRS), resting state MRI (rsMRI) and task-based functional MRI (fMRI) examining brain activation to food images. Thus far, analyses have examined correlations between 6-month changes in body mass index (BMI) and brain structure and function indexed by DTI, rsMRI, and fMRI. Analyses are still underway for brain volume and MRS, as well as differences associated with omega-3 fatty acid supplementation.
Preliminary analyses show a negative correlation between BMI change and DTI fractional anisotropy in the right uncinate fasciculus and a positive correlation between BMI change and functional connectivity (rsMRI) between the dorsolateral prefrontal and somatosensory cortices. No significant correlations were found between changes in BMI and brain activation to food compared to non-food images. Additional analyses will be forthcoming to examine whether brain structural and functional connectivity are enhanced with omega-3 fatty acid.
Overall, preliminary results indicate that 6-month weight loss is associated with structural and functional connectivity with ventrolateral prefrontal and limbic regions associated with reward and dorsolateral prefrontal regions associated with cognitive control.

Title: Functional MRI of macaque monkeys during task switching

Authors: *E. PREMEREUR[1], P. JANSSEN[1], W. VANDUFFEL[1,2,3];
[1]KU Leuven, Leuven, Belgium; [2]Harvard Med. Sch., Boston, MA; [3]Athinoula A. Martinos Ctr. for Biomed. Imaging, Boston, MA

Abstract: The ability to switch from one task to another is central to intelligent behavior, as it allows an organism to cope efficiently with the demands of swiftly changing environments. Human functional magnetic resonance imaging (fMRI) studies have indicated the importance of prefrontal (PFC) and anterior cingulate cortex (ACC) during task switching (Liston et al., 2006; Woodward et al., 2006; Wylie et al., 2004). In addition, lesion and inactivation studies in monkeys have demonstrated impairments in task switching following both PFC (Dias et al., 1996) and ACC (Rushworth et al., 2003; Shima and Tanji, 1998) lesions. Except for set-shifting (Nakahara et al., 2002) and visual search experiments (Wardak et al., 2010), no task switching paradigms, particularly those requiring shifts in operant behavior, have been used during fMRI in monkeys. In our study, macaque monkeys (N=2) were trained to switch between saccades and arm movements. After a brief period of fixation, a blue or green target appeared. A separate go-cue (brightening of a spot) instructed the monkey to make either a saccade to the green target, or to move the arm ipsilateral to the blue target (Premereur et al., 2015). Furthermore, we used a fixation task in which the monkeys had to fixate centrally while a grey distractor appeared at the same position as the target. We performed a contrast-agent enhanced fMRI experiment (3T, 1.25 mm isotropic voxels, 2s TR). Each run contained all tasks, randomly presented in 40s blocks.

Switch trials were defined as the first trial of a block requiring another operant behavior compared to the previous block. Note that only correctly performed switch trials were included. Stay trials were defined as a correct trial (immediately following another correct trial), randomly chosen from the same blocks from which the switch trials were selected. Data were collected in 102 runs for monkey R (903 switch and stay trials, each) and 111 runs for monkey U (632 trials). We compared the activation for Switch vs Stay trials (conjunction analysis for both animals; $p<0.001$, uncorrected for multiple comparisons), and found increased activation mainly in ACC (anterior area 24), prefrontal areas 45A/B and 46v, orbitofrontal area 12, some extrastriate visual areas and ventral striatum, and to a lesser extent in parietal area LIP. Since macaque monkeys display similar performance during task switching paradigms compared to humans (Caselli and Chelazzi, 2011), they can be used as a valuable model for the investigation of this complex behavior. Our results pave the way for detailed electrophysiological and causal investigations of the cortical and subcortical network instrumental in task switching.

Title: Cortico-hippocampal contribution to the generation of contextual information

Authors: *S. BERNARDI[1,3], J. MUNUERA[2], M. RIGOTTI[4], S. FUSI[2], D. SALZMAN[2,2,3]; [1]Psychiatry, [2]Neurosci., Columbia Univ., New York, NY; [3]Psychiatry, New York State Psychiatric Inst., New York, NY; [4]IBM T.J. Watson Res. Ctr., Yorktown Heights, NY

Abstract: Identical stimuli often produce different outcomes (and thereby different emotional responses) depending upon the context in which they are encountered. One mechanism the brain

employs to infer chances of reward or punishment and to regulate emotional responses is to abstract 'cognitive contextual structures'. These contexts can be described as the set of circumstances that help us derive situationally informed meaning from the world. Previous studies have established the importance of the prefrontal cortex (PFC) in rule-guided behavior, and recent studies have shown that the amygdala, a brain structure long thought of as a key mediator of emotion, along with the PFC, also represents abstract contextual information. In particular, Saez et al. (2015) showed that the amygdala, ACC and OFC all represent abstract contexts defined by task sets; a task set is the set of CS-US contingencies in effect within a block of trials. The formation of a neural representation of task set may be created if neural signals providing a memory of a previous trial converge with neural signals representing the current trial. Thus neural signals providing information about the previous trial may be conceptualized as a providing a vital input to the formation of a representation of task set. We sought to determine whether the hippocampus (HPC) or dorsolateral prefrontal cortex (DLPFC) might provide this input by encoding the episodic memory of the previous trial. Alternatively, HPC and DLPFC might explicitly already represent task sets. We have been obtaining simultaneous electrophysiological recording from neurons in the HPC, the ACC and the DLPFC while two rhesus monkeys utilize knowledge of task sets to select an action that maximizes reward rate upon viewing an image. Using a linear decoder, we have observed that all task-relevant variables, including stimulus identity, context, planned operant action, and expected reinforcement may be decoded in each area. However, context could in principle be decoded if neural signals merely reflect a memory trace of the previous trial, since each trial type appears in only one context. We are therefore determining whether the decoding of context derives from signals that represent memory traces, a function long associated with the HPC. Alternatively, neural representations in these areas could reflect the linked trials within a task set. Assuming that neural representations of context truly reflect task sets, and not merely memory traces, a critical question concerns the extent to which these representations are created in a parallel or serial manner across brain structures that include HPC, DLPFC, ACC, OFC, and the amygdala.

Title: Population dynamics of excitatory and inhibitory neurons in mouse parietal cortex during decision-making

Authors: ***F. NAJAFI**[1], G. F. ELSAYED[2], E. A. PNEVMATIKAKIS[3], J. P. CUNNINGHAM[4], A. K. CHURCHLAND[1];
[1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Neurosci., Columbia Univ. Med. Ctr., New York, NY; [3]Simons Ctr. for Data Analysis, Simons Fndn., New York, NY; [4]Statistics, Columbia Univ., New York, NY

Abstract: Decisions are shaped by the interaction of current sensory inputs, past choices, past outcomes, and the internal state of the animal. Decision bias due to choice history and animal's internal state helps explain behavioral flexibility during the same sensory inputs. In this work we tested the hypothesis that previous choices drive a transient change in network dynamics that interacts with present evidence and biases the animal's choice in a time-dependent manner. We used two-photon calcium imaging to study population neural responses in the mouse posterior parietal cortex (PPC) during a decision-making task. To assess whether information about the previous choice and current sensory signals is carried by different subclasses of neurons, we used transgenic mice expressing tdTomato in their inhibitory neurons (GAD2-Cre crossed with Ai14 reporter line). Head-fixed mice mounted on a wheel learned to make judgements about the total rate of a series of clicks and flashes relative to an experimenter-defined category boundary. Mice reported their choices by licking to a left or right waterspout. To record neural activity, mice were injected with AAV9-Synapsin-GCaMP6f in their parietal cortex. Imaging was performed over the course of training. In each session, approximately 500 neurons were simultaneously recorded, while mice performed ~300 trials. Analysis of the behavioral data demonstrates that: 1) mice can learn the decision-making task and their performance depends on the stimulus strength (i.e., the difference between the presented rate and the learned category boundary); 2) mice have bias to repeat their previous rewarded choice; 3) this bias is time-dependent and transient. Preliminary analysis of neural population responses suggests that: 1) PPC population activity carries information about the current stimulus and the previous choice; 2) the influence of choice history on PPC population activity is time-dependent: it diminishes as the inter-trial interval increases; 3) excitatory and inhibitory neurons reflect decision and bias parameters in different

ways. Our findings demonstrate that choice history transiently modifies ongoing PPC dynamics; the modification of population activity changes the representation of incoming sensory stimuli, hence the animal's decision. Additionally, our results begin to shed light on how different neural subclasses contribute to the representation of internal and external signals during decision-making.

Title: Complementary contributions of high-dimensional representation and noise correlation to cognitive processes

Authors: ***M.-R. ABOLGHASEMI-DEHAQANI**[1], A.-H. VAHABIE[1], B. NOUDOOST[2], A. SOLTANI[3];
[1]Sch. of Cognitive Sci., Inst. For Res. In Fundamental Sci., Tehran, Iran, Islamic Republic of; [2]Dept. of Cell Biol. and Neurosci., Montana State Univ., Bozeman, MT; [3]Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Recent work in neural decoding has highlighted the importance of high-dimensional neural representations in cognitive functions. Independently, investigations into interactions between neurons have pinpointed reductions in the noise correlations between neurons as a mechanism for enhancing sensory and motor processes. However, the interactions or relative contributions of high-dimensional representations and changes in noise correlations have yet to be explored within a single population dataset. To explore the role of these coding properties during a cognitive task, we examined neural activity in populations of simultaneously recorded Frontal Eye Field (FEF) neurons in monkeys trained to perform a memory-guided saccade task. In this task, the monkeys were trained to saccade to the remembered location of a visual target, which appeared in 1 of 16 possible locations (2 eccentricities and 8 angles). Importantly, this

simple task requires multiple cognitive operations, including encoding of the location of a visual target (stimulus encoding), maintenance of this information over time (working memory), and finally generating a saccadic eye movement to the remembered location (saccadic preparation). We applied a combination of decoding and encoding methods to the simultaneously recorded neural data. We found that the information content of the neural response increased between sensory encoding and saccade preparation, but differently for the single-cell and population responses. Specifically, we found that population of FEF neurons greatly enhance their ability to encode locations far beyond their original response field, but only during saccade preparation only when population activity is taken into account. In other words, the information content of the population response has expanded across space during saccade preparation. We showed that this expansion relies on a high-dimensional neural representation. Finally, we found that a reduction in the noise correlation can further increase the information content of the population; however, this contribution can be detected only when the change in signal correlation is accounted for since the latter is much larger and affects both the single-cell and population responses. Overall, our results provide new insights into which properties of neural population codes are most relevant for encoding information and different cognitive processes.

Title: Neurophysiological mechanisms for representing abstract components of mental states

Authors: ***J. MUNUERA**[1], M. RIGOTTI[3], S. FUSI[1], C. D. SALZMAN[1,2,4];
[1]Neurosci., [2]Psychiatry, Columbia Univ., New York, NY; [3]IBM T.J. Watson Res. Ctr., Yorktown Heights, NY; [4]Psychiatry, NYPSI, New York, NY

Abstract: Contingencies between stimuli, actions, and reinforcement outcomes often differ dependent upon the situation. Serial reversal-learning is a behavioural task that can be used to explore the mechanisms underlying such context-dependent adjustments in action selection and reinforcement anticipation. In serial reversal-learning, two or more stimuli reverse their contingencies multiple times within an experimental session. Upon a reversal, agents may update independently their understanding of contingencies of each stimulus-response-outcome association, or they may learn to grasp that within a block of trials, the set of associations for all stimuli defines a task set. Knowledge of task sets allow a computationally more efficient strategy of exploiting knowledge that the association of one stimulus has changed to infer that contingencies have also switched for the other stimuli within a task set (i.e. by applying inference, a strategy recently demonstrated to be invoked by monkeys, see Saez et al., 2015). This strategy requires the formation and utilization of neural representations of task sets. We investigated the mechanisms that can underlie the formation of representations of task sets. In each of two contexts, rhesus monkeys learned to associate each of 4 images (conditioned stimuli, CSs) to an operant action (hold or release a button) and an unconditioned stimulus (US - either a drop of juice or its absence). Each context was thereby defined by the set of operant and reinforcement contingencies for the CSs, i.e. the task set. Within each context, we manipulated the temporal statistics of events such that particular trial types tended to occur in temporal proximity to each other, creating two sub-contexts. Switches between sub-contexts did not change contingencies so learning about sub-contexts could not be driven by error signals. Instead, learning about sub-contexts relied on the formation of a link between the current trial and the previous trial, a link that could be formed through a Hebbian mechanism if different interconnected neurons represent the current and most recent trial, respectively. We recorded single neuron activity in the amygdala, OFC, and ACC to determine if neural signals merely reflect a memory trace of previous trials, or if they reflect the formation of neural representations of sub-context and context. In all 3 brain areas, the neural representations reflected the linked sets of trials that form sub-contexts and contexts by virtue of the temporal statistics of events. This could underlie a process of abstraction that creates novel, abstract mental states reflecting task sets, a process vital for flexible cognitive behaviour.

Title: Prefrontal cortico-thalamic networks for cognitive control

Authors: *J. M. PHILLIPS[1], N. A. KAMBI[1], L. FISH[2], Y. B. SAALMANN[1];
[1]Psychology, [2]Univ. of Wisconsin-Madison, Madison, WI

Abstract: Cognitive control, our ability to flexibly adapt behavior according to goals, context and rules, is known to depend on the prefrontal cortex (PFC). The PFC is densely and reciprocally interconnected with the mediodorsal nucleus of the thalamus (MD). Although the anatomical connectivity suggests that MD may play an important role in cognitive control, this possibility remains relatively unexplored. We hypothesize that MD supports cognitive control through its ability to regulate information transmission across PFC areas. To test our hypothesis, we use diffusion MRI to map MD-PFC anatomical connectivity in macaque monkeys, which guides subsequent multi-site recordings from interconnected MD and PFC network sites in the same animals. We performed high-resolution (1.0 mm isotropic) diffusion-weighted imaging on 6 anesthetized macaque monkeys using the GE MR750 3T scanner with a 16-channel receive-only head coil (MRI Instruments). 60 diffusion directions (b=1000 s/mm^2 and NEX=14) and 112 b=0 images were acquired. FSL was used for EPI distortion, eddy current and motion correction, prior to Bayesian estimation of diffusion parameters and probabilistic tractography. Our tractography results were broadly consistent with anatomical tracer studies. Specifically, lateral PFC areas predominantly connected with lateral, likely parvocellular, MD; medial PFC connected with caudodorsal MD; and orbitofrontal cortex connected with medial, likely magnocellular, MD. However, our results further suggest a guiding principle: directly connected PFC areas are also indirectly connected via MD. This connectivity pattern is similar to that observed between another higher-order thalamic nucleus, the pulvinar, and visual cortical areas. These findings suggest that (1) there is an indirect cortico-thalamo-cortical pathway between directly connected PFC regions, a key requirement for our hypothesized role of MD in regulating information transmission between PFC areas, and (2) this may be a more generalized anatomical scheme underlying higher-order thalamo-cortical interactions. The connectivity maps for each animal allow precise targeting of MRI-compatible laminar probes to interconnected sites in lateral PFC areas 46 and 9/46 as well as their overlapping projection zones in MD, for detailed investigation of MD-PFC network dynamics.

Title: A fine-timescale investigation of ventral tegmental area neuronal signalling in working memory

Authors: *V. GLYKOS, S. FUJISAWA;
RIKEN Brain Sci. Inst., Saitama, Japan

Abstract: The midbrain ventral tegmental area (VTA) is a major source of dopamine (DA) in the mammalian brain. Midbrain VTA neurons receive multiple afferent inputs to encode signals that regulate and guide behaviour via diverse efferent projections. Despite abundant classical conditioning studies demonstrating the correlative link between VTA subpopulations with reward processing, attention and aversive conditioning, little is known about the midbrain neuronal signaling in goal-directed behaviour such as working memory (WM). Recent evidence revealed a gradual increase in striatal DA levels and prefrontal cortical-VTA coordinated activity while rodents performed a WM task. However, the fine-timescale activity of VTA neurons during WM remains unknown. We performed *in vivo* electrophysiological recordings of VTA neurons while mice (n=4) performed a visual-cued version of a WM behavioural task on a Tmaze apparatus. We found that VTA neurons adjust their firing pattern to a prolonged firing state, instead of the transient phasic one, in situations where information about previously encountered stimuli is required to be held on-line, and manipulated in order to guide behaviour. Accordingly, the greatest proportion of VTA neurons (76% of 219 units) exhibited a pronounced elevated activity in the final parts of the trial (i.e. WM, reward delivery and consumption). Moreover, during the WM-component, 15% of the single units significantly differentiated their firing activity, consistent with the animal's future choices (i.e. choice-predicting units). These results suggest that VTA neurons code future action as well as reward expectation errors during WM.

Title: Information coding by large scale neural ensembles from the macaque prefrontal cortex

Authors: *R. BARTOLO, R. C. SAUNDERS, P. G. BROWNING, A. R. MITZ, B. B. AVERBECK;
NIMH/NIH, Bethesda, MD

Abstract: Information processing in the brain is performed by large populations of neurons working in parallel. However, characterizing information in large populations has been difficult because it has not been possible to record large numbers or neurons (>> 10s) simultaneously from awake, behaving animals. However, multi-electrode recording techniques are making it possible to perform large scale recordings. In the present study, we recorded single and multiunit activity using 8 microelectrode arrays (96 channels per array) implanted bilaterally in the prefrontal cortex (PFC) of macaque monkeys (Macaca mulatta). In a given recording session, we were able to isolate hundreds of neurons (>500) during the execution of an oculomotor saccade task, and maintain the isolations for a large number of trials (~1500 trials). In the task the animal had to make a saccade to a target presented to the left or right of a fixation point. We were interested in estimating information scaling with population size, as many theoretical models have suggested that information saturates in large neuronal populations. Therefore we selected multiple random subsets of neurons at a range of population sizes within a recording session (25-500) and estimated information in each subset. Spike counts (0-500ms after target presentation) and saccade direction from 90% of the trials (randomized) were used to train a generalized linear model regularized with early stopping. From the remaining 10% of trials, half were used determine when to stop the training and the remaining trials were used for estimating decoding performance. We further projected population activity on the linear decision boundary, and used the distribution of projected data to estimate d-prime. We found that decoding accuracy rapidly increased as a function of the sample size, and was nearly perfect for samples with more than 150 neurons. On the other hand, d-prime continued to increase with ensemble size. We have also compared information coding in the original data with information coding in data in which the correlations between neurons were destroyed by shuffling trials between neurons, within condition. For ensembles greater than about 200 neurons, information was larger in the shuffled ensembles than it was in the original ensembles. Additional analyses will further allow us to characterize these effects.

Title: Fast dopaminergic modulation of prefrontal neuronal circuit activity

Authors: ***K. TAO**, S. FUJISAWA;
RIKEN Brain Sci. Inst., Wako, Saitama, Japan

Abstract: Prefrontal cortex is one of the major projecting target of dopamine neurons in the ventral tegmental area (VTA). These mesoprefrontal dopamine neurons has been considered to modulate prefrontal network activity tonically through volume transmission as well as phasically in a synaptic fashion. However, the effect of phasic firing of dopamine neurons on prefrontal circuit activity in a sub-second time frame remains elusive. Here we show that, in a classical reward conditioning paradigm using head-fixed mice, fast-spiking interneurons (FS INs) in the medial prefrontal cortex (mPFC) respond both to water rewards and reward predicting cues. Both water rewards and optogenetic stimulation of dopaminergic neurons in the VTA elicited firing of FS INs in the mPFC. Conversely, the vast majority of regular-spiking neurons were inhibited by these manipulations. Subcutaneous injection of SCH23390, a dopamine receptor D1 (D1R) antagonist, suppressed firing of FS INs induced by rewards or optogenetic stimulation. Further, we optogenetically identified the activity of dopamine transporter (DAT)-positive neurons in VTA and confirmed that their firing following reward predicting cues preceded the responses of FS INs. These results suggest that mesoprefrontal dopamine firing inhibit overall neuronal activity in the mPFC in a D1R-dependent manner, presumably in concert with glutamatergic inputs from lower order cortices or thalamic nuclei.

Title: Frontal ensemble dynamics signal shifts between distinct modes of sensorimotor behavior

Authors: *M. J. SINISCALCHI[1], V. PHOUMTHIPPHAVONG[2], F. ALI[2], M. LOZANO[2], A. C. KWAN[2,3];
[1]Interdepartmental Neurosci. Program, Yale Univ., New Haven, CT; [2]Psychiatry, [3]Neurobio., Yale Univ. Sch. of Med., New Haven, CT

Abstract: The ability to shift between repetitive and goal-directed actions is a hallmark of cognitive control. Previous studies have reported that adaptive shifts in behavior are accompanied by changes of neural activity in frontal cortex. However, neural and behavioral adaptations can occur at multiple time scales, and their relationship remains poorly defined. Here, we developed a novel adaptive sensorimotor decision-making task for head-fixed mice, requiring them to shift flexibly between multiple auditory-motor mappings. Two-photon calcium imaging of secondary motor cortex (M2) revealed different ensemble activity states for each mapping. Notably, when adapting to a conditional mapping, transitions in ensemble activity were abrupt and occurred before the recovery of behavioral performance. By contrast, gradual and delayed transitions accompanied shifts toward the non-conditional, repetitive mode of action selection. Moreover, muscimol inactivation of M2 selectively disrupted shifts to the conditional mode of behavior. These results demonstrate distinct ensemble signatures associated with the initiation and termination of sound-guided action selection, and suggest that M2 leads in engaging goal-directed response strategies that require sensorimotor associations.

Title: Frontal cortical local field potentials (LFPs) reflect working memory processing over long delays

Authors: *C. D. HOLMES[1,2], C. PAPADIMITRIOU[1], L. H. SNYDER[1,2];
[1]Neurosci., [2]Biomed. Engin., Washington Univ. in St. Louis, Saint Louis, MO

Abstract: Converging evidence shows that the dorsolateral prefrontal cortex (DLPFC) and frontal eye fields (FEF) are critical for working memory. During the memory period of a delayed response task, both DLPFC and FEF neurons code for memorized spatial locations via persistent, spatially-tuned increases in activity. While single-unit activity tells us what information is coded for by cortical networks, it fails to inform us of network-wide processing and interactions between neurons. LFPs are understood to reflect synchronized synaptic activity of local neuron populations and may offer a window into network-level processing.
We recorded LFPs in DLPFC and FEF of macaques performing a long-duration (5-15 s) memory-guided saccade task. During fixation periods, LFP power was generally inversely proportional to the frequency squared, except for a marked positive deviation in the beta-band (20-35 Hz). During target presentation, beta-band power decreased while both low-frequency (2-10 Hz) and gamma-band power (40-110 Hz) increased relative to the fixation period. All three bands had greater power for contralateral compared to ipsilateral targets. During the memory period, low-frequency power returned to fixation period levels and had no sustained tuning for target laterality. Beta-band power increased above fixation period power ~1 s after the target disappeared, then gradually decreased below fixation period power throughout the remainder of the period. Gamma-band power dropped to fixation period level immediately after the target period, then gradually decreased below throughout memory. In both DLPFC and FEF, both beta- and gamma-band power remained tuned for target position during memory. Beta-band tuning was strong for both areas while gamma-band tuning was only strong in DLPFC.
Greater power for contralateral versus ipsilateral targets is consistent with increased power arising from synchronized network activity and synchronized network activity forming a substrate for spatial memory. However, the fact that memory period power decreases below the fixation period power suggests something more complex is occurring. One possibility is that some circuits synchronize during fixation. During memory, networks globally desynchronize, dropping power below that seen during fixation. However, some circuits remain synchronized,

thereby maintaining memory. Additionally, while neurons seem to code for memories similarly between DLPFC and FEF, the areas had different spectral profiles. Thus, network-level processing between these areas may differ. These results are a step toward better understanding how memory networks process spatial information.

Title: How is neural activity in premotor and parietal cortex influenced by bottom-up and top-down information about the value of reach choices?

Authors: *A. NAKAHASHI, P. CISEK;
Dept. Neurosciences, Univ. De Montreal, Montreal, QC, Canada

Abstract: Many studies have shown that neural activity in sensorimotor regions not only represents the action plans to be executed, but also reflects the outcome values of the potential actions, indicated by a specific feature of the stimulus (e.g. color or shape). In our study, outcome value was simultaneously indicated by two types of visual features, one “bottom-up” and the other “top-down”, to investigate how different kinds of information influence value-dependent modulation of activity in sensorimotor regions. A monkey was trained in a center-out reach decision task, in which each trial is initiated after the monkey fixates and moves a cursor into the center circle. After some delay, two reach targets appear at the right and left of center. Each target’s value is indicated by two independent visual features: bottom-up (BU) cues based on luminance, and top-down (TD) cues based on a learned mapping of a line orientation. Each cue has three levels of desirability scores, and the total of the two scores determines the number of rewards given upon a successful reach to that target. After a GO signal, the monkey indicates his choice by moving the cursor to the target of his choice, receiving the corresponding number

of rewards. The monkey was trained to maintain eye fixation until he reaches a target. We are recording from dorsal premotor cortex (PMd) and area 5 of posterior parietal cortex (PPC), which have previously been shown to exhibit value-related neural modulation. Data to date show that 1) both regions contain cells whose firing rate increases within 200ms from target-onset, 2) when the decision is made based on BU information (targets differ in BU but not in TD cues), directionally-tuned cells show divergence in the firing rate that reflects the monkey's choice, which occurs earlier than when the decision is made based on TD information (targets differ in TD but not in BU cues). Additional analyses examine value-dependent modulation when only a single target is presented, and during trials in which the values of both targets are equal, but the BU and TD cues are in conflict.

Title: Neural constraints on the cognitive capacity of crows

Authors: *J. M. ROSE[1], D. BALAKHONOV[2];
[1]Univ. of Tuebingen, Tuebingen, Germany; [2]Univ. of Tuebingen, Tübingen, Germany

Abstract: The remarkable cognitive abilities of birds, especially crows and parrots, have recently attracted growing scientific interest. Mounting evidence demonstrates that these birds surpass many mammals, for instance they are capable of tool use, episodic memory, theory of mind and executive control. A core component of cognition is working memory, the ability to flexibly memorize and manipulate information over short periods of time. This neural system shows a tight limit regarding how much information can be handled simultaneously. This 'capacity' of working memory is often seen as a unit for general cognitive capacity and is a close correlate of individual fluid intelligence in humans. The present study aimed to determine working memory capacity of carrion crows. Two crows were trained on a working memory paradigm that allowed to model capacity as a function of load on working memory (a change localization task). The paradigm was adapted for crows from an experiment in monkeys in order to directly compare the working memory capacity of both species. Through the use of head-tracking we were able to test capacity for both visual hemifields independently. On all used

stimulus-sets (2, 3, 4 and 5 items), both crows performed the paradigm well above chance. As predicted, performance decreased as a function of the number of items the animals head to memorize. Overall, the performance of the crows was comparable to that of monkeys. The same holds for different estimates of capacity, including an information theoretical approach. Both species show a largely independent capacity between the two visual hemifields, such that the driving factor in performance is the number of items memorized in one visual hemifield. These results demonstrate that crows and monkeys have similar working memory capacity and possibly comparable neural strategies for working memory. In tune with the literature, or results indicate the high cognitive capacity of crows.

Title: Functional characterization of specific interneuron subtypes in the prefrontal cortex for memory-guided behavior.

Authors: ***T. KAMIGAKI**, Y. DAN;
Univ. of California, Berkeley, Berkeley, CA

Abstract: Prefrontal cortex (PFC) plays a pivotal role in maintaining the task-relevant information in short-term memory for regulating the upcoming motor responses. However, the circuit mechanisms underlying memory-guided behavior remain poorly understood. In the present study, we imaged calcium signals from the dorsomedial PFC (dmPFC) of mice performing a delayed Go/No-Go task. Each trial consisted of sample, delay, and test periods. During the sample period a target or non-target stimulus was presented, followed by the delay period during which water was inaccessible. The test period began when the water port was presented; licking in Go trials was rewarded (Hit), and licking in No-Go trials was punished (False Alarm). We found that the dmPFC showed robust activity during the delay period and different subpopulations of pyramidal neurons signaled Go and No-Go action plans. Optogenetic

manipulation of different subtypes of GABAergic interneurons in the dmPFC, even transiently during the early part of the delay period, caused dissociable effects on task performance. Moreover, cell type specific calcium imaging revealed the distinct nature of task-related activity in different interneuron subtypes. Our results suggest that the dmPFC is a crucial component of short-term memory network and different interneuron subtypes make distinct contributions to memory-guided behavior.

Title: Distinct roles of orbitofrontal cortex in response execution and inhibition during a stop-signal task

Authors: ***J. YOSHIDA**, A. SAIKI, S. SOMA, K. YAMANAKA, S. NONOMURA, A. A. R. DAVILA, M. KAWABATA, M. KIMURA, Y. SAKAI, Y. ISOMURA;
Tamagawa Univ., Tokyo, Japan

Abstract: Humans and animals can optimize their behavioral response adaptively by response inhibition; e.g., delaying the start of response (proactive inhibition). In a standard stop-signal task, which is often used to evaluate the response inhibition, subjects have to respond to a GO cue as quickly as possible (GO trials), but have to stop the response if a STOP cue follows the GO cue (STOP trials). The proactive inhibition will delay the GO response depending on previous experience of STOP trials. Previous studies suggest that the orbitofrontal cortex plays a critical role in the response inhibition. However, little is known about actual neural correlates with the proactive inhibition at a single neuron level in the orbitofrontal cortex. To examine the orbitofrontal neural correlates with proactive inhibition, we established a novel stop-signal task (called as Cancel-Signal task) which is suitable for precise measurements of task performance and multi-neuronal activity in head-fixed rats. In the Cancel-Signal task, rats responded to a GO cue more slowly after STOP trials than GO trials. This result means rats made proactive inhibition on a trial-by-trial basis in the Cancel-Signal task. In multi-neuronal recording during their task performance, we found some of the orbitofrontal cortex neurons showed functional spike activities in relation to task events such as the GO response and its preparation. These

activities were changed dynamically between after STOP trials and after GO trials, which suggests that the orbitofrontal cortex could encode the distinct information for response execution and inhibition.

Title: Thallium, a chemical warfare neurotoxic agent, is removed by metallothionein and prussian blue, without a redistribution to brain effect in rats

Authors: ***L. N. ANAYA RAMOS**[1], A. MONROY[1], S. GRACIA[2], S. GALVAN[3], A. DÍAZ[3], S. MONTES[3], C. RÍOS[3];
[1]Univ. Autonoma Del Estado De Morelos, Cuernavaca, Mexico; [2]Univerisidad Autónoma del Estado de Morelos, Cuernavaca, Mexico; [3]Dept. de Neuroquímica, Inst. Nacional de Neurología y Neurocirugía, Ciudad de México, Mexico

Abstract: Thallium (Tl) is a neurotoxic heavy metal, included in the EPA listing of main pollutants. The metal provoked cases of accidental and intentional poisoning in human beings. It is increasingly used in industry, pointing to concern about exposure risk in animals and humans. Tl salts are absorbed by virtually all routes and show a heterogeneous distribution in all organs and tissues. Few days after intoxication the patients develop gastrointestinal and cardiac symptoms and nervous system dysfunction. The use of chelating agents as antidotes is controversial, since Tl may be redistributed from depot organs to brain, its target organ. Prussian blue (PB) has an efficiency of 70% and is the antidote of choice according to FDA. Metallothioneins I and II (MT) are endogenous metal-binding proteins with antioxidant and chelating properties. They have been proposed as neuroprotective molecules in brain diseases, and in the protection from heavy metal toxicity. The present study was designed to determine the effect of exogenously administered MT on acute thallotoxicosis. Male Wistar rats were

intoxicated with a single subletal dose of thallium acetate (16 mg/kg) and randomly allocated into 4 experimental groups: control group (C), Prussian Blue group (PB) 50mg/kg dose, metallothionein II group (MT) 100 μg and metallothionein in combination with Prussian Blue (MT+PB) group. All treatments began 24 h after thallium intoxication and were maintained for four days. Animals were killed 24 h after the last administration of antidotes to determine Tl contents in 6 organs and 6 brain regions. In all cases, $p<0.05$ was considered of statistical significance. Both PB alone or in combination with MT diminished significantly (70%) the Tl concentration in all organs and brain regions as compared to control group, treated only with Tl. The administration of MT alone showed non-significant thallium elimination in organs and brain regions compared to control group except in the kidney (60%). In addition, the combination MT+PB showed a significantly diminished Tl concentration (14%) superior than the reduction produced by PB alone. Results indicate that MT alone or in combination is able to reduce kidney Tl, without a redistribution to brain effect.

Title: Synaptic mechanisms of memory consolidation during NREM sleep

Authors: *Y. WEI, G. PRASHANTH, M. BAZHENOV;
Dept. of Med., Univ. of California San Diego, San Diego, CA

Abstract: Memory traces acquired during wakefulness and initially stored in the hippocampus are progressively transferred to the neocortex during non-rapid eye movement (NREM) sleep. Replay during sleep of temporally ordered spike sequences in cortical neurons related to memory events was proposed to be a neuronal substrate of memory consolidation. However, specific mechanisms behind memory consolidation during NREM sleep, especially stage 2 sleep, are still poorly understood. In this new study we tested how sleep spindles, one of the

electrophysiological hallmark feature of stage 2 sleep, affect the dynamics of synaptic weights in thalamocortical network. Further, we examined how the synaptic weights acquired during stage 2 sleep influence the slow oscillations during following stage 3/4 sleep. Our computational model of the thalamacortical network with spike-timing dependent synaptic plasticity (STDP) included changes in the level of the neuromodulators (reduction of acetylcholine and histamine; increase of GABA) that resulted in transition from stage 2 to stage 3/4 sleep. Spindle oscillations consisted of 7-14 Hz brief bursts of rhythmic waves that last 0.5-3 seconds, while slow oscillations (<1 Hz) were characterized by repetitive Up and Down states in all cortical neurons. Following our recent study (Wei et al., J Neurosci, 2016), we included stimulation to a small group of cortical pyramidal cells to mimic hippocampal input (sharp wave - ripple events). We found, that during stage 2 sleep, synaptic weight changes were local and asymmetrical around the stimulation sites. Such changes in synaptic weights led to the organized spatiotemporal pattern of Up state propagation during following slow oscillation, even in the absence of stimulation. This organized spatiotemporal pattern resulted in the changes of synaptic weights that extended to the entire network. When we modified synaptic connections before stage 2 activity to model memories acquired during wakefulness, we found that spindles increased these selected synaptic weights locally, resulting in a high probability of specific spike sequence replay during the following slow oscillation. Our study provides evidence that sleep spindles and sleep slow oscillation influence synaptic changes in a different way. The spatial extent of synaptic changes due to spindles was much smaller than that due to slow oscillation. Surprisingly, sleep spindles, preceding slow oscillation, had protective effect on the local synaptic changes, which would be otherwise diminished by the global synaptic dynamics during sleep slow oscillation alone.

Title: Slow-wave sleep improves learning through spike sequence replay

Authors: ***G. P. KRISHNAN**[1], M. KOMOROV[1], S. SKORHEIM[2], M. BAZHENOV[1];
[1]Univ. of California San Diego, LA Jolla, CA; [2]HRL Labs., Malibu, CA

Abstract: Sleep improves performance in cognitive tasks involving long-term memories. Such tasks often relay on learning sequences such as, e.g. finger tapping task, motor adaptation task or serial reaction time task. Replay during sleep of spike sequences associated with a previously learned task is thought to be the mechanism for synaptic reorganization underlying memory consolidation. In this new study, we used computational models to explore how replay during sleep may lead to increase in performance. We used thalamocortical network models with conductance based neurons and state dependent neuromodulators (acetylcholine, histamine and GABA) to generate sleep and waking states. STDP and homeostatic plasticity were implemented, allowing synapses to change both in awake and sleep states. To simulate sequence learning, the model was presented with multiple trials of sequential input to a group of selected cortical neurons. Performance of this task was measured by the success of the sequence completion - the percentage of a correct complete sequence recall when only the first input was presented. During initial training phase, ordered firing of neurons led to synaptic reorganization; we observed an increase in performance at the end of the training (50 sec). Two identical models were then compared. In the first model, neuromodulators were altered (reduction of acetylcholine and histamine) resulting in slow wave sleep (SWS) like activity (for 100 sec). The second (control) model remained in the awake state for the same time duration. No training was performed at that time in either of two models. Following this consolidation phase, the level of neuromodulators was changed again in the first model to bring it back to awake state. Performance of the sequence completion was then measured in both models. We found a significant increase in performance (around 20%) in the model that experienced SWS state. To reveal the neuronal mechanisms, we analyzed spike sequences of the cortical neurons during SWS state of the model and found that the learned sequences were reactivated spontaneously during the Up states of the slow waves. Synaptic weights between neurons increased in the direction corresponding to the sequence replay while reduced in the opposite direction leading to synaptic reorganization that facilitated completion of the sequence learned during initial training phase. We concluded that our model capture the critical neuronal processes involved in memory enhancement following sleep, as it has been reported in animal and human studies. It predicts that spontaneous reactivation of the learned sequences during SWS represent a key mechanism of memory consolidation.

Title: Discrete-time approach to large-scale simulations of realistic brain networks.

Authors: ***N. RULKOV**[1], M. KOMAROV[1], G. P. KRISHNAN[1], I. TIMOFEEV[2], S. CHAUVETTE[2], M. BAZHENOV[1];
[1]UCSD, La Jolla, CA; [2]Laval Univ., Quebec City, QC, Canada

Abstract: Large-scale modeling of a realistic brain network is a computationally expensive task that have to deal with multiple time scales of the neuronal dynamics. In order to simulate large-scale networks with the order of millions of neurons, different types of the reduced neuron models have been proposed but they commonly lack the ability to reproduce specific patterns of the neuronal activity. In this study, we focused on the development of discrete-time (or map-based) neuron models that are computationally efficient and designed to implement dynamics of different slow and fast intrinsic currents similar to conductance based neurons. Map-models use difference equations capturing dynamics of a neuron in discrete moments of time with relatively large intervals (~0.5 msec) that significantly reduces the overall computation time. In the past, we reported application of such models to simulate awake-like activity including cortical gamma oscillations (Bazhenov, et al., J Neurophys, 2008). Here, we discuss application of the new class of models to generating sleep slow oscillation (SO). SOs are characterized by periodic transitions between active (or Up) and silent (or Down) states in the membrane voltage of cortical and thalamic neurons. Experimental and modeling studies suggest: (i) Up-states are initiated due to progressive accumulation of spontaneous miniature EPSPs and maintained by recurrent excitatory connections and intrinsic depolarizing currents (such as persistent Na+ current), (ii) Up-states are terminated by progressive activation of the intrinsic inhibitory currents (such as Ca^{2+} dependent K^+ current), synaptic depression and synaptic inhibition. The novel map-based approach to cortical cell design allowed us to model the critical mechanisms for SO generation and closely match the activity observed in experiments and in the conductance-based models. The model included 4 discrete time variables capturing (a) the fast spike generation dynamics, (b) the slow dynamics of persistent Na^+ and Ca^{2+} dependent K^+ currents, (c) K^+ leak current allowing for modeling effects of neuromodulation. As reported in vivo, a network of map-based pyramidal cells and inhibitory interneurons revealed propagating waves of the Up state initiation and highly synchronous Up state termination. High computational efficiency of the new models makes it feasible for numerous simulations of the large-scale networks for the different connectivity configurations and parameters of intrinsic neuronal activity. Overall, our study demonstrates computational efficiency and validity of discrete-time approach in large-scale simulations of cortical networks.

Title: Modeling of coordinated sequence replay in ca3 and ca1 during sharp wave-ripples

Authors: *P. MALERBA[1], A. L. FODDER[2], M. W. JONES[2], M. BAZHENOV[1];
[1]Med., UC San Diego, San Diego, CA; [2]Sch. of Physiology, Pharmacol. & Neurosci., Univ. of Bristol, Bristol, United Kingdom

Abstract: During slow-wave sleep (SWS), the cortex is decoupled from external inputs, and can be devoted to consolidating previously acquired labile memories into stable memories. Reactivation of specific neural activity patterns - replay - during SWS has been observed in the hippocampus and neocortex and is believed to represent a neuronal substrate of memory consolidation. Hippocampal replay - in which ordered sequences of pyramidal cell firing recruited during behavior are reactivated during sleep - happens during sharp wave - ripple (SWR) events (150-200 Hz, lasting 60-100 ms), and is thought to be crucial for memory consolidation. Indeed, suppressing ripples disrupts memory formation and consolidation. Despite the importance of replay within the broader phenomenon of sleep-mediated memory consolidation, the neural mechanisms underlying hippocampal sequence replay are still unknown.
In this work, we build on our previous research to develop a model of hippocampal spike sequence replay during sleep. We represented CA3 and CA1 activity with a network model of synaptically coupled pyramidal and basket cells. Noise-induced activation of CA3 pyramidal cells triggered a cascade of spiking (the SW), with size controlled by the spread of recurrence in the network. SW activity resulted in strong excitatory input to area CA1, inducing a ripple. SWR occurred stochastically in the model, and their location and size were controlled by the convergence between pyramidal cells connections within CA3. Different SWRs involved distinct populations of CA1 neurons and, ultimately, led to distinct sequences of pyramidal cell spiking. In our model, a pattern of CA3-CA1 synaptic projections - Schaffer Collaterals - induced coordination between neuronal firing sites in CA1 and CA3, so that localized sharp-wave CA3 events produce consistently localized CA1 ripples. This model was then applied to study spontaneous reactivation of subsets of CA1 and CA3 pyramidal cells. We looked for the triplets showing ordered reactivation in CA1 across multiple ripples, and found that the presence of NMDA receptors at CA1-CA3 projections was critical to obtain above chance likelihood of encountering successful (“memorized”) triplets. The model predictions were tested in

simultaneous recordings of LFP and place cell activity from CA3 and CA1 in rats, including analysis of correlations between local field potential across different channels as a function of time. Our study predicted the role of CA1-CA3 interaction for hippocampal sequence replay and revealed specific role of NMDA receptors at Schaffer Collaterals in coordinating reactivation between the two regions.

Title: Precise timing of sharp wave - ripple complexes affects spatio-temporal pattern of sleep slow oscillations in a model of memory consolidation.

Authors: *P. SANDA, P. MALERBA, G. KRISHNAN, M. BAZHENOV;
Dept. of Med., UCSD, San Diego, CA

Abstract: Memory consolidation during sleep is known to depend on strength and coordination of sleep rhythms. During slow-wave sleep, cortical activity is organized in slow oscillations, in which the neuronal population switches rhythmically (< 1 Hz) between active (Up) and hyperpolarized (Down) states. Within this slow and widespread rhythm, slower oscillations are nested by other sleep rhythms - notably by sleep spindles and hippocampus sharp wave - ripples (SWRs). The interaction among different sleep rhythms enables an exchange of information between hippocampus and neocortex, and it is believed to form the neural substrate of sleep-dependent memory consolidation. The mechanisms involved in coordination of these rhythms are not fully known, and so is how the rhythm interaction can mediate memory consolidation. To address these questions, we build a computational model of thalamo-cortical-hippocampal network generating SWRs in the hippocampal CA1-CA3 network and slow oscillations in the thalamocortical system. We found that cortical network regulated the global time relationship between the SWRs and the slow waves. As reported in vivo, majority of SWRs occurred in the model near the onset of the Up states of slow oscillation. Impact of SWRs on the spatio-temporal pattern of slow waves depended on the slow oscillation phase at which SWR occurred. The SWRs arriving at the very end of an Up state or the later phase of a Down state allowed a global

change in the spatiotemporal pattern of the next Down-Up transition. Importantly, SWRs occurring in tight proximity of Down-Up state transition were capable of triggering multiple local cortical Up state initiation sites, therefore promoting ordered spiking of the cortical neurons. We then used a reduced version of our model implementing specifically crafted connectivity map between hippocampal and cortical networks. We found that a memory trace in the hippocampus, represented by a subset of cells orderly firing within a SWR event, can affect the initiation sites and the spatio-temporal pattern of the cortical Up state. We concluded that while cortical slow waves control SWR timing, SWRs can affect precise pattern of activity and the order of cell firing during Up states of slow oscillation. Our study predicts how hippocampal SWRs, presumably reflecting memory traces stored in the hippocampal network, initiate specific sequences of cortical cell firing, thus manifesting spike sequences replay during sleep.

Title: Effect of learning cues on sleep-related memory consolidation depends on the phase of sleep slow oscillation

Authors: Y. WEI, G. PRASHANTH, *M. V. BAZHENOV;
Dept. of Med., Univ. of California San Diego, San Diego, CA

Abstract: During awake, new information is initially encoded in both hippocampus and neocortex, while during the following sleep, especially slow-wave sleep (SWS), the newly acquired memory traces are spontaneously reactivated, leading to consolidation of synaptic changes in the neocortex. A technique, called targeted memory reactivation (TMR), provides novel perspectives that auditory or olfactory cues can benefit memory reactivation during sleep. Recent empirical studies revealed that auditory cues or stimuli preferentially enhance memory consolidation when presented at a specific phase of slow oscillation during SWS. Our recent study revealed that synaptic plasticity promotes replay the spike sequences of the cortical neurons associated with recent learning (Wei, et al., J Neurosci, 2016). In this new study, we aim to understand the mechanisms behind effects of external stimulation (representing learning-related cues) on memory consolidation using a computational model of the thalamocortical

network displaying sleep slow oscillation (< 1 Hz) like activity. Synaptic weights between pyramidal cells in the cortex were regulated by spike-time dependent plasticity (STDP). We used a closed loop stimulation (lasting 100ms) of thalamic or cortical neurons at different phases of slow oscillations, similar to the experimental setup. We found that when an external stimulation was presented during the Down state (90^0-270^0) of slow oscillation, the Up state was likely to initiate around the stimulation site and it propagated towards other network sites. This was also the optimal phase of stimulation to maximize synaptic changes. The spatiotemporal pattern of slow oscillation became organized due to the external stimulation, which then determined the changes of synaptic weights between neurons. The synaptic connections in the direction of slow wave propagation were enhanced and in the opposite direction were decreased. In contrast, when the stimuli were presented during the Up state (270^0-90^0) of slow oscillations, the effect of stimulation on synaptic weights became significantly reduced. Initiation of Up states occurred independently on the stimulation site and the spike sequences were replayed less frequently. Our modeling findings are in agreement with recent experimental data that revealed that the learning-related cues would preferentially strengthen associated memories when they are delivered at the Down phase of slow oscillation. Our study proposes a possible mechanism for such phase dependence of the stimulation effects and provides insight into how the memory consolidation may be affected by sensory cues applied during sleep slow oscillation.

Title: Effects of surface electrical stimulation on the cortical neurons

Authors: ***M. KOMAROV**[1], P. MALERBA[2], P. NUNEZ[3], E. HALGREN[2], M. BAZHENOV[2]; [1]Univ. of California San Diego, LA Jolla, CA; [2]Med., Univ. of California San Diego, La Jolla, CA; [3]Tulane Univ., New Orleans, LA

Abstract: Recent development of novel microelectrode arrays, capable of efficient surface electrical stimulation of the brain, opens novel avenues of interacting with brain neurons. While these new techniques continue and extend past efforts, e.g., deep brain stimulation, our understanding of how electrical stimulation affects specific types of neurons at different

locations within a cortical tissue mass remains limited. In this study we develop a method, combining current density calculations and morphological reconstructions of real cortical neurons, to estimate their activation profile in the cortex. We assumed a surface placement of the electrode grid capable of providing a predetermined current between any grid electrodes (as, e.g., in the ENIAC chip). Our method is based on a commonly accepted idea that electrical microstimulation initiates anti-dromic action potentials in axon initial segments or in nodes of Ranvier (Tehovnik et.al., J Neurophys, 2006). By calculating current density profiles for one or a few stimulation sites, we identified an area where current is strong enough to initiate anti-dromic propagation and activate a cell. Next, we used publicly available databases (Ascoli et al., J Neurosci, 2007) of the morphological reconstructions of neurons to create an "averaged" anatomy for the most frequently observed types of neurons in layers I-V. With this approach we estimated the probability that a cell of a certain type has an axonal segment in the area with above threshold current density. This probability reflects a likelihood of anti-dromic activation and, therefore, predicts the initial effect, which is caused by surface stimulation. We found that excitatory neurons in layers II-IV (pyramidal neurons in LII-LIV and spiny stellate cells in LIV) have a highest probability of activation with maximal likelihood for layer LIV. On the other hand, layer V is divided into two different groups: thin-tufted pyramidal neurons have prominent activation probability, while thick-tufted cells are very unlikely to be directly recruited by stimulation. Among different classes of inhibitory interneurons, tuft-targeting inhibitory cells (Layer I, Martinotti and Bitufted cells) have high probability of activation across all layers, while, soma- and proximal dendrite-targeting basket cells can be activated only in supragranular layers. Hence, a steep difference in basket cells activation across the layers is evident, and shapes the overall activation profile due to superficial electrical stimulation in cortex. Finally, we applied these results to develop a simplified computational model to simulate neuronal activity induced by superficial stimulation.

Title: Pre-activation of neural activity patterns during REM sleep corresponds with rapid learning of a novel motor skill in rats

Authors: *M. J. ECKERT, M. TATSUNO;
Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Neural activity during rest is hypothesized to participate in the consolidation of memory traces. Many studies have demonstrated that neural activity recorded during training on a behavioural task is replayed during subsequent rest and sleep. The majority of this evidence comes from declarative memory tasks and has shown that replay occurs primarily during slow-wave sleep following task training. Pre-play of neural activity prior to a task or experience has also been demonstrated, although support for pre-play in not consistent. Limited evidence also shows that motor skill tasks and brain-machine interface tasks are also reactivated during SWS following training. To date there is little evidence for replay or pre-play during REM sleep, with the exception of one study using a declarative memory task (Louie and Wilson, 2001). This is surprising given that behavioral studies support a role for REM sleep in the consolidation of motor skill learning in particular. Here we provide evidence that pre-activation of neural activity patterns (i.e. prior to task training) occur during REM sleep when there is rapid learning of a motor skill task, but not when learning of the task occurs gradually. We implanted 4 rats with tetrode arrays in the forelimb region of primary motor cortex and recorded single-unit activity during sleep and training on the single pellet reaching task. Daily recordings included a 3 hr pre-task sleep period, 30 minutes of training on the reaching task, and 3 hr of post-task sleep. Rats were naïve to the task at the start of recording (except to test paw preference) and daily recordings continued until they reached asymptotic levels of performance. Two of the rats showed rapid learning on the task, becoming very skilled within 5-6 days. The other two exhibited a slower and more variable gain in proficiency across 2 weeks, although they ultimately achieved similar success rates as the fast learners. Analysis of principal component reactivation of spiking activity (Peyrache et al., 2009) revealed a marked increase in pre-task activation during REM sleep in the 2 fast learning rats, specifically on days when the rapid gain in skill occurred. This increase in pre-task activation was not as evident in post-task REM sleep, nor was it evident in either pre- or post-task SWS. Furthermore, the pre-task REM activation was not present in the slower learning rats, suggesting that it was important for the rapid acquisition of the motor skill. Although our results are preliminary, they provide evidence that activation of neural ensembles during REM sleep facilitates rapid acquisition of a motor skill.

Title: Parvalbumin-expressing interneurons coordinate hippocampal oscillatory dynamics that promote network stability

Authors: *N. OGNJANOVSKI[1], J. WU[3], M. ZOCHOWSKI[2], S. J. ATON[4];
[1]Molecular, Cellular, and Developmental Biol., [2]Dept. of Physics, Univ. of Michigan Aton Lab., Ann Arbor, MI; [3]Applied Physics, [4]Molecular, Cellular, and Developmental Biol., Univ. of Michigan, Ann Arbor, MI

Abstract: Sleep plays a critical role in promoting various forms of memory consolidation, and it is known that activity in hippocampal area CA1 is essential for consolidating episodic memories. Using chronic electrophysiology, we find that in the hours following single-trial contextual fear conditioning (CFC), fast-spiking (FS) interneurons show greater firing coherence with sleep-specific CA1 network oscillations. Post-CFC pharmacogenetic inhibition of parvalbumin-expressing (PV+) FS interneurons blocks fear memory consolidation. This effect is associated with loss of two network changes associated with normal consolidation: 1) augmented sleep-associated delta (0.5-4 Hz), theta (4-12 Hz), and ripple (150-250 Hz) oscillations, and 2) stabilization of CA1 neurons' functional connectivity patterns. We tested whether ed oscillations in FS- interneuron firings leads to long term changes in CA1 network connectivity, by recording CA1 neurons before, during, and after rhythmic optogenetic stimulation of PV+ interneurons. In mice expressing channelrhodopsin 2 in PV+ interneurons (PV:ChR2), stimulation across a range of frequencies (2-18 Hz) led to frequency-specificrhythms in the CA1 LFP and enhanced neuronal spike-field coherence. These effects were strongest for stimulation frequencies of 4-10 Hz. Optogenticall-induced coherent firing also significantly increased the reliability (i.e., stability) of spike-timing relationships between neurons. Intriguingly, stability of network connectivity remained high relative to baseline even after optogenetic stimulation ended. A second set of experiments was carried out to test the long-term effects of PV+ interneuron-induced network coherence. Following a 30 min period of stimulation at 7 Hz, neuronal activity was continually recorded over the next 2 h. Stimulation of PV+ interneurons at 7 Hz significantly increased stability of CA1 network functional connectivity - a change that lasted through the entire post-stimulation period. Moreover, rhythmic stimulation induced a long-lasting change in the strength of connections between neurons, which also lasted for at least 2 h post-stimulation. Taken together, these data suggest that rhythmic coordination of network activity by PV+ interneurons - at frequencies that are significantly augmented following learning - has long-lasting effects on both the stability and strength of network connections.

Title: Hippocampal influence of anterior cingulate activity for memory consolidation

Authors: ***D. V. WANG**, S. IKEMOTO;
NIH, Baltimore, MD

Abstract: Hippocampal-cortical interaction during sleep promotes information transformation for memory storage in the cortex. In particular, hippocampal sharp-wave ripple associated neural activation is important for this transformation process during slow-wave sleep. The anterior cingulate cortex, or ACC, has been shown crucial for storage and expression of long-term memories of previous experiences. However, little is known about how ACC activity is influenced by hippocampal ripple activity during sleep. We report here that the hippocampal ripple activity triggers immediate ACC neural firings. By recording from ACC and hippocampal CA1 simultaneously in mice, we found that while almost all ACC neurons showed increased activity prior to hippocampal ripple activity, a subpopulation (20%) also showed a second greater activation immediately after ripple activity. This post-ripple activation of ACC neurons correlated positively with ripple amplitude. Moreover, the same neurons were activated upon electrical stimulation of the CA1. These results suggest that a small population of pre-activated ACC neurons is selectively influenced by hippocampal ripple activity. This post-ripple activation of ACC neurons during sleep may play a critical role in memory consolidation.

Title: Neurophysiological correlates of the influences of spatial context on hippocampal reactivation in a rodent reconsolidation paradigm

Authors: *S. NAGL[1], B. HARPER[1], P. MALERBA[2], M. BAZHENOV[2], J.-M. FELLOUS[1]; [1]Psychology, Univ. of Arizona Dept. of Psychology, Tucson, AZ; [2]Dept. of Med., UC San Diego, La Jolla, CA

Abstract: Hippocampal place cells reactivate in sharp-wave ripples (SWRs) during rest/sleep periods following a spatial task in rodents. Explained variance (EV) is a macroscopic measure of the extent to which the pattern of pairwise correlations present during a task persists in the reactivation epoch.

We used a 12-hour memory reconsolidation paradigm. The maze consisted of a circular open field with 8 equidistant peripheral feeders. Rats learned to collect rewards from 3 feeders (Set1) in context A. After a 3h consolidation period, animals learned to collect rewards from 3 other feeders (Set2) in the same or a different context. Rats were then prompted to recall Set1 in context A. The task was flanked by 2 epochs of random reward delivery on all 8 feeders ("Random" epochs). We recorded from the right dorsal distal area CA1 of the hippocampus of adult male Brown Norway rats.

We categorized cells with place fields that overlapped with either the Set1 or Set2 trajectories, but not both. We found that the degree to which Set1 cells displayed greater firing contributions within the SWRs of Post-Set2 Rest was significantly correlated with worse performance during Recall of Set1, and that this result was most pronounced in same context condition.

EV analyses indicated that reactivation was consistently more frequent after Random epochs when compared to learning epochs (Set1 or Set2). Reactivation was variable in Post-Set1 and Post-Recall Rests, but the proportion of experiments that showed significant reactivations in both conditions was comparable. In general, cells reactivated less in Post-Set2 Rests. Interestingly, in a subset of the different context experiments, EV analyses revealed there were correlations between the Pre-Set2 learning epochs, which occurred after exposure to the new context, and Set2 learning. These preliminary results suggest that the reactivation of hippocampal cell assemblies may critically depend on the context in which learning occurs, and may occur even if the task does not require explicit learning.

We next compared our results with a computational model of CA3-CA1 SWR generation during

sleep. We considered two subsets of CA1 cells to represent memories of Set1 and Set2, and represented the context by the amount of overlap between the two sets. We also considered the populations of CA3 cells projecting with NMDA connections onto Set1 and Set2 CA1 cells. The model predicts that the degree of overlap between two subsets of CA3 cells controls the degree to which Set1 cells spike in ripples in which Set2 reactivates.

Title: Physiological correlates of forgetting of long-term memory in the hippocampus.

Authors: *D. E. ARKELL[1], S. MARTIN[2], O. HARDT[1];
[1]CCNS, Univ. of Edinburgh, Edinburgh, United Kingdom; [2]Univ. of Dundee, Dundee, United Kingdom

Abstract: Fully consolidated long-term memories can be erased by a constitutive active decay process that involves the synaptic removal of GluA2-containing AMPA receptors (GluA2/AMPARs) (Migues et al, 2016). The precise signaling mechanisms that lead to the decreases in synaptic potentiation via AMPAR-endocytosis have not yet been fully described, but both long-term depression (LTD) and depotentiation (DP) present possible candidate mechanisms. Both lead to a sustained reduction in AMPAR expression at the post-synaptic density (PSD). Many studies have shown that blocking NMDARs promotes long-term potentiation (LTP) and long-term memory persistence, as well as inhibiting LTD, DP and the subsequent removal of synaptic AMPARs (Davis et al, 1992; Villarreal et al, 2002; Kim et al, 2007; Li et al, 2009). This indicates that NMDAR signaling could underpin the activity-dependent removal of GluA2/AMPARs, and thus DP or LTD could promote decay– like forgetting of long-term memories. Here, we thus used *in vivo* electrophysiology, in freely moving rats, to test whether a bilateral DP stimulus to CA3 accelerated decay of previously induced LTP. fEPSPs were bilaterally recorded in the CA1 to assess changes in potentiation. These showed stimulus driven decreases in amplitude, signifying synaptic DP. Using the NMDAR antagonist AP5, and the GluN2B subunit antagonist RO25-6981, we then examined

whether DP was GluN2B-dependent, while GluA2-3Y was used to determine whether DP required synaptic removal of GluA2/AMPARs. Finally we explored whether DP induction could deteriorate consolidated object location memory. In summary, our study describes physiological mechanisms that could be involved in the active decay of long-term memories in the hippocampus.

Title: The role of adult born neurons in memory consolidation during sleep-wake cycles

Authors: *D. KUMAR[1], M. HAYASHI[1], X. HAYASHI[1], G. CHANGARATHIL[1], M. WINTZER[2], T. J. MCHUGH[2], T. SAKURAI[1], M. YANAGISAWA[1], M. SAKAGUCHI[1]; [1]Univ. Tsukuba, WPI-IIIS, Tsukuba-Shi, Japan; [2]RIKEN Brain Sci. Inst., Wako, Japan

Abstract: Mammalian sleep contains rapid eye movement (REM) and non-REM sleep, both could employ different mechanisms for memory consolidation. Previous reports showed that memory-associated odor stimulation during non-REM sleep enhanced memory consolidation[1]. In addition, boosting slow oscillations or inhibiting sharp wave-ripples during non-REM sleep potentiated or interfered with memory consolidation[2,3]. On the other hand, REM sleep deprivation inhibited memory consolidation[4]. However, the memory circuit that is responsible for memory consolidation during each sleep stage has not been clearly shown. We have shown

that hippocampal adult-born neurons are incorporated in memory circuits after learning[5]. Therefore, we silence the activities of the adult-born neurons during specific stages of sleep after learning using optogenetics, which provides reversibility in intervention with higher time resolution and target specificity. The intervention reveals that the activities of the adult-born neurons is necessary for memory consolidation during specific stage of sleep.

Title: The role of adult hippocampal neurogenesis in spatial memory reconsolidation

Authors: *M. LODS[1], G. FERREIRA[2], E. PACARY[1], A. GORON[1], N. D. ABROUS[1], S. TRONEL[1];
[1]Neurocentre Magendie, Bordeaux, France; [2]UMR1286 NutriNeuro, Bordeaux, France

Abstract: Adult neurogenesis refers to the creation of new neurons in the dentate gyrus of the adult hippocampus. A decade of research has established the role of adult neurogenesis in memory formation, in particular in spatial learning. We have recently demonstrated that, in rats, spatial learning in the water maze selects a population of neurons which is around 1 to 2 week-old, increases it survival and dendritic arborisation. However, these neurons do not participate to this particular spatial learning since too immature. Indeed, adult-born neurons participate to memory processes when they are functionally integrated into the hippocampal network (≈ 6 week-old). Our hypothesis is that, when mature, this selected population would be involved in reconsolidation. Indeed, after the learning, memory undergoes a process of consolidation to become stable. But memory can become labile again when reactivated and needs to go trough a process of reconsolidation to become stable again.

We developed a behavioural protocol in the Morris water maze to demonstrate that spatial learning undergoes reconsolidation. We then analyzed the activation of neurons born one week before spatial training, at the time of reactivation. Our results demonstrate that this selected population is activated after memory reconsolidation. In order to investigate a causal relationship between adult neurogenesis and spatial reconsolidation, the team designed a DREADD retrovirus. Injected in the dentate gyrus of rats, this retrovirus allows us to specifically activate or inhibit the learning-selected new neurons during the reconsolidation process in the water maze test. The preliminary datas show that inhibiting, at the time of reactivation, the learning-selected immature population of new-neurons impairs memory retention. Specifically activating this same population enhances memory precision. All together our results show a clear involvement of the hippocampal neurogenesis in spatial memory reconsolidation.

Title: Validation and biological relevance of a real-time ripple detection module for open-ephys

Authors: *C. L. AGUIAR[1], E. F. OLIVEIRA[3], L. R. ZACHARIAS[2], L. B. PERES[2], K. DIBA[5], D. C. SORIANO[4], J. P. LEITE[2];

Abstract: Recent evidence suggests that sharp-wave ripples events (SWR), registering as 140-250 Hz “ripple” oscillations in the local field of electrodes at the CA1 pyramidal hippocampal layer, provide effective windows for the propagation of information out of the hippocampus and affect activity throughout the neocortex. Indeed, during slow wave sleep, cortical neurons fire after SWR, in concert with spindle oscillations in the local field potentials. Despite recent evidence reporting a hippocampal SWR influence on prefrontal cortex unit activity, it remains unknown whether these events are required for systems memory consolidation. Here, we sought to implement and validate a real-time ripple detection module for the Open-Ephys

(http://www.open-ephys.org/) graphical user interface (GUI) to optogenetically modulating specific circuits upon the onset of hippocampal SWR. For this, we have developed in C++ a simplified ripple detection module and added it to the Open-Ephys GUI. Briefly, the module calculates the root mean square of a 2 s sample of local field potential recording and determines its average and standard deviation (STD). The threshold for ripple detection amplitude was defined as the mean + 2*STD. Next, we have integrated our module with Pulse Pal, a module developed to control an open source device that generates precise sequences of voltage pulses (https://sites. google.com/site/pulsepalwiki/home). We first used simulated ripple data to test our algorithm for latency and accuracy (Sethi and Kemere, 2014). The round-trip latency for our simplified ripple detection module is around 35 ms. Changing the size of the Open-Ephys software buffer can reduce the latency, though it also can increase false positive and/or negative rates. The compromise between software buffer size, latency, and accuracy of SWR detection will be further investigated. Besides, ongoing experiments to evaluate the biological relevance of the module combine in vivo large-scale electrophysiological recordings in anesthetized and freely moving rats with optogenetic modulation of cortical circuits. We anticipate the tools we have developed can be useful to directly investigate some memory processes involving coordination between the hippocampus and its downstream circuits. Finally, our module will be further adjusted for online detection of fast-ripples to probe the relationship between temporal lobe epilepsy and memory impairments.

Title: Optical stimulation of the pathway from the basolateral amygdala to the entorhinal cortex in rats impairs retention of cued response learning in a Barnes maze

Authors: *K. L. WAHLSTROM, R. T. LALUMIERE;
Behavioral and Cognitive Neurosci., Dept. of Psychological and Brain Sci., Iowa City, IA

Abstract: Previous work on multiple memory systems suggests that spatial and cued-response learning are mediated by hippocampus-based and caudate-based systems, respectively. Other

work suggests that the basolateral amygdala (BLA) modulates the consolidation for both types of learning, suggesting that BLA outputs to distinct regions mediate this ability. The medial entorhinal cortex (mEC) is a critical region in the hippocampus-based system for processing spatial information and, as an efferent target of the BLA, is the likely mechanism by which the BLA influences spatial learning. The caudate is a critical region for processing visual and cued information for response learning and, as another efferent target of the BLA, is the expected mechanism by which the BLA modulates cued-response learning. Studies, however, have suggested that these two systems compete with one another in the control and consolidation of each type of learning. That is, activation of one system may alter and impair the learning associated with the other system. Therefore, the present study examined whether optically stimulating activity in the BLA◊mEC pathway alters the consolidation of cued-response learning. To address this issue, the BLA of male Sprague-Dawley rats was bilaterally transduced to express ChR2(E123A), and fiber optic probes were implanted in the mEC to provide illumination of BLA axons. A Barnes maze was used to assess cued-response learning. The Barnes maze consisted of an open, circular platform with a series of ports along the periphery, one of which led to an escape chamber. During the training trials, the escape port was marked with a distinct cue directly above it, and the port and cue were moved in unison to a different direction for each trial to prevent the animal from using a spatial strategy to solve the task. On day 1 (training), rats were given 8 training trials on the cued-response learning task, followed immediately by 15 min of optical stimulation of the BLA◊mEC pathway in the theta-frequency range. On day 3, rats were returned to the Barnes maze for a single retention test in which the target port, together with the cue, was located in a random direction. Rats that had received optical stimulation of the pathway had impaired retention, as indicated by longer latencies to find the escape port. These findings indicate that theta-frequency stimulation of BLA◊mEC projections interfered with the consolidation of cued-response learning, consistent with the hypothesis that these two neural systems compete with one another. Ongoing experiments are examining whether stimulation of the BLA◊caudate pathway enhances the consolidation for cued-response learning.

Title: Synaptic connections and electrical coupling within reverberating cell assemblies triggered by chandelier neurons in rodent amygdala

Authors: *M. BHAGAVATHI PERUMAL, R. SULLIVAN, P. STRATTON, P. SAH; Queensland Brain Insititute, Brisbane, Australia

Abstract: Chandelier neurons (ChN) are a special subset of GABA neurons that make synapses at the axon initial segment (AIS) of pyramidal neurons, the key site for generation of action potential. The ChN in the basal amygdala (BA) and cortex have been reported to excite pyramidal neurons that form a disynaptic feedback excitation to the ChN. In modified horizontal brain slice preparations we observed ChNs in the BA evoked a reverberating feedback excitation with high temporal synchrony. The reverberating feedback event followed the disynaptic component with latency approximately 4 ms and frequency 180-250Hz (n=16) and also occurred spontaneously (n=37). Pyramidal neurons received GABAergic inputs during ChN triggered reverberating feedback excitation (n=6) and spontaneous events (n=20). High frequency synchronisation requires strong synaptic connections and electrical coupling. The BA ChNs received strong excitatory inputs from local pyramidal neurons with mean amplitude of 195±101 pA (n=15). Other GABA neurons also received strong glutamatergic inputs with mean amplitude 181±100 pA (n=4). Bath application of gap junction blocker abolished reverberating events (n=4). Reverberating events were observed as sharp wave ripple complex like oscillations in the local field potential (n=6). These findings suggest BA contains reverberating cell assembly like networks that are driven by ChNs. Strong synaptic connections and non-synaptic mechanisms operate in synchrony for generation of sharp wave like network oscillations in BA.

Title: Activation of purinergic P2 receptors in basal forebrain promotes wakefulness by exciting basal forebrain cortically-projecting neurons

Authors: *C. YANG[1], A. KALINCHUK[1], K. A. JACOBSON[2], R. E. STRECKER[1], R. W. MCCARLEY[1], R. BASHEER[1], R. E. BROWN[1];
[1]Psychiatry, VA Boston Healthcare Syst., West Roxbury, MA; [2]NIH/NIDDK, Bethesda, MD

Abstract: Adenosine triphosphate (ATP) serves as the cellular energy source of all organisms and is an important glio- and neuro-transmitter in the brain. While ATP-derived adenosine, acting on inhibitory purinergic P1 receptors, is an important cellular mediator of sleep homeostasis, the role of ATP, acting on purinergic P2 receptors (P2Rs), in the control of sleep and wakefulness is poorly understood. Our data presented here suggests that a P2R agonist applied into the basal forebrain (BF) increases wakefulness in vivo and excites BF putatively cortically-projecting neurons in vitro. We unilaterally infused 1 mM of a non-hydrolysable ATP analog (ATP-gamma-S) into the male mouse BF during the light (sleep) period via reverse microdialysis and found that the percentage of time spent in wakefulness increased from 33.0% to 42.5% ($p=0.0694$, $n=3$). The mean duration of wake episodes increased from 52s to 67s. Non-rapid eye movement (NREM) sleep percentage decreased from 58.2% to 48.5% ($p=0.0122$) and NREM episode duration decreased from 92s to 76s. No change in episode number or REM sleep was observed. These data suggest that activation in BF P2Rs increases wakefulness without causing sleep fragmentation. Using whole-cell recordings from coronal brain slices prepared from GAD67-GFP knock-in mice (male and female), we found that ATP-gamma-S induced large depolarizing responses in GFP-negative cholinergic neurons (20.7±4.2 mV, $n=5$) and two types of large, putative cortically-projecting GABAergic (GFP+) neurons with large or small hyperpolarization-induced inward currents (12.1±1.4 mV, $n=5$; 18.3±2.6 mV, $n=6$ respectively). The input resistance was markedly decreased suggesting an opening of cation-channels during P2R activation. These depolarizing responses were significantly decreased by a P2XR antagonist (30 μM PPADS). Taken together, these data support our hypothesis that activation of BF P2Rs induces wakefulness by exciting BF cortically-projecting neurons and suggest that pharmacological agents acting on P2Rs may be useful for combating drowsiness following short or long-term sleep deprivation.

Title: Temporal backpropagation of basal forebrain neuronal activity during associative learning reveals stepwise expansion of the reward prediction model

Authors: H. MANZUR, K. VLASOV, *S.-C. LIN;
Neural Circuits and Cognition Unit, Lab. of Behavioral Neurosci., Natl. Inst. On Aging (NIA), NIH, Baltimore, MD

Abstract: Understanding how animals learn to predict reward is a central question in neuroscience. However, it has remained difficult to study the early phase of new associative learning to determine what animals have actually learned, and when. Here, by tracking the temporal evolution of a reward prediction error (RPE) signal in the basal forebrain (BF) during learning, we show that animals' internal reward prediction model undergoes stepwise expansion to incorporate new reward predictors. BF RPE signal predicts reward-seeking behavior in single trials throughout learning and temporally backpropagates from the time of reward to the reward-predicting stimulus in discrete steps. A new stimulus that objectively predicts reward is incorporated into the internal model only when BF RPE backpropagates to that stimulus. These results show that stepwise expansion of the reward prediction model through RPE backpropagation is an effective strategy to systematically explore complex decision trees to learn novel associations.

Title: Optogenetic dissection of basal forebrain neuronal circuitry reveals GABAergic identity of salience-encoding neurons

Authors: *A. SCAGLIONE, J. LIANG, R. LAM, S.-C. LIN;
NIA-NIH-IRP, Baltimore, MD

Abstract: The survival of animals depends critically on prioritizing responses to motivationally salient stimuli that predict reward or punishment. Recent studies have identified a distinct population of neurons in the basal forebrain (BF), which will be referred to as BF bursting neurons, that encode the motivational salience of attended stimuli using robust bursting responses. Activation of BF bursting neurons generates an event-related potential in the frontal cortex and leads to faster decision speeds, while inactivation of the same neurons leads to rapid behavioral stopping. A critical question about BF bursting neurons that remains unanswered is their neurochemical identity. To address this issue, we optogenetically tagged the three major cortically-projecting BF neuronal populations (cholinergic, GABAergic and glutamatergic neurons) while recording BF neuronal activity in mice performing a reward-guided reaction time task. BF bursting neurons with properties similar to those previously descried in rats were observed in mice. BF bursting neurons were optogenetically tagged in Vgat-cre mice but not in ChAT-cre and Vglut2-cre mice, supporting their GABAergic identity. Moreover, optogenetically activating each of the three major cortically-projecting BF neurons modulates the activity of BF bursting neurons in specific ways. These results establish for the first time the GABAergic identity of BF bursting neurons, and reveal how they are under the control of other cortically-projecting BF neurons.

Title: Forebrain cholinergic and midbrain dopaminergic neurons broadcast related but distinct signals during reinforcement learning

Authors: *J. F. STURGILL, A. KEPECS;
Neurosci., Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Neuromodulatory centers can dramatically reconfigure cortical circuits across widespread brain areas to influence perception, attention, and learning. In contrast to midbrain dopamine neurons and other classical neuromodulatory populations, cholinergic (ChAT) neurons in the basal forebrain (BF) project across the full extent of neocortex and are believed to underpin higher cognitive functions. Yet until recently, the technical challenge of recording ChAT neural activity in behaving animals has hampered our understanding of the principles governing their activation. In recent work from our lab, optogenetic identification of ChAT neurons in an auditory stimulus detection task revealed that ChAT neurons respond rapidly (~20ms) to reinforcers (reward, punishment) and are modulated by reinforcement expectation or surprise. A putative role in reinforcement prediction invites comparison to dopamine neurons for which a key conceptual advancement was that they compute reward prediction error (RPE): the difference between reward expectation (as informed by a predictive stimulus) and reward feedback. Here, we adopt an analogous behavioral and computational approach to understand the principles governing ChAT neuron activation. Do ChAT neurons respond only to reinforcers or also to outcome-predictive sensory cues? Are the outcome-related responses modulated by the degree of surprise, as for dopamine neurons? And computationally, do ChAT responses represent an unsigned counterpart to dopaminergic RPE? Using fiber photometry we monitor in parallel the responses of basal forebrain ChAT neurons and midbrain dopamine neurons to predictive cues and reinforcement feedback. In a classical conditioning paradigm, we pair novel odor stimuli with reward or punishment and later reverse these contingencies. To validate this approach and provide a reference point, we measure bulk GCaMP responses of dopaminergic neurons (DAT-cre) and recapitulate canonical features of RPE. We find that ChAT neurons rapidly acquire cue responses to predictive stimuli. We further demonstrate that reinforcement responses of ChAT neurons vary not only according to expectancy but also with behavioral state. Lastly, taking advantage of the ability of fiber photometry to track chronic changes in activity across a neuronal population, we delineate the temporal profile of the emergence, evolution and reversal of ChAT responses to predictive cues and reinforcers.

Title: High density recording in rat basalo-cortical networks.

Authors: *P. GOMBKOTO, M. GIELOW, C. CHAVEZ, L. ZABORSZKY;
Rutgers The State Univ. of New Jersey, Newark, NJ

Abstract: Traditionally, the cortical cholinergic input system has been viewed as a nonspecific, diffuse modulatory system. However, cholinergic corticopetal neurons in the basal forebrain (BF) occupy an inhomogeneous distribution whereby dense clusters of neurons are interrupted by regions of low cellular density, in humans as well as in rodents and monkeys (Zaborszky et al., 2015). A preliminary analysis of the cortical targets of these clusters suggest that cell clusters in the BF project to cortical areas that are interconnected.
We addressed the organization of the basalo-cortical network via optogenetic stimulation to identify the cholinergic neurons in the BF, then observe the specific cortical modulation patterns in orbitofrontal (VO/VL) and visual cortex following BF spikes. We used high resolution silicon based electrode arrays to record from the BF and cortex simultaneously. We also designed 3D-printed electrode drivers housed inside a 3D-printed cap that serves to protect the high density silicon electrode arrays. An electrode array was implanted into VO/VL and another, into the visual cortex (V1/V2). These areas were presumed to receive strong projections from the BF cell clusters that we targeted with our optrodes, based upon our prior detailed analysis of the projection pattern of clusters. Additionally, EEG electrodes (surface silicon probe: size 12.96 mm2, contact distance 600 μm) were positioned in nearby non-visual cortical regions to investigate the specificity of cholinergic effects around the visual cortex probe.
We calculated BF cholinergic spike-triggered averages of the local field potentials (stLFP) and of the EEGs at specific cortical locations. We found that a specific BF cholinergic unit activation elicits a spatially distinct oscillation pattern within the visual (V2) and VO/VL cortex. In the visual cortex, theta oscillation of LFPs increased for 500 ms following a cholinergic spike, at specific electrode locations. Based on cross-correlation analysis, we also found monosynaptic connection between a specific cholinergic unit and a V2 cell. However, a neighboring non-cholinergic unit in the BF, which was connected to cholinergic neuron, did not change the stLFP/EEG patterns inside and around the visual cortex respectively. In the VO/VL beta band oscillations decreased following cholinergic activation and were also spatially localized. This

data suggest that the basal forebrain projection system is not diffuse but provides spatially segregated input.

Title: Connectome of the basal forebrain corticopetal system.

Authors: ***P. VARSANYI**, L. ZABORSZKY;
CMBN, Rutgers Univ. Newark, Newark, NJ

Abstract: Cholinergic and non-cholinergic neurons of the basal forebrain (BF) project to the entire cortex. Despite its broad involvement in cortical activation, attention, memory, the functional details are not well understood due to the anatomical complexity of the region, where different functional systems, interdigitate with the cholinergic space. Three decades of research suggests that the BF cholinergic system integrates multiple information that leads to spatially and temporally specific release of acetylcholine in the cortex but the mechanisms by which its release is regulated in a behavioral context remains largely unknown. A critical step is to understand the input-output relations of BF neurons. Conventional tract-tracing experiments using electron microscopy (Zaborszky et al., 2015) were invaluable to define synaptic inputs to identified cholinergic neurons, however, these studies were not adequate to address the extent of specificity of input-output pattern. Therefore, constructing a brain-wide connectivity model that allow analyzing densities of different cell types and connectional data from different animals should lead to more realistic models for addressing function in behavioral studies. As compared to the cortex, there is no apparent geometrical organization in the BF that requires special tools in order to analyze data from different animals.
In more than 40 brains that received conventional retrograde or virus tracer injections in the cortex, cholinergic and non-cholinergic neurons in the BF were mapped with the Neurolucida (MicroBrightField) system. After mapping fluorescently labeled cells, sections were restained with Nissl and images of sections were aligned to existing Neurolucida maps.
We are building a single reference brain to use as a common 3D space based on gapless series of sections, in which cholinergic BF neurons were mapped from every 50 μm thick section. The

rest of the brain is reconstructed from series of sections mapped with 200 µm section distances. Interpolations are used to construct a gapless approximation of the entire brain. After an automatic registration the software allows to view together both the Nissl-images of the sections and the associated vectorial dataset. The spatial registration is carried out using mixed rigid body, affine and B-Spline based elastic transformations. This connectome model that captures the organizational principles of the basalo-cortical network will facilitate the understanding of the aberrant processing in basalo-cortical networks and may help the development of new treatment strategies to ameliorate the cognitive symptoms in Alzheimer and related degenerative diseases.

Title: Basal forebrain cholinergic-auditory cortical network: primary versus belt auditory cortical areas.

Authors: *C. M. CHAVEZ, L. ZABORSZKY;
Ctr. for Mol. and Behavioral Neurosci., Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstract: Cortical acetylcholine (ACh) release is critical for learning, memory, attention, and plasticity. The basal forebrain (BF) provides cholinergic input to the entire cerebral cortex supporting these functions. Here, we explore the cholinergic and non-cholinergic BF projections to the auditory cortex using classical retrograde and monosynaptic viral tracers deposited in electrophysiologically identified regions of the auditory cortex in Sprague Dawley and Chat::Cre transgenic rats. Cholinergic input to both primary (A1) and non-primary auditory cortical (belt) areas originate in a restricted region in the caudal BF within the globus pallidus (GP) and in the dorsal part of the substantia innominata (SId). However, there were significantly more cholinergic cells projecting to A1 than to belt areas. Monosynaptic tracing revealed that inputs to A1 projecting BF cholinergic neurons were restricted to the GP, caudate-putamen (C-P), and the medial part of the medial geniculate body (MGM), including the posterior intralaminar thalamic group. Similarly, inputs to auditory belt projecting BF cholinergic cells originate within the GP, C-P, and MGM. However, additional afferents to belt-projecting BF cholinergic neurons were

found in broader areas including the ventral secondary auditory cortex, insular cortex, secondary somatosensory cortex, and the central amygdaloid nucleus. These findings provide evidence for a differential innervation pattern between primary and secondary auditory cortical regions that may contribute to the functional differences and how ACh release is regulated in the A1 and auditory belt areas.

Title: Input-output organization of the cholinergic basal forebrain

Authors: *M. R. GIELOW, L. ZABORSZKY;
Rutgers Univ., Newark, NJ

Abstract: Cholinergic cells of the basal forebrain individually terminate in discrete cortical areas, and collectively innervate the entire cerebral cortex. Acetylcholine efflux is differentially controlled across different cortical areas and timescales, contributing to varied processes including sleep and waking, attention, learning, plasticity, and memory. However, the anatomical mechanism of control for this differential efflux remains mysterious, in part due to the anatomical complexity of the region. In the current anatomical tracing study we compare the relationship of inputs and outputs of the cholineric basal forebrain. The resulting maps indicate that this system is highly modular in its organization. We suggest an architecture of the basal forebrain cholinergic system by which individual groups of cholinergic cells may be individually controllable based on their anatomical properties.

Title: Functional integration and segregation of magnocellular cell groups in human basal forebrain: resting state study at ultra-high field, meta-analysis, and test-retest reliability

Authors: *R. YUAN[1], B. BISWAL[1], L. ZABORSZKY[2];
[1]New Jersey Inst. of Technol., Newark, NJ; [2]Rutgers Univ., Newark, NJ

Abstract: The heterogeneous corticopetal cell groups of the basal forebrain (BFC), including cholinergic, GABAergic and glutamatergic neurons, have shown to modulate cortical activation, sensory processing, attention, learning and memory through their projection to the entire cortex. Recent advances in the ultra-high field 7T fMRI provided potentially unprecedented spatial resolution of functional MRI images to systematically study the sub-division of BFC. In this study, first, using a probabilistic 3D postmortem map of the BFC (Zaborszky 2008) and a high resolution functional connectivity dataset, the BFC was divided into functionally distinct 3 sub-divisions. Second, the overall connection of each BFC sub-division was exanimated with a test-rest study. Third, meta-analysis was used to study the related topics of each sub-division. The data-driven parcellation method gave rise to three sub-divisions along the rostral–caudal axis of the basal forebrain. The rostral subdivision is highly associated with the anterior cingulate [BA24/32], the thalamus, the hippocampus [BA28/35], the insula [BA 13], the superior [BA22] and middle temporal gyrus [BA21], the middle [BA11] and inferior frontal gyrus [BA47], the precuneus [BA31]. The functional connection of the middle subdivision are the lateral globus pallidus, putamen, caudate, the cingulate gyrus [BA24/32], the thalamus, the insula [BA13], the frontal gyrus [BA32/27], the hippocampus [BA27]. The caudal subdivision is mainly related with the putamen, lateral globus pallidus, hippocampus, thalamus, cerebellum, claustrum, insula, the precentral gyrus [BA4/6], and the medial frontal gyrus [BA6/13]. Interestingly, all three clusters have shown consistent overlaps at specific target regions, including the hippocampus, insula, the thalamus and, cingulate gyrus, contributing to distinct topographical patterns. For example, the rostral sub-division is connected with the anterior part of the thalamus, while the caudal sub-division is highly connected with the medial dorsal thalamus. Meta-analysis also suggests that the various sub-divisions are associated with specific functional topics. The rostral subdivision is related to reward, decision making, and motivation. The medial subdivision is associated with emotional regulation, anxiety and threat. The caudal subdivision relates to motor, sensorimotor and auditory process. To sum up, this study demonstrates that BFC can be

subdivided into distinct functional sub-divisions, and the connectivity pattern of each sub-division is associated with different networks and cognitive processes.

Title: Optogenetic stimulation of cortically projecting basal forebrain parvalbumin neurons cause short latency arousals in mice

Authors: ***J. T. MCKENNA**[1], S. THANKACHAN[1], C. SHUKLA[1], J. M. MCNALLY[1], J. C. ZANT[1], S. WINSTON[1], K. DEISSEROTH[3], R. E. BROWN[1], R. BASHEER[1], R. W. MCCARLEY[2];

[2]Research/Psychiatry, VA Boston Healthcare System/Harvard Med. Sch., Brockton, MA;
[3]Psychiatry and Behavioral Sciences/Bioengineering, Stanford Univ., Stanford, CA

Abstract: This study focused on the specific role of basal forebrain (BF) GABAergic parvalbumin (PV) neurons in arousal. We had previously shown that BF cortically projecting neurons discharge at a high rate during wakefulness and regulate cortical gamma band (40Hz) oscillations associated with feature binding, attention and consciousness (Kim et al., 2015). These neurons are excited by acetylcholine and are involved in mediating the arousal effects of

BF cholinergic neurons (Yang et al., 2014; Zant et al., 2016). We hypothesized that the direct input of BF PV neurons to cortical PV neurons would mediate a short latency arousal when optogenetically stimulated. We also compared these latencies to those of cholinergic neuronal stimulation.

We unilaterally/bilaterally injected double-floxed adeno-associated viral vectors expressing Channelrhodopsin2 (AAV-ChR2-EYFP) into the BF of PV-Cre mice outfitted with cortical EEG & EMG electrodes for sleep-wake recordings. Optical stimulations (5s stim/min, 10ms pulses @ 40 Hz) were performed using blue laser (20mW, 473nm) for 6h (ZT2-ZT8) with simultaneous EEG/EMG recordings. For stimulations that occurred after at least 10s of NREM, latency to arousal was calculated as the time from the beginning of stim to end of the last slow wave activity leading to EEG desynchronization, and compared with that of mock-stim baseline day (BL, laser off). For comparisons, the median statistic was used because of the skewed, non-normal distribution of responses. Post-hoc immunohistochemistry was performed to confirm transduction efficiency, selectivity, and location of the optical fiber tract.

We observed that uni-/bi-lateral stimulations (N=10) significantly increased both the time spent in wakefulness compared to BL day by 22.61±3.0% ($p=<0.001$), and % transitions from NREM to wakefulness (BL day, 64.27±3.8%; Stim-day, 75.2±2.3%; $p=0.03$). The median latency for transitions from NREM to wakefulness was significantly decreased in both conditions of unilateral (BL, 16.9±2.7s vs stim, 7.18±1.5s; $p=0.02$; N=4) and bilateral (BL, 20.0±1.8s vs stim, 3.9±1.2s; $p<0.001$; N=6) stimulations.

In summary, optogenetic stimulation of BF PV neurons increased overall amounts of wakefulness. The median latency for NREM to wakefulness was shorter following optogenetic stimulation of BF-PV when compared to non-stim baseline values. These values were also shorter than those associated with optogenetic stimulation of BF cholinergic neurons (median: 10.6s). Thus, our data suggests that BF PV neuronal excitation causes rapid EEG arousal, likely due to fast cortical disinhibition elicited via direct innervation of the inhibitory interneurons.

Abstract: Basal forebrain (BF) neurons play a crucial role in cortical activation, attention, sleep-wake behavior and reward processing. Of the three major BF neurotransmitter classes, glutamatergic neurons are the least well understood. Recent optogenetic gain-of-function experiments suggest that stimulation of BF neurons expressing the vesicular glutamate transporter type 2 (vGluT2) strongly promotes wakefulness. However, currently little is known about the subtypes of BF vGluT2 neurons and their properties which mediate this wake-promoting effect. Thus, here we have investigated the anatomy and physiology of vGluT2 neurons in a transgenic mouse model that expresses a red fluorescent protein (tdTomato) in vGluT2 neurons (vGluT2-tdTomato mice). In vitro, whole-cell recordings were made from tdTomato+ neurons (n=53) in intermediate/caudal BF regions of young (12-22d) vGluT2-tdTomato mice. Compared to cholinergic neurons, vGluT2+ neurons had a higher maximal firing rate, smaller afterhyperpolarizations and briefer action potentials. Compared to GABAergic

neurons, vGluT2+ neurons had a lower maximal firing rate and were hyperpolarized by the cholinergic agonist, carbachol, whereas GABAergic neurons were excited. A subset of vGluT2+ neurons exhibited T-type calcium currents and burst firing. However, there were marked subregional differences in hyperpolarization-activated cation currents, low-threshold calcium currents and in the inhibitory effect of carbachol. Immunohistochemical staining (n=4) revealed that major subgroups of BF vGluT2+ neurons express the calcium-binding proteins calbindin and calretinin, but not parvalbumin. Anterograde tracing using adeno-associated viral vectors expressing channelrhodopsin2-enhanced yellow fluorescent fusion proteins revealed major projections of BF vGluT2+ neurons to BF cholinergic and parvalbumin neurons as well as to extra-BF areas including frontal cortex, lateral habenula, lateral hypothalamus and ventral tegmental area (VTA). This work suggests there are several subtypes of BF vGluT2 neurons which differ in their intrinsic membrane properties, calcium binding content, cholinergic modulation and likely also their projections. Cortical projections and intra-BF connections of vGluT2+ neurons to cholinergic and GABA/parvalbumin neurons are consistent with an important role in sleep-wake control. Prominent projections of vGluT2+ neurons to lateral habenula, lateral hypothalamus and VTA suggest an additional, unexpected role in reward processing.

Title: Reward-timing prediction errors in the brain

Authors: ***C. CHEN**, I. MONOSOV;
Washington Univ. In St. L, Saint Louis, MO

Abstract: Predicting the timing of important events, such as rewards, is crucial for behavioral strategy in an uncertain environment. Previous literature suggests single neurons could be timing important events through anticipatory ramping activity (Goel and Buonomano, 2014; Llyod and Dayan, 2015; Blanchard, Strait, and Hayden, 2015; Bermudez and Schultz, 2014).
We recently discovered single neurons in medial basal forebrain (mBF) and internal capsule bordering dorsal striatum (icbDS) that display anticipatory ramping activity after onset of conditioned stimuli (CSs) associated with uncertain reward delivery up to trial outcomes (White and Monosov, in review; Monosov et al., 2015). This suggests mBF and icbDS may contain mechanisms for predicting timing of events under uncertainty.
We studied mBF and icbDS uncertainty-selective ramping neurons while monkeys participated in a behavioral procedure in which reward was certain, but timing of delivery was uncertain. We conditioned monkeys with 4 CSs associated with 0.25, 0.50, 0.75, or 1.00 probability of reward delivery after 1.5 seconds (s). On trials when rewards were not delivered in 1.5 s, rewards were delivered 4.5 s after CS onset.
We found reward delivery 1.5 s after CS onset elicited a phasic excitatory response in mBF ramping neurons. The magnitude of response was inversely correlated with probability of reward. No phasic response was observed after 4.5 s. In contrast, we found reward delivery either 1.5 or 4.5 s after CS onset elicited a phasic excitatory response in many icbDS ramping neurons. The magnitude of response did not vary significantly across different CSs or times of delivery.
We tested if phasic responses in mBF and icbDS could be a reward prediction error (RPE) generated by the difference between reward and predicted value at the time of reward delivery. We recorded neurons while monkeys experienced 5 CSs associated with 0.00, 0.25, 0.50, 0.75, or 1.00 probability of reward delivery. This procedure did not introduce temporal uncertainty as timing of trial outcomes did not vary. We found neither population of mBF or icbDS neurons generated phasic responses upon reward delivery.
We propose phasic responses in mBF ramping neurons do not encode traditional RPEs, but a timing prediction error generated roughly by the difference between reward time and predicted time of delivery. We propose phasic responses in icbDS ramping neurons also do not encode RPEs, but a reward timing response generated upon resolution of trials with temporal uncertainty.
We propose a neuron model based on phasic responses in mBF and icbDS ramping neurons to demonstrate their possible usefulness for behavior in uncertain environments.

Title: Impaired familiarity discrimination after neonatal perirhinal lesions in rhesus macaques

Authors: *A. R. WEISS, W. GUO, J. BACHEVALIER;
Emory University/YNPRC, Atlanta, GA

Abstract: The contribution of the perirhinal cortex (PRh) to recognition memory is well characterized in adults. PRh lesions severely impair recognition memory when assessed with either Visual Paired Comparison (VPC) or Delayed Non-Match to Sample (DNMS). Similar recognition memory deficits on both tasks followed neonatal PRh lesions (Neo-PRh; VPC: Zeamer et al., 2015; DNMS: Weiss & Bachevalier, 2016), although the severity of the deficits was more pronounced in DNMS than VPC. Thus, for VPC, performance remained significantly better after Neo-PRh lesions than after adult-onset PRh lesions (Nemanic et al., 2004), suggesting that other brain areas could partially compensate. Conversely, for DNMS, recognition memory deficits were of the same magnitude after early-onset Neo-PRh lesions and adult-onset PRh lesions (Meunier et al., 1993). One procedural difference that could explain the difference in severity of memory deficits is the familiarization time with the sample objects. VPC uses a cumulative 30s familiarization, whereas in DNMS the monkeys are exposed to the sample for only the length of time it takes to displace it (3-7s). Given that PRh has been shown to play a role in familiarity judgments (Bowles et al., 2007), it is possible that better performance of Neo-PRh animals on VPC may have resulted from longer exposure with the objects. To test this possibility, we used the Constant Negative task (Browning et al., 2013), which allowed for repeated exposures to objects. The same Neo-PRh monkeys (n=6) and their controls (Neo-C, n=3) were given 60 discrimination problems. For each problem, one object was the unrewarded "constant negative" stimulus (S-) and another novel object was the rewarded stimulus (S+). Each of the 60 S- objects were presented once every daily testing session, and became familiar over several days. In contrast, the S+ objects presented with the S- were always novel. Neo-PRh and Neo-C monkeys made similar numbers of errors before reaching the learning criterion of 90% correct [$t(7)=-1.07$, $p=.32$], but the groups differed in the number of trials needed to reach criterion [$t(7)=-2.54$, $p=.04$]. Additional linear regression analyses revealed that the rate of learning significantly differed between the groups [$t(67)=5.31$,$p<.01$], with Neo-C showing faster learning (steeper slopes) than Neo-PRh. These data suggest that group Neo-PRh may

require more exposures to an object before judging it as familiar and help to account for the differential patterns of functional compensation on VPC and DNMS tasks. The results provide further support to the view that PRh is involved in familiarity judgements. This work was supported by grants MH-58846 and NSF-GRFP DGE-1444932.

Title: Lesions of the postrhinal cortex impair extinction learning in a latent inhibition paradigm

Authors: *N. E. DEANGELI, T. P. TODD, D. J. BUCCI;
Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: The postrhinal cortex (POR) is part of a network of posterior cortical regions that provide the hippocampus with processed sensory information. Consistent with this, prior lesion studies have demonstrated that POR is critically involved in hippocampal-dependent processes, such as contextual fear conditioning. However, the precise contribution of POR to learning and memory remains unclear. Based on electrophysiological findings and the connectivity of POR with attentional regions such as posterior parietal cortex, it has been postulated that POR may be involved in monitoring the environment for changes in stimuli and altering attention to those cues accordingly. To causally test this, we examined the effects of POR damage using a latent inhibition procedure. In a typical latent inhibition paradigm, prior non-reinforced exposure to a stimulus retards learning when the same stimulus is subsequently paired with a significant outcome (compared to conditioning to a novel cue). Attention-based accounts of latent inhibition posit that pre-exposure to the stimulus in the absence of reinforcement decreases the associability (attention) of that stimulus. Here, rats with either sham lesions or electrolytic lesions of the POR were first trained to lever press for food reinforcement. Half of the rats in each group rats were then assigned to the pre-exposure condition and received ten presentations of a 30-sec white noise conditioned stimulus (WN) each day for six days. Rats in the non-pre-exposure groups remained on a random-interval 60-sec schedule throughout this phase of the experiment and did

not receive presentation of the WN. During the subsequent conditioning phase, rats in all four groups received one pairing of the WN and a 0.5-mA, 0.5-sec footshock during each of six daily sessions. Then in the final phase of the experiment (extinction training), rats in all groups received four presentations of the 30-sec WN per day for ten days (no shock was delivered during the extinction phase). Suppression ratios were calculated for each WN presentation. Lesions of POR had no impact on responding during either the pre-exposure or conditioning phases. However, conditioned responding to the WN was slower to extinguish in the POR-pre-exposure group compared to the other three groups. These findings suggest that while decremental changes in associability may be intact following POR damage, the ability to increase attention when a stimulus is no longer paired with an expected outcome may be impaired when POR is dysfunctional.

Title: Representations of context in the postrhinal cortex

Authors: *V. R. HEIMER-MCGINN, B. KENT, R. D. BURWELL;
Dept. of Cognitive, Linguistics and Psychological Sci., Brown Univ., Providence, RI

Abstract: The brain's ability to understand spatial context is central to many higher-order cognitive functions including episodic memory. Despite its importance to cognitive function, there are many open questions about how context is encoded and represented in the brain. The parahippocampal cortex in primates and the homologous postrhinal cortex (POR) in rodents are thought to process spatial information, whereas the perirhinal cortex (PER) is known to process object information. A prevailing view of medial temporal lobe function emphasizes that the POR provides spatial information to the hippocampus (HC) and the PER provides non-spatial information. The PER and POR each project to the HC both directly and indirectly through the lateral and medial entorhinal areas. By one view, the spatial pathway conveys both spatial and

contextual information to the HC. By another view, the HC, itself, configures spatial and object information into representations of context. Neither view takes into account the robust, multilevel connections across the so-called spatial and non-spatial pathways. For example, the PER provides a robust input to the POR. Available evidence suggests that representations of context may be formed in the POR, upstream of the hippocampus. We hypothesize that the POR combines object and spatial information to build a model of the local spatial context (including the spatial layout of objects, patterns, and features of the environment), and that it monitors the local environment in order to update the current representation when changes occur. In this study we recorded neuronal activity and local field potentials (LFPs) in the POR of rats during performance on a non-spatial biconditional discrimination task (nsBCD) designed to differentiate the neuronal correlates of objects, location, and context. In this task, dynamic floor patterns determine which object in a pair is correct. For example, one object of a pair would be correct on a striped floor and the other on a dotted floor. Automated projection of visual stimuli and online tracking of head position and direction allowed precise measurement of behavioral correlates. Nearly one-third of POR cells were significantly modulated by a combination of object identity, object location, and context (defined as floor pattern). LFP analysis revealed that ~40% of POR cells were phaselocked to theta oscillations. Also, changes in theta power predicted trial outcome independently of running speed, with lower pre-stimulus theta power associated with higher accuracy. Our findings support the hypothesis that POR forms a representation of the local environment, and signals changes to the environment as they occur.

Title: Emergence of object-location conjunctive coding in the postrhinal cortex and hippocampus

Authors: *V. J. ESTELA[1], R. D. BURWELL[2];
[1]Neurosci., [2]Cognitive, Linguistic, and Psychological Sci., Brown Univ., Providence, RI

Abstract: Episodic memory, or the recollection of autobiographical events in time and space, requires the ability to fully represent and recall context. Contexts are intricate representations that consist of places combined with objects and patterns, including the specific spatial arrangements of these features. Structures in the medial temporal lobe, specifically the perirhinal (PER) and postrhinal (POR) cortices, are crucial for contextual learning. Our guiding hypothesis is that the POR integrates object information from the PER with spatial information from the posterior parietal cortex to represent the spatial layout of objects, patterns, and features in the local environmental context. Such representations are then made available to other regions for context-guided behavior. We further hypothesize that the hippocampus (HC) relies on POR context representations for associative learning and episodic memory. Prior studies reported that both the POR and the HC exhibit object-location conjunctive coding (Furtak, Ahmed, and Burwell, 2012; Komorowski, Manns, & Eichenbaum, 2009). Such conjunctions emerge with learning in the HC, but the timing of the emergence of object-location conjunctions in the POR is unknown. One possibility is that object-location conjunctions in the POR reflect the representation of the spatial layout of objects in the local context, whereas such conjunctions in the HC reflect the binding of objects in context for episodic memory. If our hypothesis is correct, object-location conjunctions should be present in the POR before they emerge in the HC. To test this prediction, we will record simultaneously in the POR and HC during performance on the location bi-conditional (locBCD) task. In this task, the location in a bowtie-shaped maze determines which of two objects is correct. For example, if the objects to be discriminated are a star and a circle, the star might be correct on the west side of the maze and the circle would then be correct on the east. This task capitalizes on the propensity of rats to explore objects on the floor as well as available evidence that cortical input to the POR is primarily visual. We have shown that rats can learn concurrent and sequential pairs in this and similar tasks. We predict that as rats learn new discriminations, object-location conjunctive coding will be evident in the POR before it is evident in the HC. Such a finding would be consistent with the interpretation that object-location conjunctive coding in the HC relies on POR representations of context. Future studies will address this interpretation in circuit analysis experiments that combine electrophysiology and optogenetics in rats performing the locBCD task.

Title: Inactivation of the lateral posterior thalamic nucleus on neuronal correlates in rat posterior parietal cortex during performance on a visuospatial attention task

Authors: *F.-C. YANG[1], R. D. BURWELL[1,2];
[1]Cog., Lin. & Psychological Sci., [2]Dept. of Neurosci., Brown Univ., Providence, RI

Abstract: The posterior parietal cortex (PPC) has been identified as important for visuospatial attention. In rats, this region receives input from visual cortex and from the lateral posterior nucleus of thalamus (LPO), the functional homolog of the primate pulvinar. The LPO and pulvinar are also implicated in attention. In primates, the pulvinar differentially projects to two subdivisions of the PPC. Recent studies showed functional differentiation of these PPC subdivisions, with one region supporting top-down attention and the other supporting bottom-up attention (Cabeza, 2008). The rodent PPC can also be subdivided into dorsal and caudal subdivisions (dPPC and cPPC). We previously reported that neuronal activity in the dPPC and cPPC is consistent with top-down and bottom-up attentional functions. Our previous work showed that neuronal activity in LPO and parietal subdivisions correlated with multiple phases of a visuospatial attention (VSA) task, including onset of the visual stimuli, decision-making, task-relevant location, and behavioral outcome. To further understand how posterior parietal activity depends on the LPO, we simultaneously recorded neuronal activity in the LPO, dPPC, and cPPC in male Long-Evans rats during performance on the VSA task. On some trials LPO activity was optogenetically inhibited. Our VSA task was adapted from the five-choice serial reaction time task for a double-sided, bowtie shaped enclosure atop the Floor Projection Maze. Trials alternated from side to side. For each trial, rats were required to attend to three locations. In one of these locations, a target stimulus was randomly and briefly illuminated. An approach to the correct target location was followed by a liquid reward. For analysis, a trial was divided into behavioral epochs including stimulus onset, selection behavior, and reward. We recorded neuronal activity of six rats, and isolated 318 cells in the dPPC, 225 cells in the cPPC, and 474 cells in the LPO. We report that LPO and PPC cells signal stimulus onset and selection behavior consistent with the interpretation that the LPO and PPC are engaged in both top-down and bottom-up visuospatial attention. We also observed that LPO and PPC cells responded to allocentric and egocentric task-relevant locations. Preliminary analyses showed that behavioral correlates of LPO and PPC neurons disappeared or changed during optogenetic inhibition of LPO activity supporting our hypothesis that the parietal activity depends on the LPO inputs when visuospatial attentional demands are high. Further analyses and detailed results will be presented.

Title: The role of the rodent retrosplenial cortex in context-guided behavior

Authors: *E. HWANG[1], F.-C. YANG[1], R. D. BURWELL[2];
[1]CLPS, [2]CLPS, Neurosci., Brown Univ., Providence, RI

Abstract: Research in rodents and primates has addressed the role of the retrosplenial cortex (RSP) in spatial information processing, giving rise to theories of RSP function, including translating across different spatial reference frames, processing contextual associations with objects, and encoding the spatial locations of permanent landmarks. Damage to the RSP, the postrhinal cortex (POR) and RSP-POR disconnection impair contextual fear conditioning in rats, suggesting that the two regions interact in contextual learning (Burwell et al, 2004, Keene & Bucci, 2008). Anatomical studies of the rodent brain show that the RSP and the POR are interconnected (Burwell & Amaral, 1998). How these connections contribute to contextual information processing, however, is not clear. We have shown that the POR exhibits object-location and object-context conjunctive coding in simple object discrimination and context-guided object discrimination. We hypothesize that the RSP provides task-relevant spatial information to the POR for the purpose of representing context and forming contextual associations. If so, we would expect RSP neurons to show spatial correlates, but not object-location conjunctions, in a context-guided discrimination task. We recorded neuronal activity in the RSP in male Long-Evans rats during performance on the location biconditional discrimination (locBCD) task (Fig.1). This task was adapted from the conditional discrimination task from Komorowski et al. (2009) for a double-sided, bowtie shaped enclosure atop the Floor Projection Maze (Jacobson, et al. 2014). Trials alternated from the east to the west side of the maze. Fixed, distinctive floor patterns and distal cues distinguished the east side from the west side. On each trial, a pair of 2-dimensional objects was presented on the floor. For each pair of objects, one was correct in the east and the other, in the west. An approach to the correct location was rewarded. On some trials novel objects were presented in order to disambiguate location correlates from object-location conjunctions.

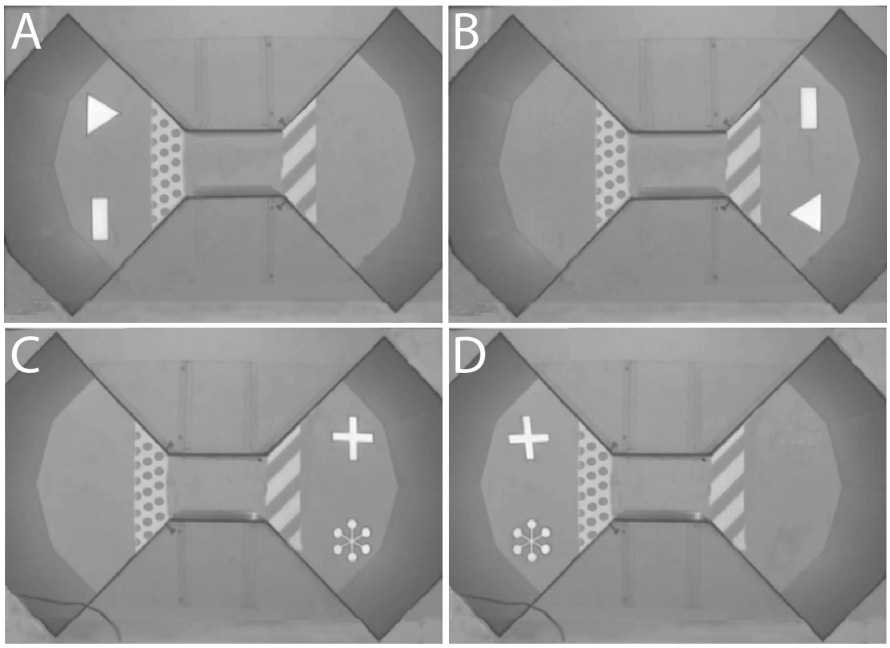

Fig 1. Location-guided biconditional discrimination task. Two object pairs are shown in A/B and C/D. Side of the maze (east or west) determines which object is correct. For example, in A the triangle would be correct and in B the rectangle would be correct.

Title: Encoding of episodic events by the retrosplenial cortex

Authors: ***G. FOX**, J. Z. TSIEN;
Med. Col. of Georgia, Augusta Univ., Augusta, GA

Abstract: The retrosplenial cortex (RSC), a posterior midline structure possessing vast connections with the hippocampal formation, anterior thalamic nuclei, and select areas within the cortex, has been shown to have a role in the acquisition and consolidation of spatial, contextual, and episodic memory. Of notable interest, the RSC may serve as a long-term memory storage site. However, little is known about the dynamic patterns of RSC cells during episodic events. By taking advantage of *in vivo* neural recording techniques coupled with optogenetics, we monitored the activities of various neurons in the RSC of freely behaving mice during multiple fearful events. In our behavioral paradigm, wild-type mice or optogenetically labeled mice were subjected to the following fearful events: foot shock, elevator drop, earthquake, and air puff. Large numbers of neurons were recorded and their identities were further examined by optogenetic stimulation. We demonstrated that principal cells within the RSC respond robustly to various fearful episodic events, apparently following a power-of-two-based mathematical rule. Additionally, optogenetically-identified interneurons were manipulated during fearful stimulation. These results will be valuable to understand how the RSC generates a cell-assembly level representation of fear memory engrams.

Title: Retrosplenial cortex lesions produce retrograde and anterograde context amnesia following overtraining

Authors: R. HUSZAR, M. C. EDDY, N. E. DEANGELI, D. J. BUCCI, 03755, *T. P. TODD; Psych & Brain Sci., Dartmouth Col., Hanover, NH

Abstract: The retrosplenial cortex (RSC) is positioned at the interface of primary cortical sensory areas and the parahippocampal - hippocampal memory system and is thus well-suited to contribute to learning and memory processes. Indeed, the RSC has been shown to have an important role in both spatial and contextual learning. For example, both pre- and post-training lesions of RSC attenuate contextual fear conditioning. The system that supports contextual fear

conditioning is dynamic (Fanselow, 2010). For example, pre-training lesions of the hippocampus produce deficits with "weak" training (e.g., 1 shock). However, with "overtraining" (e.g., more than 3 shocks), pre-training hippocampus lesions do not attenuate contextual fear conditioning, although post-training lesions abolish context fear. Thus, with enough training, the hippocampus is not required for context learning. The purpose of the current experiment was to examine the role of the RSC in contextual fear conditioning after overtraining. All rats first received 25 tone-shock pairings in Context A. The next day, half of the rats received sham lesions of the RSC and the other half received electrolytic lesions. Following recovery from surgery for 2 weeks, all rats were returned to Context A. We found that RSC-lesioned rats exhibited less freezing behavior compared to the sham-lesioned controls. A subsequent test of tone-specific fear in Context B revealed no differences between groups, indicating that RSC lesions produced a selective deficit on contextual fear. All rats then received retraining (i.e., 25 tone-shock pairings) in Context B. When fear to Context B was assessed, RSC-lesioned rats once again exhibited attenuated freezing behavior. The tone was then tested in Context C, and no lesion induced deficits were observed. Overall, lesions of the RSC produced both retrograde and anterograde deficits with overtraining in a contextual fear conditioning paradigm. In contrast, previous studies have demonstrated that hippocampal lesions produce retrograde, but not anterograde, amnesia following overtraining (e.g., Wiltgen, 2006). Thus, the current studies suggest that RSC has essential role in contextual fear conditioning and that other systems or pathways are unable to compensate for the loss of RSC function.

Abstract: The retrosplenial cortex (RSC) has been of interest to memory researchers for over 30 years. Recently, this interest has been rekindled by reports suggesting that RSC is a storage site of spatial memory. To further elucidate this role we performed a thorough characterization of the

RSC in contextual fear memory, a task that has been extensively used to examine the hippocampus. We show that the RSC is activated during contextual memory formation, and that an intervention that blocks memory also blocks this activation. Using Pde4d downregulation as a tool, we next show that systemic inhibition, hippocampal knockdown (KD) or KD in the RSC all enhance fear memory. Both Pde4d inhibition and Pde4d KD increase the number of mature spines in RSC, a mechanism implicated in memory. This research highlights the parallels in plasticity mechanisms between RSC and hippocampus and provides the most compelling evidence for RSC as a storage site of memory to date.

Title: Going the distance: the effect of geometry on spatial representations

Authors: *M. V. KURUVILLA, J. A. AINGE;
Psychology & Neurosci., Univ. of St Andrews, St Andrews, United Kingdom

Abstract: Grid cells have been theorized to provide a neural metric for spatial information. However, evidence of distorted grid patterns presents some interesting questions regarding how our perception of space and distance is affected by environmental geometry. Recently, it was demonstrated that grid cell symmetry distorts when rats are placed in a trapezoid (Krupic, J., Bauza, M., Burton, S., Barry, C., & O'Keefe, J. (2015). *Nature*, *518*(7538), 232-235). Here, we assessed the impact on spatial memory and navigation when rats had to learn to consistently stop at a certain distance in either a trapezoidal or rectangular box. We predicted that rats distance perception would be altered in the trapezoid relative to the rectangle. The experiment was conducted in box that could be configured to form either a rectangle (1.9m * 0.9m) or trapezoid

(1.9m diagonals, 0.9m long parallel wall, 0.2m short parallel wall). Rats were habituated to both configurations for a total of 60 minutes before the start of the experiment. In the practice phase, rats were trained in a rectangle to run in a straight line, stop within a 0.15m zone (1.23m – 1.37m) and return back to the starter box for a food reward. In the test phase rats completed the same task across 10 trials, 5 trials each in the rectangle and trapezoid configuration. The stopping zone in the trapezoid configuration was increased by +/- 10% to account for potential changes in distance perception as a result of an alteration in geometry. Rats stopped significantly earlier in the trapezoid compared to the rectangle suggesting that their perception of space had been changed by the local geometry of the environment even though global spatial cues were available and consistent. It could be the case that rats were solving this task using either a distance or a place strategy. To assess the use of a distance strategy, rats we re-tested, with global cues concealed by a curtain. Again, rats stopped significantly earlier in the trapezoid compared to the rectangle indicating an altering of spatial representation as a result of a change to local geometry and in the absence of a global cue-dependent place strategy. Additionally, across trapezoid but not rectangle trials, rats stopped significantly earlier in the absence of global cues than in their presence. This suggests that the absence of global cues exacerbates the disruption of spatial representation caused by local geometry. We would predict that distortion of grid cell symmetry in trapezoids would be greater in the absence of global cues, which is the focus of on-going experiments.

Title: Object representation along the proximodistal axis of CA1

Authors: *J. A. AINGE, B. M. VANDREY;
Univ. of St Andrews, St Andrews, United Kingdom

Abstract: Models of episodic memory in the medial temporal lobe often suggest that the spatial and non-spatial content of an episode reaches the hippocampus via the medial entorhinal cortex (MEC) and lateral entorhinal cortex (LEC), respectively. However, these models are challenged by evidence that the LEC plays a critical role in binding these two types of information together

prior to the hippocampus. Further, the LEC contains neurons which are spatially tuned to objects. Notably, object-related firing in the LEC strongly resembles object-modulation of place cells in the hippocampus; neurons in both structures encode object location, respond to object displacement, and fire at locations where an object was previously located. However, the origin of object-modulation in hippocampal place cells is unknown. One possibility is that LEC input drives spatial representation of objects in the hippocampus. To explore this hypothesis, we implanted microdrives in rats (n=5), with tetrodes targeting either the proximal, bordering CA2, or distal, bordering subiculum, parts of CA1. These regions receive differential input from the entorhinal cortex, so this strategy permitted us to record from neuronal ensembles which primarily receive MEC or LEC input. Place cells were recorded during exploration in an open-field containing objects which underwent a series of spatial manipulations, including object dislocation and novel object-place recognition. Recordings from place cells receiving LEC input resulted in greater influence of objects on place cell firing, although object-modulated and non-object-modulated place cells were recorded in both regions. Object-modulation of place cells in CA1 conformed to patterns which have been described previously. These findings influence our understanding of how entorhinal-hippocampal communication supports the integration of item and location information in episodic memory.

Title: Investigating the molecular organisation of superficial layers of the lateral entorhinal cortex

Authors: *B. M. VANDREY[1], D. L. F. GARDEN[2], J. A. AINGE[1], M. F. NOLAN[2];

Abstract: Episodic memory relies on the hippocampus and its surrounding cortical network. The entorhinal cortex makes substantial contributions to information processing within this network.

Recent work suggests that the lateral entorhinal cortex (LEC) is critical for binding together features of an episode and processing spatial information about objects. However, the relationship between LEC circuit components and cognitive function is unclear. Further, an obstacle to progress is the lack of tools for manipulation of independent populations of neurons in the LEC. Recent work in the medial entorhinal cortex (MEC) found that MEC layer 2 (L2) contains two populations of cells that project to discrete regions of the hippocampus and are labelled by the protein markers reelin and calbindin. Cre-expressing mouse lines were identified which give genetic access to these sub-populations. Based on this work, we aimed to investigate whether L2 of the LEC is similar in organisation and molecular identity to MEC, and whether Cre driver lines used for investigation of MEC can be repurposed to give genetic access to specific cell populations within LEC L2. We find that L2 of the LEC bifurcates into two molecularly distinct sub-layers based on the distribution of reelin and calbindin. In the more superficial layer (L2a) the majority of neurons are positive for reelin, whereas in the deeper layer (L2b) the majority of neurons are positive for calbindin. To develop a strategy for targeting cells in LEC, we injected adeno-associated virus encoding a fluorescent reporter into the LEC of Sim1:Cre mice, which we found previously to label stellate cells in L2 of the MEC (Sürmeli et al. (2015), Neuron 88:1040-1053). In LEC, Cre was expressed specifically in cells in L2a that express reelin and project to the dentate gyrus (DG). We used patch-clamp recordings to further examine the properties of the labelled cells. Cre positive neurons were morphologically and electrophysiologically similar to 'fan-cells' (cf. Tahvildari and Alonso (2005), J. Comp. Neurol. 491: 123-140). In summary, we provide a novel comparison of the organisation and molecular characteristics of L2 of LEC and MEC. Further, we report that the Sim1:Cre line provides genetic access to the sub-population of LEC L2 cells which project to the DG. Our results establish a framework for investigating circuit mechanisms by which L2 of the LEC contributes to episodic-like memories.

Title: Efferent projections of the calbindin-positive entorhinal neurons in the rat: Connectional differences between the medial and lateral entorhinal cortex

Authors: *S. OHARA[1], K. ITOU[1], M. SHIRAISHI[1], M. GIANATTI[2], Y. SOTA[1], S. KABASHIMA[1], M. ONODERA[1], K.-I. TSUTSUI[1], M. WITTER[2], T. IIJIMA[1];
[1]Tohoku Univ. Grad Sch. Life Sci., Sendai, Japan; [2]NTNU, Trondheim, Norway

Abstract: The entorhinal cortex, which constitutes the major gateway between the hippocampus and the neocortex, can be subdivided into two domains: the medial and lateral entorhinal cortices (MEC and LEC). MEC is known to be involved in spatial navigation, while LEC is thought to concern with processing information of various types of sensory modalities. These functional differences are mainly attributed to the differences in the input-output connectivity of these two cortices. Although previous studies have examined the connectivity of entorhinal cortex in detail, the difference in the connectivity of specific neuron types in these two cortices has not been addressed in detail. Here we focused on the calbindin-positive neuron (CB+ neuron) located in layer II of the entorhinal cortex.
Calbindin (CB) is a calcium binding protein, which is localized in various forebrain area implicated in learning and memory. CB may play a role in synaptic plasticity, as reduced amount of CB caused impairment in spatial memory and deficit in maintaining long-term potentiation in the hippocampus. Recent studies have shown that the CB+ neurons in MEC show grid firing patterns, and are related to temporal-association memory. Interestingly, it also has been reported that there are differences in the distribution patterns of CB+ neurons between MEC and LEC (Gianatti et al., 2015). In rats, the MEC CB+ neurons intermingle with the dentate gyrus-projecting neurons (reelin-positive neurons) in layer II, while the LEC CB+ neurons localize exclusively deep to the Reelin-positive neurons in layer IIb (also referred to as layer IIIa in our previous study). In this study, we examined the projection of the CB+ neurons, and compared the connectivity of CB+ neurons in MEC and LEC. A retrograde tracer (fluorogold) was injected into either the hippocampus (dentate gyrus, CA3, CA1, subiculum), extrahippocampal regions (medial prefrontal cortex, insular cortex, piriform cortex, nucleus accumbens, amygdala), or the entorhinal cortex itself, and the distribution of the retrogradely labeled CB+ neurons were examined in the entorhinal cortex. We found that there are connectional differences between the MEC and LEC CB+ neurons. A substantial percentage of MEC CB+ neurons projected to the hippocampus and a comparable proportion projected to the LEC. In contrast, LEC CB+ neurons preferentially targeted the extrahippocampal infralimbic cortex, rather than the hippocampus. LEC CB+ neurons also showed strong intrinsic connections targeting the MEC. These anatomical differences of the MEC and LEC CB+ neurons might underlie the functional difference between the MEC and LEC.

Title: Cholinergic modulation of neuronal network activity in the entorhinal cortex

Authors: S. DESIKAN[1], D. E. KOSER[1,2], A. NEITZ[1], *H. MONYER[3,1];
[1]Clin. Neurobio., German Cancer Res. Ctr., Heidelberg, Germany; [2]Clin. Neurobio., Univ. of Heidelberg, Heidelberg, Germany; [3]DKFZ / A230, Heidelberg, Germany

Abstract: For decades the medial septum and the diagonal band of broca (MS/ DBB) have been considered the pacemaker of hippocampal and entorhinal cortical theta activity. The septo-entorhinal pathway mainly comprise glutamatergic, cholinergic and GABAergic long-range projections. The functional aspects of glutamatergic and GABAergic long-range projections have been studied, while the contirbution of septal cholinergic projections to entorhinal cortex (EC) remains elusive. *In vitro* investigations using bath-application of cholinergic receptor agonists, or electrical stimulation to release endogenous acetylcholine (ACh), have shed light upon cholinergic function within EC, but questions remain because of the lack of selectivity and specificity of these techniques. On the basis of these premises, the following pressing questions arise: How do cholinergic projections from MS/ DBB contribute to the recruitment of neurons in EC? What is the mechanism by which they do so?
To investigate whether MS/ DBB cholinergic neurons innervate specific layers and cell types in the EC, we trangenically expressed mCherry and channelrhodopsin-2 in septal cholinergic neurons and utilized *in vitro* patch-clamp recordings in acute brain slices to determine postsynaptic target cells in EC. Anterograde axonal tracing from MS/ DBB revealed extensive cholinergic innervations in the superficial layers (LI-III) of medial and lateral EC. Following optogenetic stimulation of MS/ DBB axons in LI-III of EC, we observed fast monosynaptic nicotinic receptor mediated excitatory post synaptic currents and slow membrane depolarizations mediated by muscarinic receptor activation. By demonstrating functional information regarding cholinergic projections from MS/ DBB, this study will contribute to a better understanding of temporally coordinated neuronal activity within the EC.

Title: Cellular evidence for the lack of contribution of CA1 and CA3 to familiarity and the selective involvement of the deep layers of the perirhinal and lateral entorhinal cortices

Authors: *E. ATUCHA TREVINO[1], A. KAREW[2], T. KITSUKAWA[3], M. SAUVAGE[1]; [1]Functional Architecture of Memory, Leibniz Inst. For Neurobio., Magdeburg, Germany; [2]Ruhr Univ., Bochum, Germany; [3]Osaka Univ., Osaka, Japan

Abstract: Recognition memory relies on two memory retrieval processes, recollection and familiarity. Recollection reflects the retrieval of specific information about events whereas familiarity is described as a vague feeling of déjà vu. While it is well-accepted that the hippocampus supports recollection, it is still unclear whether it also supports familiarity or whether the parahippocampal region, especially the perirhinal (PER) and lateral entorhinal cortices (LEC), does. One of the reason why this remains elusive is the low accessibility, in humans, to imaging techniques with spatial resolution high enough to dissociate the source of activity among adjacent brain regions. Importantly, studies in rodents have brought evidence for a functional segregation of the hippocampal subfields CA1 and CA3 along their proximodistal and longitudinal axes as well as between the PER and the LEC and their deep and superficial cell layers, but their contribution to familiarity has not been studied yet. Here, we combined an odor memory task yielding judgements based on familiarity with high resolution molecular imaging involving the detection of the immediate early gene Arc and mapped cellular activity in these areas. We report that even the ventral part of CA1 and CA3, thought to process the most odor stimuli, failed to be recruited while the deep layers of the PER and the LEC, believed to contribute to more cognitive processes than their superficial layers, were. These data provide robust cellular evidence for the lack of contribution of the hippocampus to familiarity and for the engagement of the parahippocampal region during this process.

Title: Entrainment without boundaries: thalamocortical mechanisms of parsing and grouping complex auditory patterns

Authors: *A. BARCZAK[1], M. N. O'CONNELL[1], T. MCGINNIS[1], D. ROSS[1], P. LAKATOS[1,2]; [1]Nathan S. Kline Inst. For Psychiatric Res., Orangeburg, NY; [2]Psychiatry, New York Univ. Sch. of Med., New York, NY

Abstract: Previous studies have shown that ongoing neuronal oscillations across multiple levels of the auditory pathway can entrain to rhythmically structured auditory stimuli. Since our auditory environment is composed of a continuous flow of complex, multi-timescale information (e.g. speech/species specific communication), inputs must be parsed and grouped into blocks so that they can be further processed and interpreted by lower- and higher-order regions, respectively. Our study aims to explore the neural mechanism for the perceptual parsing and grouping of repeating complex random tone sequences amid a continuous flow of auditory stimuli. Human psychophysical studies suggest that the recognition of novel auditory patterns occurs automatically about halfway through the first repetition. We hypothesized that if low frequency neuronal activity plays a role in parsing, this activity would be entrained or synchronized in frequency and phase to the repeating patterns, which would result in an increase in delta phase concentration during the first repetition. To examine pattern-related thalamocortical oscillatory effects we used linear-array multielectrodes to record cortical laminar and thalamic neuroelectric activity while subjects passively listened to a stream of rapidly presented (20 Hz) pure tones and bandpass noise bursts. At random intervals, and without any physical boundary or pause in the stimulus stream, complex auditory patterns were created by repeating 11 of the randomly presented sounds 5 times. The resulting pattern repetition rate was 1.7 Hz. We found significant delta entrainment to the patterns in most primary auditory cortical areas and some thalamic regions like the medial geniculate nucleus and the pulvinar. Interestingly, entrainment was earlier and stronger in the pulvinar and in the supragranular (rather than infragranular) layers of primary auditory cortex. Based on these observations we hypothesize that a “top-down,” pulvinar to supragranular layer projection might be responsible for the parsing and grouping of complex auditory patterns.

Title: Beat perception induces fluctuations in motor system excitability

Authors: *D. CAMERON[1], J. EVERLING[1], T.-C. CHIANG[1], J. A. GRAHN[2,1];
[1]Brain and Mind Inst., [2]Dept. of Psychology, Univ. of Western Ontario, London, ON, Canada

Abstract: Humans synchronize movements with the perceived, regular emphasis (the beat) in musical rhythms. Neural activity during beat perception is dynamic, time-locked, and heavily based in the motor system. Excitability in the motor system may fluctuate during beat perception, as indexed by the amplitude of motor-evoked potentials (MEPs) evoked by transcranial magnetic stimulation (TMS). In a previous study, MEP amplitude was greater when listeners heard rhythms with a strong beat vs. a weak beat, but only for MEPs elicited 100 ms before the beat, *not* for MEPs elicited at random time points relative to the beat (Cameron, et al., 2012). Thus, motor system excitability may not be uniform across the entire rhythm, but instead may fluctuate, rising at particular times on or before the beat. Here, we sought to characterize the dynamics of motor system excitability during beat perception, using MEP amplitude as our index of excitability. Participants (n=23) listened to strong beat, weak beat, and nonbeat auditory rhythms (35s each). During each rhythm, TMS was applied to left primary motor cortex at 100 time points spread across the entire the beat interval. MEP amplitudes were recorded with electromyography from the right hand (first dorsal interosseous muscle). To measure fluctuations in excitability, linear and cosine functions (the latter for frequencies corresponding to 1, 2, and, 4 times the beat rate) were fit to MEP amplitudes and compared across rhythm types. Motor system excitability dynamics differed for strong beat vs. weak beat and nonbeat rhythms: Excitability increased linearly over the beat interval (in anticipation of upcoming beat positions) in strong beat rhythms, but not in weak or nonbeat rhythms. Additionally, excitability fluctuated at the rate of individual events (the beat rate subdivided by four) to a greater extent in strong beat rhythms than in weak and nonbeat rhythms. These results suggest that during beat perception, motor system excitability 1) anticipates upcoming beats, and 2) tracks subdivisions of the beat.

Title: Sensory expectation of time and space is modulated by task relevance: evidence of neural and behavioral effects from model-based MEG

Authors: *R. AUKSZTULEWICZ[1,2,3], K. FRISTON[3], A. NOBRE[2];
[1]Dept. of Psychiatry, [2]Oxford Ctr. for Human Brain Activity, Univ. of Oxford, Oxford, United Kingdom; [3]Wellcome Trust Ctr. for Neuroimaging, Univ. Col. London, London, United Kingdom

Abstract: Although the notion that the brain generates internal predictions to optimize behavior is now well established, it is unclear to what extent these predictions are modulated by current task demands. Here we tested whether expectations of different stimulus features (location and latency) can be independently learned in a dynamically changing environment, and whether task relevance of specific predictions modulates their encoding and updating. In the experimental paradigm, healthy participants (N=20) were asked to discriminate location or latency of visual targets which could appear in either hemifield and either early (~0.8s) or late (~1.2s) following an auditory cue. Unknown to the participants, cue features (pitch and composition) could independently predict the location and latency of the target with varying validity (90%, 70%, or 50%). Alternating blocks of task relevance (location or latency discrimination) were administered during MEG data acquisition. To analyze the effects of expectation and relevance on oscillatory neural activity, we used convolution modeling for induced responses, with regressors coding for cue, target, and response onsets as well as nuissance variables (e.g. eye movements and pupil size). Further, we modelled reaction time data using a Hierarchical Gaussian Filter (HGF) model to infer single-trial estimates of predictions and prediction errors at various levels of stimulus processing. Using these estimates of individual participants' behavior as additional regressors in the MEG analysis, we inferred the effects of predictions and prediction errors on induced activity. Sensor-level MEG analysis revealed that in both temporal and spatial tasks, gamma (30-48Hz) power induced over temporal sensors by auditory cues increased with predictability strength, independent of its relevance. Crucially, frontal alpha (8-13Hz) desynchronisation induced by visual targets increased with the strength of both spatial and temporal expectations only when they were relevant for the task, mimicking behavioral effects on discrimination accuracy. A model-based source-space analysis, using the trial-by-trial HGF regressors, indicated that target-induced gamma activity in the visual cortex reflected precision-

weighted prediction errors rather than predictions about the upcoming stimulus. These results provide novel evidence for modulatory effects of task relevance on learning and utilizing internal predictions in a dynamic context.

Title: Are humans aware of their timing errors: Temporal error monitoring

Authors: *B. AKDOGAN, F. BALCI;
Psychology, Koc Univ., Istanbul, Turkey

Abstract: One of the core features of human and animal timing ability is that time intervals can be judged with high average accuracy but with limited precision. For instance, when participants are asked to repeatedly reproduce a time interval based on their subjective experience, their reproduction times will form a nearly Gaussian distribution with a mean equivalent to the target interval and manifest substantial variance around the mean. This phenomenon indicates that some of our temporal judgments are deviations from the target times, which can be referred to as timing uncertainty. Although recent work suggests that the degree of timing uncertainty can be accessible to the decision-maker, whether and how humans can monitor trial-based errors in their timing behavior constitutes an understudied topic. Therefore, in four complementary experiments, we investigated whether individuals know if and to what extent they are early or late with respect to a target duration in an individual trial. Specifically, participants were tested in the temporal reproduction task and were then asked to judge the accuracy of their temporal estimates in the absence of explicit feedback. After each reproduction, they were prompted to rate their confidence in their temporal estimates and to indicate whether they under- or over-reproduced the target interval. The results revealed an inverse relationship between confidence ratings and the degree of temporal deviations, such that the participants reported lower levels of confidence with the increase in the divergence in their temporal estimates from target intervals. Furthermore, it was shown that participants successfully distinguished whether their

reproduction times were shorter or longer than the target intervals. These findings suggest that humans are able to monitor not only the magnitude but also the direction of the errors in their temporal judgments at a level indicating a clear *temporal error monitoring* ability.

Title: Hemispheric asymmetries in the temporal processing of spatial targets

Authors: *R. XU, L. WELCH;
Cognitive, Linguistic and Psychological Sci., Brown Univ., Providence, RI

Abstract: Multiple lines of evidence suggest an asymmetry in the time-course of perceptual processing between the two visual fields. For example, recent behavioral (Matthews et al, 2013), electroencephalography (Verleger et al, 2011) and rTMS (Verleger et al, 2010) research describe a processing advantage for targets in the left visual field (LVF). This advantage is thought to reflect differences in the initial allocation of attention, with compensation that occurs in later stages of processing to prevent the false perception that with simultaneous events, the right event lags the left. However, it is unclear whether observation of an LVF advantage can be partially attributed to early sensory features of an object that captures attention in an involuntary manner because previous studies employed target pairs that differed in color. To test whether there are inherent functional differences in visual processing between the two hemispheres, we removed the color difference between target pairs while preserving other experimental features. Eighteen young adults were asked to judge the simultaneity (SJ; did the two targets appear at the same time?) and temporal order (TOJ; was the first target an odd number?) of two targets in two rapid serial visual presentation (RSVP) displays. The two RSVPs were presented simultaneously, one in LVF and the other in RVF, and each contained one black numeric target embedded in a stream of black letter distractors. Consistent with previous findings (Matthews et al., 2013), our results demonstrate a clear temporal advantage for left targets in the TOJ, but not SJ, task. These results show that the LVF advantage found previously does not depend on target pairs differing in low-level saliency (color). A comparison of the perceived subjective equality (PSE) for the odd-numbered target presented to LVF and to RVF revealed the magnitude of the perceived-timing difference to be ~190ms, comparable to two cycles of attention's reported temporal resolution (Rogers-Ramachandran & Ramachandran, 1998). Since retinal stimulation during the two tasks

was identical, we cannot make any stimulus-driven interpretations for the TOJ v SJ task differences. This suggests that subjects perceived left targets significantly sooner than right targets during the temporal order task, but compensated for this difference in their simultaneity judgments. We argue that judgments of simultaneity and temporal order may rely on different neural mechanisms, and the visual field asymmetry observed for the TOJ cannot be attributed to having targets with different perceptual saliencies.

Title: Hyperscanning study on synchronized singing between two people using fNIRS

Authors: ***N. OSAKA**[1], T. MINAMOTO[2], K. YAOI[1], M. AZUMA[3], M. OSAKA[3];
[1]Kyoto Univ., Kyoto, Japan; [2]NICT Cinet Osaka Univ., Suita, Japan; [3]Osaka Univ., Suita, Japan

Abstract: Our brain have been developed to communicate with others, however it seems unclear how our brain achieves interactive communication. Here, we report the neural synchronization for singing and humming between two people, simultaneously measuring two brain activities using an fNIRS-based hyperscanning . Using a functional near-infrared spectroscopy (fNIRS), brain activity of two peoples was measured while they performed a cooperated humming or singing with face-to-face and face-to-wall (preventing them from observing other's face by a wall). The results showed a significant increase in the neural synchronization in the left inferior frontal cortex (IFC) in both the singing and humming regardless of existence of the wall, in comparison to the single singing/humming. On the other hand, the right IFC showed an increase in the neural synchronization during humming but not singing, possibly due to higher dependence on musical processing. Those results suggest a usefulness of the fNIRS-based hyperscanning in natural social interaction.

Title: Rhythm processing deficits in nonfluent variant primary progressive aphasia relate to atrophy of the supplementary motor area

Authors: *J. SCHAEVERBEKE[1], M. GRUBE[2,3], R. BRUFFAERTS[1,4], V. NEYENS[1], E. DRIES[4], T. GRIFFITHS[2], R. VANDENBERGHE[4,1];
[1]KU Leuven, Leuven, Belgium; [2]Newcastle Univ., Newcastle, United Kingdom; [3]Tech. Univ. of Berlin, Berlin, Germany; [4]UZ Leuven, Leuven, Belgium

Abstract: Primary progressive aphasia (PPA) patients exhibit deficits in processing of rhythm and timing of sequences of non-linguistic acoustic stimuli, in particular the non-fluent variant (NFV) of PPA (Grube et al, 2016). The current study aimed to determine the neuroanatomical basis for these deficits. A consecutive case series of 17 PPA patients (65.7 ± 8.8 years) (four logopenic variant (LV), six NFV, seven semantic variant (SV)) and 22 cognitively intact controls (63.8 ± 6.5 years) participated. All participants underwent a T_1-weighted MRI, which was analyzed using voxel based morphometry (VBM, SPM8), and completed a psychoacoustic test battery including four rhythm tasks (single time-interval duration discrimination; isochrony deviation detection; strongly and weakly metrical pattern discrimination). The outcome measure for each of the tasks was the threshold obtained by adaptively adjusting the difference between reference and target stimuli. For each task, a voxel-wise linear regression was conducted between modulated cortical gray matter (GM) and task performance, with age and gender as nuisance variables. The significance threshold was set at voxel-level uncorrected $P<0.001$ and cluster-level family wise error (FWE)-corrected $P<0.05$, and Bonferroni-corrected for the number of regressions (n=4). In PPA patients, performance on strongly metrical pattern discrimination correlated with GM loss in the left supplementary motor area (SMA) and the medial wall of the superior frontal gyrus ($P_{FWE\text{-}corrected}= 0.04$, 829 voxels, $Z=4.73$; -18, 5, 66;

Z=4.28; -6, 20, 60). Patients who were more impaired on discrimination of strongly metrical patterns had less GM in this cluster (rho=-0.94). No other significant correlation was found in the PPA group, and no significant correlation was found in the controls. Atrophy of SMA may be causally involved in both the rhythm processing deficits and in the characteristic non-fluent speech apraxia, which is a core criterion of NFV PPA. This finding is consistent with the SMA playing a key role in one shared sensory-motor timing system that is relevant for speech production and rhythm perception.

Abstract: Disrupted midbrain dopamine contributes to cognitive symptoms of PD. Past work has implicated frontal neurons expressing D1 dopamine receptors (D1DRs) in temporal processing; here we investigate if these neurons are sufficient to compensate for midbrain dopamine dysfunction. We study elementary cognitive processing using an interval timing task. This task requires subjects to estimate a brief interval of time over several seconds. Interval timing is ideal to study cognitive function depends on dopamine, involves executive functions such as working memory and attention to time, involves similar neuronal processing in humans and rodents, and is consistently impaired in human diseases involving dopamine. Animals with depleted dopamine in mesocortical circuits showed impaired interval timing. We report three main results. First, both PD patients and mice with disrupted midbrain dopamine have attenuated

delta activity (1-4 Hz) in the medial frontal cortex (MFC) during interval timing. Secondly, MFC neurons expressing D1DRs had distinct patterns of neuronal activity and optogenetically stimulating these neurons facilitated temporal processing by MFC neurons. Finally, stimulating MFC D1DR neurons specifically at delta frequencies (2 Hz) rescued deficits in temporal control of action caused by disrupting midbrain dopamine. Our results suggest that cortical networks can be targeted to improve dopamine-dependent cognitive processing.

Title: A Synergistic model of the cerebellum and the basal ganglia for temporal information processing

Authors: ***O. KATAKURA**[1], T. YAMAZAKI[1,2];
[1]Grad. Sch. of Communication Engin. and Informatics, The Univ. of Electro-Communications, Tokyo, Japan; [2]Artificial Intelligence Res. Center, AIST, Tokyo, Japan

Abstract: Timing perception is an essential sense for our living. Despite of its importance, the neural mechanisms remain unclear. Many lines of studies have suggested that at least, the cerebellum and the basal ganglia play critical roles in temporal information processing. It is thought that the cerebellum processes less than 1 second for precise motor control, and the basal ganglia processes more than 1 second for more cognitive tasks. In particular, electrophysiological studies have shown that in time reproduction tasks, the cerebellum and the basal ganglia exhibit different temporal profiles of their neuronal activity patterns, suggesting that these two areas work together synergistically to represent the passage of time, which is proposed as a relay hypothesis (Tanaka et. al. 2013). In this study, we built a simple model of the cerebellum and the basal ganglia by extending internal clock models (Yamazaki and Tanaka 2005). We modeled the granular layer (GL, the network between the granule cells and the Golgi cells in the cerebellum) and the network between the external globus pallidus (GPe) and the sub-

thalamic nuclei (STN) as internal clocks. These neurons became active and inactive in turn with time, and the populations of active neurons represent time. On the other hand, the other components including the cortex (Ctx), the striatum (Str), the internal globus pallidus (GPi), the thalamus (Tha), the pontine nuclei (PN), the Purkinje cells (Pkj), and the cerebellar nuclei (CN), were simplified as single neurons. We modeled the direct, indirect, and hyper-direct pathways of the cortico-thalamo-cortical system and the cortico-cerebellar system. Each internal clock had plasticity on the synapses from GL to Pkj and those from STN to GPi, respectively. After repetitive training to learn the passage of time, activities of the CN and Tha showed peaks at the learned timing. The activity of CN showed narrow peak, that is, the activity increased just before the learned timing. In contrast, that of Tha shown wide peak, that is, the activity increased constantly from the onset to the learned timing. These results imply that the cerebellum could encode short and precise timing and the basal ganglia could encode long and broad timing, supporting a relay hypothesis on the representation of time by the cerebellum and the basal ganglia. The cortico-thalamo-cortical recurrent system and cortico-cerebellar system could cause interplay between the cerebellum and the basal ganglia.

Title: Interval timing in adult stutters - Role of beta connectivity in default mode-related functional segregation.

Authors: A. GHADERI[1], M. NAZARI[1], *W. H. MECK[2];
[1]Psychology, Univ. of Tabriz, Tabriz, Iran, Islamic Republic of; [2]Duke Univ. Dept. of Psychology and Neurosci., Durham, NC

Abstract: Stuttering is a speech disorder related to deficits in motor control across time and abnormal movement planning or preparation. It is associated with frequent interruptions and pauses in speech, particularly at the beginning of words and sentences, leading to unplanned sound prolongations. Evidence suggesting timing impairments in stuttering includes anomalies within the basal ganglia dopaminergic system and abnormal beta oscillations in the putamen, both of which share a close association with interval timing. Moreover, altered topological properties of brain connectivity networks have emerged as an important feature of neurological dysfunction and altered time perception. Consequently, the aims of this study were to establish

the nature of the interval timing deficit in adult stutters using an auditory, duration-discrimination task reliant on a maximum likelihood procedure. Sub-second (250-ms) and supra-second (2.5-s), 1kHz pure tones were used as baselines in a three-alternate forced choice task. Independent thresholds were generated three times using 30 trial blocks for each base duration. Following this, we recorded EEG activity in participants during a resting state or default mode. A graph theoretical analysis was applied to the EEG data in order to investigate the brain's topological properties in stutterers compared to controls. EEG coherence in different frequency bands was used as edges and various thresholds were applied and binary adjacent matrices were created. Finally, clustering coefficients and global efficiency scores were used to report functional brain segregation and integration in the stutterers compared with normal participants. These results show that individuals who stutter (n=18) exhibit impairments in their temporal discrimination thresholds for both sub-second and supra-second auditory durations compared to controls (n=18). Furthermore, stutterers exhibit an abnormal functional brain connectivity network in both the standard beta band (12.5-25 Hz) and the high beta band (25-30 Hz). Consistent with previous findings, this beta band abnormality occurred during resting state brain activity indicating a deficit in the default-mode network. Both clustering coefficient and global efficiency measures were impaired in stutterers. Overall, our results suggest that, in the beta band (12.5-30 Hz), individuals who stutter exhibit a decreased level of functional integration and increased modularity that directly contributes to the observed deficits in timing and time perception. These findings are discussed within the context of the striatal-beat frequency model of interval timing.

Title: Prefrontal-subthalamic delta/theta coherence shapes temporal processing during interval timing

Authors: *R. KELLEY, J. GREENLEE, N. NARAYANAN;
Univ. of Iowa, Iowa City, IA

Abstract: Prefrontal networks may control subthalamic neurons via the hyperdirect pathway-- a monosynaptic projection from frontal cortex to the subthalamic nucleus. This pathway has the potential to powerfully influence cognitive processing. We used an interval-timing task to study PD-related cognitive dysfunction in human STN-DBS patients and in mice. During human STN-DBS implantation, we simultaneously recorded from STN (LFP) and PFC (EEG) while subjects performed an interval-timing task. Our data show low-frequency power bursts in both STN and PFC that align to the onset of interval-timing. Granger connectivity analysis of neural recordings demonstrates sustained top-down signaling between PFC to STN consistent with hyperdirect pathway-mediated temporal processing. We also found that single STN neurons could be modulated during timing tasks. Finally, we tested the hypothesis that low-frequency STN-DBS could rescue impaired interval timing performance. Our preliminary data indicate that 4 Hz STN DBS can improve time estimation. Our results suggest that the STN is a key integration site for temporal processing. This may point to a rapidly-translatable treatment strategy for cognitive symptoms of PD that extends the clinical applications of STN-DBS.

Title: The influence of frequency on perceived temporal rate is larger in demanding listening situations

Authors: *B. HERRMANN, I. S. JOHNSRUDE;
Dept. of Psychology, The Univ. of Western Ontario, London, ON, Canada

Abstract: Acoustic features co-vary in natural environments (e.g., a sound's pitch changes with changes in the sound's temporal rate). Such structural covariations provide redundancy in fast-changing, acoustically complex soundscapes and might support hearing in difficult listening situations. The current study investigated how changes in frequency induce (illusory) temporal rate change percepts. The illusion is thought to arise from expectations matching the learned

structural covariations in natural acoustic environments. However, it is unknown whether reliance on learned structural covariations depends on situational task demands or whether structural covariations are stably utilized. Here we ask whether the magnitude of the perceptual illusion increases in unpredictable listening situations and when perception occurs under distraction.
Participants listened to amplitude-modulated sounds with modulation rates (~5 Hz) either decreasing or increasing over time, and identified the direction of the rate change. Sounds also either decreased or increased in carrier frequency (~1300 Hz) over time, but participants were instructed to ignore such changes. Experiment 1 confirmed that perception of the sound's temporal rate was biased by frequency such that sounds were perceived as speeding up when frequency increased and as slowing down when frequency decreased (temporal rate-change illusion). In experiments 2 & 3, frequency and temporal rate changes were small or large, and participants were cued either to expect an easy or difficult rate change (Exp2) or frequency change (Exp3), or were given an uninformative neutral cue. The magnitude of the illusion increased when participants were uninformed (neutral) about the difficulty of the upcoming sound. In experiments 4-6, participants listened to the amplitude-modulated sounds and performed a congruent distractor task at different difficulty levels. Memory load in the distractor task (Exp4 and Exp5) only weakly affected the illusion magnitude, whereas the illusion magnitude increased with increasing number of objects to be tracked in a multiple object tracking task (Exp6).
In sum, when the difficulty of a sound's temporal rate change is unpredictable or sound perception is demanding because of a congruent distractor task, the influences of frequency changes on a sound's perceived temporal rate change are increased, leading to a magnified illusion. The results suggest that in difficult listening situations, listeners might rely more strongly on learned structural covariations for sound perception than in less demanding situations.

Title: Regulation of electrophysiological surprise responses by temporal ordering

Authors: *M. SCHWARTZE, S. A. KOTZ;
Maastricht Univ., Maastricht, Netherlands

Abstract: Adaptation to a dynamic environment requires adequate reactive and predictive adjustments of behavior, potentially reflecting a neurocognitive bias to minimize surprise by maximizing expectations about changes in the environment. The efficiency of predictive adjustments of behaviour depends in part on the ability to exploit temporal information in order to tune into the course of events in the environment. In the current study we used three fundamental temporal ordering principles (isochrony, proximity, periodicity) to investigate their impact on the time-course, size, and topographical distribution of two electrophysiological markers of neurocognitive behaviour. The P50 and P3b components of the event-related potential of the electroencephalogram (EEG) were obtained from 24 participants who listened to sequences of 320 pure tone pairs consisting of equidurational (300 ms) 512 standards (600 Hz) and 128 pseudorandomly interspersed deviants (660 Hz) while they counted the deviants embedded in each sequence. Whereas the P50 has been linked to sensory gating (i.e., the gating out of old relative to new information), the P3b has been directly associated with an element of surprise and the updating of a mental model of the environment in response to a change. Results indicate that the temporal ordering principles tested can be used separately and in combination to step-wise down-regulate the P50 component (amplitude suppression) and to up-regulate the P3b component (amplitude enhancement). This pattern suggests that temporal ordering principles offer a means to systematically modulate, and thereby potentially also to optimize, the quality of basic sensory and more complex forms of perceptual neurocognitive behavoir.

Title: Temporal averaging: geometric or arithmetic mean.

Authors: *Y. REN, Z. SHI;
Ludwig-maximilians-Universität, Muenchen, Germany

Abstract: Efficient encoding of information is essential to sensory system, especially for processing dynamic and complex sensory inputs. Over the past decades, extensive work has shown that we are able to summarize statistical properties, such as averaging, of various features (e.g., positions, orientations, speeds and frequencies) for a given group of objects both in visual and auditory modalities. However, to date little is known what type of averaging statistics has been used in temporal perceptual coding. To be more specific, we aim to identify whether a linear or logarithmic encoding is used for representing the mean of temporal intervals. To investigate this issue, here direct estimations of temporal intervals from both auditory and visual modalities were measured by asking participants to compare the average duration of a sequence of intervals to a single probe interval. Three sets of intervals (A, B, and C) were used for testing, where the arithmetic and geometric mean of the sequences were as follows: the arithmetic mean of sequence A was equal to that of sequence B (0.8s), but greater than the value of sequence C(0.725s), while the geometric mean of sequence A was equal to that of sequence B (0.710s) but smaller than the value of sequence C(0.789s). The results showed overall estimations of 0.701s, 0737s and 0.683s for the sequence A, B and C respectively, which is consistent with logarithmic averaging. These findings suggest that temporal averaging uses geometric mean as the main statistical summary process, where logarithmic encoded intervals are likely directly averaged before decoding process.

Title: Brain oscillations in perception, timing and action

Authors: *D. S. GUPTA[1], L. CHEN[2,3];
[1]Biol., Camden County Col., Blackwood, NJ; [2]Key Lab. of Machine Perception (Ministry of

Education), [3]Dept. of Psychology and Beijing Key Lab. of Behavior and Mental Hlth., Peking Univ., Beijing, China

Abstract: Catching a thrown ball requires a tight coupling between perception and motor control. In a recent work (Gupta and Chen in: Current Opinion in Behavioral Sciences 2016, 8:161-166), we examined various studies, supporting the proposed multidimensional information processing across various perceptual and motor tasks. In this work, we examined how perception, timing, and action can be understood in terms of the coupling of gamma band oscillations, which represent the local activities of brain circuits, to a specific phase of long-range low-frequency oscillations. We proposed a temporal window of integration that emerges from cross-frequency coupling that serves to produce optimized action. In this poster, we will further look at more studies to understand how the information processing in multidimensional processing domains, resulting from the synchronization of local circuits in brain networks, may form an important basis of the interaction of the brain with the four-dimensional physical world.

Title: Resolving the dopamine paradox in interval timing: How a phasic dopamine release can reset the clock, whereas tonic dopamine fluctuations alter perceived time

Authors: *H. VAN RIJN[1], P. MOSTERT[2], P. A. M. MEDIANO[3], Z. FOUNTAS[3];
[1]Univ. of Groningen, Groningen, Netherlands; [2]Donders Inst. for Brain, Cognition and Behavior, Nijmegen, Netherlands; [3]Imperial Col., London, United Kingdom

Abstract: Typically, interval timing models assume that the subjective perception of time commences by the resetting of an internal clock, irrespective of whether this internal clock is hypothesized to be implemented as an pacemaker, as oscillating neurons, or as other structures that provide a temporally regular signal. Whereas most models are agnostic about the underlying signal that results in the resetting of the internal clock, the Striatal Beat Frequency model, the most prominent neurobiological model of the clock stage, assumes that a phasic release of dopamine resets the phases of clusters of oscillators. Interestingly, dopamine has been shown to have more subtle effects as well: when tonic dopamine levels are pharmacologically manipulated, the subjective experience of time is affected. Although both effects have been reported in multiple studies using multiple paradigms, no explanation has been given that can explain this paradoxical finding that a phasic boost resets the clock, but tonic fluctuations affect the internal clock in subtle but consistent ways (i.e., higher tonic dopamine levels resulting in a faster running internal clock). Here we will present a computational neuroscience model, implemented in BrainStudio (http://brain-studio.org) and based on biologically plausible neuron models, that explains how a phasic dopamine boost can reset an internal clock, but tonic dopamine levels affect the speed by which subjective time passes. By combining this more detailed implementation of the Striatal Beat Frequency model with an integrated process model of interval timing (Taatgen, Van Rijn, Anderson, 2007, Psychological Review, 114(3), 577-598; Van Rijn, Gu, Meck, 2014, Advances in Experimental Medicine and Biology, 829, 75-99), we can explain how the beginning of an interval is triggered, and what neurobiological mechanism explains cognitive and pharmacological distortions on subjective time.

Title: A neural correlate of human time sense

Authors: C. K. DESAI[1], *M. I. LEON[2];
[1]Psychology, California State University, Bakersfield, Bakersfield, CA; [2]Psychology, Cal State Univ, Bakersfield, Bakersfield, CA

Abstract: We measured broadband EEG power from scalp electrodes positioned over the posterior parietal cortex of subjects performing a Go/No-Go temporal bisection task. During practice trials, subjects categorized one of two randomly presented tone stimuli as short or long. Each trial began by cueing the question, “Is it long?” or “Is it short?” At the termination of each tone, subjects decided “Yes” by reaching to depress a choice button, or “No” by remaining still. Experimental sessions included seven additional tones of intermediate durations, with all nine tones being randomly interleaved across trials. Subjects were tested with a short (0.57 sec - 1.74 sec) or a long (1.15 sec - 3.48 sec) set of durations across two different sessions. As the tone increased in duration, subjects demonstrated a greater probability of choosing long. In addition, the neural signal began to reflect the subject’s increasing likelihood of a long decision. The duration at which this first became evident coincided with the subject’s bisection point, where long and short decisions are equally likely. Our findings demonstrate a neural correlate of human time sense.

Title: The links between perceptual timing and language skill in mid- vs. early adolescence: the St Thomas More School Project

Authors: *M. GRUBE[1,2], C. DAVISON[2], F. SMITH[2], S. KUMAR[2], T. D. GRIFFITHS[2];
[1]TU Berlin, Berlin, Germany; [2]Newcastle Univ., Newcastle-upon-Tyne, United Kingdom

Abstract: We have previously tested the relationship between auditory analysis and language skill in children in a series of experiments based on the systematic examination of multiple auditory domains (pitch, time and timbre) from simple features in single sounds or time intervals to complex sequences. The work demonstrated a relationship between pitch or temporal sequences and language skill in a large cohort of eleven-year-old school children [Grube et al: PMID 22951739]. The present study examined the specific relationship between time-sequence and language skill and how this changes over adolescence. Specifically, our previous data from eleven-year-old children demonstrated a relationship between the analysis of short isochronous rhythms and language skill whilst in young adults the analysis of longer more abstract, beat-based timing was important [Grube et al: PMID 24168197]. Here, we examined the relationship of both types of auditory skill and language skill in large cohorts of eleven- and fourteen-year-old children. 237 eleven year olds and 234 fourteen year olds each underwent 3 hours of testing in total (including both auditory and language). The groups represent complete year groups from a non-selective government-funded school. The four timing tasks comprised discrimination of single time intervals, deviation from isochronous rhythm, regularity detection (the ability to detect a 'roughly' regular beat) and metrical rhythm discrimination [Grube et al: PMID 20534501 and 22951739]. Language assessment included rhyme decision, spelling, word reading, non-word reading, rapid automated naming (digits and objects), and spoonerisms. Pairwise correlation analysis was carried out on data from ~ 190 eleven year olds and ~ 200 fourteen year olds. In the eleven years olds a limited but significant and consistent correlation between isochronous sequence analysis and language skills was demonstrated after accounting for non-verbal intelligence [average rho before: 0.23, and after: 0.19; $p < 0.05$, Bonferroni-corrected]. In the fourteen year olds a moderate to large and significant correlation was found between isochronous sequence analysis and language skill [average rho before: 0.33, and after: 0.22; $p < 0.05$, Bonferroni-corrected], and also between regularity detection and language skill [average rho before: 0.31, and after: 0.22; $p < 0.05$, Bonferroni-corrected]. The data confirm an important relationship between rhythmic and language skill consistent with the notion of a 'temporal scaffolding' mechanism common to generic auditory and speech domains. This specific nature of this relationship is not fixed but evolves over adolescence.

Title: Midbrain adaptation may set the stage for the perception of a musical beat

Authors: *V. G. RAJENDRAN[1], J. A. GARCIA-LAZARO[2], N. S. HARPER[1], N. A. LESICA[2], J. W. H. SCHNUPP[3,1];
[1]Univ. of Oxford, Oxford, United Kingdom; [2]Ear Inst., UCL, London, United Kingdom; [3]Biomed. Sci., City Univ. of Hong Kong, Kowloon Tong, Hong Kong

Abstract: It is a well-appreciated ability of humans (and possibly other species) to spontaneously perceive a quasi-periodic pulse in rhythmic sounds such as music. Recent work using electroencephalography (EEG) in humans has revealed a possible neural substrate of beat perception (Nozaradan et al., 2011; 2012). Through an approach termed "frequency-tagging," neural entrainment to the beat is identified as the selective enhancement of beat and meter-related frequencies in the amplitude spectrum of the EEG relative to the prominence of those frequencies in the envelope of the sound. This approach has led to a substantial body of work exploring sensory, motor, and cognitive aspects of beat perception, but sheds little light on where and how beat processing first emerges in the auditory pathway. We recorded from the inferior colliculus (IC) of anaesthetized gerbils in response to a subset of the rhythmic patterns used in these previous EEG studies. When we apply frequency-tagging analysis, the results are inconclusive: population local field potential (LFP) responses from gerbil IC would appear to entrain to beat and meter-related frequencies like in human EEG, but firing rates from single and multi-units at the same recording sites do not. However, time-domain analyses reveal that both LFP and spiking activity show larger responses to sounds occurring on the beat relative to otherwise identical sounds that are not on the beat. We split our 249 single and multi-units into clusters to reveal seven representative classes of neural responses that show characteristic differences in response latencies, strength of onset responses, and sustained activation. These clusters also differ in how suppressed responses become as a result of sounds in recent stimulus past. We quantified this sensory adaptation by fitting an exponential function to response strength as a function of time since the previous sound occurrence, and we find that the asymmetry between beat and non-beat responses is captured sufficiently by predictions based solely on these exponential fits. Together, this suggests that midbrain-level adaptation may play a role in biasing the neural representation of rhythmic patterns to favor the configuration that we as humans eventually perceive as a beat.

Title: The action congruency effect on the feelings of agency

Authors: *R. VASTANO[1,2], T. POZZO[1,3], M. BRASS[2];
[1]Robotics, Brain & Cognitive Sci., Fondazione Inst. Italiano Di Tecnologia, Genova, Italy; [2]Dept. of Exptl. Psychology, Ghent Univ., Ghent, Belgium; [3]Univ. de Bourgogne, INSERM U1093 Cognition, Action et Plasticité Sensorimotrice, Dijon, France

Abstract: Several studies suggest that the awareness and the feeling of control about one's own actions and ensuing effects are due to predictive mechanisms shaping the sense of agency. For instance, we experience a strong sense of agency when the predicted effects of an action match the perceived effects. In this vein, the sense of agency is considered retrospectively, after the action is completed and its consequences are known. However, recently it has been suggested that agency also has a prospective component. One aspect of this prospective component relates the fluency of action selection which prospectively informs our sense of agency.
In this study we investigate whether the awareness of an external stimulus, which affects the action selection and thus the intention-action-outcome flow, modulates the feelings of agency as indicated by the intentional binding effect. To this aim we used the imitation-inhibition task combined with a time estimation task. Participants lifted their index or middle finger in response to a number, while simultaneously observing either congruent (i.e. the same) or incongruent (i.e. the opposite) finger movements of a mirrored right-hand. Their lifting movements caused an auditory effect after a variable delay. At the end of each trial, participants estimated the time between their action and the ensuing effect.
The results show that the incongruent condition elicited a smaller temporal binding effect than the congruent condition. In order to investigate whether this effect was due to observing a congruent or incongruent finger movement, or to interference in general, we investigated intentional binding with a stroop-like task as well. In this task, no finger movements were shown and the participants performed finger lifting movements with a colored target. After their action the same auditory effect was delivered and they performed the time estimation task.
In accordance with a general interference hypothesis, we again found reduced temporal binding

in the incongruent condition. This effect presumably depends on the experience of conflict that disrupts the normal flow of information from intention, to action, to outcome elicited by the incongruent conditions. The influence of congruency on agency therefore does not depend on a specific type of stimuli.

Title: Temporal expectation biases duration judgment

Authors: ***T. W. KONONOWICZ**, V. VAN WASSENHOVE;
CEA, NeuroSpin Center, INSERM, Univ. Paris-Sud, Gif S/ Yvette, France

Abstract: Timing processes in humans are typically classified into implicit and explicit timing: explicit timing requires explicit usage of the temporal dimension to estimate duration of a given time interval. On contraire, implicit timing entails the use of the temporal dimension to create temporal expectation with respect to the upcoming stimulus. The simplest form of temporal expectation is linked to the buildup of anticipation informed by the hazard rate function, that is the probability that an event will occur given that it has not yet occurred. As temporal expectation is known to affect sensory processing, we set out to test how temporal expectation affects duration perception in order to address the interplay between implicit and explicit timing processes which are rarely considered.
We asked participants to discriminate time intervals while recording brain signals using combined EEG and MEG. On each and every trial the standard duration (860ms) was presented, followed by the presentation of the comparison interval (770, 860, 950ms; 10%, 80%, 10% of all trials respectively). Crucially, the inter-stimulus intervals (ISI), that is interval between the SI offset and the CI onset, were uniformly distributed which allowed participants to build up a steady anticipation function with regard to the occurrence of the comparison interval, as evidenced by the proportion of ‘short’ and ‘long’ responses. To investigate how the expectation of the comparison interval affects duration perception, we split trials according to their short and long ISI (‘early’, ‘late’). Within these two groups we investigated differences in the oscillatory power and inter-trial coherence (ITC) between trials subjectively perceived as ‘short’ and ‘long’.

For the ‘late’ trials the processing of the comparison interval has been associated with the modulation of alpha and beta power, and the modulation of the ITC, predominantly in the theta band. Specifically, the trials perceived as long exhibited larger alpha and beta desynchronization and increased ITC, suggesting increased expectation level in the ‘longer’ trials. Importantly, no difference between the ‘short’ and ‘long’ trials was observed for the ‘early’ trials. Together, these results demonstrate that temporal expectation modulated duration judgments by desynchronization of oscillatory power and enhancement of ITC.

Title: Role of interhemispheric cortical connections in time perception: a case study with agenesis of the corpus callosum

Authors: *M. OKAJIMA[1], A. FUTAMURA[2], M. HONMA[2], M. KAWAMURA[2], Y. YOTSUMOTO[1];
[1]Dept. of Life Sci., The Univ. of Tokyo, Tokyo, Japan; [2]Dept. of Neurol., Showa Univ. Sch. of Med., Tokyo, Japan

Abstract: When we pay attention to the duration of a given event while ignoring other irrelevant events, our perception of the target event duration is susceptible to the other irrelevant distractor events. Our previous study demonstrated that the duration of a target stimulus is perceived as longer in the presence of a flickering distractor stimulus, and that such effect is larger when the position of the distractor is ipsilateral rather than contralateral to the target stimulus. These results indicate that the effect of an intrahemispheric distractor on the perception of the target stimulus duration is greater than that of an interhemispheric distractor.In this study, we examined the perception of the target stimulus duration and the effects of distractors in a split-brain patient. We hypothesized that because of the lack of interhemispheric cortico-cortical connections in this patient, the effects of an interhemispheric distractor would be absent or lesser than those of an intrahemispheric distractor. One patient (ambidextrous, female, 51 years old) with agenesis of

the corpus callosum and age-matched control subjects participated in the experiment. The subjects were instructed to reproduce the duration of the target stimulus while ignoring the simultaneously displayed distractor stimulus. Both stimuli were either stable or flickering at 10 Hz. The results showed that, in the patient, the reproduced duration of the target stimulus was longer when the position of the stable or flickering distractor was contralateral rather than ipsilateral to the target stimulus. In addition, the variance of the reproduced durations was larger when the flickering distractor was contralateral. Such trends were not observed in the control subjects.In the split-brain patient, there was a difference in the effects of interhemispheric and intrahemispheric distractors on the perception of the target stimulus duration. Contrary to our expectations, the interhemispheric distractor impaired the time reproduction task more than the intrahemispheric distractor, especially when the distractor was flickering. These results lead to the following conclusions. First, there is an interhemispheric communications of temporal information even in the absence of the corpus callosum, suggesting the involvement of subcortical areas in temporal information processing. Second, the corpus callosum is necessary to inhibit this interhemispheric interference of temporal information. Finally, the ability to focus on the duration of a certain event is based on the cortico-cortical connections that prevent other simultaneous events from interfering.

Title: Time-perception training modulates fMRI activity in the cortical basal ganglia circuit

Authors: *I. C. SÁNCHEZ[1], H. MERCHANT[2];
[2]Behavioral and cognitive neurobiology, [1]Inst. of Neurobio., Queretaro, Mexico

Abstract: It is well known that intensive training in specific perceptual timing tasks leads to performance improvement and that this improvement can generalize to a different, untrained, timing task. Here, we tested whether training in a perceptual timing task could improve performance during motor timing. We recruited 19 subjects (women and men). Average age was 26.5 years. Participants performed two tasks: The first was a synchronization-continuation task (SCT) that consisted of the presentation of a gray square on a screen that appeared and disappeared at a rate of 850 ms. Participants pressed a button synchronizing their 9 responses to

the appearance of the square (Synch). After the visual cue disappeared subjects had to continue pressing the button at the same pace for other 10 taps (Cont). For the discrimination task (DT), participants had to discriminate between two time intervals of different durations, selecting the longest one. One was a standard interval with a duration of 850 ms and the other was a comparison interval ranging from 566 to 1330 ms. Following the first imaging session where subjects performed the SCT in the magnet, they underwent 7 consecutive days of training in the DT. Imaging was repeated in the 7th day, identically to the first session. For the DT we calculated the discrimination threshold for each subject and day, and fitted a power function to the data. For the SCT, inter-interval variability was calculated and compared between the pre-training and the post-training sessions. We identified the brain regions active during the Synch and Cont. We evaluated differences between pre and post-training sessions and between the phases (Synch and Cont). Analysis of the behavioral data of the Cont showed two distinct groups of participants: A group of Learners (11, L) and a group of Non-Learners (7). Only the subjects that belonged to the L had a significant decrease in its inter-interval variability after training. This clearly reflects that the 850 ms internal representation was improved and this enable the subjects to perform better during the SCT. We found increased BOLD signal during the Cont of the SCT in the L after training in regions: cerebellum Crus I and occipital lobe. We performed a contrast between the Synch and the Cont after training. During the Synch we found activation of: Brodmann Area 44 and 45, anterior intra-parietal sulcus, thalamus, caudate, hippocampus dentate gyrus, occipital lobe (V1, V2, V3 and V4) and cerebellum (Crus I and II). In contrast, we found larger activation during the Cont in the following regions: Supplementary motor area, premotor cortex, right cingulate gyrus, primary somatosensory cortex, primary auditory cortex and insula.

Title: Reversal of tactile temporal order judgment correlates with the phase of posterior alpha rhythm

Authors: *T. TAKAHASHI[1,2], S. KITAZAWA[1,2];
[1]Osaka Univ., Osaka, Japan; [2]Ctr. for Information and Neural Networks (CiNet), Natl. Inst. of Information and Communications Technol., Osaka, Japan

Abstract: The subjective temporal order of tactile stimuli, delivered one to each hand with an interval of 100-300 ms, is often inverted when the arms are crossed but not when they are uncrossed. On the basis of data from behavioral and neuroimaging studies (Yamamoto & Kitazawa, 2001,Takahashi et al., 2013), we proposed a motion projection hypothesis in which the brain reconstructs the temporal order by integrating an apparent motion signal with the hand locations in space (Kitazawa et al., 2008). Because the posterior alpha rhythm reportedly modulates apparent motion (e.g. Valera et al., 1981), our hypothesis predicts that the illusory reversal is also modulated by the alpha rhythm.
To test the hypothesis, we recorded cortical magnetoencephalographic (MEG) activity by using a 160-ch magnetometer from 16 healthy right-handed volunteers, while the participants carried out a tactile temporal order judgment task under the arms crossed condition with a fixed stimulation interval of 100 ms (left-then-right or right-then-left). Because the alpha band signals reportedly consist of a few distinct components, we applied independent component analysis to the MEG data and eventually revealed five independent components that contributed the alpha rhythm: 1) a peri-PO component that has major current sources near the parieto-occipital (PO) sulcus and the precuneus, 2) a calcarine component, 3) a tau component with current dipoles in the bilateral primary auditory cortices, 4), and 5) the right and left mu components with dipoles in the right and left Rolandic areas.
We compared the distribution of the phase of each alpha-band component between trials with correct judgment and those with inverted judgment, and found that the illusory reversal correlated with the phase of the alpha rhythm in the peri-PO component, but not with the others. The rate of inverted judgment increased to 0.51 at a “preferred” phase but decreased to 0.37 at the opposite phase. The peri-PO region including the precuneus has been shown to provide an allocentric coordinate that is implicated for visual stability (Uchimura et al., 2015). Thus the results support the prediction from the motion projection hypothesis, and highlight the importance of the peri-PO alpha component in organizing temporo-spatial perception.

Title: Neural entrainment during beat perception and its relation to psychophysical performance

Authors: *M. J. HENRY, J. A. GRAHN;
The Univ. of Western Ontario, London, ON, Canada

Abstract: The ability to pick up on regularities in environmental stimuli is apparent in infancy and supports language learning, movement coordination, and parsing auditory scenes into "objects". Here, we were interested in the seemingly unique sensitivity humans show to temporal regularities in rhythm: they spontaneously feel a "beat" in rhythmic sequences. In particular, we examined how synchronization of neural oscillations with auditory rhythms might give rise to beat perception, and in turn how entrained neural oscillations might affect psychophysical performance. In the current electroencephalography (EEG) study, participants detected near-threshold targets (changes in spectral bandwidth) embedded in long (~19-s) simple or complex auditory rhythms. Simple rhythms were composed of intervals related by integer ratios (1:2:3:4), and had a regular grouping that resulted in standard and target events always being present at "on-beat" locations given a duple meter. Simple rhythms thus induced a relatively strong sense of a beat. Complex rhythms were also composed of intervals related by integer ratios, but were grouped irregularly and thus did not induce a strong beat percept. We compared EEG spectral power at beat-related frequencies (1.25, 2.5, and 5 Hz, where 5-Hz was the base inter-tone interval) for simple and complex rhythms. We observed significantly stronger spectral power at 1.25 Hz for simple compared to complex rhythms in particular for individuals that were "good beat perceivers" as determined by a behavioral measure of beat-tapping variability. This result indicates stronger subharmonic entrainment for rhythms that gave rise to a strong sense of beat. We did not observe power differences between rhythm types at 2.5 or 5 Hz. We also examined power-envelope fluctuations in the beta (13-30 Hz) frequency band, which have been previously linked to temporal prediction of events comprising isochronous sequences. Beta power fluctuations at 5 Hz (the base inter-tone interval) were stronger for simple than for complex rhythms, suggesting that temporal prediction of upcoming events is sharpened in the presence of a strong beat percept. We found that targets were better detected when beta power increased in anticipation of a target, but that this effect was similar for simple and for complex rhythms. Thus, although beta fluctuations were stronger in the presence of a beat, high beta power was universally beneficial for psychophysical performance. The results provide the first link between electrophysiological correlates of beat perception and the psychophysical consequences of beat perception.

Title: Neural oscillatory entrainment to auditory rhythmic stimuli represents pitch as well as time

Authors: ***A. CHANG**, K. CLAYWORTH, D. J. BOSNYAK, L. J. TRAINOR;
Dept. of Psychology, Neurosci. & Behaviour, McMaster Univ., Hamilton, ON, Canada

Abstract: Neural oscillatory activities in auditory cortex entrain to external temporal regularity. Previous studies have shown that the power of induced beta oscillations (15 - 25 Hz) in auditory cortex entrain to the rate of a presented isochronous tone sequence (e.g. Fujioka et al., 2012), with reductions in beta power following sound event onsets and with the slope of the rebound predicting the onset of the next sound event. Also, the power of beta oscillations prior to the onset of a tone reflects the accuracy of temporal perception (Arnal et al., 2015). However, given that both time and pitch are important dimensions for auditory information, we hypothesize that beta power entrainment co-represents both dimensions prior to an event's occurrence. Our first study aimed to investigate whether beta power entrainment reflects predictions for pitch as well as temporal information. We employed rhythmic auditory oddball sequences containing occasional pitch deviants. The EEG results showed that beta power entrainment is affected by the predictability of pitch changes: (1) beta power entrainment depth prior to the onset of a deviance was reduced when it was unpredicted, and (2) beta power entrainment after a pitch deviant was disrupted by the degree to which it was unpredictable. These results suggest that in addition to predicting when an event will occur, beta power entrainment also reflects predictions of what pitch will occur. The second study aimed to investigate whether the degree of beta power entrainment to an auditory rhythm might also facilitate the perception of pitch information. We employed rhythmic and non-rhythmic auditory oddball sequences and recorded EEG. Participants were required to discriminate whether each deviant pitch was higher or lower than the context pitches. Psychophysical analyses showed higher sensitivity of pitch discrimination (steeper slope of the psychometric function) and shorter response times with the rhythmic

compared to non-rhythmic sequence, suggesting that temporal regularity facilitates pitch perception. The analyses of neural responses are ongoing. Preliminary results indicate that beta entrainment prior to deviance determines the sensitivity of pitch discrimination. Together, our series of studies show that predictions for both time and pitch are represented in dynamic changes in the power of beta oscillations.

Title: Neurofunctional coupling in tactile simultaneity judgment

Authors: T. KIMURA[1], T. KOCHIYAMA[2], T. KURODA[3], M. IWATA[1], H. KADOTA[1], *M. MIYAZAKI[3];
[1]Res. Inst., Kochi Univ. of Technol., Kami, Japan; [2]Brain Activity Imaging Ctr., ATR, Seika-cho, Japan; [3]Dept. of Computer Science, Fac. of Informatics, Shizuoka Univ., Hamamatsu, Japan

Abstract: In this study, we demonstrate the neurofunctional coupling that underlies tactile simultaneity judgment (SJ). Prior to the current study, our research group investigated differences in the neural correlates of tactile SJ and temporal order judgment (TOJ) using fMRI (Miyazaki et al. 2012, SfN 910.03; 2016, Sci Rep 6: 23323). We found that while the TOJ > SJ contrast exhibited stronger brain activation in the left-dominant motor-control network, the SJ > TOJ contrast exhibited stronger activation only in the posterior insula. We hypothesized that the posterior insula plays a role in discriminating tactile simultaneity. Meanwhile, the SJ > TOJ contrast should subtract brain activation involved in the common temporal processing components for SJ and TOJ. In the current study, we conducted fMRI to identify the neural correlates for the whole temporal processes for tactile SJ, using a time-irrespective control task.

During fMRI, participants ($N = 24$) received a pair of tactile stimuli across both index fingers in each trial. The stimulus onset asynchrony was -50 ms (left earlier), 0 ms, or +50 ms (right earlier). The number of driven pins in each tactile stimulator was 2 or 6 [difference in the number of pins: -4 (left greater), 0, or +4 (right greater)]. In two sessions (32 trials/session), the participants judged whether the stimulus onsets were simultaneous between both hands (SJ). In the other two sessions, they judged whether the number of stimulus pins were same (NJ). The SJ > NJ contrast revealed significant activation in the right inferior parietal lobule (IPL)/supramarginal gyrus (SMG) extending to the superior temporal gyrus (STG), and in the right inferior and middle frontal gyri ($Z > 2.58$, $P < 0.05$ FWE corrected at the cluster level). The posterior insula was thus not observed in the SJ > NJ contrast, since the insula was activated in both SJ and NJ. However, psychophysiological interaction analysis exhibited functional coupling between the right IPL/SMG and the left posterior insula with surrounding areas (e.g., STG, inferior frontal gyrus). The results suggest that the posterior insula is involved not only in discriminating tactile simultaneity but also in discriminating more general tactile coincidence. Hayashi et al. (2015, PLoS Biol 13(9); e1002262) indicated that the perceived visual duration is represented in the right IPL. We speculate that the left posterior insula discriminates coincidence of onset timing between tactile stimuli according to tactile temporal intervals represented in the right IPL.

Title: Temporal and numerical magnitude processing: two dimensions, one processing system?

Authors: ***N. SCHLICHTING**, R. DE JONG, H. VAN RIJN;
Dept. of Psychology, Univ. of Groningen, Groningen, Netherlands

Abstract: Magnitudes or quantities of different dimensions (e.g., time, number, speed or space) have been shown to interact when perceived simultaneously. These findings have been interpreted as evidence for a common magnitude system, in which magnitude information from different dimensions are encoded concurrently. Certain ERP-components (e.g., the CNV) and

brain areas (e.g., the SMA) have been linked to the perception of temporal magnitudes specifically. However, it is of yet unclear whether these EEG components are really unique to time perception or reflect the perception of magnitudes in general. In the current experiment, we recorded EEG while participants had to make judgments about duration (*time* dimension) or numerosity (*number* dimension) in a classical comparison task. Stimuli consisted of a series of blue dots appearing and disappearing dynamically on a black screen. Each stimulus was characterized by its duration (i.e., the interval between appearance of the first dot and disappearance of the last dot) and the total number of dots it consisted of. Thus, each stimulus could vary simultaneously and independently in both *time* and *number*. Participants had to judge whether the second stimulus (S2) presented in a given trial was shorter/longer (*time* dimension) or consisted of more/less dots (*number* dimension) than the first stimulus (S1), whereby either S1 or S2 was the standard stimulus with a duration of 1.8 s and consisting of 30 dots. Six different comparison intervals (1.23, 1.49, 1.63, 1.98, 2.18 and 2.64 s) and number magnitudes (20, 25, 27, 33, 36 and 44 dots) were used. Participants were informed in advance whether a judgment on *time* or *number* had to made. Behavioral results show that response accuracy, measured by the Weber Ratio and the Point of Subjective Equality, did not vary across tasks. Thus, the *time*- and *number*-task were successfully equated for difficulty. We will present EEG data analyzed in the time- (ERPs) and (time-) frequency-domain to investigate possible differences or similarities in the neural mechanisms underlying the processing of magnitudes of different dimensions.

Title: Preserved rhythm-based temporal predictions in cerebellar degeneration

Authors: ***A. BRESKA**, R. B. IVRY;
Psychology, Univ. of California Berkeley, Berkeley, CA

Abstract: The ability to time, whether estimating the duration of events or predicting the moment of upcoming events' onsets, is essential for successful interaction with the world. Animal models, imaging, and neuropsychological research have demonstrated a key role for the cerebellum in tasks requiring precise timing, but have also suggested constraints on the

functional domain of cerebellar timing. For example, patients with cerebellar degeneration are impaired in explicit perceptual timing (duration judgments) in the context of discrete events but not rhythms, as well as in motor timing in the context of discrete movements but not circle drawing. These dissociations suggest the hypothesis that, whether timing is perceptual or motor, the cerebellum is not necessary for timing continuous cyclic dynamics, but is essential for timing discrete events.To test this hypothesis, the current study examined the impact of cerebellar degeneration on temporal predictions, which constitute a form of perceptual timing, in rhythmic and non-rhythmic contexts. Each trial consisted of a stream of visual stimuli: a preparatory sequence, a predefined warning signal, and a target that required a speeded response. In the 'Rhythm' condition, the preparatory sequence was rhythmic, with the warning signal and target continuing the rhythm such that they predictably occurred on the beat. In the 'Random' condition, the intervals of the preparatory sequence were jittered in time around the fixed interval of the rhythmic stream, providing no information regarding the time of the target. In the 'Interval' condition, the preparatory stream consisted of two stimuli such that the interval between them was identical to the interval between the WS and the target. This enabled forming temporal prediction based on memorizing this discrete interval, in the absence of a rhythmic context. To prevent predictive motor responding, the target did not appear on in 25% of the trials in each condition (catch trials). Patients with cerebellar degeneration showed no deficit in rhythm-based temporal predictions, with faster responses in the Rhythmic condition compared to the Random condition; the degree of facilitation was similar to that of age-matched controls. The patients also had faster responses in the Interval condition compared to the Random condition, but this effect did not reach statistical significance and was smaller than the benefit demonstrated by the controls. These results support the generalizability of the hypothesis that the cerebellum is not necessary for timing in continuous cyclic contexts, and also the dissociation between rhythm- and memory-based temporal predictions.

Title: Can coordinated movement training enhance scores on tests of cognitive function in older adults?

Authors: *I. A. CREMEN[1], R. G. CARSON[2];
[1]Trinity Col. Inst. of Neurosci., Trinity Col. Dublin, Dublin 2, Ireland; [2]Trinity Col. Inst. of Neurosci., Trinity Col. Dublin, Dublin, Ireland

Abstract: Over the past decade, a vast research literature has emerged dealing with attempts to harness brain plasticity in older adults, with a view to ameliorating cognitive function. Since cognitive training has shown restricted utility in this regard, attention has turned increasingly to interventions that use adjunct procedures such as motor training or physical activity. As evidence builds that these have some efficacy, it becomes necessary to disentangle the characteristics of these interventions that are responsible for gains in cognitive function. In the present study, the mechanisms through which motor training interventions may lead to enhancement of cognitive function were investigated using a behavioural motor training intervention. Forty healthy community dwelling older adults (aged 65 to 90), participated in a randomised, double-blinded intervention. Participants were randomly allocated to a motor training group or an active control group. The intervention consisted of five thirty-minute sessions on consecutive days. The motor training programme was designed to accentuate multisensory integration, spatial planning and the precise coordination of muscle activity. Motor training required incremental improvements in the performance of a complex target acquisition task executed using ballistic movements of the upper limb. An active control group carried out training requiring no movement, but was otherwise equivalent and demanded comparable levels of attention. Cognitive function (motor reaction time and cognitive processing speed) was measured using the Choice Reaction Time Task (CRT) pre- and post-intervention. Both groups showed comparable results in the baseline CRT measures, however only the motor training group improved on measures of cognitive processing speed post-test, as measured by the CRT ($P>0.0156$, $r=0.416$). The active control group failed to exhibit improvements in cognitive processing speed. This result lends support to the notion that interventions emphasising a motor coordination element can lead to improvements on tests of cognitive function.

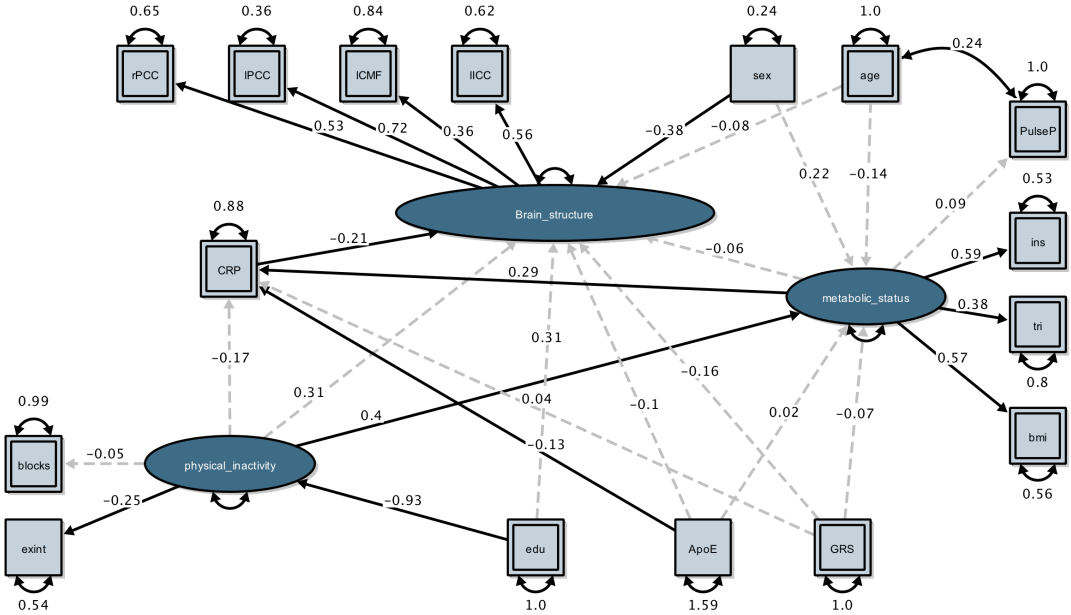
Title: Aging brain structure is related systemic inflammation & metabolic risk factors

Authors: *F. W. CORLIER[1], G. HAFZALLA[1], L. H. KULLER[2], O. L. LOPEZ[3], J. T. BECKER[4], P. M. THOMPSON[1], M. N. BRASKIE[1];
[1]Imaging genetics center, laboratory of neuroimaging, USC, Marina del Rey, CA; [2]Dept. of Epidemiology, [3]Dept. of Neurol., [4]Dept. of Phychyatry, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Systemic low-level inflammation is associated with brain atrophy and neurocognitive decline in Alzheimer's disease (AD) and normal aging. It is vital to know which risk factors trigger inflammation in old age how to prevent irreversible brain damage. Recent genome-wide association studies (GWAS) discovered AD risk polymorphisms in genes related to inflammation and immune function. Here, we investigated whether systemic inflammation mediates the established relationship between genetic and environmental AD risk factors and cortical thickness in AD-sensitive brain regions. We included 209 healthy older adults of European descent with available MR scans at year 9 of the longitudinal Cardiovascular Health Study (CHS).We estimated cortical thickness (cTh) 10 bilateral AD-sensitive brain regions using FreeSurfer. We used multiple linear regression to identify relationships between cTh in each region of interest and year-2 serum C-reactive protein (CRP), a measure of systemic inflammation, controlling for age, sex, education, and *APOE* genotype. Regions whose cTh was significantly associated with CRP included bilateral posterior cingulate, and left middlefrontal and isthmus of the cingulate cortices. We further investigated the significant associations between peripheral inflammation and those significantly related brain regions using a structural equation model (Figure 1) that included *APOE*4, a composite genetic risk score (GRS) of other AD-related genetic variants associated with immune function, physical activity measures and cardiovascular risk. We found that greater inflammation was associated with thinner cortex, (β= -0.21). Greater physical inactivity intensity was associated with higher cardiovascular risk (β=0.40) but not directly to more inflammation, Greater cardiovascular risk was associated with more inflammation (β=0.29). Our results suggest a link between systemic markers of chronic inflammation and cortical thickness. This relationship may partially mediate the effect of cardiovascular risk on brain integrity.



Path diagram representation of the structural model. Quality of fit: RMSEA= 0.007, SRMR=0.049, CFI = 0.997, TLI 0.995. Elipse shaped variables represent latent variables, square shaped variables represent manifest variables. Variables with a double edged case are continuous variables and were scaled prior to analysis.Double arrows represent correlations, and simple headed ones are for regressions. Plain arrows indicate significant loadings, dashed ones indicate relationships not statisticaly significant (Zscore <1.96) but that were takent into account in the overall fit indices.

Brain_structure represents the latent process of cortical thinning apparent through the values of cortical thickness in right (**rPCC**) and left (**lPCC**) posterior cingulate cortices, left isthmus of the cingulate cortex (**lICC**), and left caudal middle frontal (**lCMF**), all four significantly correlated to CRP blood levels in a preliminary multiple regression that controlled for age, sex, education and APOE genotype and adjusted for false discovery rate accros 16 regions evaluated. **Metabolic_status** measures the cardiovascular risk factors apearent through heart pulse pressure (**PulseP**), blood fasting insulin (**ins**) and triglycerides (**tri**), and body mass index (**bmi**). **Physical_inactivity** is inversely related to the number of blocks walked (**blocks**) and intensity (**exint**) of physical exercise performed in the weeks preceding the visit. **edu**, education (in years), **ApoE**, Apolipoprotein E associated risk score (Alzheimer's odds ratio associated to each genotype for individuals of European descent), **GRS**, genetic risk score obtained by cumulating the specific AD-odds related to single nucleotide polymorphysims in *CR1* (rs6701713), *MS4A* (rs670139 and rs610932), *CD33* (rs3865444), *ABCA7* (rs3764650), *EPHA1* (rs11767557), *IL1a* (rs180587), *IL1b* (rs1143634), *CLU* (rs11136000) genes, for individuals of European descent (Alzgene meta-analysis of caucasian studies).

Title: Forced-choice and old/new test formats reveal a stable age-related impairment of performance on the Mnemonic Similarity Task

Authors: *D. J. HUFFMAN[1], C. E. L. STARK[2];
[1]Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA; [2]Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Previous studies from our lab have indicated that healthy older adults are impaired in their ability to mnemonically discriminate between previously viewed stimuli and similar lure stimuli (e.g., Stark et al., 2013, 2015). These studies used old/similar/new and old/new test formats, including a version with confidence ratings. Previous studies have shown that the forced-choice test format (e.g., "Did you see object A or object A' during the encoding phase?") can sometimes yield different results than the old/new test format (e.g., "Did you see this object during the encoding phase?"). Additionally, the forced-choice test format relies on different assumptions (e.g., decision criteria) than the old/new test format; hence, converging evidence from these approaches would bolster the conclusion that healthy aging is accompanied by impaired performance on the Mnemonic Similarity Task. Consistent with our hypothesis, healthy older adults exhibited impaired performance on a forced-choice test format that required discriminating between a target and a similar lure (i.e., A vs A') but not on a format that required discriminating between a target and an unrelated foil (i.e., A vs X). We also tested the hypothesis that age-related impairments on the Mnemonic Similarity Task could be modeled within a global matching framework. Consistent with our hypothesis, we found that decreasing the probability of successful feature encoding in the models resulted in a similar pattern of results to the empirical data. Collectively, our behavioral results extend to the forced-choice test format the finding that healthy aging is accompanied by an impaired ability to discriminate between targets and similar lures, and our modeling results suggest that a diminished probability of encoding stimulus features is a candidate mechanism for memory changes in healthy aging. We will also discuss the ability of global matching models to account for findings in other studies that have used mnemonic similarity tasks.

Title: Management of prospective memory deficits in mild cognitive impairment

Authors: T. HUM-HYDER, *S. A. RASKIN;
Trinity Col., Hartford, CT

Abstract: Mild Cognitive Impairment (MCI) is an intermediate level of cognitive decline that is "greater than expected for an individual's age and education level" (Gauthier et al. 2008). MCI is believed to predict a trajectory towards a later diagnosis of Alzheimer's Disease (AD), which is corroborated by autopsied MCI patients who had neurofibrillary pathology in the entorhinal cortex, hippocampus, and amygdala (Markesbery 2010). Prospective memory is the ability to remember to do something. Using attention processing training, prospective memory training, and Virtual Week, we looked at the potential for attenuation of symptomology for mild cognitive impairment individuals.

Title: Familiar context effects on pattern separation in aging

Authors: A. LAWRENCE[1], *L. RYAN[2];
[2]Evelyn F. McKnight Brain Inst., [1]Univ. of Arizona, Tucson, AZ

Abstract: Research suggests that recognition memory performance declines with age (Yassa et al., 2011). However, recent work in our laboratory indicates that although older adults perform more poorly at object recognition, their recognition is boosted to the same degree as younger adults when the object is presented in the same context at study and test. Older adults may be using relatively spared scene recognition processing to boost recognition of objects presented in a scene. However, other studies suggest that older adults are simply biased by familiar background scene information to falsely recognize a similar object. We tested these two alternative hypotheses using a continuous recognition pattern separation paradigm. Young adults (n=32, mean age=19) and older adults (n=30, mean age= 71) were given three continuous recognition tasks consisting of objects, scenes, and objects in scenes. Participants indicated whether each image in the series was either the same as, similar to, or different from an image they had seen previously. Both younger and older adults performed more poorly recognizing similar scenes and objects in a scene than recognizing similar object on a white background ($t = -2.584$, $p < .01$). Interestingly, both younger and older adults demonstrated significantly greater bias to falsely recognize objects presented in scenes than objects presented on a white background ($t=2.785$, $p<.01$). This suggests that contextual information may be biasing individuals to falsely recognize similar lure objects. These findings also suggest that the degree

to which an individual is biased to falsely recognitize a similar object is not related to age, as has been previously suggested (Gutchess et al., 2007), but rather to the presence of a familiar background context.

Title: The influence of alertness training on visual processing speed in healthy older adults

Authors: *M. PENNING[1,2], P. REDEL[3], H. J. MÜLLER[3], T. SALMINEN[3,4], T. STROBACH[4,5], S. MOELBERT[3,6], T. SCHUBERT[3,4], K. FINKE[3];

Hamburg, Department of Psychology, Germany; [6]Dept. of Psychosomatic Med., Univ. of Tuebingen, Tuebingen, Germany

Abstract: Visual processing speed markedly declines during aging, which is assumed to have significant consequences for independent daily life. Hence, the idea of improving this critical attentional function in older adults seems auspicious. However, in any intervention it is crucial to exactly determine the underlying mechanisms of possible gains, as diverse attentional and motor functions could be involved. Potential benefits should be based on an improvement in the targeted function, i. e. visual processing speed. We investigated the effects of a cognitive training of fast motor responses (the CogniPlus intrinsic alertness training designed specifically for the rehabilitation of neuropsychological patients) on visual parameters assessed ‘purely’ without any

motor confounds on the basis of the Theory of Visual Attention (TVA, Bundesen, 1990). We were especially interested in TVA parameter processing speed *C* in our training group (*n* = 25). To control for unspecific effects, we also tested two demographically matched control groups, an active control group (*n* = 25) performing an unspecific working memory task and a passive (*n* = 25) control group without any training. We found a significant group × training interaction, in which only for the alertness training group, the processing speed *C* was improved, while there was no change in either control group. Hence, the training of fast motor responses enhanced 'pure' visual processing speed in healthy elderly adults. This crucial and specific transfer to the targeted parameter allows for exact conclusions about the underlying neuro-cognitive changes and has important implications for the targeted rehabilitation of cognitive functions.
We will also look at the correlation between processing speed gain and intrinsic functional connectivity.

Title: Medial temporal lobe structure, function, and protein aggregation affect memory encoding in aging

Authors: *S. M. MARKS[1], S. N. LOCKHART[1], W. J. JAGUST[1,2];
[1]Helen Wills Neurosci. Inst., Berkeley, CA; [2]Life Sci. Div., Lawrence Berkeley Natl. Lab., Berkeley, CA

Abstract: Successful memory processes require large-scale networks, many of which are affected by changes associated with aging. Early Alzheimer's pathology preferentially targets these networks and has been associated with memory impairment. This study sought to investigate the impact of pathology on the hippocampus and its associated network during episodic memory. Forty-three cognitively normal older adults and 20 young controls participated in a functional MRI paradigm designed to emphasize pattern separation, a function attributed to

the hippocampus. A subset of older adults underwent Pittsburgh Compound B and AV-1451 PET scans to measure beta-amyloid (Aβ) and tau neurofibrillary tangles, as well as structural and resting-state MRI. Cortical Aβ values were used to identify Aβ-positive individuals. Tau values corresponding to Braak 1/2 and 3/4 staging were quantified using Freesurfer parcellations. Functional connectivity between retrosplenial cortex and medial temporal lobes (MTL) was assessed using seed-based correlation of resting-state time series. Older adults performed worse on the memory task ($t_{(41)} = -6.40$, $p < 0.001$). Voxelwise analyses revealed greater activation in older adults relative to young controls during encoding of subsequent hits and false alarms (lures incorrectly identified as old). Clusters associated with subsequent hits were found in right anterior hippocampus and spanned all subfields ($p < 0.001$, $k > 250$). Clusters associated with subsequent false alarms were found in bilateral anterior hippocampus, left hippocampal tail and right perirhinal/parahippocampal cortex ($p < 0.05$, $k > 500$). There were no MTL areas where young controls activated more than older adults. Aβ status and tau were unrelated to the degree of activation within significant voxelwise clusters; however, there were complex relationships between brain activation, tau deposition, and connectivity. Specifically, parahippocampal thickness may influence memory deficits, such that thinner cortex is associated with increased false alarm activation ($r^2 = 0.20$, $p = 0.007$), decreased retrosplenial-parahippocampal connectivity ($r^2 = 0.28$, $p = 0.003$), and increased parahippocampal tau ($r^2 = 0.31$, $p = 0.02$). These results suggest that widespread activation differences underlie age-related changes in pattern separation. This activation appears related to atrophy of the parahippocampal cortex, which is in turn related to changes in connectivity and tau accumulation.

Title: Vulnerability and integrity of von economo neurons in human anterior cingulate cortex across the cognitive lifespan

Authors: ***T. GEFEN**, S. PAPASTEFAN, F. RAHMANI, E. ROGALSKI, S. WEINTRAUB, E. H. BIGIO, M.-M. MESULAM, C. GEULA;

Cognitive Neurol. and Alzheimer's Dis. Ctr., Feinberg Sch. of Medicine, Northwestern Univ., Chicago, IL

Abstract: Age is the strongest risk factor for Alzheimer's Disease (AD), likely due to typical "wear-and-tear" that occurs in permanently post-mitotic neurons across the human lifespan. The Alzheimer dementia stage is preceded by a prodromal amnestic mild cognitive impairment stage (aMCI) where both AD pathology and cognitive impairment are less pronounced. What remain unknown are the intrinsic vulnerabilities of specific neuronal subpopulations that potentially contribute to neurodegeneration and cognitive decline across the lifespan.
von Economo neurons (VENs) are highly specialized spindle-shaped cells unique to the anterior cingulate cortex (ACC) and frontoinsular cortex in primate hominids, and are implicated in higher-order cognition. VENs were found to be reduced in certain neurodegenerative diseases such as behavioral variant Frontotemporal Dementia, whereas cognitive "SuperAgers" (age 80+ individuals with memory scores equal-to-or-above individuals ~25 years younger) were found to have an abundance of VENs in the ACC. The current study sought to determine whether VENs are preferentially reduced in individuals with amnestic dementia due to AD versus other healthy cognitive aging outcomes.
Postmortem brain specimens stained with Nissl were analyzed using modified stereological methods (StereoInvestigator, MBF) from the following cohorts (N=5, per group): SuperAgers, cognitively-normal elderly (age 65+), cognitively-normal young (age 20-60), elderly individuals diagnosed with aMCI (age 65+) and elderly individuals diagnosed with amnestic dementia (age 65+) with severe postmortem AD pathology. VEN density and total neuronal counts were obtained in the ACC based on cellular morphology.
Stereological results revealed lowest VEN counts in the AD group, followed by higher counts in aMCI, older, and younger groups, respectively. VEN counts and total neuronal counts in the AD group were significantly lower compared to old and young groups ($p<0.01$), but not the aMCI group. Consistent with prior findings, SuperAgers continued to show the highest VEN counts compared to all other groups ($p<0.05$). Total neuronal counts in the ACC were highest in young controls.
Similar to other neurons in human ACC, VENs are indeed vulnerable to loss in AD, but appear to be preserved in individuals with well-preserved cognition.

Col. of Med., Seoul, Korea, Republic of; [4]Dept. of Psychiatry, Yonsei University, Col. of Medicine, Gangnam Severance Hosp., Seoul, Korea, Republic of

Abstract: Objective: This study aims to examine the status and the needs of smartphone usage, patterns of use, interest in utilizing mobile applications and preferred healthcare types with the purpose of providing mobile mental healthcare services that are efficient in improving the older adults' health conditions and quality of life. Methods: Data were collected through self-designed questionnaires with seniors and in-depth interviews with experts and social workers at a local center for dementia. The questionnaire consisted of Sociodemographic information, mobile devices utilizing characteristics, alcohol, smoking, the Korean version revised center for epidemiologic studies depression scale(CESD-R), a self-reported depression and self-reported sleep disturbance. the data of survey on 37 seniors and in-depth interviews with 7 experts were analysed. Results: 1) Most experts recommended the use of smartphones because using a smartphone exert a positive impact on the lives of the elderly. Many elderly adults were also interested in application for health care and health related education. If elderly adults want to receive health information via smartphones, applications that provide disease information or manage medication are recommended . In addition, most of the experts said that the elderly customized, detailed and sustainable smartphone education is necessary for the efficient use of smartphone. 2) As a preliminary analysis result of questionnaire survey on the utilizing status and demand for smartphone and mobile healthcare application of the elderly adult (65+) visited Seodaemun-gu Center for Dementia, there are differences in education and income between with and without smartphones. Functions commonly used in smartphones were voice calls, internet search and Social network services(in particular, Kakao talk). The preferred health care system via smartphone were information of medical disease and mental health. The majority opinion is that utilization is low due to the use of smartphones and functions are difficult overall. One of the main advantages of smartphones is that can easily get knowledge and communicate in real time. and disadvantages of smartphones were too complicated to use and too expensive to maintain.Conclusions: These results of the study will show the direction for more in-depth studies on mental health care application based on mobile devices for the elderly. In the future, the development of mental health care services related application that reflect these demands would be preferable.

Title: Objective electrophysiological evidence for reduced efficiency of face identity processing in aging

Authors: *S. LITHFOUS, J. LIU-SHUANG, B. ROSSION;
Inst. of Neurosci., Univ. of Louvain, Louvain-La-Neuve, Belgium

Abstract: Failures to identify other people through their face constitutes one of the most frequent complaints of elderly people and has been widely reported in previous studies. However, the results showed some discrepancy, suggesting that this complaint is difficult to measure behaviorally, due to decreased efficiency and slowing down in general cognitive and motor processes with age. Here we isolated face identity processing with a highly sensitive and objective approach in EEG, Fast Periodic Visual Stimulation (FPVS), in an oddball paradigm (Liu-Shuang et al., 2014). Fifteen young (mean age: 22.5 ± 1.25 years; 10 women) and 15 healthy elderly subjects (mean age: 61.5 ± 2.38 years; 10 women) participated in the study. Identical faces were presented through sinusoidal contrast modulation at a base frequency of 6 Hz (i.e. 6 images/s) during 64 s sequences, with different faces appearing every 5^{th} face (i.e. 6/5 = 1.2 Hz). Participants simply had to detect color changes of the fixation cross, with no difference in accuracy and RTs between groups. Sequences contained either upright or inverted faces and were presented randomly, with 4 sequences per orientation (i.e. 8 sequences in total). While the response at 6 Hz reflects general visual processing, previous studies in young adults showed that face individualization elicits a specific response at 1.2 Hz and harmonics (2.4 Hz, etc.). The general visual processing response was localized over medial occipital electrodes and did not differ between groups. However, the face individualization response over right occipito-temporal electrodes was reduced in elderly subjects compared to the young subjects. Moreover, the difference in amplitude of face individualization responses between upright and inverted faces was reduced in the elderly compared to young subjects. Using a sensitive and objective approach in EEG, these results demonstrate a decline of face individualization in aging independently of general cognitive factors, and suggest that holistic processing – i.e., the ability to perceive all features of a face at a single glance in a unified representation - may explain this decline.

Title: The relationships between age, fMRI correlates of familiarity and recognition memory

Authors: *M. A. DE CHASTELAINE, J. T. MATTSON, T. H. WANG, B. E. DONLEY, M. D. RUGG;
Ctr. for Vital Longevity, Univ. of Texas at Dallas, Dallas, TX

Abstract: Studies investigating the effects of age on episodic memory performance generally report larger age-related deficits in recollection- versus familiarity-based recognition. Nevertheless, the neural correlates of familiarity are often reported to differ with age. Here, we used an associative recognition task to investigate the relationships between age, the neural correlates of familiarity, and recognition memory performance. Young, middle-aged and older participants (n = 136) were scanned during an associative recognition test following a study phase in which word pairs were visually presented in the context of an elaborative encoding task. Test items comprised studied, rearranged (items studied on different trials) and new pairs. fMRI familiarity effects were operationalized as greater activity for studied test pairs incorrectly identified as 'rearranged' than for correctly rejected new pairs. The reverse contrast was employed to identify 'novelty' effects. Simple recognition memory (proportion of studied items identified as studied or rearranged minus new item false alarm rates) was lower for the older relative to the younger group, while recognition for the middle-aged group did not differ from either the young or older groups. Whole brain analysis identified 7 small clusters (bilaterally in the supramarginal gyrus, caudate nucleus and precuneus, and the left superior frontal gyrus) where familiarity or novelty effects were larger for the younger group relative to the two older groups. These age-related differences were overshadowed however by the identification of an extensive number of canonical familiarity- sensitive regions that were age-invariant. Some of these canonical regions, such as the intra-parietal sulcus and caudate nucleus, also showed age-invariant positive correlations with recognition performance. Novelty effects in bilateral hippocampus covaried reliably across participants with recognition memory, and also with an index of recollection. The latter findings indicate that fMRI hippocampal novelty effects reflect a generic memory signal.

Title: Training the aging brain: a multi-level network analysis

Authors: *J. M. HICKS[1], R. NENERT[1], L. A. ROSS[2], K. M. VISSCHER[1];
[1]Univ. of Alabama At Birmingham, Birmingham, AL; [2]The Pennsylvania State Univ., University Park, PA

Abstract: One strategy shown to be effective in improving cognitive performance of older adults is known as Speed of Processing (SOP) training. SOP training shows reliable effects that lead to improvements in performance on tasks similar to the training paradigm as well as important life activities. While SOP training yields reproducible behavioral effects, the neural mechanisms underlying these effects are largely unknown. We aim to determine how SOP training affects the resting-state brain networks of older adults. Yet because the brain is a vastly complex structure with many interconnected units, understanding the organization of these connections and how they change through training is a challenging endeavor. A further challenge is how to accurately define these interconnected units of the brain. Current analytical methods require the experimenter to make assumptions about how the brain is subdivided into parts within a network, but clearly, these assumptions can influence the outcomes of analyses. Thus, we use resting-state functional connectivity data along with a k-means clustering algorithm to create parcellations of cortical and subcortical gray matter across multiple spatial scales. The resulting parcellations demonstrate validity as they identify previously defined brain regions, group regions that are known to be connected, and exhibit a high degree of bilateral symmetry. We found a significant correlation between the degree of behavioral improvement with training and a change in global

network characteristics, suggesting SOP training may improve cognitive performance by altering network structure. Further, the relationship to behavior exists primarily at a limited set of spatial scales, suggesting that behaviorally relevant network changes occur at a favored range of spatial scales. This work shows that the spatial scale of parcellations influences the sensitivity of analyses of network structure and that improvements in speed of processing may be a result of subtle changes in network structure.

Title: Cortisol and limbic system volumetrics across the adult lifespan

Authors: *S. D. MOFFAT[1], G. ENNIS[1], E.-M. QUINTIN[2], U. SAELZLER[1], C. HERTZOG[1]; [1]Psychology, Georgia Inst. of Technol., Atlanta, GA; [2]McGill Univ., Montreal, QC, Canada

Abstract: The hippocampus, anterior cingulate cortex, and amygdala, regions within the limbic system, are rich in glucocorticoid receptors and play an important role in the regulation of the hypothalamic-pituitary-adrenal (HPA) axis. Research suggests that chronic elevations of cortisol may have a deleterious influence upon the structure of some limbic regions, especially during older adulthood when neuroplasticity is reduced. For example, increased exposure to cortisol has been related to smaller hippocampal volume in older adults. However, few studies have examined the relationship of cortisol to extra-hippocampal limbic structures across the adult lifespan. We investigated whether the relationship between cortisol and specific regions of interest (ROI) within the limbic system would be moderated by age. Specifically, we assessed diurnal cortisol output (area under the curve or AUC) and diurnal cortisol slope and related these measures to hippocampal and amygdalar volume and caudal and rostral anterior cingulate cortical thickness. Participants (M_{age} = 53.1 years, SD = 18.04, range = 23 - 83, N = 51) collected 7 salivary cortisol samples on 10 consecutive days: upon waking, 30 minutes later, and then approximately every three hours until 9 PM. Magnetic resonance imaging (MRI) was performed 2.4 years later on a 3T Siemens scanner with an MPRAGE pulse sequence. MRI data were processed with Freesurfer. Hippocampal and amygdalar volumes were adjusted for intracranial volume. There were significant interactions between age and cortisol on left and right caudal anterior cingulate thickness and left and right amygdalar volumes. In older but not younger adults, a flatter diurnal cortisol slope was related to a thinner right caudal anterior cingulate cortex and higher diurnal cortisol output was related to smaller left and right amygdalar volumes. These results will be discussed in the context of allostatic load and its influence upon neural structure in older adulthood.

Title: Investigating the interaction of expectation and entropy in speech comprehension by young and older adults using eye-tracking

Authors: N. D. AYASSE, *A. WINGFIELD;
Volen Ctr., Brandeis Univ., Waltham, MA

Abstract: Although older adults are known to be able to use context effectively to understand spoken language, not all situations are as straightforward as they are in the laboratory; at times, the context may fit multiple semantic competitors, and choosing the correct one can be crucial for correct comprehension. Given the inhibitory control deficit and working memory reduction common in aging, it is critical to understand how older adults can achieve comprehension. An experiment is reported to explore the interaction of constraining contextual cues (expectancy) and the degree of competition (response entropy) using sentences with either high or low expectancy for a sentence-final (target) word and with either high or low response entropy. These target words were then paired with either a high or low contextual competitor in a variation on a visual world eye-tracking paradigm. Participants heard recorded sentences while being presented visually with two potential target words on a screen. Participants were instructed to move a cursor over the target word as quickly as possible as the sentence unfolded. As this task is being performed, their eye movements to the referents on the screen were recorded. Results support the expectation that lower expectancy and higher entropy slow comprehension, and that expectancy and entropy interact such that participants are differentially slower to comprehend a sentence with low expectancy and high entropy. Results will be discussed in terms of adult aging and individual difference effects. Work supported by NIH Grants RO1 AG 019714 and T32 GM 084907

Title: Inferring the intentions of others across the lifespan

Authors: ***A. REITER**[1], A. DIACONESCU[3], B. EPPINGER[2], S.-C. LI[2];
[1]Lifespan Developmental Neurosci., [2]TU Dresden, Dresden, Germany; [3]ETH Zürich, Zürich, Switzerland

Abstract: Inferring others' mental states is a core function of social cognition (Frith & Frith, 2005, *Curr Biol*). What are the other's intentions - can I trust him or her? The appropriate interpretation of others' behavior as well as adapting our own behavior flexibly to it is key for human interactions. Emerging findings indicate that these mechanisms change over the course of the lifespan (e.g., Bailey et al., 2015, *Cogn Emot*). However, to date, the underlying computational and neurophysiological mechanisms are poorly understood. To this end, we applied a social learning paradigm (cf. Behrens et al., 2008, *Nature*; Diaconescu et al., 2014, *PLOS CB*) in younger (20-30 years) and older (60-80 years) adults . Using hierarchical Bayesian learning models, we investigate social learning in an uncertain social environment, i.e., when the intentions of a young vs. older adviser change dynamically over the course of a probabilistic reinforcement learning task. Comparing the predictions of different logistic models in accounting for the participants' choices, we find that both age groups integrate social and statistical information to guide decision-making; furthermore, social information is particularly weighted in trials where the statistical information is ambiguous ($\Delta BIC \geq 52$). Both age groups use social information less when advice is unreliable ($t=3.72$, $p<.001$). That is, they adapt their behavior flexibly to changing social conditions. However, difference scores for social and statistical information were found to differ on a trend level between age groups ($t=1.81$, $p=.07$), indicating that the elderly may be less sensitive to statistical information, whereas they value social advice similarly as younger adults. By means of computational modeling in an age comparative design, we demonstrate that a Bayesian hierarchical generative model can describe the observed behavior of both age groups Based on this computational model, we will further explore the effects of aging on dealing with uncertainties in social information. The applied paradigm in combination with computational modeling of inter-individual differences in social learning appears as a promising step towards mechanistic accounts of lifespan differences in socio-emotional processes.

Title: Reduced white matter integrity and aberrant increases of cerebral blood flow in the episodic memory network in cognitively normal older adults with β-amyloid pathology

Authors: *H. OH[1], A. E. LEVITANUS[2];
[1]Dept. of Neurol., [2]Psychology, Columbia Univ., New York, NY

Abstract: While approximately 30% of cognitively normal older adults present with beta-amyloid (Aβ) deposition, a pathological hallmark of Alzheimer's disease, the understanding of early neural markers that are associated with Aβ pathology is largely limited. Previous studies using functional magnetic resonance imaging have shown Aβ-related hyperactivation in brain regions highly implicated in episodic memory. To better understand the impact of Aβ deposition on the absolute level of functional and structural correlates in the episodic memory network, we examined whether and how Aβ deposition relates to cerebral blood flow (CBF) and white matter structure integrity (WMI) among cognitively normal older adults. We assessed cerebral blood flow and white matter integrity that were measured by arterial spin labeling and diffusion tensor imaging (DTI), respectively, in cognitively normal older adults who participated in the Alzheimer's Disease Neuroimaging Initiative (ADNI). A level of Aβ deposition was quantified by 18F-Florbetapir positron emission tomography (PET). Forty and 47 cognitively normal older adults (mean age = 72.8, 25 females) were included for CBF and DTI results, respectively, and classified into either Aβ+ or Aβ− according to the criteria set by the ADNI processing pipeline. Effects of dichotomized and continuous Aβ measures on CBF and WMI in a priori regions of interest were assessed using analyses of covariance and multiple regression models. For behavioral measures, baseline scores and slopes representing longitudinal changes in the 11-item ADAS-cog and RAVLT immediate recall and percent forgetting were assessed and related to biomarker measures. For CBF, higher Aβ deposition was associated with lower CBF in entorhinal cortex but increased CBF in posterior cingulate cortex. A higher level of CBF in posterior cingulate cortex was further associated with greater longitudinal decline in RAVLT among Aβ+ older adults. For WMI, higher Aβ deposition was associated with significant reduction in integrity in most association fibers including superior longitudinal fasciculus, inferior fronto-occipital fasciculus, cingulum, and body of corpus callosum. The present results suggest that, despite cognitively normal functioning, Aβ-related differences in cerebral blood flow and white matter tract integrity are present in the episodic memory network in cognitively normal older adults. These functional and structural differences associated with Aβ pathology

would be important to be accounted for in cognitive aging research, while serving as an early biomarker for pathological brain aging associated with Alzheimer's disease.

Title: Reduced acetylcholinesterase activity is associated with impaired deactivation of the precuneus and the temporoparietal junction during episodic memory encoding in prodromal Alzheimer's disease

Authors: *J. KUKOLJA[1], N. RICHTER[1], Ö. A. ONUR[1], L. KRACHT[3], M. TITTGEMEYER[3], B. NEUMAIER[4], M. SCHMIDT[2], M. DIETLEIN[2], G. R. FINK[1];

Abstract: *Background*: The cardinal symptom of Alzheimer's disease (AD), progressive loss of episodic memory impairment, is attributed to extensive neuronal degeneration, especially of cholinergic populations. Cholinergic transmission enhances encoding of new information into long-term memory. However, this enhancement requires simultaneous suppression of off-line consolidation of previously encoded content. We hypothesized that both processes are impaired in patients with mild cognitive impairment (MCI) due to AD. We tested whether a local cholinergic deficit underlies a disequilibrium of activations and deactivations during memory encoding.
Methods: Cerebral acetylcholinesterase (AChE) activity, a surrogate marker for the integrity of cholinergic networks, can be measured *in vivo* using positron emission tomography (PET) with the tracer [^{11}C]N-methyl-4-piperidyl acetate (MP4A). In the present study we used MP4A-PET and fMRI to relate neuronal activity to AChE activity. fMRI was measured during encoding of visual items in 20 healthy elderly subjects and 20 patients with amnestic MCI. The subsequent

memory effect was evaluated by contrasting items which were subsequently remembered against those which were forgotten.
Results: Across groups, a typical deactivation of the precuneus, posterior cingulate, angular and supramarginal gyri was observed during encoding of subsequently remembered items. In the right supramarginal and angular gyri this deactivation was significantly greater in the control group than in patients. Within this area, AChE activity was significantly decreased in patients than in controls. Across groups, a significant positive subsequent memory effect was observed in the anterior hippocampus. In the right fusiform gyrus controls showed greater activation than patients.
Conclusion: In an approach combining cholinergic PET and fMRI, we show that a local cholinergic deficit was associated with an impaired suppression of regions which are typically deactivated during long term memory encoding. We conclude that the cholinergic system is crucially involved in redistributing neural network resources in active tasks, but that this process is disturbed in MCI due to AD. The failure to suppress regions which are usually active during rest and are thought to be involved in off-line processes like memory consolidation may contribute to deficits in encoding of new information. These results indicate that cholinergic therapy may be beneficial in patients showing a relevant cholinergic deficit even at earlier disease stages than manifest AD.

Title: Changes in functional connectivity across the lifespan reflect declines in cognitive efficiency

Authors: *M. P. TURNER, N. A. HUBBARD, L. M. HIMES, M. A. MOTES, B. RYPMA; Sch. of Behavioral and Brain Sci., Univ. of Texas at Dallas, Richardson, TX

Abstract: Background: Functional connectivity (FC) is a measure of the extent to which brain regions undergo activity synchronously in time and form a task-relevant network. Models of cognitive efficiency suggest that optimal task performance results from simultaneously maximizing the speed of cognitive processes and minimizing expenditure of cognitive resources. Previous studies have shown that structural connectivity in the brain changes with advancing age. In this study, we used functional magnetic resonance imaging during performance of a processing speed task to determine how FC differs across multiple healthy groups of different ages (younger, middle-ages, and older), as well as groups with compromised white-matter (Multiple Sclerosis; MS). Method: Five groups of participants, 11 healthy younger adults, 11 healthy middle-aged adults, 19 healthy older adults, 15 middle-aged MS patients, and 12 older MS patients (total N = 70) were scanned during performance of an fMRI-adapted version of the Digit Symbol Substitution task (DSST). To measure FC, dorsolateral prefrontal cortex (DLPFC), known to be heavily involved in processing speed tasks, was chosen as a seed region. FC was assessed for each participant and group via comparison of voxels in the brain with those in this DLPFC seed region. Results: Each participant's FC was plotted as a function of DSST reaction time. A quadratic polynomial regression was significant ($p < 0.0001$), and demonstrated an inverted-U shaped relationship between degree of FC and behavioral performance. Conclusions: The changing relationship between FC and performance across the lifespan can be explained in the context of cognitive efficiency models. When processing paths are more direct, neural activity is reduced and processing speed is faster. When the integrity of direct processing links between nodes is reduced, more indirect links must be traversed, so neural activity is increased and processing speed is slower. Younger adults who perform faster utilize more direct (i.e., efficient) connections, than those who perform slower. These individuals use less direct connections, increasing both reaction time and DLPFC activity. In older adults, however, connections between cortical regions are known to degrade. Faster performing older adults may be able to make use of intact indirect connections, while those with slower performance have fewer intact connections, limiting performance and DLPFC activity.

Title: Neuromodulatory effects on memory networks in aging are topographically selective and modulated by structural network density

Authors: *S. W. DAVIS[1], D. MURPHY[2], B. LUBER[3], S. H. LISANBY[4], R. CABEZA[2]; [2]Ctr. for Cognitive Neurosci., [1]Duke Univ., Durham, NC; [3]Exptl. Therapeut. & Pathophysiology, [4]Div. of Translational Res., NIH, Bethesda, MD

Abstract: Functional neuroimaging studies have shown that, compared to younger adults, older adults show a more distributed activation pattern, perhaps as a consequence or a benefit of changes in structural morphology. It has been suggested that the distributed activation in older adults reflects compensation for reduced neural resources, but this hypothesis is difficult to test using only imaging data, which is only correlational. To address this issue, we manipulated the causal relationship between neural resources and distributed activity in older adults using transcranial magnetic stimulation (TMS). We defined local and distributed connectivity using graph techniques: local connectivity measured within modules, and distributed connectivity measured between modules. Given that functional connectivity depends on structural connectivity, we expected that success-related connectivity would be constrained by white matter structure. Thus, we predicted that (1) while 5Hz TMS would boost local activity and increase within-module connectivity, 1Hz TMS would depress local activity and increase more long-distance between-module connectivity, and that (2) that this effect would be constrained by white-matter connectivity, such that the 5Hz-related increase in connectivity would be related to 1st-order connections, while 1Hz-related increases in between-module connections were related to indirect structural connectivity between more distant regions. Both predictions were confirmed, providing support for the compensatory interpretation of distributed activity in older adults and demonstrating the power of TMS in clarifying the interpretations of activation patterns observed in aging populations. These findings provide an integrated, causal explanation for changes in networks interactions associated with successful cognition in older adults.

Title: Age-related white matter micro- and macro-structural changes associated with functional connectivity decline in resting state network

Authors: L. HIMES[1], N. A. HUBBARD[1], M. TURNER[1], *B. P. RYPMA[1,2];
[1]Behavioral & Brain Sci., Univ. of Texas at Dallas, Richardson, TX; [2]Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Healthy aging is associated with neural changes in both structure and function yet the relationships between these changes are not fully understood. One manifestation of age-related structural changes is a decrease in white matter integrity measured by fractional anisotropy (FA). Healthy aging is also associated with an increase in white matter lesions. One manifestation of age-related functional changes is a decrease in resting state functional connectivity. We investigated whether white matter integrity affected resting state networks across a wide-range age sample. We hypothesized that individuals with lower FA (older adults) would have less functionally connected resting-state networks compared to individuals with higher FA (younger adults). We also investigated to what extent white matter lesions are related to FA.
White matter integrity (FA) was estimated by diffusion tensor imaging (DTI). White matter lesion burden (LB) was estimated using T2-FLAIR magnetic resonance imaging. Twenty-two ($N = 22$) participants ages 21-66 ($M = 42.68$ [$SD = 12.26$]; 17 female) were selected. Resting state connectivity was measured using global brain connectivity (GBC), a measure of functional connectivity of each voxel within the resting network.
GBC decreased with age in nodes within multiple resting networks (all regions $p < .05$, $k > 11$), and LB significantly predicted GBC decreases in these regions (all regions $p < .05$, $k > 11$). FA was a significant predictor of age-related GBC decrease (all ps $< .05$). Further, LB increased with age ($r = .48$, $p < .05$) and was significantly predicted by FA ($r = .46$, $p < .05$).
Age-related FA decreases are associated with disconnection of multiple networks at rest. These findings may reflect a decrease in the overall cohesiveness of resting networks in aging due to white matter micro- and macrostructure damage. Functional decline of resting state networks and micro- and macro-structural decline might differentially affect cognitive changes in healthy aging.

Title: Changes in functional organization of the human brain with age

Authors: *S. HRYBOUSKI[1], F. OLSEN[2], J. MCGONIGLE[3], R. CARTER[2], P. SERES[2], N. MALYKHIN[2];
[2]Biomed. Engin., [1]Univ. of Alberta, Edmonton, AB, Canada; [3]Ctr. for Neuropsychopharm., Imperial Col. London, London, United Kingdom

Abstract: Introduction: The predominant theory of brain aging suggests that association cortices are most affected by the aging process, while primary visual, somatosensory, motor and auditory systems of the brain are not. Independent Component Analalysis (ICA) can be used to detect age-related changes in brain network dynamics. In the current study we tested the hypothesis that functional networks, which are localized to frontal, temporal, and parietal association cortices, show reduction in functional connectivity with age, while primary sensory and motor networks remain preserved in healthy cognitive aging. **Methods:** A total of 140 healthy volunteers (18-88 years old) were recruited for this study. Participants were excluded if they had unstable medical illness, history of psychiatric or neurological disorders and the use of medications that might affect brain structure or function. Older individuals with Mild Cognitive Impairment (MCI) and dementia were also exlcuded from the study. T2*-weighted images were acquired on a 1.5T Siemens Sonata system. SPM12, FSL 5.0, and ANTS software packages were used to preprocess the functional data. Network analyses were performed using GIFT (v4.0) software. The number of components for the spatial GroupICA analysis was assessed using ICASSO bootsrapping procedure (500 iterations) and Group-Information-Guided ICA was used to estimate resting-state networks in each volunteer. We evaluated age-related changes functional connectivity by (1) examining independent component (IC) spatial maps to study intra-network properties; (2) comparing network signal using multitaper approach; (3) investigating age-related changes in between-network connectivity. **Results:** Based on previous literature we identified visual, sensorimotor, default-mode, auditory, ventral attention, and frontal-parietal networks. Results showed general reduction in intra-network connectivity with age not limited to association cortices only. Spectrum analysis showed that fMRI signal from older individuals shows reduced low-frequency (0.01-0.10 Hz) power. Similar to reduction in intra-network communication, analysis of between-network connectivity revealed broad reductions in cross-

network communication with age. **Conclusions:** Our findings demonstrate broad changes in within- and between-network functional connectivity in healthy aging, which are not restricted to the association cortices.

Title: GABA levels in occipital cortex decline with age and correlate with fluid processing ability

Authors: *T. A. POLK[1], J. M. CARP[2], B. R. FOERSTER[3], L. OSSHER[5], M. PETROU[3], M. SIMMONITE[4], D. H. WEISSMAN[4];
[1]Psychology, Univ. of Michigan Dept. of Psychology, Ann Arbor, MI; [2]18F, Washington, DC; [3]Radiology, [4]Psychology, Univ. of Michigan, Ann Arbor, MI; [5]Dept. of Clin. Neurosciences, Univ. of Oxford, Oxford, United Kingdom

Abstract: Work in non-human primates has shown that the selectivity of neural receptive fields in visual cortex declines with age (*Nat. Neurosci.* **3:**382) and that administering gamma-aminobutyric acid (GABA), the brain's primary inhibitor neurotransmitter, reverses such age-related declines in neural selectivity (*Science* **300**:812). Furthermore, reduced neural selectivity is associated with reduced fluid processing ability in older humans (*Jnl Neurosci* **30**:9253), suggesting that age-related declines in GABA might contribute to age-related declines in cognition. Here, using magnetic resonance spectroscopy at 3T, we aim to explore whether GABA levels in visual cortex decline with age in human beings and whether individual differences in GABA are related to fluid processing ability. We used a MEGA-PRESS sequence with frequency spectral editing to distinguish GABA from other metabolites (*NMR Biomed* **11**:266). Spectra were obtained from a 3 x 3 x 2.5 cm voxel placed in the occipital cortex of 17 young adults (mean age 20.7 years) and 18 older adults (mean age 76.2 years). Participants also performed 11 fluid processing tasks outside the scanner. Occipital GABA levels were significantly reduced in the older subjects compared to the younger subjects. Furthermore, higher GABA levels correlated with better performance in 10 out of the 11 behavioral tasks. We also

performed a principal component analysis on the behavioral data and regressed the first principal component against GABA levels. We found that higher GABA levels were significantly associated with better performance across tasks as assessed by this summary measure. These results indicate that age-related declines in GABA may contribute to age-related declines in fluid processing ability.

Title: Differences in execution efficiency between young and elderly healthy adults during an incidental/ intentional learning/memory visuospatial task

Authors: M. JUNCO-MUÑÓZ[1], O. MEJÍA-RODRÍGUEZ[2], J. CERVANTES-ALFARO[4], *M. OLVERA-CORTES[3];
[1]División de neurociencias, Ctr. de investigación Biomédica de Michoacán, Inst. Mexicano Del Seguro So, Morelia, Mexico; [2]División de Investigación Clínica, [3]Ctr. de investigación Biomédica de Michoacán, Inst. Mexicano Del Seguro So, Morelia, Mich., Mexico; [4]Facultad de Medicina, Dept. de Posgrado, Univ. Michoacana de San Nicolás de Hidalgo, Morelia, Mexico

Abstract: The development of explicit access to the implicit learned information called incidental learning, is an important learning mechanism and along with visuospatial information highly vulnerable to aging. The effect of aging on an incidental (INC)/intentional (INT)-learning/memory tests for visuospatial location information was assessed in twenty four right handed participants grouped by age in a young adult (n=14, 25-45 years old, 5 female) and an elderly adult group (n=10, 65-85 years old, 7 female). All participants were screened with the RAVEN, BDI and BAI inventories to be included. The study was approved by the Research and Ethics Committee of the IMSS. A virtual maze which included 7 common objects at specific placements was presented on a PC to each participant; then, these 7 objects and 7 new objects were presented to them and the subjects responded, if the object was in the maze and where (INC1-remember). Following, the objects in the maze were intentionally studied by the participants (INT-test). The 7 objects presented in the maze, the 7 objects presented in the INC1

test and 7 new objects were presented to the participants (INC2). They had to remember if the object was in the maze and indicate where, also, if the object was seen in the INC1 test or was new (INC2). The total number of remembered correct objects (RCO-INC1&INC2/RCO-INT) and correctly remembered positions (RCP-INC1&INC2/RCP-INT) (positions marked with the exact location of the objects' figures in the maze) were measured. Recognition errors were classified as false-negative or false positive, position errors (index error) and inversions (incorrect object in a correct position). The data were compared using the Mann-Whitney U test and correlations (Pearson) between behavioural variables and age, years of study and CI were made. Statistical significance was considered at $p < 0.05$. The young adult group had a higher number of total RCO and RCP in INC1&INC2 and INT test than the elder adult group. The elder adult group had more false-negative errors in the INC tests and both more false-positive and negative errors in the INT test. A negative correlation between years of study and RCO/RCP in the INT was observed, but not correlation existed in the INC test. A negative correlation between the number of correctly remembered positions and age as well as a positive correlation between the error and age were observed for the INT test. Elderly adults showed mayor number of position errors in INC1, whereas in the INT showed only object errors with increased false positive errors. The differential accuracy under INC/INT learning conditions suggest a difference in the underlying retrieval processes used to perform the tasks.

Title: Prefrontal gray matter volume mediates age effects on self-initiated encoding strategies

Authors: R. A. HUSA[1], B. A. GORDON[2], *B. A. KIRCHHOFF[1];
[1]Psychology Dept., St. Louis Univ., Saint Louis, MO; [2]Radiology Dept., Washington Univ. in St. Louis, Saint Louis, MO

Abstract: Aging is associated with decreased self-initiated use of effective elaborative encoding strategies. Currently, relatively little is known regarding what factors drive age differences in self-initiated use of encoding strategies. Prior research has shown that prefrontal cortex plays an

important role in supporting complex self-initiated strategic processes. The goal of the present research is to investigate whether declines in prefrontal regional gray matter volume with age make a significant contribution to age differences in self-initiated use of elaborative encoding strategies. The relationships among age, prefrontal regional gray matter volumes, and self-initiated use of encoding strategies were in examined in 39 healthy younger adults (age range 18-35) and 38 healthy older adults (age range 65-80). Freesurfer was used to measure gray matter volume in 12 prefrontal regions of interest. Self-initiated encoding strategy use was assessed by asking participants to give retrospective item-by-item strategy reports after performing a verbal intentional encoding task. Participants reported the frequency with which they used rote repetition, visual imagery, sentence generation, and/or personal relevance strategies as well as no strategy to encode individual words. A composite elaborative encoding strategy score was calculated for each participant by determining the frequency with which he/she used any elaborative encoding strategy (visual imagery, sentence generation, and/or personal relevance) to encode the studied words. Preliminary results from this study revealed that age was negatively correlated with the composite measure of self-initiated use of elaborative encoding strategies and self-initiated use of the personal relevance strategy. Importantly, left caudal middle frontal gray matter volume mediated the effect of age on self-initiated use of elaborative encoding strategies. In addition, right caudal middle & bilateral lateral orbital frontal gray matter volumes mediated the effects of age on self-initiated use of the personal relevance encoding strategy. These results suggest that age differences in prefrontal regional gray matter volume are a significant contributor to age differences in self-initiated use of effective elaborative encoding strategies.

Title: Moderation effect of serum cortisol on neurocognitive association in non-demented elderly subjects

Authors: *A. C. LAW[1,2], W. K. W. LAU[3], M.-K. LEUNG[4], T. M. C. LEE[4];
[1]The Univ. of Hong Kong, Hong Kong, China; [2]Neural Dysfunction Res. Lab., [3]Dept. of Psychiatry, The Univ. of Hong Kong, Hong Kong, Hong Kong; [4]Dept. of Psychology, The Univ. of Hong Kong, Hong Kong, China

Abstract: Dysregulation of the hypothalamus pituitary adrenal (HPA) axis accompanied by elevated basal cortisol levels are often associated with poorer cognitive functioning during aging. The current study aimed to investigate the mechanistic relationships between serum cortisol levels, regional brain volumes, and cognitive processing speed in a group of non-demented elderly people. Forty-one male and female healthy elderly participants were included. Blood samplings were done in the late morning to minimize the diurnal effect of cortisol. Serum cortisol levels were measured using commercially available enzyme-linked immunosorbent assay (ELISA). Regional gray / white matter volumes (GMV/WMV) were obtained by whole-brain anatomical scanning. Cognitive processing speeds were assessed by digit-symbol and symbol search test, from the Chinese version of the Wechsler Adult Intelligence Scale - third edition (WAIS-III). Mediation and moderation analyses were performed to study the mechanistic relationship among serum cortisol levels, regional brain volumes, and processing speeds. Whole-brain regression analysis revealed that serum cortisol levels positively predicted the WMV of the right thalamus, the GMV of the left thalamus and right cerebellar tonsil, and negatively predicted the WMV and GMV of the left middle temporal gyrus (MTG). Furthermore, significant moderation effects of serum cortisol were observed on the relationship between GMV of the left MTG and processing speed, as well as GMV of the left thalamus and processing speed. This study provided the first piece of evidence supporting the moderating effects of serum cortisol levels on the relationship between regional brain volumes and processing speeds in the healthy elderly subjects. This observation enriches our understanding of the role of cortisol in brain morphology and cognitive functioning in older individuals.

Title: Influence of age, hearing acuity and speech prosody on processing effort revealed through pupil dilation.

Authors: *N. M. AMICHETTI[1], E. ATAGI, 02454[2], Z. BROWN[2], A. WINGFIELD[2];
[1]Neurosci., Brandeis Univ., Waltham, MA; [2]Brandeis Univ., waltham, MA

Abstract: Speech prosody refers to the pitch contour, word stress, pauses and final vowel lengthening of words immediately prior to clause boundaries. It is important for sentence comprehension as it signals to the listener the location of syntactic boundaries. As the prosodic pattern of speech normally coincides with the syntactic boundaries, this provides an advantage as it reduces processing effort. To examine the effects of prosody on sentence comprehension and effort, we utilized sentences in which the prosodic pattern was placed in conflict with the syntactic structure -thereby disrupting the processing advantage normally provided by prosody. To investigate the effects of age and reduced hearing acuity, normal-hearing young adults and older adults with good-hearing and older adults with mild-to-moderate hearing loss listened to sentences with either a neutral prosodic pattern, a prosodic pattern that coincided with the syntactically defined clause boundary or with a prosodic pattern that was conflicting and were asked to recall post-listening. Pupil dilation was used as a measure of processing effort, with larger dilations reflecting larger amounts of effort, and was continuously recorded throughout the experiment. For all groups, recall performance varied by condition in a graded fashion with better performance in the congruent condition and incongruent condition producing the most errors. This pattern was observed within each group in the pupillometry traces, with the incongruent sentences eliciting the greatest amount of pupil dilation, followed by sentences heard in the neutral condition and congruent condition. Further, the size of the dilations varied across groups, with the older adults showing larger pupil excursions than the young adults, and especially so for the older adults with a hearing impairment. Of interest is when older adults show larger pupil dilations even when the resolution of syntax and prosody is successful, implying that while older adults may reach comparable levels of performance, they do so at a higher cognitive cost.

Title: The relationship of glucose metabolism to cognition in non-diabetic older adults

Authors: *G. E. ENNIS[1], U. SAELZLER[1], G. UMPIERREZ[2], S. D. MOFFAT[1];
[1]Psychology, Georgia Inst. of Technol., Atlanta, GA; [2]Sch. of Med., Emory Univ., Atlanta, GA

Abstract: The prevalence of prediabetes, a condition of glucose intolerance between normal glucose control and diabetes, has increased significantly in older adults aged 65 to 74 years, from 41.3% in 1999 – 2005 to 47.9% in 2006 – 2010 (Casperson, Thomas, Beckles, & Bullard, 2015). This is concerning because prediabetes may worsen cognition and neural structure during an age period when cognition typically declines. The relationship of the three types of prediabetes – impaired fasting glucose (IFG), impaired glucose tolerance (IGT), and combined IFG/IGT - to cognitive function in older adults is not clear. In a group of non-diabetic older adults (M_{age} = 71.1 years, *SD* = 5.2), we compared cognitive functioning in IFG, IGT, and IFG/IGT groups to a normal glucose tolerance (NGT) group. We also examined the relationship of fasting glucose and 2-hr post load glucose to cognitive impairment identified in the IFG, IGT, and/or IFG/IGT groups. Participants were assigned to NGT or prediabetes groups based on results from a 2-hour oral glucose tolerance test. Participants were tested using a battery of cognitive tests that assessed processing speed, working memory, executive functioning, and episodic memory. Our pilot sample included 5 with NGT, 5 with IFG, 5 with IGT, and 6 with IFG/IGT. There were no significant age or education differences between the groups. We found that the IGT and IFG/IGT groups performed significantly worse on episodic and working memory tasks relative to the NGT group. Fasting glucose was not significantly related to cognitive functioning; however, higher 2-hr post load glucose was significantly related to worse episodic and working memory performance. These findings suggest that glucose intolerance, even prior to the development of diabetes, may result in cognitive dysfunction in older adults. Results will be discussed in the context of potential physiological mechanisms, such as insulin resistance, that may be responsible for cognitive decline in older adults with prediabetes.

Title: Behavioural and neural deficits in error detection related to higher age

Authors: *E. NIESSEN[1], G. R. FINK[2], H. HOFFMANN[3], P. H. WEISS[1], J. STAHL[3];
[1]Res. Ctr. Juelich, Juelich, Germany; [2]Univ. Hosp. Cologne, Cologne, Germany; [3]Univ. of Cologne, Cologne, Germany

Abstract: With increasing age, cognitive control processes steadily decline. Prior research suggests that healthy older adults have a generally intact performance monitoring system, but show specific deficits in error awareness, i.e., the ability to detect committed errors. We examined the neural processing of errors across the lifespan (73 participants; age range 20-72 years) by analysing the error (-related) negativity (Ne/ERN) and the error positivity (Pe) using an adapted version of the Go/Nogo task. At a stable overall error rate, higher age was associated with a greater proportion of undetected errors. While the Ne/ERN could be associated with the processing of errors in general, the Pe amplitude was modulated by detected errors only. Furthermore, the Pe amplitude for detected errors was significantly smaller in older adults, in contrast to the Ne/ERN amplitude which was similar across all ages. Structural path models suggest that through those age-related changes in Pe amplitude, an indirect effect on the sensitivity index d' was observed. Data show behavioural and neural deficits in error detection associated with aging.

Title: Patients with hippocampal damage demonstrate impairments in spatiotemporal binding and precision but not spatial strategy

Authors: *B. KOLARIK[1], T. L. BAER[1], K. SHAHLAIE[2], G. GURKOFF[2], A. P. YONELINAS[1], A. D. EKSTROM[1];
[1]Univ. of California, Davis, Davis, CA; [2]Neurolog. Surgery, Univ. of California Davis Med. Ctr., Sacramento, CA

Abstract: Separate lines of research suggest roles for the human hippocampus in both spatial navigation and episodic memory yet reconciling these different perspectives has proven

challenging. Specifically, past studies suggest that hippocampal damage causes dense amnesia but also impairs the ability to employ an allocentric (landmark) based strategy to find hidden targets. We have previously demonstrated, in a single patient with bilateral damage to the medial temporal lobes (MTL), relatively intact coarse (allocentric) spatial memory for locations in a virtual water maze, but impairments in the precision of the spatial representation relative to controls (Kolarik et al, 2016). These findings are consistent with a novel model of hippocampal function termed the precision and binding model (PBM) (Yonelinas, 2013), which postulates roles for the hippocampus in complex, high-resolution binding as part of a larger role in both spatial navigation and episodic memory. In the current study, we extend these findings by including additional features in our experimental design such as a longer delay between acquisition and probe trials, and employing a larger cohort (N=5) of MTL patients. Participants navigated a virtual room on a desktop computer, learning the locations of 3 separate hidden targets over multiple training trials. After a filled delay of 10 minutes, participants were instructed to navigate to each of the three locations, three times each. By requiring participants to remember not only the locations, but also the order in which they were learned, we are able to test the hypothesis that MTL damage impairs spatiotemporal binding. Replicating our previous effects, we found that patients demonstrated only limited allocentric memory deficits, with a specific impairment instead in the precision of their trajectories relative to controls. Importantly, we also noted a tendency for patients, compared to controls, to go to the wrong target, indicating an error in remembering which target to visit when. To quantify this, we calculated the direction and magnitude of swap errors (e.g., correct target = 1 but patient navigates to target 2 = +1 swap error). Patients made more swap errors than controls after the delay, which differ from a perseverative error because patients did not simply visit the most recent target but rather visited the targets in the wrong order. Critically, however, there was no evidence of patients wandering randomly in the environment. Together, our findings suggest a role for the hippocampus in spatial precision and spatiotemporal binding, consistent with the Precision and Binding Model.

Title: Novel episodic memory paradigm reveals common and dissociable brain areas involved in processing spatial and temporal information

Authors: *J. S. LIEBERMAN, A. M. SCHEDLBAUER, A. D. EKSTROM;
Ctr. for Neurosci., Univ. of California Davis, Davis, CA

Abstract: A critical component of episodic memory is the spatial and temporal information associated with a given event. While prior studies of episodic "source" memory have identified neural correlates of context encoding and retrieval as a whole, these paradigms do not attempt to dissociate between spatial and temporal elements of source memory. To address this issue, participants encoded a series of objects in one of two contexts (either a spatial location or a temporal event), and then were tested on their memory of which contexts the objects were encoded in. Participants underwent whole-brain 3T fMRI scanning during both the encoding and retrieval parts of the experiment. Functional scans were acquired at 2x2x2.2 mm voxel resolution. During encoding, each trial consisted of a 6-s period in which the participant was briefly visually presented with an object and cued to imagine it in either a spatial or temporal context, followed by another 6-s period in which they rated how vividly they were able to imagine the item in context on a 1 to 4 scale (1 = "unable to imagine" and 4 = "imagined very vividly"). Retrieval trials consisted of an item recognition followed by a source recognition question, each of which lasted 6 seconds. Participants were first shown an object and asked to indicate if they had seen the object earlier in the experiment. They were then asked to decide whether they had placed the object in the spatial or temporal context, or if it was a new object. We used univariate analyses in SPM to examine differences and commonalities in which brain regions were recruited during correct retrieval of the two contexts. Preliminary results in 8 participants showed that correct retrieval recruited the hippocampus and other areas of the temporal lobe, regardless of whether the item had been encoded in the spatial or temporal context. However, spatial retrieval was associated with significantly greater activation than temporal retrieval in several locations in posterior parts of the brain, such as the occipital pole, cuneus, lingual gyrus, intracalcarine cortex, and lateral occipital cortex. Temporal retrieval showed significant activation in a wider range of locations within the frontal, parietal, and occipital lobes such as the lateral and orbital frontal cortex, superior parietal lobule, and occipital fusiform cortex, as well as subcortical regions such as the thalamus, caudate nucleus, and putamen. Our findings replicate past results from the lab suggesting dissociable components of spatial and temporal retrieval but also suggest commonalities with past source memory retrieval paradigms, providing a novel means for understanding the neural basis of episodic memory.

Title: A graph theory approach to spatiotemporal contextual encoding and retrieval in human episodic memory

Authors: *A. SCHEDLBAUER[1], J. S. LIEBERMAN[2], A. D. EKSTROM[3];
[1]Univ. of California Davis, Davis, CA; [3]Psychology, [2]Univ. of California, Davis, Davis, CA

Abstract: Episodic memories capture events from our daily lives and often involve rich contextual details, particularly the spatial and temporal components of the experience. Encoding and retrieval of these features is thought to rely on regions within the medial temporal lobe (MTL), with current theories proposing additional important contributions from neocortical areas, such as prefrontal and parietal cortices. However, current work has yet to 1) describe the interactions between these disparate regions *and* 2) compare the overlapping and distinct global networks involved in both encoding and retrieval of contextual information. To address these issues, participants underwent functional magnetic resonance imaging (fMRI, N=8) while completing an episodic memory task in which they were instructed to mentally place a specific object in a self-generated spatial or temporal context. After each item presentation, subjects rated their success in visualizing the object in the appropriate context using a confidence judgment (1 low - 4 high). Using a multivariate rather than a univariate approach, we conducted a functional connectivity analysis using beta-time series correlations to determine the interactions between 46 regions throughout the brain. Resulting encoding and retrieval network topology was examined and quantified using graph theoretical techniques. Examining encoding during high versus low confidence and retrieval during successful versus unsuccessful trials revealed dense, large-scale increases in connectivity that typified network topology (uncorrected for differences in trial numbers). Furthermore, when comparing the changes in connectivity of specific areas (i.e. change in z-score of node degree and betweenness centrality) during spatial and temporal encoding and retrieval, regions within the MTL (hippocampus, parahippocampal gyrus) maintained relatively stable connectivity patterns. In contrast, neocortical regions (e.g. superior frontal gyrus, precuneus, lingual gyrus) significantly altered their connectivity to other regions during encoding versus retrieval. The differential connectivity patterns for spatial and temporal encoding and retrieval suggested that network signatures distinguish between different aspects of contextual memory processing. This preliminary work emphasizes the importance of modeling

task-related network dynamics to understanding the neural basis of episodic memory encoding and retrieval.

Title: Navigation in virtual reality with vestibular and proprioceptive input diminishes orientation-dependent spatial representations

Authors: ***M. J. STARRETT**[1], J. D. STOKES[1], O. KREYLOS[2], A. D. EKSTROM[1];
[1]Psychology, [2]Geology, Univ. of California, Davis, Davis, CA

Abstract: Representations of spatial information from the environment are critical for accomplishing cognitive operations in everyday life. A ubiquitous finding in studies of human spatial navigation shows that while participants are able to accurately recall information about relative locations of objects in an environment, participants perform better when recalling information aligned to preferred orientations, such as the surrounding spatial geometry of a room. One limitation of these studies, however, is they are typically conducted in room-sized environments or employ real-world environments that are difficult to control experimentally. We developed a virtual reality (VR) interface that incorporates visual input and self-based cues to assess orientation dependence of spatial representations in a large-scale, virtual environment. Participants wore an Oculus head-mounted display and were secured in an omnidirectional treadmill. After being familiarized with eight target stores, participants were placed in a virtual city with dimensions of approximately 310x220 meters. Beginning from a unique starting location, participants navigated to each of the eight stores in a randomized order. After reaching the final store, the environment was removed from view and participants completed 28 trials of the judgement of relative directions (JRD) pointing task ("Imagine standing in store A, facing store B; point to store C") using a controller to orient an arrow toward the target direction. Critically, each trial involved participants imagining orientations that were either aligned

(orthogonal) or misaligned with the streets of the city. Participants completed six blocks of navigation and JRD. Results showed that pointing error on the JRD task did not differ for aligned and misaligned trials initially, but that this difference emerged after repeated exposure to the environment, suggesting that orientation-dependent representations did not emerge until participants had considerable familiarity with the environment. To further probe the effects of familiarity with the surrounding spatial geometry on the orientation-dependence of spatial representations, we included a condition in which participants were briefly exposed to a map of the city prior to beginning the experiment. Preliminary findings suggest that participant spatial representations were initially orientation dependent. Together, these findings suggest that orientation-dependent representations may be an artifact of testing in small-scale rooms and/or familiarity with the environment and thus do not emerge until participants have learned the surrounding spatial geometry.

Title: A novel, network-based approach to memory modulation

Authors: ***K. KIM**[1], A. SCHEDLBAUER[2], M. ROLLO[1], A. D. EKSTROM[2], N. TANDON[1]; [1]Univ. of Texas Houston, Houston, TX; [2]Univ. of California Davis, Davis, CA

Abstract: Direct brain stimulation via intracranial electrodes implanted for electrocorticography (ECoG) permits modulation of endogenous electrical signals with significantly greater spatial and temporal specificity than non-invasive approaches. It also provides access to deep brain structures, such as the hippocampus, that are difficult, if not impossible, to target non-invasively. Stimulation studies of memory structures, however, have produced mixed results, with some reporting improvement, some impairment, and others, no consistent changes. We hypothesize that to effectively affect cognitive function using brain stimulation, it is essential to modulate the connected set of nodes comprising a network - rather than local activity - that is involved in the function of interest. Memory retrieval recruits the medial temporal lobes (MTL) as well as parts of parietal and prefrontal cortex. In particular, coherent (i.e., phase synchronized) low-frequency

oscillations between these brain regions are critical for successful memory retrieval (Watrous et al., 2013). Here we used frequency-specific, multi-target electrical stimulation to modulate such low-frequency coherence between the memory network nodes. Using ECoG data collected while the patients performed a memory retrieval task, we first mapped frequency-specific, coherent, oscillatory activity (pairwise phase coherence, Vinck et al., 2010) between different brain regions associated with successful memory retrieval. Then we identified two nodes that a) were significantly connected in the network during successful retrieval, and b) exhibited significant coupling difference for temporal vs. spatial retrieval. In a subsequent session, electrical stimulation was applied to these target nodes while patients performed a spatiotemporal retrieval task. Theta-band frequency (4Hz) stimulation was delivered on a trial-by-trial basis for two seconds preceding the retrieval cue onset, with a fixed phase-lag (e.g., 0°, 180°) between the two target regions. Stimulation with a phase-lag (180°) impaired temporal retrieval while not affecting spatial retrieval. Our preliminary findings thus suggest that stimulating the core nodes at the appropriate phase-lag may effectively modulate the network function, and while in this case it impaired memory processes, this sets the ground work for further studies.

Title: Mental simulation of routes during navigation involves adaptive temporal compression

Authors: *A. E. ARNOLD[1], G. IARIA[3], A. D. EKSTROM[2];
[2]Psychology & Ctr. for Neurosci., [1]Univ. of California Davis, Davis, CA; [3]Psychology, Univ. of Calgary, Calgary, AB, Canada

Abstract: Mental simulation is a hallmark feature of human cognition, allowing features from memory to be flexibly used during prospection. While past studies demonstrate the preservation of real-world features such as size and distance during mental simulation, their temporal dynamics remain unknown. Here, we compare mental simulations to navigation of routes in a large-scale spatial environment to test the hypothesis that such simulations are temporally compressed in time, a hypothesis based on findings from place cell recordings in the rodent hippocampus during pre-play/replay events. Additionally, we hypothesized that the temporal compression rate would be adaptive, changing based on the speed at which environmental features used for the simulations were originally experienced. Over three separate experimental conditions that varied movement speed (*N* for condition 1: 28, condition 2: 26, condition 3: 26), our results show that simulations occurred at 2.39x the speed it took to navigate a route, increasing in compression (3.57x) for slower movement speeds. Additionally, participant self-reports of vividness (medium movement condition: $\beta = -0.19$, $p = 0.004$) and spatial coherence (fast movement condition, $\beta = -0.21$, $p = 0.003$) of the simulations were significant predictors of simulation duration, providing an important link between subjective experiences of simulated events and how spatial representations are combined during prospection. These findings suggest that simulation of spatial events involve adaptive temporal mechanisms, mediated partly by the fidelity of memories used to generate the simulation.

Title: Low-frequency oscillations in the human hippocampus during real-world and virtual navigation

Authors: *M. COPARA[1], A. D. EKSTROM[2], J. GOTMAN[3], V. D. BOHBOT[4];
[2]Psychology, [1]UC Davis, Davis, CA; [3]Montreal Neurolog. Inst., McGill Univ., Montreal, QC, Canada; [4]Dept. of Psychiatry, Douglas Inst. - McGill Univ., Verdun, QC, Canada

Abstract: Low frequency oscillations (LFO) are a hallmark of spatial navigation in the rodent hippocampus. While past studies have also identified LFOs in the human hippocampus during virtual navigation (VR), these oscillations are of lower prevalence and peak at a lower frequency than those in the rodent. To date, however, technical barriers have prevented recordings of LFOs in the human hippocampus during free ambulation and comparing with recordings in VR. We surmounted this barrier by recording intracranial hippocampal EEG from ambulating patients with intractable epilepsy while they performed both real-world and virtual navigation tasks. Specifically, patients freely ambulated in a real-world environment by searching for five hidden locations in a room; they also navigated a virtual maze on a desktop computer using a joystick. Raw traces during searching for hidden locations revealed clear evidence of low-frequency rhythmicity, with power spectral density (PSD) plots showing peaks around 7-9Hz on some electrode contacts and 1-4 Hz on other contacts, both showing significantly greater power than stop periods in the same session. Similarly, we observed increased LFOs during recall of the previously learned targets and during real-world walking, in which patients ambulated in an unconstrained manner with no specific task demands. Our findings suggest that real-world movement elicits LFOs and that these are reduced during stopping periods. During VR navigation, we again found significant levels of LFOs, although raw traces and PSDs suggested a lower peak frequency than during real-world navigation. Comparing the distribution of significant contacts during virtual navigation with real-world searching demonstrated a significant cross-over interaction, with a greater number of contacts showing increases in the delta band (1-4 Hz) during virtual than real-world searching compared with the theta/alpha band (8-12 Hz). Together, our findings help resolve an important debate regarding LFO in the human hippocampus. First, we show prominent LFOs during real-world searching, walking, and recalling locations, which were present across the low frequency spectrum (1-12 Hz). These effects were consistently higher during movement than stopping periods, implicating movement itself as a generating mechanism for these oscillations. Second, we found that virtual movement induced oscillations peaking within a lower frequency band than real-world searching. Together, these findings confirm previous theoretical proposals suggesting that virtual movement in humans may shift the frequency-wise prevalence to a lower range than real-world movement.

Title: Evidence for oscillatory coding akin to phase precession in the human hippocampus

Authors: *S. E. QASIM[1], A. J. WATROUS[1], I. FRIED[2], J. JACOBS[1];
[1]Biomed. Engin., Columbia, New York, NY; [2]Neurosurg., UCLA, Los Angeles, CA

Abstract: Theta phase precession is a well established example of temporal coding in the rodent hippocampus, whereby the oscillatory phase when a neuron spikes decreases across successive cycles of the theta rhythm. Given that hippocampal oscillations are thought to underlie behavior in other species and tasks, we sought to test for a similar temporal code between neuronal spiking and oscillations in humans. We analyzed single-neuron and local-field-potential (LFP) data recorded from surgical patients performing a virtual navigation task. During spiking episodes a significant number of cells in amygdala and hippocampus (11% and 15%, respectively) exhibited significant circular-linear correlation between “low theta” (1-4 Hz) LFP phase and spike latency. These patterns were more prominent during periods of movement rather than stillness in our virtual reality task. Though a small number of cells exhibited this relation with the phase of “high theta” (4-10 Hz), this pattern was not robust statistically in any particular region.
Our data show, for the first time we know of in humans, the existence of a relation between timing in a spiking episode and the phase of neuronal oscillations. This pattern appears to be similar to the phase precession observed in rodents. Because this effect was focused in the low theta band, it recapitulates previous findings indicating a special role for oscillations in this range in human navigation.

Title: Recurring spatiotemporal patterns in cortical high gamma and their behavioral correlates: evidence for human memory replay

Authors: *X. JIANG[1], I. SHAMIE[2], S. CASH[4], T. THESEN[5], E. HALGREN[3]; [1]Neurosciences, Univ. of California San Diego, La Jolla, CA; [3]Radiology, Neurosciences, and Psychiatry, [2]UCSD, La Jolla, CA; [4]Neurosurgery, Epilepsy Div., Massachusetts Gen. Hospital, Harvard Med. Sch., Boston, MA; [5]Comprehensive Epilepsy Ctr., New York Univ. Sch. of Med., New York, NY

Abstract: Animal studies support the hypothesis that in slow-wave sleep, replay of waking neocortical activity under hippocampal guidance leads to memory consolidation. However, no direct electrophysiological evidence exists in humans. We analyzed 4-day long human intracranial recordings to reveal consistent spatio-temporal patterns of cortical High Gamma present during waking. In all subjects, more of the waking patterns (most of which were novel) had more matches with activity in the sleeps following the reference waking period than with activity in preceding sleeps. This predominance of matches to after-waking sleep activity was also observed for patterns that occurred in waking time periods that involve performing tasks with multisensory stimuli (e.g. watching movies), as well as for patterns that overlap with human face-containing movie frames for subjects that watched the same movie. In addition, High Gamma activity in matched patterns was coupled to elevated neocortical spindle power, slow oscillation power, and broad-band hippocampal activation. We therefore conclude that replay of large-scale cortical activation patterns during sleep may embody a predicted neural mechanism of human memory consolidation.

Title: Multivariate pattern analysis of human intracranial electrocorticography predicts speed during virtual navigation

Authors: *A. A. ROBBINS[1], P. HORAK[1], A. C. CONNOLLY[1], B. JOBST[1,2];
[1]neurology, Geisel Sch. of Med., Lebanon, NH; [2]Neurol., Dartmouth-Hitchcock Med. Ctr., Lebanon, NH

Abstract: Spatial navigation is often used in experimental neuroscience to investigate the mechanisms of learning and memory. These tasks allow for insight into the dynamics of the brain processed that occur in order to complete navigational tasks. In this study we recorded intracranial EEG (iEEG) from depth and cortical electrodes that were implanted in patients with intractible epilepsy. The virtual navigation task was built using the "Source Engine" (Valve™), and was designed to mimic rodent pellet chasing. In this task subjects collect 64 coins which randomly appear one at a time in a grid-like fashion within the environment. Power within six different frequency bands (delta, theta, alpha, beta, low gamma and high gamma) was used to train a linear discriminant analysis (lda) classifier to predict the speed of movement within the environment. This classification method was able to accurately predict movement speed (stopped, slow or fast) in the six subjects that were tested ($p < 0.01$). Power from electrodes within the frontal, temporal and hippocampal regions were the most prominent regions with predictive accuracy. Within those regions, the theta band was more often predictive than the beta, low gamma and high gamma bands ($p=0.0047$); but not the delta or alpha bands. These results are consistent with previous studies showing that slow frequency oscillations change with speed in virtual environments. The inclusion of frontal and temporal lobe electrodes in our analysis suggests that regions other than the hippocampus are responsive to changes in speed and may be important for sensory integration of memory processes.

Title: An isotropic 3D spatial representation of a multi-level building in the human brain

Authors: *M. KIM, E. A. MAGUIRE;
Wellcome Trust Ctr. For Neuroimaging, Inst. of Neurol., Univ. Col. London, London, United Kingdom

Abstract: The world is three-dimensional (3D) but most previous neuroscientific studies have investigated spatial memory and navigation on a horizontal two-dimensional plane, leaving much unknown about how 3D spatial information is represented in the brain. Gravity adds complexity to 3D navigation by imposing energy constraints on movement along the vertical dimension, and it has been proposed that the brain might use a planar encoding strategy, with consequently reduced sensitivity to the vertical dimension. However, a previous fMRI study we conducted revealed that vertical and horizontal place information was equally well encoded in the hippocampus (Kim et al., submitted). This previous experiment was based within a 3D lattice-like virtual environment, whereas 3D space is often compartmentalized by walls and floors. Thus, vertical and horizontal spatial information might be asymmetrically represented within multi-level buildings. We addressed this issue by investigating behavioural and fMRI responses while participants moved within a virtual reality multi-level building (Figure 1A). If 3D space is isotropically processed, the neural representation of each place should be equally distinguishable, predicting a similar degree of repetition suppression for both vertical and horizontal axes. By contrast, if vertical information is under-represented, the neural representation of two locations that only differ by floor (e.g. A1 and C1 in Figure 1A) would be more similar, and hence show a greater repetition suppression effect. Preliminary results suggest that the human hippocampus has a symmetric representation of space in this building (Figure 1B). In addition, we found that retrosplenial cortex, another structure implicated in navigation and spatial processing, contained global context information (e.g. the specific room within the building) with equal sensitivity to

vertical and horizontal axes (Figure 1B). These results suggest that the 3D world can be isotropically represented in the human brain even when space is compartmentalized.

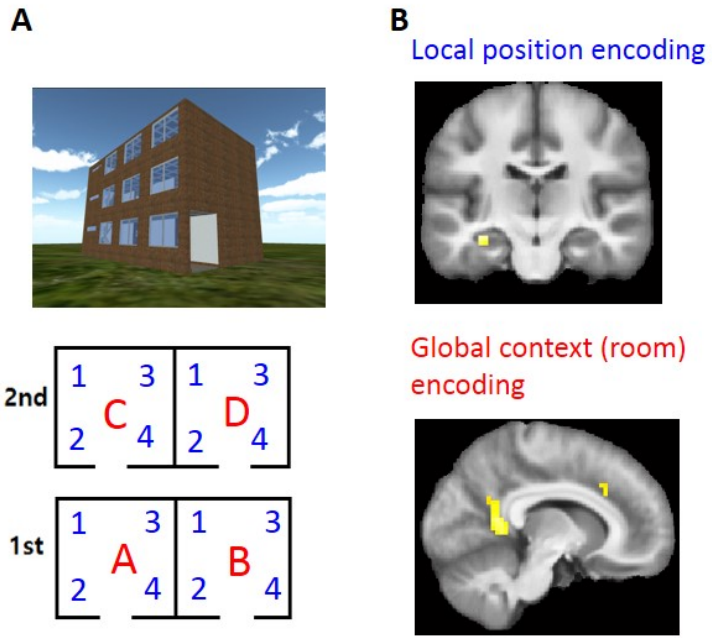

Figure 1. **A** Top panel, a view of the outside of the virtual building. Bottom panel, a schematic of the 16 locations within the building, which had two main floors. **B**, Top panel, anterior hippocampus contained significant local position information as revealed by repetition suppression effects. Bottom panel, retrosplenial cortex encoded room information.

Title: The role of the human hippocampus in map reading and route following

Authors: *Z. J. URGOLITES[1,4], S. KIM[5], R. O. HOPKINS[6,7], L. R. SQUIRE[4,1,2,3];
[1]Dept. of Psychiatry, [2]Dept. of Neurosciences, [3]Dept. of Psychology, UCSD, La Jolla, CA; [4]Veterans Affairs San Diego Healthcare Syst., San Diego, CA; [5]Dept. of Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA; [6]Dept. of Psychology and Neurosci. Ctr., Brigham Young Univ., Provo, UT; [7]Dept. of Medicine, Pulmonary and Critical Care Div., Intermountain Med. Ctr., Murray, UT

Abstract: Two views have been central to discussions about the function of the hippocampus. One view grew out of work with humans and emphasizes the importance of the hippocampus for memory. By this view, the hippocampus is important for the formation of declarative (long-term) memory, not for immediate memory or for its maintenance by what is ordinarily termed working memory. The second view grew out of work with rodents and emphasizes the importance of the hippocampus for spatial navigation. The suggestion is that the hippocampus is needed to perform certain on-line spatial computations. In one sense these views are compatible because spatial memory is a type of memory. However, a puzzle arises when one turns to tasks of spatial navigation that are manageable within working memory. Do these tasks depend on the hippocampus? In the present study, participants navigated an array of dots on the floor by following paths indicated on maps (Figure 1). The paths involved 1 to 9 turns. Participants held the map in their hands in a fixed position throughout each trial. Thus, the role of long-term memory in the task was minimal. Nevertheless, participants needed continually to translate the spatial coordinates of the map into geographical coordinates, because the orientation of the hand-held maps was frequently rotated away from true north as participants made turns. Patients with lesions limited to the hippocampus (N=5) performed similarly to controls (N=13) across all path lengths ($p > 0.10$). Patients and controls also had similar and constant error rates at each turn regardless of whether a turn occurred early or late in the path ($p > 0.10$). In contrast, patients were markedly impaired at remembering factual details about the experiment ($p < 0.01$). These findings show that the hippocampus is essential for forming long-term declarative memory and that it does not support the spatial computations needed for map reading and route following when the task is manageable within working memory.

Figure 1. A sample map from the experiment. This map consists of 5 turns.

Title: Functional connectivity in the human medial temporal lobe during memory-guided spatial navigation

Authors: ***S.-F. WANG**[1], V. CARR[3], S. E. FAVILA[4], J. BAILENSON[2], A. D. WAGNER[1]; [1]Dept. of Psychology, [2]Dept. of Communication, Stanford Univ., Stanford, CA; [3]Dept. of Psychology, San Jose State Univ., San Jose, CA; [4]Dept. of Psychology, New York Univ., New York, NY

Abstract: The medial temporal lobe (MTL) plays a critical role in both spatial navigation and episodic memory. Previous studies suggest that, within the MTL, parahippocampal cortex (PHC) is important for representing spatial environments while perhinal cortex (PRC) is important for representing objects within an environment. Data in rodents indicate that neurons in hippocampal

subfields dentate gyrus (DG), CA3, and CA1 differentially respond to the global environment, locations within environments, and valence of objects. A central question is how do these MTL cortical regions and hippocampal subfields interact to support memory-guided spatial navigation. To answer this question, we combined high-resolution fMRI with a virtual reality paradigm in which subjects relied on memory to navigate through two different macroscopic environments to traverse to reward-associated locations. We applied functional connectivity (FC) analyses to determine how activity covaries across MTL cortical and hippocampal subregions while subjects navigated to learned target locations within each environment. Analysis of activity throughout the entire task (i.e., during both navigation and non-navigation periods) revealed that activity in DG/CA3 and CA1 more strongly covaried with that in PHC (DG/CA3 and PHC: $r = 0.23$, $p<0.01$; CA1 and PHC: $r = 0.27$, $p<0.01$) than with that in PRC and entorhinal cortex (ERC) (DG/CA3 and PRC: $r = 0.13$; DG/CA3 and ERC: $r = 0.12$; right-CA1 and right-PRC: $r= 0.12$; CA1 and ERC: $r = 0.14$). Within MTL cortex, PRC and ERC activity covaried ($r = 0.37$). When the same analyses were repeated for the navigation period only, correlations between hippocampal subfields and PHC were even stronger. These results suggest that, during memory-guided spatial navigation, PHC and hippocampal subfields increase their functional interactions, forming a functional network that enables successful navigation to goal-relevant locations. Future analysis will examine how FC within the MTL varies with macroscopic environments and locations and how FC between the MTL and the reward system vary with the value of the memory-guided navigational target.

Title: The hippocampus operates in a continuous manner during spatial memory

Authors: *B. M. JEYE, J. M. KARANIAN, S. D. SLOTNICK;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: There is a long-standing debate as to whether recollection is a threshold/all-or-none process or a continuous/graded process. In the current spatial location memory fMRI study, we examined activation profiles in the hippocampus to determine the nature of processing in this region. During encoding, participants viewed abstract shapes in the left or right visual field.

During retrieval, the same shapes were presented at fixation and participants classified each shape as previously in the “left” or “right” visual field followed by an “unsure”-“sure”-“very sure” confidence rating. The contrast of accurate versus inaccurate memory for items previously presented in the left visual field (left-hits > left-misses) produced two activations in the hippocampus ($p < 0.001$, corrected for multiple comparisons to $p < 0.05$). The analogous contrast for items previously presented in the right visual field did not produce any significant activations in the hippocampus. The corresponding activation profiles were generated by plotting the magnitude of activity as a function of memory strength for left items (left-miss-“very sure”, left-miss-“sure”, left-miss-“unsure”, left-hit-“unsure”, left-hit-“sure”, left-hit-“very sure”) and right items (right-hit-“very sure”, right-hit-“sure”, right-hit-“unsure”, right-miss-“unsure”, right-miss-“sure”, right-miss-“very sure”). The threshold model dictates that there is a threshold in the activation profile above which only high memory strength items show activation (e.g., left-hit-“very sure” activity > 0 and right-miss-“very sure” activity = 0), while the continuous model dictates that the activation profiles will be completely overlapping (i.e., all activations should be > 0). In support of the continuous model of recollection, the activation profiles were completely overlapping, as all of the activation magnitudes were significantly greater than zero. Receiver operating characteristics (ROCs, hit rates versus false alarm rates) were generated and fit with the two-high threshold model and the unequal variance continuous model, but both models adequately fit each ROC. Although an equal variance continuous model did not adequately fit a hippocampal spatial memory ROC in a previous study, the present differential activity for items in the left and right visual fields and adequate fit for the unequal variance model indicate that the equal variance model does not reflect hippocampal function. The present results demonstrate that the hippocampus operates in a continuous manner during spatial location memory and highlight the utility of analyzing activation profiles to determine the nature of neural processing.

Title: Use of hippocampally-dependent navigation strategies is associated with low self-reported stress and high trait mindfulness

Authors: D. BOWES[1], A. RAINS[1], K. KONISHI[2], L. DAHMANI[2], V. D. BOHBOT[2], *N. C. SCHMITZER-TORBERT[1];
[1]Dept. of Psychology, Wabash Col., Crawfordsvlle, IN; [2]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada

Abstract: Mindfulness training (mindfulness-based stress reduction, MBSR) has been found to be effective in reducing stress and improving cognitive function, and to produce changes in regional grey matter density in brain areas including the hippocampus. Most studies of MBSR's effects on cognitive function have focused on improvements in attention and working memory, but some studies have found improvements in declarative memory following MBSR training. Other work has shown that even in participants who have not completed mindfulness training, regional grey matter density in the hippocampus is positively associated with measures of dispositional (trait) mindfulness. Here, we investigated if dispositional mindfulness was associated with the use of spatial navigation strategies in a set of virtual navigation tasks. Participants (n = 111) were recruited through Amazon's Mechanical Turk service after completing the Five Facet Mindfulness Scale (FFM). Participants completed up to four automated versions of existing navigation tasks: the 4 on 8 virtual maze (Iaria, Petrides, Dagher, Pike, & Bohbot, 2003), the Concurrent Spatial Discrimination Task (CSDLT, Etchamendy, Konishi, Pike, Marighetto, & Bohbot, 2012), a wayfinding task set in a virtual town and a virtual water maze. Results from the behavioral tasks fit our expectations based on previous research (performance on the wayfinding and water maze task was strongly related, and flexible performance on the CSDLT was associated with better performance on the wayfinding and water maze task). Only the 4 on 8 task was associated with trait mindfulness, with participants who reported using hippocampus-dependent place spatial strategies also reporting higher scores on the Describe FFM subscale but not other FFM subscales. In a second study, participants completed the Calgary Symptoms of Stress Inventory (C-SOSI), and participants (n = 96) with high (C-SOSI > 50) and low (C-SOSI < 50) stress scores were recruited to complete the FFM and the 4 on 8 virtual maze. C-SOSI scores were negatively correlated with several FFM subscales, and participants reporting high levels of stress were less likely to use hippocampus-dependent spatial strategies (though, a small number of participants reporting very high scores, C-SOSI > 100, were more likely to use spatial strategies). These data provide some support for the claim that hippocampus-dependent spatial strategies may be associated with both dispositional mindfulness and self-reported stress. Programs which aim to reduce stress by increasing mindfulness (as in MBSR programs) may thus be associated with an increase in the use of hippocampally-dependent navigation strategies.

Title: The functional role of hippocampal subregions: a high-resolution fMRI study of memory

Authors: *M. C. MACGILLIVRAY[1], S. HRYBOUSKI[2], Y. HUANG[3], C. R. MADAN[5], P. SERES[3], R. CARTER[3], N. V. MALYKHIN[4];
[1]Neurosci. and Mental Hlth. Inst., Edmonton, AB, Canada; [2]Neurosci. & Mental Hlth. Institute, Biomed. Engin., [3]Biomed. Engin., [4]Neurosci. and Mental Hlth. Institute, Biomed. Engin., Univ. of Alberta, Edmonton, AB, Canada; [5]Psychology, Boston Col., Chestnut Hill, MA

Abstract: Introduction: While it is well accepted the hippocampus plays a role in memory, the role of its subregions is less well understood. The hippocampus can be divided into subregions along its longitudinal axis. Human and animal literature has suggested the posterior hippocampus is involved in spatial navigation, while the role of the anterior hippocampus is may be involved in the stress response. The main goal of the present study was to investigate the functional role of hippocampal subregions using high-resolution fMRI.
Methods: Twenty-three healthy volunteers were recruited for this study. Participants were excluded if they had unstable medical illness, history of psychiatric or neurological disorders and the use of medications that might affect brain structure. Written informed consent was obtained and the research was approved by the University of Alberta Health Research Ethics Board. Participants viewed a 4x4 grid containing symbols in various locations and were cued to focus on certain aspects of the grid (symbol, location or both conditions). A breathing belt and heart rate (BioPac inc) monitor were used to collect physiological measurements to correct for breathing and heart rate.
Functional volumes were acquired using a 2D T2*-Weighted EPI sequence (Voxel Size:1.5x1.5x1.5 mm^3) on a 4.7T Varian Inova system. High resolution 2D T2-weighted FSE scan were acquired coronally for hippocampal tracing. 3D T1-weighted MPRAGE images were acquired for creation of CSF and WM nuisance regressors.
Results: Behavioural results show that participants performed best during the symbols condition (95%) while performance on the more difficult location and both conditions was (78%).
The strongest activation during encoding was observed in the both condition across the entire hippocampus, and in the body and tail. In addition, more activation occurred in the hippocampal tail vs. hippocampal head across all conditions.
Conclusions:

Analyses suggest differential processing of memory task conditions by hippocampal subregions. The hippocampus appears to be the most involved in encoding of the both condition vs. symbol and location conditions. The hippocampal tail is more active than the head across conditions.

Title: Hippocampal-cortical fMRI network distinctions between two types of item-context memory

Authors: ***S.-S. KIM**[1], M. HERMILLER[2], J. VOSS[2];
[1]Med. Social Sci., [2]Northwestern Univ., Chicago, IL

Abstract: Accumulating evidence suggests functional distinctions between two cortical networks of the hippocampal system: the anterior-temporal (AT) and posterior-medial (PM) networks. The AT network has been associated with item-oriented and semantic memory whereas the PM network has been associated with context-oriented and episodic memory. However, these are broad memory constructs and few direct comparisons have been made to test functional selectivity of these networks for different types of semantic or contextual memory. We designed a novel human-subject fMRI task to test memory for item-scene associations versus item-location associations using very similar formats across memoranda type. These are widely considered as two examples of contextual memory that should be relatively selective for the PM network. Functional connectivity analyses indicated stronger interconnectivity of PM network regions than AT network regions for both memory types. However, neural correlates of item-scene memory differed from those of item-location memory in that: (1) evoked activity was significantly greater in prefrontal cortex for item-scene compared to item-location memory, (2) the opposite activity pattern (item-location > item-scene) was identified for parahippocampal regions, and (3) functional connectivity patterns included more connectivity among AT network regions (particularly frontal cortex) for item-scene than item-location associations. These

findings generally support the association between hippocampal-PM networks and contextual memory, but indicate that different types of contextual memory vary significantly in terms of network recruitment. Item-scene association memory was more heavily associated with additional recruitment of regions within the AT network, suggesting less PM-specificity for this type of contextual memory.

Title: Identifying optimal transcranial magnetic stimulation sequences for enhancement of hippocampal-cortical network connectivity and memory

Authors: ***M. HERMILLER**[1], S. VANHAERENTS[1], T. RAIJ[3,2], D. BRIDGE[1], J. VOSS[1]; [1]Med. Social Sciences, Neurology, and Psychiatry, [2]Physical Med. and Rehabil., Northwestern Univ., Chicago, IL; [3]Rehabil. Inst. of Chicago, Chicago, IL

Abstract: Hippocampal-cortical networks identified by fMRI have established roles in memory encoding and retrieval. Our previous findings indicate that multi-day repetitive transcranial magnetic stimulation (rTMS) of the lateral parietal cortex can enhance associative memory and increase fMRI connectivity among multiple hippocampal-cortical network regions. However, these studies used 20-Hz rTMS trains, whereas patterned TMS such as theta burst stimulation (TBS) might be more optimal for modulation. In this study, we compared the effects of single-session intermittent TBS (iTBS), continuous TBS (cTBS), and 20-Hz rTMS on fMRI connectivity and on both item and source memory. On each of four separate experimental days, subjects (N=11) studied 96 unique words that were presented in one of eight colors. Colors were divided into two broad categories (e.g., blue or red) and each category was further divided into four shades (e.g., navy or cyan). In this way, memory for each color category and precise shade could be tested. Words were later tested in an old/new recognition test followed by forced-choice associative recognition of the source color. MRI-navigated TMS was delivered to lateral parietal cortex during the retention interval, using either rTMS, iTBS, cTBS, or sham on each of the four days, in counterbalanced order across subjects. Preliminary analyses indicate better source accuracy for the cTBS condition relative to all other stimulation conditions (sham p=0.06; iTBS

p=0.06; rTMS p=0.04). Changes in fMRI resting-state connectivity during the retention interval due to stimulation will also be discussed. These findings suggest that short-term effects of TMS on memory performance vary across stimulation frequencies and patterns. This research has implications for the optimization of noninvasive stimulation for enhancement of hippocampal-cortical memory networks.

Title: The role of dorsolateral prefrontal cortex in viewing behaviors guided by episodic memory

Authors: *D. R. O'YOUNG[1], D. J. BRIDGE[2], J. L. VOSS[2];
[1]Northwestern Univ. - Chicago, Chicago, IL; [2]Med. Social Sciences, Neurology, and Psychiatry at the Feinberg Sch. of Med., Northwestern Univ., Chicago, IL

Abstract: Episodic memory is traditionally observed in humans through explicit/declarative responses. Eye-movement tracking, when recorded in parallel with traditional methods, can also be used to observe the expression of episodic memory, as with differences in viewing of familiar versus novel memoranda. This experiment aims to determine the relationship between episodic memory, explicit responses, and viewing behaviors and to test the causal role of the dorsolateral prefrontal cortex in these cognitive and behavioral phenomena. Subjects first studied scene-face pairs, then, during subsequent cued recall testing, were given a studied scene as a cue and after which they selected the associated face from a display of three previously studied faces, only one of which was originally paired with the scene. Previous research with this task [Hannula and Ranganath, Neuron 63, 592-599, 2009] shows that increased viewing of correctly selected faces, relative to incorrectly selected faces, occurs 500-750 ms after onset of the three faces. Furthermore, accurate responses corresponded to activity in the left lateral prefrontal cortex following cue presentation, whereas increased viewing of associated faces corresponded to activity in the medial temporal lobes during this period. We found that these increases in viewing

of correct faces occurred when subjects reported face recollection when given the scene cue, but not when recollection was absent ($P<0.01$). This suggests that disproportionate viewing of correctly matching faces represents an influence of successful explicit memory retrieval on viewing behavior, which is counter to previous interpretations of disproportionate viewing as indicators of implicit memory processing. Preliminary analyses suggest that continuous theta burst stimulation of the left dorsolateral prefrontal cortex using TMS causes attenuation of the 500-750-ms disproportionate viewing effect, but no change in explicit response accuracy. These results suggest that episodic memory retrieval sufficient to support accurate explicit memory responses influences viewing behavior, and that dorsolateral prefrontal regions are more selectively involved in this influence of memory retrieval on visual exploration than they are in explicit/declarative memory expression.

Title: Intranasal insulin modulates networks involved in an episodic memory task: an fMRI study

Authors: *D. C. COCKRELL[1], S. E. ADAMS[2], R. J. MORAN[2];
[1]Virginia Tech. Carilion Sch. of Med., Roanoke, VA; [2]Virginia Tech. Carilion Res. Inst., Roanoke, VA

Abstract: Intranasal insulin (INI) administration has been shown to improve memory in some patient and healthy adult populations. Importantly, the intranasal route of delivery for insulin has demonstrated elevated CNS insulin levels in humans without altering peripheral plasma insulin or glucose levels. Despite the demonstrated effects of INI on memory, no study to date has used functional magnetic resonance imaging (fMRI) to examine the neural mechanisms underlying insulin-related memory task performance in healthy adults. We hypothesized that INI administration would modulate activity levels in parahippocampal and hippocampal regions of the brain in response to a memory task and that INI administration would improve overall memory task performance. Lastly, we hypothesized that there would be no difference in peripheral glucose and insulin levels following INI administration compared to saline. Part 1 of the study involved 8 participants undergoing blood draws after receiving separate intranasal administrations of both insulin and saline. Samples were collected and analyzed to determine

peripheral levels of glucose and insulin following administration over a period of 90 minutes. Part 2 of the study involved 40 participants undergoing a randomized, double-blinded intranasal administration of either insulin (n=20) or saline (n=20) followed by a memory task. The encoding phase of the memory task involved participants viewing 180 images (60 indoor scenes, 60 outdoor scenes, 60 scrambled images) during an fMRI scan. The recall phase of the task was conducted one hour later, as participants viewed a new set of images that included the indoor and outdoor scenes seen previously in addition to 60 new similar scenes and were asked to determine if each image had been seen before. Part 1 of the study found no significant differences between INI and saline administration in plasma insulin ($p = 0.752$) or glucose ($p = 0.679$) levels after baseline correction. Part 2 identified INI dependent activations in the right rectus gyrus and frontal lobe regions in addition to memory task performance modulation with significantly elevated activations of bilateral fusiform and parahippocampal gyri for remembered images compared to forgotten images (all FWE corrected, $p < 0.05$). Importantly, insulin enhanced activity in regions which were correlated with remembering, specifically in the right parahippocampus, right mid cingulum, and bilateral rectus gyri. These findings suggest that INI may support memory encoding by increasing network activations in the parahippocampus via inputs from the prefrontal and cingulate cortex.

Title: Ultra-high resolution imaging of the medial temporal lobe at holistic episodic recollection

Authors: *X. GRANDE[1,2], J. A. BISBY[3,4], D. BERRON[1,2], E. DÜZEL[1,2,3], N. BURGESS[3,4]; [1]Inst. f. Kogn. Neurologie u. Demenzforschung, Magdeburg, Germany; [2]German Ctr. for Neurodegenerative Dis., Magdeburg, Germany; [3]Inst. of Cognitive Neurosci., [4]Inst. of Neurol., Univ. Col. London, London, United Kingdom

Abstract: A crucial characteristic of episodic memory is holistic recollection. Functionally this is reflected by comprehensive cortical reinstatement of the elements that form a memorized event. A recent study showed that the hippocampus is involved in the reinstatement of event elements, including those incidental to a task (Horner, Bisby, Bush, Lin, & Burgess et al., 2015). We obtained submillimetre (0.8 isotropic) resolution data at 7Tesla using the same multi-element event paradigm to investigate the specific involvement and the interplay of hippocampal subfields in the process of holistic episodic recollection. Theoretical models and animal studies propose that hippocampal subfield CA3 completes partial cues and subfield CA1 reinstates the completed pattern via backprojections in cortical regions. Therefore, we expect hippocampal subfields CA3 and CA1 to be involved in the holistic recollection of events upon partial cues. We hypothesize that the connectivity between subfield CA3 and CA1 reflects the amount of cortical reinstatement of incidental event elements. The study contributes to our understanding of the interaction between the hippocampal circuit and cortical regions to accomplish holistic episodic recollection.

Title: Hippocampal subfield volumes contribute to episodic memory development

Authors: ***A. KERESZTES**[1], A. R. BENDER[1], N. C. BODAMMER[1], M. WERKLE-BERGNER[1], Y. L. SHING[2,1];

Abstract: Successful memory formation and retrieval crucially depends on the ability to distinguish between overlapping memory representations. The CA3 and dentate gyrus (DG) subfields of the hippocampus (HC) have been implicated in the orthogonalization of mnemonic contents by implementing pattern separation on neural inputs to the HC (Yassa & Stark, 2011). It is still unclear how pattern separation fits into cognitive process models of human memory and how the structural maturation of the HC subfields is related to episodic memory development.

Challenges in addressing these problems are manifold, and include difficulties in disentangling multiple HC-related episodic memory processes and limitations of standard magnetic resonance imaging (MRI) methods for reliable delineation of HC subfields. To address these challenges, we used high-resolution structural MRI, acquired on a 3T scanner in a sample of children (N = 69, aged 6–14 years) and young adults (N = 33, aged 18-26 years) to investigate the relationship between structural maturation of HC subfields and pattern separation and episodic memory processes. Participants performed an incidental learning task designed to assess pattern separation behaviorally (Bakker et al., 2008; Stark et al., 2013). Participants also completed additional tests measuring recognition memory, recollection and familiarity, associative and item memory, as well as context memory. Entorhinal cortex, subiculum, CA1/2, and CA3/DG were manually segmented by experienced, reliable raters. We observed age-related increases in subiculum, CA1/2, and CA3/DG volumes, in behavioral measures of pattern separation, as well as in measures of episodic memory processes. Results revealed age-invariant associations between HC subfields and episodic memory processes: specifically, pattern separation was most strongly associated with DG/CA3 volume, whereas general recognition performance was most strongly related to CA1/2 volume. The present results corroborate earlier findings linking HC subfields to pattern separation, and extend this relationship into child development. More importantly, these results characterize the parallel trends of HC subfield development and pattern separation maturation, and establish their age-invariant contributions to episodic memory processes. In sum, by taking a developmental perspective, the present study provides an important step in bridging the gap between computationally inspired models of HC networks and episodic memory theories.

Title: Episodic and autobiographical memory in humans and robots

Authors: *T. J. PRESCOTT[1], D. CAMILLERI[1], A. DAMIANOU[1], U. MARTINEZ[2], N. LAWRENCE[1];
[1]Univ. Sheffield, Sheffield, United Kingdom; [2]Univ. of Leeds, Leeds, United Kingdom

Abstract: Human episodic and autobiographical memory can be considered as an attractor network operating in a latent variable space whose dimensions encode salient characteristics of the physical and social world in a highly compressed fashion. Instantaneous memories then correspond to points in this latent variable space and episodic memories to trajectories through this space. Seeding such a mechanism with appropriate cues will allow retrieval of a past episode, but the same system can also serve to fill-in and enrich the representation of the current situation, providing the potential for more informed action. As part of the development of a broader brain-based architecture for social cognition in a humanoid robot we are exploring the hypothesis that suitably a configured systems-level model of human memory can support effective Synthetic Autobiographical Memory (SAM) for robots. The operation of the perceptual systems that provide input to episodic memory can be analogised to deep learning processes that identify psychologically meaningful latent variable descriptions. Deep Gaussian Process (DGP) neural network models have many attractive properties including the ability to discover highly compressed latent variable spaces, to form attractors that encode temporal sequences, and to act as generative models. The core element of our robot SAM system is therefore constituted by a set of DGP models that represent memories of multiple heterogeneous sensory modalities through a compressed latent feature space and a set of anchor points. The model "knows" how to combine these two elements to reconstruct past memory, or to generate fantasy memories (imagination). Chunking and pattern separation are also naturally manifested within this formulation. By linking sensory primitives of multi-modal memories to verbal descriptions of episodes stored elsewhere in the system the SAM model also provides a way to ground linguistic accounts in remembered experience. Our current implementation of robot SAM for the iCub humanoid robot is able to demonstrate effective memory formation and retrieval of human faces, actions, objects, and sequences of agents acting on objects. The system is also able to imagine possible sequences, such as a person's future action. Future work aims to extend this research to more brain-like models of episodic memory, incorporating insights from fMRI and neurobehavioural data concerning the interaction of the hippocampal system with primary and secondary sensory cortical areas, and thus provide an embodied test of theories and computational models of human episodic memory function.

Title: Modelling trans-thalamic coherence of cortical gamma-band activity in MEG

Authors: ***F. ROUX**[1], P. J. UHLHAAS[2], J. GROSS[2];
[1]Sch. of Psychology, Univ. of Birmingham, Birmingham, United Kingdom; [2]Inst. of Neurosci. and Psychology, Univ. of Glasgow, Glasgow, United Kingdom

Abstract: Emerging data from electrophysiological recordings in thalamo-cortical (TC) circuits indicate that thalamic alpha rhythms could coordinate cortico-cortical communication by establishing coherent gamma-band activity in distinct cortical areas during cognitive processing (Saalmann et al., 2012). This thalamic coordination of cortico-cortical communication could arise from the abundant non-reciprocal projections that route inputs from one cortical area to another cortical area by passing through higher-order thalamic nuclei such as the pulvinar (Theyel et al., 2009; Schmid et al., 2012). Given that alpha oscillations are a prominent feature of magnetoencephalographic (MEG) recordings, the analysis of whole brain activity with MEG could provide important insights into the role of thalamic alpha rhythms in establishing coherent gamma-band activity in distinct cortical areas. However, due to the rapid decay of magnetic fields, the localization of thalamic sources with MEG has remained challenging as thalamic generators may be shadowed by sources located much closer to the sensors. Here, we assess how differences in field strength produced by thalamic and cortical sources influence the reconstruction of TC interactions by simulating a set of coherent dipoles in the thalamus and cortex. Specifically, simulated thalamic and cortical regions were coupled through cross-frequency interactions at alpha (10Hz) and gamma (70Hz) frequencies and their amplitude levels were varied parametrically. Our simulations show that the coupling of cortical gamma-band power to the phase of thalamic alpha activity can be reconstructed from MEG-data if the amplitude of thalamic dipoles is larger than the amplitude of cortical dipoles. The reconstruction of TC interactions, by contrast, is deteriorated by weaker thalamic sources. The present findings suggest that TC interactions including TC transmission delays can be reliably reconstructed from MEG-data despite the spatial decay of magnetic fields and in the presence of simultaneously active cortical sources. These data support previous evidence from our group on the reconstruction of TC interactions in resting-state MEG-recordings and may have important implications for the assessment of transthalamic cortico-cortical coherence with MEG.

Title: Whole brain dynamic resting state functional connectivity of the basal nucleus of Meynert & ventral striatum

Authors: *S. ZHANG, S. HU, C.-S. R. LI, 06519;
Yale Univ. Sch. of Med., New Haven, CT

Abstract: Background: The basal nucleus of Meynert (BNM) provides the primary cholinergic inputs to the cerebral cortex and has been implicated in the etiology of Alzheimer's and Parkinson's disease. Our previous study (Li et al, 2014, NeuroImage) examined resting state functional connectivity (rsFC) of the BNM and ventral striatum (VS). Recent studies suggest that rsFC is dynamic, whereby distinct network connectivities characterize individual time periods in transition. The dynamic nature of rsFC provides additional information on network connectivities and may shed new light on cerebral functions in health and illness. Here, we examined the dynamic rsFC of the BNM and VS.
Methods: In resting state fMRI data (3T, 10 minutes, eye closed) of 80 healthy adults, we computed seed-region based correlation with a sliding window approach to obtain a series of correlation maps for each individual subject. The correlation maps were converted to z score maps (by Fisher's z transform), which were pooled across all subjects and clustered using a K-means algorithm. On the basis of the clustering results, images in one group (state) were averaged to generate a state "z map" for each individual subject, and these state "z maps" were used for group comparisons.
Results: The results of 1000 runs of K-means clustering suggested an optimal cluster number of 4 according to Bayesian Information Criterion (BIC) for both BNM and VS seeds. Group analysis showed that these 4 states dynamic networks provided important additional information comparing to traditional rsFC networks. For instance, the BNM is characterized by dynamic connectivity to a vmPFC-pCingC (default mode, state I), mPFC-striatal-cerebellar (executive control, state II), mPFC-thalamic-insular (saliency, state III) and mPFC-striatal-motor cortical (action, state IV) network. Furthermore, the transitions between these four states were all observed, but some of them were more frequent than others. For example, transitions from state I

to II were much more than transitions from state I to III and state I to IV (all p's = 0.002). **Conclusions**: The findings support dynamic rsFC of the BNM and VS. These dynamic rsFC networks provide additional information on cerebral dynamics that elude traditional analytics. Supported by NIH grants K25DA040032, DA023248, AA021449.

Title: Delta phase-amplitude coupling in cued-attention task reflects task behavior

Authors: *R. CHACKO[1], E. C. LEUTHARDT[2];
[1]Washington Univ. In St. Louis SOM, Saint Louis, MO; [2]Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Introduction: Recent studies indicate that there are interactions between oscillations of different frequencies within local brain regions and across distant locations. One theory suggest this activity is epiphenomena of synchronized spike timing. This theory holds that phase-amplitude coupling PAC reduces the potential information represented in an electrode. We investigate this possibility by comparing changes in PAC between task and rest conditions.
Methods: We recorded brain activity from 6 subjects with implanted ECoG arrays. We define electrodes that encode task conditions as task-relevant. We evaluate PAC by comparing differences in modulation index (MI) during task and rest conditions using a monte-carlo resampling procedure. We compare the number of significant changes in PAC for task-relevant and task-irrelevant electrodes using a chi-squared test.
Results: On average we find a reduction in PAC during the task. Exceptions show increases in delta-beta and delta-gamma phase-amplitude coupling. We find task-relevant electrodes are more likely to exhibit changes in phase amplitude. However, this effect did not reach statistical significance in a single patient analysis.
Discussion: The general reduction in PAC in task-relevant electrodes during the task conditions fits the theory that a reduction in PAC represents an increase in information content. However, exceptions suggest this theory is too simple to account for the diversity of PAC behavior.

Title: Rapid network reconfigurations within the alpha band following single pulses of TMS

Authors: ***J. O. GARCIA**[1], Q. K. TELESFORD[2,1], A. ASHOURVAN[2,1], D. S. BASSETT[2], J. M. VETTEL[1,2,3];
[1]U.S. Army Res. Lab., Aberdeen Proving Ground, MD; [2]Dept. of Bioengineering, Univ. of Pennsylvania, Philadelphia, PA; [3]Psychological & Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Alpha band activity (8-12Hz) is an intrinsic brain oscillation of prominent study due to its robustness in both resting state and task-dependent EEG paradigms. Hypothesized functions of this oscillation range from priming the brain for incoming information in a 'brain state' of *inactivity* (Adrian & Matthews, 1934) or *cortical idling* (Pfurtscheller et al., 1996), to a *gate* of perceptual information (Jensen and Mazaheri, 2010), or even an *access controller* to a knowledge system (Klimesch et al., 2012). Collectively, alpha activity consistently represents a diffuse, communicative signal with multiple functions (Basar et al., 1999), but the parameters that govern these functions remains elusive. Recent analyses on neural measures have used a more hodological approach of *interacting systems* rather than a topological perspective of *important brain areas* (Bortolleto et al., 2015), leveraging methods in network science to investigate system interactions (e.g., Bassett & Bullmore, 2006). We hypothesize that these multiple functions in alpha activity may be parameterized via metrics of modularity within a network science framework. In this study, we employ single-pulse transcranial magnetic stimulation (TMS) to measure the rapid network reconfigurations following stimulation of four entry points in right and left occipital and parietal cortices. We compute connectivity across pairs of estimated brain sources using debiased weighted phase lag index (dwPLI, Vinck et al., 2011), and we examine dynamic network communities by optimizing a modularity quality function using a Louvain-like greedy algorithm (Blondel et al., 2008; Jutla et al., 2011). Dynamic communities from non-TMS, *resting-state* intervals reveals distinct communities from coordinated activity within bilateral frontal and posterior regions as well as lateralized temporal regions. We find that TMS to (1) parietal regions increases the network allegiance between the

posterior and frontal communities, revealing that regional node pairs from these cortices consistently change network communities together, (2) the left occipital region decreases node allegiance within the frontal community, suggesting independent node change, and (3) overall nodal changes in community assignment after TMS cohere into a more complex organization than the resting-state community assignments. This research extends the resonant frequency account (Rosanova et al., 2009) of single pulse TMS to networks outside of the 'natural frequency' of the stimulation site and extends previous findings of local-global interactions from the temporal domain (Garcia et al., 2011) to the spatial domain.

Abstract: Across the visual attention network, classical effects of attention on low frequency (alpha) suppression have been characterized in human EEG, and high frequency spiking activity has been investigated in many animal neurophysiology studies. However, detailed electrophysiological analyses on spatial selectivity and the effects of attention across these frequency domains in the human brain have not been reported. Here, we analyzed ECoG signals recorded from 8 epilepsy patients performing an Eriksen flanker task variant. Following a spatial cue and variable delay interval, subjects differentiated between two shapes at the cued location in an array of distracters, allowing us to measure selectivity within 25 degrees of visual angle. Using our probabilistic atlas of the human visual system (Wang et al., 2014), we localized electrodes to visual topographic areas and identified those with cue-evoked spatially-selective high-frequency broadband power (HFB). In the V3 complex (V3A/B), posterior intraparietal cortex (IPS0-2), and the lateral occipital complex (LO1/2), HFB power signaled the location of the up-coming target throughout the delay, and attention-related spatially-specific modulation persisted in response to the target. In these areas, we also found that alpha suppression was spatially selective in these intervals. Further, the strength of the HFB selectivity was strongly correlated with the selectivity of the alpha suppression. This parallel representation of space in low and high frequency bands suggests a coordinated functionality of processing that may integrate information transfer across these cortical areas.

Title: Changes in lateral prefrontal cortex oxygenation as a function of oddball task difficulty: A near-infrared spectroscopy study

Authors: *W. RIZER, J. ADAY, S. CONGER, J. CARLSON;
Psychology, Northern Michigan Univ., Marquette, MI

Abstract: The detection of goal-relevant stimuli in the environment is important for survival, but not all stimuli are easy to detect. Research on the P300 event-related potential indicates that as targets become more difficult to detect the posterior P300 attenuates. Functional MRI research suggests that target detection involves attention processes supported by the prefrontal cortex. However, the extent to which target difficulty differently activates the prefrontal cortex is unknown. We addressed this knowledge gap by collecting oxygenated (HbO) and deoxygenated hemoglobin (HbR) concentrations during an oddball task, which contained easy and difficult conditions, using a near-infrared spectroscopy (NIRS) optode array affixed above 10-20 coordinates Fp1 and Fp2 (N = 20). Reaction times were faster in the easy (M = 484.06) compared to difficult condition (M = 558.63), additionally participants missed fewer targets in the easy (M = 1.55) compared to difficult condition (M = 7). NIRS data was time locked to target onset and data from 5-10s post-target was averaged and analyzed. Both HbO and HbR had main effects for optode with lateral increases in HbO ($p = 0.04$) and lateral decreases in HbR ($p = 0.012$). An interaction between optode and condition approached significance for HbO ($p = 0.082$) and was significant for HbR ($p = 0.001$) with lateral optodes in the difficult condition recording the lowest HbR. The data indicates that lateral prefrontal regions (covered by the array) use more oxygen than medial prefrontal regions during both oddball tasks, but to a greater extent in the difficult condition.

Title: Decoding attentional states using multi-voxel pattern analysis.

Authors: ***S. MEYYAPPAN**[1], A. RAJAN[1], Y. LIU[2], R. SITARAM[3], G. R. MANGUN[2], M. DING[1];
[1]Univ. of Florida, Gainesville, FL; [2]Univ. of California, Davis, CA; [3]Pontifical Catholic Univ. of Chile, Santiago, Chile

Abstract: Functional magnetic resonance imaging (fMRI) data are traditionally analyzed using univariate approaches in which each voxel is treated independent of all the other voxels. Rich information contained in the multi-voxel patterns of brain activation is ignored. Advances in the

field of machine learning, pattern recognition, high resolution brain mapping, and associated computational techniques have begun to change that. In this study we applied multi-voxel pattern analysis (MVPA) to examine the neuronal substrate underlying the control of visual spatial attention. Functional MRI data were recorded from thirteen healthy subjects performing a cued visual spatial attention task. Each trial began with a cue, instructing the subject to either attend the left or the right hemi-field. After a random delay, a grating (Gabor patch) was presented in one of the two hemi-fields, and the subject was asked to discriminate the spatial frequency of the grating in the cued hemi-field and ignore the grating appearing in the un-cued hemi-field. Trial-by-trial BOLD response to the cue was estimated using the beta-series method. Linear support vector machine classifiers were applied to these beta values in multiple ROIs located in the occipital, parietal and frontal cortices. The following results were found: Decoding accuracies were significantly above chance level in ROIs in the parietal and occipital cortices. Multi-voxel patterns in visual ROIs along the dorsal pathway were more predictive of spatial orienting than those along the ventral pathway. Importantly, a traditional univariate analysis was also carried out using general linear model (GLM), and it revealed no differential activations between the two attention conditions. These findings demonstrate the value of MVPA analysis in uncovering neuronal mechanisms of cognitive functions.

Title: Informational connectivity reveals representation-specific gating of information in object-based attention

Authors: ***A. D. SHELDON**[1], E. SAAD[2], B. R. POSTLE[3];
[1]Psychology, Univ. of Wisconsin-Madison, Madison, WI; [2]Psychiatry, Univ. of Wisconsin - Madison, Madison, WI; [3]Psychology, Univ. of Wiscosin-Madison, Madison, WI

Abstract: What are the consequences, for the neural representation of visual objects, of the selection of one from among multiple objects that are simultaneously present in the visual field? To assess this, we scanned subjects with functional magnetic resonance imaging (fMRI) while they performed a change-detection task in which the stimulus (one of three types -- a face; a doughnut; or an abacus) flickered with a cycle of 750 msec on/250 msec off, and subjects counted the number of "state changes" that the stimulus undergoes during a block. (The face shifted between two expressions; the doughnut between whole and with a bite-sized chunk removed, and the abacus between two configurations of beads.) The experimental task began with the 500 msec presentation of a search target (drawn from the set of three stimulus types) followed by a 7-sec delay, followed by a "search array" comprising the target plus a second stimulus, both flickering and periodically changing state. Multivariate pattern analysis (MVPA) at the level of ventral occipitotemporal cortex revealed evidence for biased competition between the two representations. The onset of the search array was associated with an initial decline in MVPA evidence for the Target stimulus (relative to Target-alone), followed a gradual strengthening. For the Nontarget, in contrast, the initial decline in MVPA evidence was steeper than that of the Target, and Nontarget evidence remained suppressed throughout the presentation of the search array. To assess possible downstream consequences of selection, we next applied an "informational connectivity" (IC; Coutanche and Thompson-Schill, 2013) analysis. IC measures the covariance of multivariate pattern discriminability between anatomically disparate regions of the brain, thus serving as an informational analogue of functional connectivity measures that assess covariation in signal intensity across regions. Importantly, IC can vary independent of the strength of information assessed in a local region. We employed a roving searchlight to assess IC between ventral occipitotemporal cortex (the seed region) and the rest of the brain, independently for both Target and Nontarget items. The results revealed markedly stronger IC for Target than Nontarget stimuli with several regions of dorsal frontoparietal cortex that are associated with endogenous shifts of spatial attention. This implies that one consequence of top-down object-based attention may be the privileged transmission of sensory information to downstream regions associated with the representation of attentional salience, and with the control of behavior.

Title: Do brain regions activated by unexpected outcomes represent the content of predictions?

Authors: *K. R. VELNOSKEY, G. MCCARTHY;
Psychology, Yale Univ., New Haven, CT

Abstract: Prior research on attention reorienting has identified a fronto-parietal network that responds to unexpected stimuli (Kim, 2014). However, it remains unknown whether the brain regions composing this network represent these predictions. We used a novel fMRI task in which the prediction and outcome were separated temporally to examine each process individually. We were particularly interested in temporal-parietal cortex (TPC) and dorsolateral prefrontal cortex (DLPFC), as TPC is implicated in context updating (Lee & McCarthy, 2016) and DLPFC is involved in working memory (McCarthy et al., 1994). Both of these processes may be related to making and updating predictions.
Participants (N=20, 12 female) used a color cue, which indicated the statistical likelihood of two possible outcomes, to predict whether an upcoming stimulus would be a face or house. Participants indicated their predictions via button press while the cue was on the screen, and were then shown either a face or house outcome. We first identified regions that responded to unpredicted stimuli by contrasting low probability to high probability outcomes using a whole-brain univariate general linear model (GLM). This contrast revealed activity in the following 13 regions: left and right DLPFC, paracingulate cortex, left and right middle temporal gyrus, left frontal pole, left insula, right frontal pole and insula, posterior cingulate cortex, precuneus, left and right TPC, and occipitotemporal cortex. We then used a Gaussian naïve Bayes pattern classifier within each region to determine whether the participant's prediction was represented there before the outcome occurred. We classified predictions above chance (50%) in three regions: left DLPFC (M=53.59, $S.E.$=0.77, t=4.75, p<0.001, one-tailed), paracingulate cortex (M=52.67, $S.E.$=1.09, t=2.51, p=0.011, one-tailed), and the right middle temporal gyrus (M=52.55, $S.E.$=1.11, t=1.87, p=0.04, one-tailed). However, our analyses did not reveal a representation of the prediction in the right TPC. We found that only some of the regions involved in responding to unpredicted stimuli represent content about held predictions. Others may be involved in signaling a mismatch between prediction and outcome. Analyses of task dependent connectivity between perceptual regions and regions responding to unpredicted stimuli are being conducted to clarify activity in response to unexpected events. This experiment reveals that the fronto-parietal network responding to unexpected events does so in a heterogeneous way, and that future experiments are needed to clarify the roles that individual regions play in making and updating predictions.

Title: Difference in phase synchrony pattern between spatial and non-spatial attention based on electrocorticography

Authors: *Y. PARK[1], T. KIM[1], J. PARK[1], J. KANG[2], D. JANG[1];
[1]Hanyang Univ., 222 Wangsimni-Ro, Seongdong-Gu, Seoul, Korea, Republic of; [2]Neurol., Univ. of Ulsan, Col. of Medicine, Asan Med. Ctr., Seoul, Korea, Republic of

Abstract: In recent past, the functional role of inferior parietal lobe and other regions in the spatial attention and non-spatial attention has been studied using fMRI and electrocorticography (ECoG). However functional connectivity for spatial attention and non-spatial attention among the regions has not been observed from ECoG signals. In this study, we observed the phase synchrony of ECoG signals between each electrodes and showed different patterns of phase synchrony between spatial and non-spatial attention.
ECoG signals were recorded during the spatial and non-spatial tasks using grid electrodes covered frontal, temporal and parietal regions. The spatial and non-spatial attention tasks were adopted from a paradigm that examined the spatial and non-spatial attributed of the same pattern stimuli (Malhotra et al., 2009). To remove line noise, a 60Hz notch filter was used. MATLAB and HERMES toolbox were used to process ECoG signals. ECoG signals were segmented into 2000 msec epochs from 400 msec before the stimulus to 1600 msec after the stimulus. To calculate instantaneous phase of each electrode signal, a FIR band-pass filter from 4 to 8 Hz (theta band) and Hilbert transform were processed on each 2000 msec epoch. The averaged phase difference of every 400 msec interval between two electrodes was used to calculated phase locking value (PLV) and we obtained PLV for five time intervals (-400~0, 0~400, 400~800, 800~1200, 1200~1600 msec). Finally we calculated PLV differences between baseline (-400~0 msec) and each interval to estimate task dependent changes of phase synchrony.
As results of this study, we observed different PLV pattern in baseline and different increasing pattern of PLV between spatial and non-spatial attention.

Title: Neural mechanisms of attentional control in spatial and feature attention

Authors: ***A. RAJAN**[1], S. MEYYAPPAN[1], H. WALKER[1], Y. LIU[2], G. MANGUN[2], M. DING[1];
[1]J. Crayton Pruitt Family of Dept. of Biomed. Engin., Univ. of Florida, Gainesville, FL; [2]Univ. of California, Davis, CA

Abstract: Attention can be directed to spatial locations or to object features. Relative to feature attention the control mechanisms of spatial attention have been more extensively studied. The longstanding question is whether attention control mechanisms are specific to the type of information being selectively attended to. To further investigate this question we recorded fMRI data while the subject performed a novel cued spatial/feature attention task. Each trial started with an auditory cue directing the subject to attend either to a spatial location (left or right) or a color (red or green). Following a random time delay, two stimuli in the form of colored (one red and one green) rectangles were presented in the left and right visual fields (valid trials). The subject discriminated the orientation of the target rectangle (horizontal or vertical) and ignored the distractor rectangle. For spatial attention the target rectangle was the rectangle appearing in the cued visual field. For feature attention the target rectangle was the rectangle appearing in the cued color. On 8% of the trials (invalid trials), only one rectangle appeared, which was either in the uncued location or in the uncued color. We found the following results. First, the behavioural performance was similar for the spatial and the color conditions. Second, the reaction time for invalidly cued trials were significantly longer than validly cued trials for both spatial and color conditions, demonstrating the behavioural benefit of attentional cuing. Third, spatial and colour cues evoked a common set of dorsal frontal-parietal regions. Fourth, contrasting color-cue evoked BOLD activation with spatial-cue evoked BOLD activation revealed that (1) regions within the dorsal frontoparietal network, namely, frontal eye field (FEF), intraparietal sulcus (IPS), superior parietal lobule (SPL) was more activated in the spatial condition and (2) the default mode network regions, including the medial prefrontal cortex (MPFC), posterior cingulate cortex (PCC)/ventral precuneus, angular gyrus was more activated in the color condition. Multivoxel pattern analysis was further applied to examine the similarities and differences in the neural representations of spatial and feature attentional signals. Key words: Cued Attention, Feature Attention, Frontoparietal Network, EEG, fMRI

Title: Orienting of spatial attention with event-related functional magnetic resonance imaging

Authors: *T. S. CONTENÇAS[1,2], M. N. SILVA[3], L. RIBEIRO-DO-VALLE[3], R. M. AZEVEDO, Neto[3], E. AMARO, Júnior[3];
[1]UNIP, Santos, Brazil; [2]Icb, [3]USP, São Paulo, Brazil

Abstract: Introduction: Previous research has identified two major ways in wich attention can be directed to an object: voluntary or automatic. The purpose of this study is to identify the brain networks involved in voluntary attention using event-related functional magnetic resonance integrated with eye-tracking. **Methods:** We present the results of 20 young healthy (mean age 21,7±3,4). Each trial began with a Fixation Point (FP) and one white ring on each side. The prime stimulus (S1) was represented by a central arrow pointed to the ring on the left or right side of the FP. Fifty milliseconds after of the S1 a target stimulus (S2) appeared represented by a vertical line. In the valid condition, the S2 appeared in the same position of the S1. In the invalid condition, the S2 appeared in the opposite position of the S1. In the neutral condition, the S1 did not appear. The conditions were intermixed in an order optimized to produce maximal signal discriminability using a genetic optimization algorithm. Data was acquired in three runs. BOLD acquisitions were performed on a 3T scanner (Philips Achieva) with integrated MRI compatible Eye Tracker (Magconcept). TR was 2s, TE=30ms, voxels dim of 3x3x3mm. Images were analyzed using FSL software. Preprocessing included motion correction, spatial smoothing and transformation of image into standard. The activation group maps (by using the general linear model) were thresholded at Z-voxel>2.3 and cluster-wise corrected p-value<0.05. **Results:** Reaction time (RT) was shorter when the S2 appeared on the valid condition as the S1 compared to the invalid condition (405 ± 18 ms and 488 ± 19 ms, $p < 0.001$). The attentional effect was 83 ± 11 ms. The RT of the neutral condition was of 525 ± 19 ms. In general, we could detect areas similar to those described in the literature. Valid versus Neutral Trials: This contrast showed bilateral activations in fusiform gyrus, left superior frontal gyrus, left medial orbitofrontal gyrus, left precuneus. Invalid versus Neutral Trials: This contrast showed bilateral activations in the superior frontal gyrus and occipital lobe, left inferior frontal gyrus, lateral orbitofrontal gyrus,

left temporal pole. Invalid versus Valid Trials: This contrast showed bilateral activations in the lateral orbitofrontal gyrus, middle frontal gyrus, intraparietal sulcus and supramarginal gyrus, right superior frontal gyrus, left inferior frontal gyrus, left angular gyrus. **Conclusions:** These findings show participation of the temporal-parietal junction during endogenous orienting with symbolic cues. This finding may imply that the same neural networks mediating automatic and voluntary control of visuospatial selective attention.

Title: Suppression impairment in aging during bimodal selective attention

Authors: *A. ATHREYA[1], C. HUMPHRIES[1], M. T. KASSEL[1,2], K. A. ALTONJI[1], M. SABRI[1];
[1]Dept. of Neurol., Med. Col. of Wisconsin, Milwaukee, WI; [2]Psychology, Univ. of Wisconsin Milwaukee, Milwaukee, WI

Abstract: We investigated the effects of aging on brain activation in the auditory cortex and the frontal-parietal (FPN) and cingulo-opercular (CON) executive control networks during bimodal selective attention using functional magnetic resonance imaging (fMRI). FMRI was acquired in 18 younger (mean=26.1, SD=5.7) and 18 older (mean=62.4, SD=4.9) adults with normal hearing thresholds and cognitive function. In five task runs, two independent streams of consonant-vowel (CV) syllables were presented simultaneously in the visual and auditory modalities. Subjects attended to either the auditory (AA) or visual (AV) modalities and performed a two-alternative forced-choice (ABX) discrimination task, with the other modality serving as a distractor. Distractor syllables were either fixed (Fixed) or randomly changing (Rand). A passive listening/viewing (PLV) condition served as control. ANOVAs on reaction time (RT) and d' scores with group, distractor and modality as repeated measures revealed main-effects of distractor, with Fixed faster in RT and higher in d' than Rand. Modality by group interaction

indicated slower RT in AA than AV, in the young. A main-effect of modality revealed overall greater d' in AV than AA. Voxel-wise multiple linear regression, focusing on the encode period of the trial (i.e., AB) was applied to the individual time series. Analyses showed: left superior temporal gyrus (STG) enhancement (AA: Rand>PLV) during AA only in older adults; right STG suppression (AV: PLV>Rand) during AV only in young adults, with older adults showing an increase in signal, bilaterally (lack of suppression). In addition, right lateral occipital cortex enhancement (AV: Rand>PLV) was observed during AV only in older adults, with no sign of visual suppression (AA: PLV>Rand) in either group. Effects of distraction observed only for AV (Rand>Fixed) showed greater activation in CON (bilateral lateral and medial prefrontal cortices, bilateral superior frontal gyri, right anterior insula) and FPN (bilateral middle frontal gyri, MFG) for older adults during randomly presented distraction, while activity decreased in the right MFG for younger adults. Overall these results indicate that older compared to younger adults have greater difficulty suppressing specifically task-irrelevant auditory information when faced with bimodal stimulation.

Title: White matter integrity of executive control networks predicts selective attention performance in healthy aging

Authors: ***M. T. KASSEL**[1,2], C. HUMPHRIES[2], K. A. ALTONJI[2], D. C. OSMON[1], M. SABRI[2];
[1]Psychology, Univ. of Wisconsin - Milwaukee, Milwaukee, WI; [2]Neurol., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: The present study investigated the impact of white matter microstructural changes in healthy aging on cross-modal selective attention (SA) performance. Eighteen younger (mean=26.1, SD=5.7) and 18 older (mean=62.4, SD=4.9) healthy adults with normal hearing

(audiometric thresholds ≤25 dB HL 500 - 4,000 Hz) underwent structural MRI (T1- and diffusion-weighted scans) and performed a two-alternative forced choice task employing distraction manipulation (random vs. fixed) during functional MRI (activation not reported here). Reaction times (RT) for correct responses were computed for each of the distraction conditions (random, fixed). The distraction manipulation was quantified using the RT Distraction Index [(RTDI; random minus fixed distraction; 6.38 ms for young (p=.445), 19.20 ms for old (p=.026); group differences (n.s.)]. Fiber tracts connecting the cingulo-opercular (CON) and frontoparietal (FPN) executive control networks were identified using probabilistic white-matter tractography using seed regions defined based on Power et al. (2011) meta-analysis. Mean radial diffusivity (RD), an indicator of myelin degradation, was computed for right and left CON and FPN white matter tracks. Separate multiple regression analyses revealed a relationship between FPN (p=.009), CON (p=.005), and RTDI, indicating that greater slowing of RT due to increased distraction (random > fixed) was associated with decreased white matter integrity. Between group ANOVA with network and hemisphere as repeated measures revealed a main effect of group (p<.001), illustrating that older adults have decreased integrity (higher RD) compared to young. Within-group comparisons indicated a main effect of network (p<.0001), such that the CON displayed greater overall integrity compared to the FPN. A network by hemisphere interaction was also evident (p=.003), demonstrating that the left FPN has lower integrity than the right FPN, however there was no difference in laterality apparent in the CON. In sum, while group differences in performance were not observed, older adults did display a decrease in white matter integrity compared to young. Collectively, the present results suggest that decreased SA performance can be explained by greater demyelination in executive control networks in healthy aging.

Title: Control of spatial attention by alpha and gamma neurofeedback in human cortex

Authors: ***Y. BAGHERZADEH BIOKI**, D. BALDAUF, D. PANTAZIS, R. DESIMONE; McGovern Inst. For Brain Res. at MIT, Cambridge, MA

Abstract: Studies in people and animals have shown that enhanced alpha synchrony is associated with inattention and distracting information, whereas enhanced gamma synchrony is associated with attention to targets. To test whether alpha and gamma synchrony play a causal role in the control of attention, we used MEG neurofeedback to train subjects to manipulate alpha or gamma power over parietal cortex. We tested the effects of these oscillatory changes on both behavioral performance in an attention task and on visual evoked potentials recorded from visual cortex. The study consisted of three phases: (1) a pre-training session with a classic Posner paradigm, (2) neurofeedback phase with one or multiple sessions of feedback training to increase an asymmetry of oscillatory power between the left and right visual hemisphere (alpha in Exp1 or gamma in Exp2) and (3) a post-training session with the same Posner paradigm as in the pre-training session. The evoked responses elicited by the target stimuli in the Posner paradigm served as an index of attention being deployed in valid, invalid and neutral trials, respectively. During feedback trials a Gabor pattern was presented in the center of the screen, the contrast of which was modulated according to a real time measure of the hemispheric asymmetry in the alpha (or gamma) range. We found that subjects were able to control the asymmetry between their left and right hemisphere in the frequency range of interest, both within and between feedback sessions. Increasing alpha in one hemisphere lead to reduced visually evoked responses (Exp1) while increasing gamma in one hemisphere lead to enhanced evoked responses (Exp2) . The results support the idea that alpha and gamma synchrony play reciprocal roles in the control of spatially directed attention, even in the absence of explicit instructions.

Title: Modulating performance on a sustained attention task with network targeted brain stimulation

Authors: *S. LAGANIERE[1,2], A. PASCUAL-LEONE[1,3], M. HALKO[1,3];
[1]Neurol., Beth Israel Deaconess Med. Ctr., Boston, MA; [2]Berenson_Allen center for non-invasive brain stimulation, Boston, MA; [3]Berenson-Allen center for non-invasive brain stimulation, Boston, MA

Abstract: Background Recent studies of human functional connectivity implicate a direct relationship between resting network activity and cognitive performance (c.f. Rosenberg et al 2016). In sustained attention tasks, changes in activity within the default network (DN) and dorsal attention network (DAN) correspond to changes in ongoing performance (Esterman et al. 2014). These same networks can be modulated with transcranial magnetic stimulation (Eldaief et al 2011; Halko et al 2014). The cerebellar nodes of these networks may offer unique access points for driving entire network activity by virtue of their anatomical connectivity to cerebral cortex via the thalamus. We hypothesized that targeted brain stimulation applied to discrete cerebellar functional connectivity nodes involved in attention would correlate with both changes in network connectivity and performance on a sustained attention task. Methods Resting-state functional connectivity was acquired on normal healthy subjects and used to precisely locate individualized network nodes of two networks (DN and DAN) within their cerebellum. Before and after stimulation, fMRI was collected during resting-state and task-state. During the 10-minute task-state fMRI, subjects performed a continuous performance task (gradCPT) for the entire sequence (Esterman et al. 2014). Subjects then received one session of targeted brain stimulation to either the DAN or DN using an intermittent theta-burst (iTBS) protocol. Commission errors, omission errors, reaction times, and reaction time variability during the task were assessed. Subject-level changes in functional connectivity within the DAN and DN (post vs. pre) were correlated to changes in behavioral measures and stimulation site. Results: Attentional performance - as measured by changes in commission errors on the gradCPT- was modulated by site-specific stimulation of the cerebellum. Preliminary data in 6 subjects suggest that the within network increases in connectivity in the default network corresponds to decreased commission errors on the sustained attention task. Conclusion Targeted brain stimulation to discrete networks involved in attention modulates both functional connectivity within the network and performance on a sustained attention task.

Title: Neural practice effect during cross-modal selective attention: general and modality-specific effects

Authors: J. XIA, Y. LI, Y. JIANG, L. SHEN, *Q. CHEN;
South China Normal Univ., Guangdong, China

Abstract: Practice and experiences gradually modify the central nervous system, from the synaptic level to large-scale neural networks. Studying the effect of practice on cortical plasticity is crucial for us to understand the neural mechanisms of cortical reorganization as well as the mechanisms of functional recovery after brain injuries. It remains unknown, however, the supra-modal and modality-specific effects of practice during cross-modal selective attention. In two fMRI studies, we adopted a cross-modal interference paradigm in conjunction with the fMRI hybrid design. In alternating task blocks, participants attended to either the visual or the auditory component of the audiovisual stimuli and ignored information from the unattended modality. The temporal position of each and every trial in a given block was included as a covariate to calculate how neural activity changed as the first and second order function of the time of practice. Results from the two fMRI studies consistently showed that with the progress of practice, neural activity linearly decreased in the frontoparietal central executive network (CEN) while increased in the default mode network (DMN). In addition, neural activity in the supplementary motor area (SMA) changed as the second order function of practice by showing increased transient neural activity at the onset and offset of a block while sustained during the block. Critically, the practice effect in the CEN and the DMN occurred independent of the modality attended, indicating the general mechanisms of selective attention. On the other hand, increasing extent of functional decoupling between the auditory and the visual systems was observed with the progress of practice, and varied as a function of the modality attended. During auditory attention, the auditory system was functionally decoupled with both the dorsal and ventral visual stream with the practice; during visual attention, the auditory system was decoupled with the ventral visual stream only. Taken together, both supra-modal mechanisms in the CEN and DMN and modality-specific mechanisms in the sensory systems associated with practice were revealed during cross-modal attention.

Title: Functional changes in early latency medial prefrontal cortex activity following attention bias modification training: A near-infrared spectroscopy study

Authors: *J. ADAY, W. RIZER, J. CARLSON;
Northern Michigan Univ., Marquette, MI

Abstract: Attention bias modification (ABM) is a computerized cognitive training regimen that attempts to reduce attentional biases towards threat by continuously directing participants' attention away from threatening stimuli. fMRI studies utilizing ABM have found training-related changes in prefrontal cortex (PFC) activity and previous research from our lab has shown structural changes in PFC volume. Near-infrared spectroscopy (NIRS) is a noninvasive method of measuring oxygenated (HbO) and deoxygenated (HbR) hemoglobin, which are indirect measures of neural activity. Relative to fMRI, NIRS has several advantages including mobility, affordability, ease of use, and temporal resolution. Although ABM has been shown to modulate prefrontal activity using fMRI, the temporal resolution of these ABM effects on prefrontal activity remain poorly understood. To explore this, we had participants undergo 6 weeks of at-home ABM training using a cellphone app. Before and after training, participants performed an event-related dot-probe task while their brain activity was recorded using NIRS. There was an optode x session interaction 2-5 seconds post-stimulus presentation, such that optodes measuring more medial prefrontal activity showed decreases in HbR from pre to post-training. ABM training also resulted in greater HbR for congruent trials relative to incongruent and baseline trials in the medial prefrontal cortex. These results are consistent with previous fMRI studies implicating the PFC in ABM training and indicate that training-related changes in the PFC can be recorded using NIRS, suggesting early (2-5 sec) ABM-related effects on PFC activity.

Title: Effects of attention state regulation training on resting-state functional connectivity

Authors: *A. EICHENBAUM[1], S. M. YOUSEF[2,3], C. GALLEN[1], E. S. POOL[1,5], A. J. W. CHEN[1,4,5], M. A. SILVER[1,2,3], M. D'ESPOSITO[1];
[1]Helen Wills Neurosci. Inst., [2]Vision Sci. Grad. Group, [3]Sch. of Optometry, Univ. of California, Berkeley, CA; [4]Univ. of California, San Francisco, CA; [5]Veterans Admin. Northern California Hlth. Care Syst., Martinez, CA

Abstract: Attention state regulation training has been shown to enhance cognitive functioning. There is some evidence to suggest that the resulting improvements in cognition are associated with changes in activity and connectivity in the Default Mode Network (DMN) and frontal-parietal (FP) networks; however, these findings have been inconsistent. Additionally, a critical component of successful paradigms is training across different modalities and contexts. Therefore, to better understand the neural bases by which training can enhance cognitive functioning, we examined how intrinsic brain networks derived from resting-state fMRI data are affected by an intensive multi-domain attention state regulation training paradigm.
During training, subjects (n=8, mean age = 23.8) attended classes where they learned about and practiced attention state regulation techniques applied to game scenarios and personal life goals. State regulation techniques were applied in both simple and complex cognitive contexts, with an overarching emphasis on using these techniques to manage distractions. The seven-week training paradigm incorporated classroom and individualized coaching with aspects of experiential skill application. Before and after the seven-week course of training, a 5-minute resting-state fMRI scan was collected to examine training-induced changes in connectivity in intrinsic networks. A battery of behavioral tasks measuring attention and working memory was also administered before and after training. The fMRI data were parcellated into regions of interest (Power et al., 2011), focusing on the DMN and FP networks.
Training resulted in improved performance on the SART (sustained attention to response task) ($p = .04$), a measure of sustained attention and inhibitory control. Training also increased within-network connectivity in the DMN ($p = .02$) and connectivity between the DMN and FP networks ($p = .02$) but did not alter connectivity within the FP network ($p = .12$). These findings may indicate that attention state regulation training enhanced subjects' ability to filter out and ignore distractions during an internally-oriented state (i.e., at rest). Further experiments will examine

how the specific components of this training paradigm (e.g., classroom versus game play) contribute to behavioral and neural changes, as well as the relationships between changes in behavior and functional connectivity.

Abstract: Attention is the ability to select relevant information and, at the same time, inhibit irrelevant stimuli in a goal-directed behavior. Attentional Network Task (ANT) is useful to evaluate different systems of attention, such as alert, orientation and executive attention. For executive attention, participants indicate the orientation of the central target arrow, among four distractor flanker arrows. There were congruent (where the target and the flanker arrows point to the same orientation) and incongruent (where a conflict occurs, because the target arrow points to a different orientation from the flanker arrows) trials. With this task, a lower accuracy and

longer reaction times for incongruent vs. congruent trials are observed. Individual differences have been reported on the executive system, specifically associated to a dopamine receptor. In our workgroup, we are interested in evaluating the genetic association of the cannabinoid receptor 1 (CB1) because it is widely distributed in brain regions involved in attention and memory functions. The CNR1 gene codes for the CB1 receptor. We are interested in two polymorphisms of a single nucleotide in this gene: rs2023239 (T>C), which has been associated with addiction and impulsive behavior, as well as a larger CB1 expression at the prefrontal cortex; and rs1406977 (A>G), which has been associated with less prefrontal mRNA levels for CB1 and reduced working memory behavioral accuracy. Therefore, we could consider the C and G allele as risky ones for rs2023239 and rs1406977, respectively. The aim of this study was to test whether efficiency in the ANT is associated with the polymorphisms rs2023239 and rs1406977 of the CNR1 gene. Our results showed a main effect of genotype: C carriers of rs2023239 and G carriers of rs1406977 showed a lower percentage of correct responses in the whole task compared to the carriers of the complementary alleles, regardless of the trial type. These results show that the alternative genotypes of rs2023239 and rs1406977, previously associated with lower presence of CB1 protein or mRNA, are also associated with the ability to score higher on the executive system of the ANT, which suggest a potential function of the CB1 receptor and endocannabinoids to modulate this cognitive function.

Title: The AttentionTrip: A game-based assessment of attention networks in autism

Authors: L. E. MASH[1], *J. TOWNSEND[2], Q. LUO[3], R. KLEIN[5], L. CHUKOSKIE[4]; [1]SDSU/UCSD Jt. Program in Clin. Psychology, San Diego, CA; [2]Dept Of Neurosci, [3]Dept Of Biol. Sci., [4]Inst. for Neural Computation, UCSD, La Jolla, CA; [5]Psychology & Neurosci., Dalhousie Univ., Halifax, NS, Canada

Abstract: A well-accepted model of attention specifies three distinct functional networks: alerting, orienting, and executive control (Posner & Petersen, 1990). These network constructs can be measured using the Attention Network Test (ANT; Fan et al, 2002) in which participants make responses to a target stimulus in the presence of both informative and uninformative cues and flankers. However, this task is necessarily long and repetitive, may yield invalid data in participants with low motivation or poor engagement. Klein and colleagues have developed a more engaging game-based assessment of the attention networks measured by the ANT. In this instrument (the AttentionTrip), participants use a driving wheel to navigate a small space ship through a wormhole or blood vessel. Players pilot the ship while responding to target stimuli. The game incorporates spatial and temporal cues as well as congruent and incongruent target flankers. In tests of typical adults, the AttentionTrip yielded robust indices for each of the three target attention networks (Klein & Wilson, 2013). A more enjoyable assessment of attention networks could particularly benefit individuals with ASD (e.g., poor motivation may affect results on or willingness to complete the traditional ANT). Attention is of high interest in ASD and attentional deficits may be among the earliest foundational features of the disorder (Keehn et al, 2013). A previous study in children with ASD found that the ANT can identify attention impairment in this group (Keehn et al, 2010). The current study examined the AttentionTrip for suitability of use with individuals on the autism spectrum. In a sample of teens and young adults with ASD, the AttentionTrip produced reliable indices for the three target attention networks (alerting, orienting and executive function).The goal of the second phase of this study is to examine teens and young adults with ASD and a matched typical sample using the ANT and AttentionTrip to: 1) directly compare results from the two instruments and 2) to replicate results from Keehn et al, 2010. There is increasing interest in the use of video games for assessment and intervention. Games have a distinct advantage in that they are intrinsically motivating, and offer opportunities to improve data quality by improving task compliance. Games such as the AttentionTrip that are based on theoretical models and specifically designed to target well-defined cognitive processes provide an important and exciting advance in neuropsychological evaluation.

Title: Greater flanker effects for real vs. images of action-based stimuli

Authors: *M. A. GOMEZ[1], R. SKIBA[2], J. C. SNOW[2];
[1]Psychology, [2]The Univ. of Nevada, Reno, Reno, NV

Abstract: Object affordances are understood to bias visuo-spatial attention. Surprisingly, however, previous studies have relied predominantly on images, rather than real world graspable objects, to examine affordance-related effects. In the present study, we examined whether real graspable tool objects elicit stronger flanker effects than matched two-dimensional (2D) and three- dimensional (3D) image displays of the same items. Using an adaptation of the Eriksen flanker paradigm, we asked participants to indicate the left/right orientation of a centrally positioned target (a spoon) while ignoring two identical flankers positioned above and below the central target. The flankers were oriented so that their handles would elicit either a congruent, or incongruent, response to that required for the target. Critically, we manipulated the display format of the target and flanker stimuli. Using a block design, on half of the trials participants viewed real object displays, and on the remaining trials participants viewed high-resolution computerized images of the same stimuli that were presented on an LCD monitor. The images were matched to the real objects for size, apparent distance, viewpoint and background. In Experiment 1 the target and flankers were 2D planar images of objects. We found that reaction times (RTs) were longer overall for real objects compared to the 2D image arrays. Critically, we found that real flankers elicited greater interference effects than in the matched image arrays. To determine whether the results for Experiment 1 were attributable to additional stereo cues in the real objects (versus the 2D images) we ran a follow-up Experiment comparing flanker interference effects for real objects versus 3D stereo arrays. Again, we found that RTs were longer for real objects compared to 2D images and that real flankers caused greater interference compared to 3D image stimuli.

Title: Investigating the influence of expertise and familiarity on segmentation of dance movements and working memory

Authors: *P. M. DI NOTA[1,2,3], M. P. OLSHANSKY[1,2], J. F. X. DESOUZA[1,2,3,4,5];
[1]Psychology, [2]Ctr. for Vision Res., [3]Neurosci. Grad. Diploma Program, [4]Interdisciplinary Program, York Univ., Toronto, ON, Canada; [5]Canadian Action and Percpetion Network (CAPNet), Toronto, ON, Canada

Abstract: Several cognitive and behavioral improvements have been demonstrated following exercise in the short-term (Di Noto et al., 2013) and with long-term expertise, especially in attention and working memory (WM). Attention can be measured by event segmentation - a perceptual process by which observed movement is partitioned into discrete meaningful units, and facilitates learning of these actions (Zacks et al., 2007; 2009). When segmenting dance, expertise in the observed repertoire has been shown to result in significantly fewer event borders (Bläsing, 2015), but generalized expertise effects in segmenting unfamiliar genres of dance or non-dance movements have yet to be shown. The present study sought to investigate differences in segmentation of a ballet dance, a Bharatanatyam dance, and a non-dance acting sequence among experts from six groups (total N=93): ballet and Bharatanatyam dancers, dancers from other genres (i.e., contemporary), athletes, musicians, as well as non-experts. Each video sequence was 1-minute long and was presented 10 times randomized across three blocks for a total of 30 segmentation trials. Additionally, WM was assessed by having subjects perform a Retrieval-Induced Forgetting (RIF) task between blocks of event segmentation. In part one, subjects were shown 60 category-exemplar word pairs from 10 categories (i.e., FRUIT – apple), including Dance, Instrument, and Sport categories that were domain-specific to our expert groups. Practice recall (Pr) was performed immediately following presentation of the items, and final recall of practiced words (Rp+), non-practiced words from practiced categories (Rp-), and non-practiced words from non-practiced categories (Nrp) was assessed between blocks 2 and 3 of event segmentation. Results show significantly fewer event borders among Bharatanatyam dancers when segmenting a familiar dance sequence relative to dancers from other genres during early trials (trials 1 to 5, $P<0.05$), providing novel evidence for genre-specific familiarity effects during dance segmentation. Consistent with previous studies, practice effects for strong and weak items and RIF were shown among all groups ($P_{Bonf}=0.000$). However, we provide novel evidence for significantly enhanced recall of words from experientially-primed categories (i.e., Dance and Instruments) among ballet dancers relative to musicians, athletes ($P_{Bonf}=0.000$), and non-experts ($P_{Bonf}=0.001$). Together these findings provide further evidence for the modulation of observed action by the specificity of one's motor repertoire, and the translational benefits of dance expertise in improving WM for domain-specific items.

Title: How crossing hands modulates neural processes involved in directing attention to painful and tactile stimuli

Authors: *K. J. SWIDER[1,2], E. WRONKA[1], C. VAN RIJN[2], J. OOSTERMAN[2];
[1]Psychology, Jagiellonian Univ., Kraków, Poland; [2]Cognition & behaviour, Univ. Nijmegen, Nijmegen, Netherlands

Abstract: Presentation of an attention-directing cue elicits a lateralized ERPs components: Early Directing Attention Negativity (EDAN) at posterior electrodes contralateral to the direction of attentional shifts (200-300 ms after cue onset), Anterior Directing Attention Negativity (ADAN) at frontal cortex contralateral to the cue direction (300-500 ms after cue onset) and Late Directing Attention Positivity (LDAP) recorded in visual cortex contralateral to the cue direction (300-600 ms after cue onset). Those components are suggested to reflect different stages in the control of attention. Interestingly, crossing hands over the body midline can bring into conflict the internal somatosensory and visual frame of reference. Such manipulation can modify early stages of orienting shifts. Thus, the main goal of the present study was to verify whether the same neuronal processes are involved in directing attention to tactile and painful stimuli in crossed and uncrossed hand position. The participants (23 right-handed volunteers) crossed and uncrossed their hands at the beginning of each of 8 painful (4 crossed & 4 uncrossed) and 8 tactile (4 crossed & 4 uncrossed) blocks of the experiment. Each of the electric stimuli was preceded by a visual cue (rightward and leftward arrows) presented in the center of a computer screen. In 80% of trials the cues indicated correctly the side of the stimuli application. There were 400 trials in total where 100 painful and 100 tactile stimuli were delivered to each hand. The participants' task was to rate their sensation after each stimuli on Numerical Rating Scale. ERPs were recorded with 64-channels EEG in response to cues which directed attention to either side. Mean amplitudes for EDAN, ADAN and LDAP were compared with a repeated measures ANOVA. The negative (EDAN, ADAN) and positive (LDAP) deflections were found over the hemisphere contralateral to the hypothesized direction of shifts of attention. The ERPs showed double dissociation of stimuli intensity and hand position effects. When hands were kept crossed the EDAN and ADAN were stronger in painful compered to tactile condition. In tactile condition, EDAN and ADAN were found only in uncrossed condition. In painful condition no such difference for neither neurocorelatas was found. Higher activation was found in uncrossed

condition compared to crossed one for LDAP but only for painful stimuli. Simultaneously, the activation was more pronounced in painful condition for all lateralized ERPs components. Summing up, our results indicate that when we change the frame of reference we can manipulate early stages of orienting shifts and such effect is stronger for tactile stimuli.

Title: Investigating the scale invariance and global connectivity of BOLD when viewing natural versus man made scenes

Authors: ***O. KARDAN**[1], M. G. BERMAN[1], J. JONIDES[2];
[1]Univ. of Chicago, Chicago, IL; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: Free viewing of pictures of nature vs. urban scenes have been shown to have restorative effects on cognition and affect, specifically improving performance in directed attention tasks [1,2]. Attention restoration theory (ART) posits that unlike man-made scenes, processing nature *modestly* grabs attention in a bottom-up fashion, allowing top-down directed-attention abilities a chance to replenish. Additionally, cognitive effort has been shown to be inversely related to fractal scaling of brain activity [3]. Thus, we hypothesized that global scale-invariance of Blood Oxygenation Level Dependent (BOLD) fMRI as indexed by the Hurst exponent of the signal might increase when processing nature scenes compared to when viewing man-made scenes. Eighteen participants viewed blocks of 50 images of nature and 50 images of urban scenes in the MRI scanner for 200 seconds in each block. For our analysis we parcellated the brain into 116 regions using the Automated Anatomical Labeling (AAL) scheme. We performed a Partial Least Squares (PLS) regression to statistically compare the scale-invariance and connectivity of these AAL brain regions for the two conditions. Global scale-invariance of BOLD dynamics over all regions significantly increased in nature blocks compared to urban blocks in 14 out of the 18 participants ($p_{adjusted} < 0.05$). However, the regions that drove these differences were idiosyncratic to participants, indicating that the multivariate results did not show a generalizable pattern of regions distinguishing nature and urban blocks ($p = 0.4611$). Additionally, global connectivity significantly increased for eight of the participants when

viewing the nature blocks, while it decreased significantly for two participants ($p_{adjusted} < 0.05$). Again, the spatial patterns were idiosyncratic to participants. The only consistent connectivity pattern that was found across participants was higher connectivity between right VI of the cerebellum and the right fusiform gyrus when viewing urban blocks ($Z_{bootstrap\text{-}ratio} > 3$). Title: Implicit discrimination of natural versus built environments as evidenced by p3 elicitation

Authors: *S. P. MAHAMANE[1], A. PORTER[3], A. HANCOCK[2], N. WAN[1], K. E. JORDAN[1]; [1]Psychology, [2]Utah State Univ., Logan, UT; [3]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Attention Restoration Theory (ART) posits that settings with certain psycho-environmental characteristics (most often natural environments) improve directed attention by aiding in the replenishment of cognitive resources. Evidence shows that natural environments, compared to built, improve people's ability to sustain focused attention and delay gratification, and increase positive affect. However, are these effects only attributable to how these environments engage visual attention or is environmental semantic category itself – being "nature" – important? To begin to address this question, we used hundreds of natural and built environment scenes in a passive looking task while recording EEG data from participants at 14 channel locations. Sixty participants viewed two blocks of trials with block order counterbalanced across participants. Stimuli for the task were selected based on data from a previous explicit categorization task performed by a separate sample of participants. In one block (nature-standard) 80 out of 100 images were nature scenes (categorized as "nature" by 60% or more of the previous sample) and 20 were built (categorized as "nature" by 40% or less). In the other block (built-standard), these category frequencies were reversed. Results showed that, in

the nature-standard block, P3 peak amplitude averaged across frontal channels was significantly higher for the low frequency built images than for the high frequency nature images. This finding suggests that, even without instruction that the task included different environmental scene categories with respect to content, participants implicitly discriminated natural from built environments using P3 as an index of stimulus novelty. However, the converse result was not significant in the built-standard block (p = .094). This inconsistency may be a result of the nature images, and thus the nature-standard block, being more restorative than the built images. These findings offer further justification to explore the role of environmental semantic content in attention restoration.

Title: Acute effects of a proprietary spearmint extract on cognition in healthy men and women

Authors: *K. A. HERRLINGER[1], B. J. LEWIS[1], J. A. LASRADO[1], K. D. SANOSHY[2], J. M. BALDWIN[2], E. MAH[2], B. A. FONSECA[1];
[1]Kemin Foods, L.C., Des Moines, IA; [2]Biofortis Inc., Addison, IL

Abstract: A proprietary spearmint extract, Neumentix™ Phenolic Complex K110-42, has shown positive effects on cognition following chronic supplementation in healthy adults with memory impairment. Two randomized, double-blind, placebo-controlled, crossover studies, (n=6/study) evaluating the acute effects of Neumentix on cognitive function were completed in full-time college students (18-24 y) and adults aged 30-50 y. Subjects completed a computerized cognitive function test battery and a Subjective Global Improvement (SGI) questionnaire 1 h before and 2 h after intake of either placebo (PL) or 900 mg Neumentix (Neu). After a 13-day washout period subjects crossed over to the opposite study product and repeated these procedures. Data (mean±SEM) were evaluated as the change from pre to post-supplementation, with P≤0.1 considered significant.
Objective measures of attention increased in both groups two hours following supplementation with Neu. In adults aged 30-50 y, scores for Feature Match (attention) were improved following acute Neu supplementation compared to PL (P=0.067). In college students, acute supplementation resulted in differences between Neu and PL for a measure of attention (Spatial

Rotations, P=0.088) and spatial working memory (Monkey Ladder, P=0.061). Within group scores for Spatial Rotations were increased following Neu (P=0.099), but were unchanged following PL. Scores for Monkey Ladder decreased following consumption of PL (P=0.041), while Neu prevented this decrease. Total SGI scores of college students were different between Neu vs. PL (P=0.093), suggesting that subjects noticed a subjective improvement in cognition with Neu vs. PL. Evaluation of pooled data (n=12) from both groups showed differences between Neu and PL for a measure of attention (Interlocking Polygons, P=0.0728), with improvements following Neu. Furthermore, pooled data from both groups showed differences between Neu and PL for subjective evaluation of memory, speed of thinking and Total SGI (P=0.027, P=0.086, P=0.057, respectively), with improvements following Neu.
These preliminary data show that consumption of Neu improved subjective assessment of cognitive improvements and objective measures of attention in both age groups. Furthermore, college students were able to maintain spatial working memory performance after consumption of Neu but not after PL. In conclusion, Neumentix, which was previously shown to have improved working memory benefits following chronic supplementation, may also have acute benefits on cognitive function which individuals were able to recognize themselves within two hours following supplementation.

Title: Effects of unilateral lesions of the insula and of the medial temporal lobe on taking risky decision: a study of epileptic patients

Authors: *Z. VON SIEBENTHAL[1], O. BOUCHER[2], I. ROULEAU[3], M. LASSONDE[4], F. LEPORE[5], D. K. NGUYEN[6];
[1]Univ. De Montreal, Outremont, QC, Canada; [2]Univ. De Montreal, Montreal, QC, Canada; [3]Univ. du Québec à Montréal, Montréal, Montreal, QC, Canada; [4]Univ. de Montreal, Montreal,

QC, Canada; [5]Univ. de Montréal, Montréal, QC, Canada; [6]Ctr. Hospitalier de l'Université de Montréal, Montréal, QC, Canada

Abstract: According to the somatic marker hypothesis, the insula and medial temporal lobe structures - especially the amygdala and hippocampus - are actively involved in risky decision making. However, the specific effects of damage to these structures remain unclear, partly due to the low prevalence of isolated lesions affecting either of these brain structures. In this study, adult patients who underwent partial or complete resection of the insula (n = 13) or of the medial temporal lobe (n = 13) as part of their epilepsy surgery, and a group of healthy volunteers (n = 20), were assessed using two tasks of decision making: the Iowa Gambling task (IGT), which assesses the ability to learn to select economically advantageous options in the long term, and Cups Task, which assesses the abilitiy to adjust to the expected value when taking risk, in terms of gain and loss separately. Group performance was compared using nonparametric tests. On the IGT, temporal lobe patients performed significantly worse than both the insular and the healthy control groups, as they failed to learn which decks were advantageous on the long term. On the Cups Task, both groups of patients showed impaired risk adjustment when facing a potential loss, when compared to healthy controls. These results suggest that the insula and medial temporal lobe structures play a crucial role in risky decision making when facing a potential loss, and that the temporal structures are additionally involved in learning the association between one's behavior and its outcome.

Title: Context and outcome uncertainty in anterior insula

Authors: *W. H. ALEXANDER, E. VASSENA;
Univ. Gent, Gent, Belgium

Abstract: Risk and uncertainty are inherent to all decisions - choosing whether to eat at an Italian or Mexican restaurant, for example, entails uncertainty as to whether the food will be

acceptable or not, i.e., outcome uncertainty. Uncertainty of this sort may be compounded by uncertainty regarding the context in which such choices are made - if a person is unaware whether they are in Rome or San Diego when making a choice about restaurants, they may lack critical information needed to choose wisely ("context uncertainty"). Frequently these two types of uncertainty are confounded - uncertainty about the context in which one is operating leads to increased uncertainty about the ultimate outcome of one's choices. Anterior insula has previously been identified as a region involved in signaling predictions and errors regarding the uncertainty of an outcome. However, it remains an open question as to whether the region might also signal context uncertainty. We investigate this question using fMRI while subjects perform a task to earn money by guessing whether one of two playing cards will be higher or lower than the other (outcome uncertainty) while simultaneously trying to determine from which of two decks the cards they observe are being drawn (context uncertainty). The design of the experiment allows dissociation of these two forms of uncertainty by holding one type of uncertainty constant while manipulating the other. We find distinct signals in anterior insula related to both types of uncertainty, suggesting that anterior insula engages in processing risk at multiple levels.

Title: Noradrenergic manipulations of dynamic uncertainty computations

Authors: *L. MARSHALL[1], A. O. DE BERKER[1,2], R. SOUTHWELL[3], G. QUATTROCCHI[1], S. LITTLE[1], S. BESTMANN[1];
[1]Sobell Dept. of Motor Neurosci., [2]Wellcome Trust Ctr. for Neuroimaging, [3]Ear Inst., Univ. Col. London, London, United Kingdom

Abstract: Learning in uncertain environments depends on our ability to flexibly update our beliefs about the world. By tracking the environment’s underlying regularities and their changes over time, one can learn to predict, from sensory cues, the likelihood of future events. Noradrenaline (NA) has been proposed to play an important role in learning under uncertainty

that arises from environmental volatility (Yu & Dayan, 2005; Payzan-LeNestour et al., 2013; Marshall et al., submitted). Parallel lines of work have linked subjective uncertainty computations to changes in pupil diameter (Preuschoff et al., 2011; Nassar et al., 2012; de Gee et al., 2014; de Berker et al., 2016), and pupil dilatation to noradrenergic neuronal activity in the locus coeruleus (Aston-Jones & Cohen, 2005; Varazzani et al., 2015; Joshi et al., 2016).
Here we manipulated NA pharmacologically to assess the neuromodulator's causal impact on learning in dynamic environments and on pupillary responses to uncertainty. In a double-blind between-subjects design, 90 healthy human volunteers were administered a NA reuptake inhibitor (reboxetine; NA+ group), a NA antagonist (prazosin; NA- group), or a placebo before undertaking a probabilistic learning task with concurrent pupillometry. On each trial, subjects were presented with one of two auditory cues and asked to predict which one of two auditory outcomes would follow. Crucially, the contingencies between cues and outcomes shifted unpredictably over time, introducing uncertainty and requiring subjects to constantly update their estimates for each stimulus.
Using a hierarchical Bayesian learning model (Mathys et al., 2011), we quantified the relationship between the different forms of subjective task uncertainty and pupil diameter, and contrasted each NA drug manipulation to placebo. Both NA interventions disrupted task learning. Across groups, baseline pupil diameter reflected subjects' trial-wise estimates of the current cue-outcome contingencies. Individual uncertainty estimates predicted the magnitude of pupil dilatation responses to trial outcomes. The magnitude of pupil evoked responses to outcome differed across groups, driven by a significant increase in pupil responsivity under our NA+ manipulation. Collectively, our results provide empirical support for the involvement of NA in pupillary responses to dynamic uncertainty computations.

Title: Acute and chronic effects of noradrenergic enhancement on transcranial direct current stimulation-induced neuroplasticity in humans

Authors: *M. A. NITSCHE[1], A. JAMIL[1], W. PAULUS[2], G. BATSIKADZE[2], M.-F. KUO[1], L. KUO[1];
[1]Leibniz Res. Ctr. For Working Envrn. An, Dortmund, Germany; [2]Univ. Med. Ctr., Goettingen, Germany

Abstract: Noradrenaline affects cognition and motor learning processes via its impact on long-term potentiation (LTP) and depression (LTD). We aimed to explore the impact of single dose and chronic application of the selective noradrenaline reuptake inhibitor (NRI) reboxetine (RBX) on plasticity induced by transcranial direct current stimulation (tDCS) in healthy humans via a double-blinded, placebo-controlled, randomized crossover study. 16 healthy volunteers received placebo or single dose RBX (8mg) before anodal or cathodal tDCS of the primary motor cortex. Afterwards, the same subjects took RBX (8 mg/day) consecutively for 21 days. During this period, two additional interventions were performed (RBX with anodal or cathodal tDCS), to explore the impact of chronic RBX treatment on plasticity. Plasticity was monitored by motor evoked potential amplitudes elicited by transcranial magnetic stimulation. Chronic application of RBX increased and prolonged the LTP-like plasticity induced by anodal tDCS for over 24 hours. Chronic RBX significantly converted cathodal tDCS-induced LTD-like plasticity into facilitation, as compared to the single dose condition, for 120 minutes after stimulation. The results show a prominent impact of noradrenaline receptor enhancement on plasticity of the human brain which might partially explain the delayed therapeutic impact of selective NRI in depression and other neuropsychiatric diseases.

Title: Serotonin depletion impairs instrumental avoidance

Authors: *H. E. DEN OUDEN[1], K. SCHMIDT[2], J. C. SWART[1], D. E. M. GEURTS[1], N. D. DAW[3], R. COOLS[1];
[1]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ., Nijmegen, Netherlands; [2]Oxford Univ., Oxford, United Kingdom; [3]Princeton Univ., Princeton, NJ

Abstract: Serotonin (5HT) has long been implicated in the motivational control of behavior, particularly aversive processing1 and behavioral inhibition[2]. One popular recent idea is that 5HT has a specific role in driving instrumental inhibition in aversive contexts[3–5], while others postulate of particular importance the role of 5HT in valence-independent control of impulsive responding[6].
To pit these theories against each other, we independently varied instrumental demands (active approach/avoid, passive avoid) and motivational value (appetitive/aversive), while manipulating 5HT levels using acute tryptophan depletion (ATD) in healthy humans (N=25, randomised double blind within-subject). On each trial, a cue informed subjects whether they were playing to get a reward or avoid a punishment. To get the desired outcome, they had to learn whether to approach (mouse-click on a box in the location of the cue), avoid (mouse-click on a box presented contra-laterally to the cue) or inhibit responding (NoGo).
As expected, participants showed a motivational bias in their response tendencies: they were more likely to approach appetitive cues, and to inhibit responding to aversive cues. This effect was paralleled by their reaction times (RT): participants were faster to respond to appetitive than to aversive cues. However, ATD did not affect these motivational valence biases.
Surprisingly, motivational valence did not alter 'avoid' responses. Avoid responses were slower than approach responses, but this was unaffected by motivational valence. Critically, ATD reduced the number of avoid responses, while also increasing the proportion of inaccurate approach responses for fast RTs, again irrespective of motivational valence. These results support a selective role for 5HT in instrumental avoidance.

Title: Neural systems supporting demand avoidance.

Authors: *C. Z. SAYALI, N. HAMZAH, B. CIULLO, D. BADRE;
CLPS, Brown Univ., Providence, RI

Abstract: Performing difficult tasks results in an experience of effort. This “cognitive effort” is usually aversive such that people will tend to avoid cognitively difficult tasks in favor of the easier ones when given the option. One influential hypothesis is that effort costs are experienced to the degree that cognitive control systems are engaged during a task. However, it has not been established what neural systems drive cognitive effort avoidance, with separate studies yielding sometimes contradictory results. The differences across studies might partly stem from design limitations in prior experiments that relied primarily on categorical comparisons. To overcome these limitations, we manipulated the level of effort during fMRI scanning by parametrically increasing cognitive demands during a demand-selection paradigm. During a “choice phase”, participants chose between two context symbols that were each associated with a block of a different difficulty level. Then, during an “execution phase”, participants executed a block of the corresponding task difficulty level. Specifically, participants completed thirteen simple number categorizations, either magnitude or parity judgments based on the color of the number. Task difficulty was manipulated by increasing the likelihood that the judgment type switched from trial-to-trial within a block. A higher frequency of switching required more cognitive control and so more cognitive effort. The association of a given difficulty level and context symbol was acquired through experience. Of 36 participants, 20 were 'demand avoiders' who tended to avoid choosing the more difficult task context, and 16 were 'demand seekers' who did not avoid or even sought the harder task. Demand avoiders showed a linearly increasing avoidance with greater task difficulty. Both groups showed comparable behavioral performance and neural activity during task execution. Likewise, executing increasingly more difficult tasks yielded linearly greater activity in the frontoparietal cognitive control network and greater deactivation in the task-negative default mode network in both groups. Preliminary analyses did not find evidence of a relationship between activation of the fronto-parietal control system across levels during execution and avoidance behavior during choice. Rather, deactivation of task-negative brain regions during execution diminished avoidance behavior in ‘demand avoiders’. These results

suggest that cognitive effort may be related to ineffectively engaging task-negative "down states", as opposed to intensely engaging cognitive control-related "up states".

Title: Neural mechanisms of avoidance behavior for high cognitive demands

Authors: ***A. M. NAGASE**[1], K. MORITA[3], K. ONODA[2], J. C. FOO[3], T. HAJI[4], S. YAMAGUCHI[2], K. SAKAI[5];
[1]Grad. Sch. of Med. Res., [2]Dept. of Neurol., Shimane Univ., Izumo, Japan; [3]Physical and Hlth. Educ., Grad. Sch. of Education, The Univ. of Tokyo, Tokyo, Japan; [4]Brain Activity Imaging Ctr., ATR-Promotions, Osaka, Japan; [5]Tamagawa Univ., Brain Sci. Inst., Tokyo, Japan

Abstract: Humans tend to choose options to minimize not only physical but also mental cost. However, it remains unclear how human choice reflects predicted cognitive demand that changes over time. Neural mechanisms of decision making to avoid high cognitive demand also remain elusive. To address these issues, we developed two choice tasks that implicitly urge subjects to predict the upcoming cognitive demands, which changed over time. We conducted two fMRI experiments using either of the tasks. In Exp. 1, two problem-related cues appeared at the beginning of each trial, and subjects were asked to choose one of the cues. After choosing a cue, subjects were given a mental division problem. There were two types of problems with low or high cognitive demand, either one of which was presented in a trial. The presentation probabilities of low- or high-demand problems were determined by the problem-related cue that was chosen at the beginning of a trial, and were varied dynamically over time. Exp. 2 was similar to Exp. 1, but used "folding the cube" problems instead of division problems. In Exp. 1 and 2, 24 (75.0%) and 17 (89.5%) subjects, respectively, showed avoidance behavior for high cognitive demands (Chi-square test, $p<0.01$). We fitted the choices of subjects who showed demand-avoidance, via maximum likelihood estimation with limitations of parameter ranges, by 9 types of models: 6 types of prediction error-based (PE), 2 types of Win-Stay/Lose-Switch (WSLS), and one other models. These models, with 1, 2, or 3 parameters, were fitted to the choice data of the subjects who showed avoidance significantly. Based on Bayesian information criteria, we determined the best-fit PE model out of the 6 PE models and the best-fit WSLS model out of the 2 WSLS models. Both of the best-fit models had 2 parameters. We then compared the best-fit PE

and WSLS models. The PE and WSLS models fitted the data of Exp. 1 comparably. On the other hand, in Exp. 2, the WSLS model gave a better fit than the PE model in 76.5% of subjects. By using the PE model, we conducted model-based fMRI analysis for the subjects who showed avoidance. This fMRI analysis revealed that signals in the right inferior frontal gyrus (IFG, Brodmann area 47) were correlated with the predicted amount of cognitive demand of chosen option commonly in both experiments (peak & cluster-level FWE, $p<0.05$). These results suggest that humans could potentially learn to avoid high cognitive demand through mechanisms approximated by the PE model, and the right IFG (BA47) represents the predicted amount of mental cost across different types of cognitive demands. Additional analysis of the neural mechanism based on the best-fit WSLS model is planned to be conducted.

Univ., Portland, OR; [6]NYU Sch. of Law, New York, NY

Abstract: The recent string of deaths of unarmed men of color at the hands of police have prompted questions regarding what factors contribute to these outcomes. A key question is whether there is a relative loss in cognitive control during interracial encounters under conditions of threat. The current study used a novel functional magnetic resonance imaging (fMRI)

paradigm to examine how brief and sustained states of arousal modulate cognitive control during out-group encounters in 54 black and white adult participants (22 black, 28 female). Participants performed a variation of the Cognitive Control Under Emotional Influences (CCUE) task (Cohen et al., 2016) that consisted of positive, negative, and neutral facial expressions as targets and rare non-targets, under sustained states of threat (anticipation of hearing an aversive noise), excitement (anticipation of winning money), or a neutral state. The current task differed from the original in that stimuli were composed of 45% male black faces and 45% male white faces, to allow for analysis of out-group encounters, and an additional 10% male Asian or Hispanic faces. Under threat, both white and black participants show increased false alarms to calm African-American faces compared to Caucasian faces ($p<0.001$). Within the threat state, differences in false alarm rates between Caucasian and African-American cues were greatest for fearful no-go trials ($p=0.018$). Pilot fMRI data from the original CCUE task (N=72, 27 black, 40 female) with fewer minority faces showed a significant interaction between sustained state and target race in the ventromedial prefrontal cortex (vmPFC) for correct trials (186 voxels, $p=0.05$, $\alpha<0.01$) and anterior cingulate cortex (ACC) for all trials (43 voxels, $p=0.01$,$\alpha<0.01$). Compared to the neutral state, activity under the threat state in both the vmPFC (correct trials, $p=0.0005$) and ACC (all trials, $p<0.001$) increased to white faces and decreased for black faces. Together, these findings suggest a loss in impulse control, specific to the race of the stimulus presented, that is modulated by both sustained states of threat and cues of potential threat. This work may provide new insights into police-citizen interracial encounters under threat and offer new approaches for intervening.

Title: Neural basis of social learning under incomplete payoff information

Authors: P. KRUEGER[1], P. KARASHCHUK[1], I. SÁEZ[1], *M. HSU[2];
[2]Haas Sch. of Business, [1]Univ. of California, Berkeley, Berkeley, CA

Abstract: You're going to a bar in hopes of meeting a romantic partner. You want to invite a friend who will not compete, but help you get a date. However, a friend's intentions are not entirely known, so you need to separate good from bad wingmen. A wide array of social behavior can be understood from a game theoretic perspective where individuals seek to gain information about others' reward structures. A useful way of organizing this information is through social categorization. Making such distinctions is ubiquitous, but little work has been done exploring this topic behaviorally or neurally. Here, we focus on the social categorization of cooperative and competitive counterparts.

Participants played a series of games with a known 2x2 payoff matrix. Before each game, participants were told if their counterpart (selected randomly from a large pool of participants) was red or green. The counterpart's payoff matrix was unknown. Participants and red players could cooperatively maximize points, whereas green players were competitive.

Behavior across many strategic learning tasks is well characterized by two types of learning: simple reinforcement learning based on rewards from trial and error, and belief-based learning about the likely actions of others. We used the Experience Weighted Attraction (EWA) model, which describes how equilibria arise in interactive games through combining both types of learning.

We fit choice behavior of each participant using the EWA model, and compared models where red and green counterparts were modeled separately or together. The dual counterpart model fit better ($t(51) = 5.04$, $p < 10^{-5}$), suggesting people tend to differentiate counterpart types. A multiple linear regression revealed that participants earn more money if they distinguish counterparts ($t(49) = 3.34$, $p = 0.0016$), and if they employ belief-based learning ($t(49) = 2.55$, $p = 0.014$).

To analyze fMRI data, we fit a general linear model to look for main effects of expected reward (ER) and reward predictions errors (RPE), and found ventromedial prefrontal cortex (vmPFC) activation for both. Next, we identified areas involved in distinguishing counterparts. First, we subtracted the residual sum of squares (RSS) from the previous model from the RSS when ER and RPE were fit from the single counterpart model. Second, we performed a linear regression on how well participants distinguish counterparts from this difference in RSS to measure which voxels use ER and/or RPE representations to encode counterpart distinctions. Our findings indicate that ER and RPE representations in the vmPFC and ER representations in premotor cortex distinguish cooperative from competitive counterparts.

Title: The neural correlates of trauma-related symptom severity in combat veterans: a neuroeconomic approach

Authors: L. RUDERMAN, R. JIA, D. B. EHRLICH, P. SALHOTRA, I. HARPAZ-ROTEM, *I. LEVY;
Section of Comparative Med., Yale Sch. of Med., New Haven, CT

Abstract: DSM categorical diagnoses for psychiatric disorders are insufficient in guiding treatment models. There is need of alternative classification models, based on the underlying basic mechanisms of psychopathological symptoms. We have recently demonstrated the usefulness of behavioral economics to psychiatric research as a framework for identifying behavioral markers using measures *independent of the pathology itself* (Ruderman et al., 2016). We focused on a neglected aspect of trauma symptoms – individual differences in uncertainty attitudes – and found that veterans with PTSD were more averse to ambiguity (unknown outcome probabilities), but not risk (known probabilities), compared to veterans without PTSD, when making choices between possible losses, but not gains. Here, we explore the neural markers of trauma-based symptomology using the same task, thereby eliminating potential biases related to self-report or re-experiencing of trauma.
We studied 39 combat veterans (16 with PTSD and 23 combat controls) to assess their attitudes towards risk and ambiguity in a monetary decision making task. Subjects made choices between a guaranteed win (or loss) of a fixed monetary amount or playing a lottery, which offered a larger gain (or loss) but also some chance of zero outcome. In half of the trials outcome probabilities for the lotteries were precisely known, while in the other half these probabilities were ambiguous. Functional MRI was used to track neural activation while subjects completed a total of 240 decisions. One choice was randomly picked for payment at the end of the experiment. Behaviorally, we replicated our recent results and found that veterans with PTSD were more averse to ambiguity under losses. Neurally, we found that overall activation in brain areas traditionally involved in value-based decision making, including the vmPFC and striatum, is negatively correlated with PTSD symptom severity (assessed by Clinician-Administered PTSD Scale [CAPS]; $p < 0.05$ under risk and under ambiguity, in both the gain and loss domains),

whereas activation in the insula is positively correlated with CAPS scores ($p < 0.01$ in both gains and losses). Interestingly, those regions are also implicated in trauma-related or fear learning PTSD studies, while the task employed here is utterly neutral and does not relate to any traumatic experiences. Our results demonstrate the potential of neuroeconomic and behavioral economic techniques for devising objective and incentive-compatible diagnostic tools, and investigating the etiology of psychiatric disorders.

Title: Neuroanatomical correlates of loss of economic rationality in aging- Testing Generalized Axiom of Revealed Preference

Authors: *H.-K. CHUNG[1], P. GLIMCHER[2,3], A. TYMULA[4,3];
[1]Psychology, [2]Neurosci., [3]Inst. for the Interdisciplinary Study of Decision Making, New York Univ., New York, NY; [4]Sch. of Econ., Univ. of Sydney, Sydney, Australia

Abstract: The population of people above 65 years old is growing and work investigating their cognitive function and decision making is of increasing importance. A previous study (Tymula, et al., 2013) found that age is a crucial factor in decision making, with older individuals making more stochastic choices. However, there is insufficient evidence on the effects of neuroanatomical aging on rationality in decision making. In our study, we used whole brain voxel based morphometry (VBM) analysis to determine where gray matter (GM) volume correlates with the behavioral measure of rationality in choice. We recruited 31 (12 male) healthy, right-handed adults over the age of 65. All subjects were functionally normal with mini-mental state examination scores ranging between 26 and 30. To quantify the degree of irrationality, we adopted the behavioral paradigm designed by Harbaugh and colleagues (2001) that estimates the number and severity of violations of the generalized axiom of revealed preference, which is a necessary and sufficient condition for utility maximisation. In individual trials, subjects chose their preferred bundle of snacks and beverages from a larger set of bundles. Assessing many such choices, we can infer whether the subject obeys transitivity and has

monotonic (within reason) preferences. High-resolution T1-weighted anatomical images were acquired with an MPRAGE pulse sequence using a 3T Siemens Allegra scanner equipped with a custom RF. We then conducted a VBM analysis relating our behavioral measure of rationality to gray matter volume. Multiple regression analysis was performed. The global GM volume, age, gender, extreme preference, numeracy skill, digit span score, Shipley vocabulary score, and education level were regressed out by including them as covariates of no interest. Our results indicate that irrationality in choice (the number of choices violating GARP and their severity) increases as GM volumes in anterior prefrontal cortex decreases. GARP violations and their severity were not correlated with the variables of no interest. In addition, the absence of correlation with mean reaction time suggests that our results cannot be explained by attentional or motivational confounds. Many studies have observed that global GM volume shrinks with age, with particularly local loss of frontal areas (see review in Matsuda, 2016). Our results show that a specific reduction in anterior prefrontal lobe GM correlates with economic irrationality. These findings point towards a neuroanatomic locus for economic rationality in the aging brain, and highlight the importance of understanding both anatomy and function in the study of aging and decision making.

Title: Endocrine modulation of value representations in mesocorticolimbic circuits following short-term fasting

Authors: *J. RIHM[1], H. SCHULTZ[1,2], J. PETERS[1,3];
[1]Dept. of Systems Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [2]Dept. of Educ. and Psychology, Freie Univ. Berlin, Berlin, Germany; [3]Dept. of Psychology, Univ. of Cologne, Cologne, Germany

Abstract: Dopaminergic neurons in the substantia nigra and ventral tegmental area (SN/VTA) are activated in response to reward-predicting cues. SN/VTA neurons also express growth hormone segretagogue receptors for the stomach-derived orexigenic hormone ghrelin. Subjective reward values during value-based decisions are represented in the ventromedial prefrontal cortex

(vmPFC) and the orbitofrontal cortex. After short-term fasting of 4 hours, subjective values of snack foods correlate with vmPFC activity. However, it is unclear if this correlation between neural activity and subjective values after short-term fasting is influenced by homeostatic hormones such as ghrelin. We investigated whether brain activity in mesolimbic and medial frontal regions in response to visual snack food cues is modulated by plasma ghrelin levels. Therefore, we took blood samples from 29 lean, healthy participants immediately before they underwent an fMRI food decision making task after short-term fasting of 4 or 8 hours in a randomized, within-subject design. We found that plasma levels of ghrelin as well as subjective hunger ratings were significantly increased after 8 hours compared with 4 hours of fasting. Functional MRI revealed that subjective value representations of snack foods in the SN/VTA were correlated with ghrelin levels and in the vmPFC with the intra-individual increase in ghrelin levels between the 4- and 8-hour fasting conditions. These findings demonstrate that reward in response to food cues is influenced by homeostatic hormone levels, highlighting the close link between reward circuits and homeostatic circuits. Furthermore, our results could help to understand dysfunctional reward processing in people suffering from homeostatic dysregulation due to obesity.

Title: Neural mechanisms of risky choice framing effects: A test of predictions by prospect theory versus fuzzy-trace theory

Authors: *C. CHICK[1], V. REYNA[2], R. WELDON[2], D. BLANSKY[2];
[1]Stanford Univ., Stanford, CA; [2]Cornell Univ., Ithaca, NY

Abstract: Although prior studies have described brain activation during risky choice framing effects, no study to date has used neural data to test competing theoretical explanations of framing effects in humans. Using a cognitive manipulation of framing effects, we tested competing hypotheses of prospect theory versus fuzzy-trace theory. In previous behavioral studies using this manipulation, fuzzy-trace theory has outpredicted prospect theory; here, we tested whether the same cognitive manipulation could also distinguish between these theories at the level of the brain. During framing effects, we observed increased activation in the amygdala, dorsal striatum, inferior parietal lobule, and ventral prefrontal cortex. In a subset of these regions,

including the caudate, angular gyrus, and supramarginal gyrus, activation mirrored the behavioral effect of our cognitive manipulation—increasing in the condition that enhanced framing effects, and decreasing in the condition that decreased framing effects. Psychophysiological interaction analyses revealed increased connectivity among the caudate and inferior parietal lobule, as well as between the inferior parietal lobule and inferior frontal gyrus, during framing effects. Our results support the prediction by fuzzy-trace theory that framing effects are driven by simplified numerical comparisons, rather than by precise valuation, and that this categorical numerical processing is subserved by a network of frontal, parietal and subcortical regions.

Title: A Bayesian model-based fMRI investigation of temporal expectancy in inhibitory control

Authors: *O. RACCAH[1], J. S. IDE[2], N. MA[1], S. HU[3], C.-S. LI[3], A. J. YU[1];
[1]Cognitive Sci., UCSD, San Diego, CA; [2]Biomed. Engin., Stony Brooks Univ., Stony Brooks, NY; [3]Psychiatry, Yale Univ., New Haven, CT

Abstract: In this work, we examine the neural basis of temporal expectancy using the stop-signal task, a classical inhibitory control task in which subjects inhibit a prepotent go response upon detecting a rare stop signal. Previously, we showed that Bayes-like learning of the need to stop, P(stop), based on recently experienced frequency of stop trials, can explain sequential effects in this task, e.g. an increase of go response time (RT) and decrease in stop error rate (ER) in response to the frequency and recency of experienced stop trials (Shenoy, Rao, & Yu, 2010). We also showed that BOLD response in the dorsal anterior cingulate cortex encodes an unsigned prediction error associated with P(stop) (Ide et al, 2013). More recently, we showed that trial-by-trial adjustment in behavioral response is not only modulated by sequential learning of P(stop), but also by Kalman filter-like learning of the expected temporal onset of the stop signal, or the expected duration of the stop-signal delay, E[SSD] (Ma & Yu, 2015). Here, we examine the neural correlates of the representation and computation of temporal expectancy, by using E[SSD] as a parametric regressor in a fMRI GLM analysis (n=80). We find that a number of cortical

regions have BOLD responses negatively correlated with E[SSD]; in contrast, we do not find any cluster that positively correlated with E[SSD]. These results begin to elucidate the neural basis of the modulation of top-down attention associated with timing-specific aspects of proactive inhibitory control.

Title: Can dynamic normalization models with asymmetric inhibition account for the "attraction" effect in choice?

Authors: ***C. XU**, J. ZIMMERMANN, K. LOUIE, P. W. GLIMCHER;
Ctr. for Neural Sci., New York Univ. Ctr. for Neural Sci., New York, NY

Abstract: Given two isopreferent multi-attribute choice options, the addition of a new but inferior option will shift subject preference towards the option closer to the new option. For example, if a high quality high price option and a low quality low price option are equally preferred, adding a high quality option with higher price into the option set will increase the probability of choosing the high quality high price option. This phenomenon has been termed the attraction effect (Huber et al., 1982; Simonson, 1989), and is supported by numerous empirical animal and human choice experiments.

Multiple previous models have proposed mechanistic explanations for the preference shifts produced by the attraction effect. Early models (Russo et al., 1983;Wedell, 1991) assumed that subjects use a heuristic strategy, in which one attribute is evaluated at a given time and options are discarded on the basis of said attribute. A recent model (Soltani et al., 2012) proposes that the attraction effect arises from range normalization, where the internal representation of all option values is encoded within a fixed range. However, such models rely on tracking the minimum and maximum value of inputs and an explicit calculation of range, which may be difficult to implement in plausible biological circuits.

Here we propose a new class of biologically-inspired model based on divisive normalization that can account for the attraction effect. We built a simple rate network based on a large body of

existing work where local inhibition produces normalization between the values of different options on a given attribute dimension, while long-range inhibition governs normalization between different attribute pools. Neurons representing a given attribute are organized together within a sub-circuit that activates an inhibitory population, which in turn inhibits the encoding population. In this way, the network locally normalizes the value of different options in individual attribute dimensions. Normalization between different attributes is implemented by long-range inhibition from the inhibitory population of one attribute sub-circuit to the excitatory population of other attributes.
We find that this attribute-based normalization circuit reproduces the attraction effect. This form of context-dependence requires an asymmetric inhibitory balance, with long-range inhibition stronger than local inhibition. These findings suggest that an alternative, biologically inspired network based on a canonical neural computation can account for context specific phenomena such as the attraction effect.

Title: EEG correlates of evidence accumulation during dynamic discrimination decisions across two spatial locations

Authors: ***N. J. WISPINSKI**[1], J. K. BERTRAND[2], A. SINGHAL[1], C. S. CHAPMAN[2];
[1]Psychology, [2]Fac. of Physical Educ. and Recreation, Univ. of Alberta, Edmonton, AB, Canada

Abstract: Making a decision is theorized to involve the accumulation of evidence for available options over time. Neural signals supporting evidence accumulation have been observed in primate neurophysiology and human electroencephalography (EEG), but primarily in detection tasks with a single stimulus. However, most real-world decisions are discrimination decisions, where information needs to be compared relatively between multiple spatially distinct stimuli. Using EEG in a discrimination decision with two stimuli, we sought to separately characterize the dynamics of neural evidence accumulation and sensory information signals. Human

participants monitored two grey circles for a change in relative brightness between the left and right circle. On every trial, individual circles could change (increase or decrease in brightness), or stay the same. As a result, a single circle changing brightness did not necessarily mean a task-relevant difference in brightness (e.g., both circles becoming brighter). Therefore, sensory information (brightness changes), and decision evidence (relative differences), were manipulated independently. Circles flickered at two different rates in order to measure steady-state visually evoked potentials (SSVEP) independently from the left and right circles. We found that the centroparietal positivity signal exhibited accumulation patterns on trials with relative brightness differences, and rapidly fell post-response. The slope, speed of onset and responses, and amplitude at response, all increased with greater relative differences in stimuli brightness. In addition, SSVEP power from the independent flicker rates of both stimuli, measured at contralateral occipital sites, tracked the dynamic changes in brightness at both spatial locations. Overall, occipital oscillations reflected spatially distinct and dynamically changing sensory information while parietal positivity reflected the relative-brightness decision evidence. The findings of parietal amplitude at response for different levels of relative brightness have important implications for models of evidence accumulation, and suggest urgency signals at play during decision making. The current research also has practical implications for measuring decision signals using EEG in traditional two-alternative forced choice paradigms. In contrast with most previous research on human decision signals using detection tasks or a single stimulus location, our results open the door for extensions of decision signals to classic paradigms using discontinuous trials, and multiple spatial locations.

Title: pupil dynamics during prolonged performance of a cued stroop task

Authors: *I. BABU HENRY SAMUEL[1], S. BURKE[2], J. CAGLE[2], M. DING[2];
[1]J. Crayton Pruitt Family Dept. of Biomed. Engin., [2]Univ. of Florida, Gainesville, FL

Abstract: Prolonged performance of a cognitive task induces mental fatigue. Anecdotal evidence suggests that pupil size is an effective index of mental fatigue. To date no studies have been carried out to examine this issue systematically. We recorded pupillometry from participants performing a cued Stroop task continuously for two hours. At the beginning of each trial a cue instructed the subject to either read aloud the target word or name the font-color of the target word presented 1500ms after the cue. Subjects rated their fatigue levels every 20 minutes. Pupil size in the 200 ms time interval prior to the cue was extracted and averaged in a moving window of 30 minutes with 20-minute overlap. The following results were found. First, the subject's fatigue level increased as a function of time-on-task. Second, pupil size decreased as a function of time-on-task. Third, the slope of the pupil size decline is not predicted by the fatigue severity score (FSS) obtained prior to the start of the Stroop experiment. Fourth, the slope of the pupil size decline and the slope of the fatigue level increase were not correlated. These findings (1) confirm the previously suggested relation between pupil size and mental fatigue, (2) show that the rate of the pupil size decrease does not reflect the trait fatigue level, and may therefore provide a measure of objective fatigability, and (3) indicate that there may be multiple mechanisms underlying the increased subjective feelings of fatigue and objective decline of pupil size.

Title: Mental representations of covert intentions on 'like' and 'dislike' are differentiated in alpha-band neural synchronies

Authors: *J. CHOI, D. YEO, K. CHA, K. KIM;
Yonsei Univ., Wonju, Korea, Republic of

Abstract: The purpose of this study is to investigate spatiotemporal and spectral characteristics of neural activities based on electroencephalogram (EEG) during maintenance of the subjective preference, 'like' or 'dislike', in response to affective pictures.Fifteen healthy university male

students participated in the experiment. The pictures consisted of pleasant, unpleasant and neutral pictures selected from the International Affective Pictures System (IAPS). The subjects were required to decide whether they 'liked' or 'disliked' each picture, then maintain the preference in mind, and finally respond with button press. Multichannel EEGs were recorded during the task.EEGs during the 'preference in mind' period (before the button press) were segmented. We investigated local synchronies in neural activities within task-relevant cortical regions by analyzing event-related spectral perturbation (ERSP), along with conventional averaged event-related potential (ERP) analysis. In addition, inter-regional neural synchronies were explored by using the weighted phase lag index (wPLI).At the period of maintaining the preference, significantly greater alpha-band power was observed for 'like' at frontal regions for both emotional and neutral pictures. Furthermore, inter-regional neural synchronies in the alpha band were significantly different, but only for neutral picture, especially, frontal and parietal regions centered at parietal regions. The alpha-band fronto-parietal neural synchrony was significantly stronger for 'like'. In conclusion, local and global alpha-band neural synchronies during critical temporal epoch were significantly differentiated according to the contents of mental representation of subjective preference in response to affective pictures.

Title: Midbrain to cerebral dopaminergic and serotonergic white-matter fiber tracts identified on the ntu-dsi-122 template

Authors: *U.-L. HSIEH[1], W.-Y. TSENG[1,2], Y.-C. LO[2], Y.-C. HSU[2], J. GOH[1,3,4];
[1]Grad. Inst. of Brain and Mind Sci., [2]Mol. Imaging Center, Inst. of Med. Device and Imaging,, Col. of Medicine, Natl. Taiwan Univ., Taipei, Taiwan; [3]Dept. of Psychology, [4]Neurobiological and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: The ventral tegmental area (VTA) and the dorsal and median raphe nuclei (DRN, MRN) of the midbrain consist of dopaminergic and serotonergic neurons, respectively, that project to various cortical and subcortical regions. Together, these two neurotransmitter systems play critical regulatory roles on cerebral functions that are implicated in various human mental

abilities including reward processing, motivation, learning, and memory. At present, it is difficult to assess the *in vivo* structural and functional contributions of these systems because the locations of the midbrain-to-cerebral connections have not yet been specified in human brain imaging templates. The aim of this study was to construct midbrain-to-cerebral dopaminergic/serotonergic white-matter fiber tracks that are known to subserve the above cognitive functions on a standard brain atlas. Fiber tracking analysis was performed on the NTU-DSI-122 (National Taiwan University, Diffusion Spectrum Imaging) template, which is an averaged white-matter template in MNI (Montreal Neurological Institute) space built on DSI data from 122 normal individuals (61 males; 61 females) with mean age (SD) of 28.0 (5.3) yrs with a range of 19-40 yrs. VTA, DRN, and MRN midbrain regions-of-interest (ROI) were defined in previous studies that targeted these areas using specialized functional magnetic resonance imaging (fMRI), positron emission tomography (PET), or manual tracing techniques. Frontal, medial temporal, and subcortical ROIs involved in the above cognitive processes were based on the Automated Anatomical Labeling atlas. Using DSI Studio, we applied whole-brain seeding to identify fiber tracts that spanned the midbrain source and cerebral target ROIs and filtered out tracts that did not pass both source and target ROIs. This analysis revealed dopaminergic tracts in the template consistent with the mesocortical (VTA to prefrontal region) and mesolimbic (VTA to anterior cingulate, ventral striatum, globus pallidus, and medial temporal regions) pathways. Also, serotonergic tracts were identified that included the ventrolateral (DRN to prefrontal, globus pallidus, and medial temporal regions) and ventromedial (MRN to prefrontal, anterior cingulate, caudate, putamen, hippocampal and entorhinal regions) bundles, as well as the dorsal raphe subcortical tract (DRN to caudate and putamen). Comparisons with structural studies in different mammalian species validated the reliability of our findings. Our findings contribute valuable imaging tools towards more specific studies investigating the roles of dopaminergic and serotonergic systems in human cognition.

Title: Total Intracranial volume growth across the third trimester using longitudinal fetal MRI

Authors: S. COHEN, 06513[1], S. KWON[2], S. CROSS[2], C. LACADIE[2], G. SZE[2], T. CONSTABLE[2], *L. R. MENT[2], D. SCHEINOST, 06513[2];
[1]Yale Univ., New Haven, CT; [2]Yale Univ. Sch. Med., New Haven, CT

Abstract: The third trimester through the neonatal period is characterized by rapid brain growth. However, longitudinal magnetic resonance imaging (MRI) studies of fetal brain volume have been limited. Increased understanding of normal, fetal brain growth could help define patterns of abnormal brain development in clinical populations.
The objective of this study was to investigate fetal volumetric brain growth from the third trimester through the neonatal period using longitudinal volumetric MRI.
Ten typically-developing fetuses underwent longitudinal volumetric MRI at 30-32 weeks post-menstrual age (PMA), at 34-36 weeks PMA, and, after birth, at 40-44 weeks PMA. Imaging was performed on a 3.0 T scanner (Siemens Skyra) using a 32 channel body or head coil. Total intracranial volume (TIV) was estimated by manual segmentation using BioImage Suite. TIV included cerebrospinal fluid, gray and white matter, cerebellum, and brain stem. Linear regression was used to correlate PMA and TIV.
The average TIV was 230.8 ml for the first fetal scan (31.1±1.1 wks PMA, N=10), 304.3 ml for the second fetal scan (35.0±0.7 wks PMA, N=8), and 412.1 ml (41.1±1.9 wks PMA, N=6). TIV exhibited a significant linear association with PMA from 30 weeks to 44 weeks ($r=0.94$, $R^2=0.88$, $p<0.001$). TIV increased at an average rate of 8.0% per week and approximately doubled in size during this period.
These longitudinal data suggest that the brain grows linearly and doubles in size from the third trimester through the neonatal period. Future studies should continue to investigate fetal brain growth using longitudinal MRI, especially in clinical populations.

Title: Altered white matter development in very preterm children

Authors: *J. M. YOUNG[1,2], B. R. MORGAN[2], M. SMITH[1,2], M. J. TAYLOR[1,2];
[1]Psychology, Univ. of Toronto, Toronto, ON, Canada; [2]Hosp. for Sick Children, Toronto, ON, Canada

Abstract: Objective: Very preterm (VPT) children born less than 32 weeks gestational age (GA) are at-risk for altered brain maturation in early development. In the present study, diffusion tensor imaging was utilized to examine structural white matter differences and its relation to cognitive function between very preterm born and term-born children at 4 years of age.
Methods: Sixty-direction diffusion and T1 anatomical data were acquired in 31 VPT children (mean GA: 28.76 weeks, 18 males) and 28 term-born children (13 males) at 4 years of age on a 3T Siemens Trio MR scanner. Using FSL's tract-based spatial statistics (Smith et al., 2006), each subject's DTI data were non-linearly co-registered to create a cohort-specific template. A mean fractional anisotropy (FA) skeleton was generated on the average FA image and thresholded at 0.25 to only represent major white matter tracts, which was then applied to each subject's FA, mean diffusivity (MD), axial diffusivity (AD), and radial diffusivity (RD) data. Within group analyses were also performed to test associations between FA values and IQ and language measures. FSL Randomise (Anderson & Robunson, 2001) was used to determine significance of the above tests, using threshold-free cluster enhancement. Group connectivity differences were further investigated using connectometry analyses in DSI Studio (Yeh et al., 2015).
Results: In VPT born children, FA values were consistently reduced compared to term-born children at 4 years of age within major white matter tracts. Affected tracts included the corpus callosum as well as bilateral areas of the corona radiata, superior longitudinal fasciculus, internal and external capsule, inferior fronto-occipital fasciculus and the left optic radiation. Scores of IQ and language fell within average limits for both groups. Within group analyses revealed significant associations in term born children between FA and IQ within regions of the superior longitudinal fasciculus, inferior fronto-occipital fasciculus, forceps minor and forceps major. No associations were found between cognitive scores and FA in the VPT born children. Connectometry analyses also revealed similar group differences.
Conclusions: Widespread, significant reductions of FA were found in VPT born children compared to term-born children within major white matter tracts. Unlike the very preterm born children, term-born children had significant linear associations between FA measures and cognitive scores. This disrupted neurodevelopment occurring in early childhood contributes to our understanding of white matter development and its relation to cognitive function in VPT children.

Title: Reduced grey matter concentrations in infants with transposition in the great arteries

Authors: *R. ELWARD[1,2], M. SAINI[1,2], D. GADIAN[1], D. CARMICHAEL[1], A. GIARDINI[2], M. DE HAAN[1], T. BALDEWEG[1], F. VARGHA-KHADEM[1,2];
[1]Univ. Col. London, London, United Kingdom; [2]Great Ormond Street Hosp., London, United Kingdom

Abstract: Transposition of the great arteries (TGA) is a congenital heart defect with a prevalence of 0.2 per 1000 live births. This condition is associated with a risk of systemic hypoxic/ischaemic (HI) brain injury in the neonatal period. Depending on their severity, HI episodes can target the hippocampus and/or the basal ganglia, sometimes producing cerebral palsy. Children and adolescents with corrected TGA have been reported to show motor coordination and cognitive deficits, and increased incidence of psychiatric diagnoses in long term follow-up. We examined the ontogeny of cognitive and motor coordination deficits in relation to structural Magnetic Resonance Imaging (MRI) evidence of the integrity of the hippocampus and basal ganglia, by conducting a longitudinal, prospective study of groups of infants treated for TGA (N=24) and their age-matched healthy controls (NC) (N=25). All infants were free from any neurological diagnoses. Voxel-Based Morphometry (VBM) analyses were conducted on T1 and T2-weighted MRIs (mean age at scan = 12.5 weeks for TGA, and 11.6 weeks for NC). The VBM results indicate that infants with TGA have reduced grey-matter volume in the hippocampus relative to NC ($p < 0.001$; $k = 54$; peak Z score = 3.35). This finding is consistent with previous reports that older children with TGA have reduced hippocampal volumes. The VBM showed no evidence of grey matter volume reduction in the caudate nucleus, putamen, or the thalamus in the TGA group relative to NC. Magnetic resonance spectroscopy (MRS) was also used for the assessment of focal brain pathology in the caudate and the thalamus. The MRS analysis revealed no evidence of pathology in either structure. The Bayley Scales of Infant Development were used to assess cognitive, fine-motor, gross-motor, expressive language and receptive language skills at two time-points (six months and 12 months). A Group X Scale X age at test ANOVA showed a significant three-way interaction ($p < 0.005$). At six months of age, the TGA group was delayed relative to NC on the gross-motor scale only ($p < 0.05$). By 12 months of age, the TGA group showed significant delays on the cognitive ($p <$

0.005), expressive language ($p<0.05$) and fine motor ($p < 0.05$) scales. We conclude that infants with corrected TGA suffer HI damage to the hippocampus during the perinatal period which has significant consequences for subsequent development within the first year of life. These data provide insight into the emergence of cognitive and motor deficits in infants with TGA.

Title: Cross-sectional comparison of spontaneous electrocortical alpha-gamma cross-frequency coupling in infancy

Authors: ***S. HEIM**[1], G. MUSACCHIA[2], S. PETERS[1], S. ORTIZ-MANTILLA[1], A. A. BENASICH[1];
[1]Ctr. for Mol. & Behavioral Neurosci., Rutgers Univ. - Newark, Newark, NJ; [2]Univ. of the Pacific, San Francisco, CA

Abstract: Recent conceptual and modeling work emphasizes the role of oscillatory communication at the level of neural populations within and across brain regions. Accordingly, studies in animal models and using adult participants have provided evidence for a systematic dynamic relation between electrocortical oscillations at different frequencies. One of the most widely held hypotheses in this field has been that the amplitude of higher-frequency brain oscillations depends on the oscillatory phase of specific lower-frequency oscillations, subject to the participant's brain state or task. The presence and putative maturational trajectory of such relations have yet to be explored in human infants. The current study examined spontaneous phase-amplitude coupling cross-sectionally, over typical development, using dense-array electroencephalography (EEG) recordings from 31 infants at either 4 (n = 15) or 7 months of age (n = 16). Spectral power was calculated on EEG collected during quiet play. Differences between groups emerged in the 6-8 Hz range as well as the 22-28 Hz range. Further analysis of these group power differences showed that the phase in the emerging alpha band (around 7 Hz)

significantly predicted gamma-range oscillations in younger (4-month-old), but not older infants. These effects were seen in voltage space as well as in current density space, at centro-parietal sensors, where both alpha-like and gamma-band oscillations showed maximum power. The present results suggest that resting coupling between the alpha and gamma bands may constitute a mechanism for organizing spontaneous brain rhythms, which reorganizes as alpha emerges as a functionally relevant, distinct oscillatory phenomenon that varies with behavioral changes.

Title: Resting brain interactions during natural sleep in typically developing toddlers are biased to the left hemisphere

Authors: ***S. J. GOTTS**[1], E. REDCAY[2], S. C. MILLEVILLE[1], A. THURM[3], S. SHUMWAY-MANWARING[4], A. MARTIN[1];
[1]Lab. of Brain and Cognition, NIMH/NIH, Bethesda, MD; [2]Psychology, Univ. of Maryland, College Park, MD; [3]Pediatrics and Developmental Neurosci. Br., NIMH/NIH, Bethesda, MD; [4]Communication Sci. & Disorders, Univ. of Utah, Salt Lake City, UT

Abstract: Resting brain activity in typically developing adolescents and young adults exhibits two distinct forms of lateralized interactions, with left-hemisphere regions biased to interact more strongly within the same hemisphere in support of language and fine-motor functions and right-hemisphere regions biased to interact more strongly with both hemispheres in support of visuospatial processing (Gotts et al., 2013, PNAS, 110, E3435-44). Whether these patterns emerge as a result of experience or are present prior to behavioral competence is unknown. In the current study, we examined resting brain activity in 32 typically developing toddlers with fMRI [Age range = 12.91 to 39.69 mos; Mean (SD) Age = 24.64 (9.35)]. Data from 3 toddlers were excluded due to excessive head motion (mean Frame Displacement, FD > 0.3 mm/TR) and one for poor MPRAGE quality, retaining 28 toddlers for analyses [Mean (SD) FD = .087 (.043)]. Resting-state data (TR=2 sec, voxel size = 2x2x3 mm^3; 8-minute scan duration) were acquired during natural sleep and were processed using the ANATICOR approach (regressors: 6 motion, ventricle signal, local white matter signal within 15mm radius, Retroicor + RVT, 1st 3 PCs of combined white matter/ventricle mask). Lateralization metrics for resting-state data were

calculated by comparing the original data orientation with L/R flipped data after first non-linearly warping the flipped to the original MPRAGE scan for each participant in order to better align homotopic locations volumetrically. As in adolescents and adults, "Segregation" effects (a bias for within-hemisphere interactions) were left-lateralized in the planum temporale, Heschl's gyrus, STG, and premotor cortex (FWE-corrected to P<.05 by permutation). In contrast to adolescents and adults, toddlers exhibited no significant right-lateralized "Integration" effects (a bias to interact more strongly with both hemispheres). Integration was limited to one left-lateralized cluster in the dorsolateral prefrontal cortex (P<.05 corrected). Neither of these patterns changed systematically with Age [with Segregation: r(26) = .034, P>.8; with Integration: r(26) = .085, P>.6] and were unrelated to head motion or hemispheric differences in signal amplitude (all P's > 0.2). Follow-up whole-brain searches for Age-dependent lateralization effects yielded uncorrected Segregation effects in the left parietal cortex and ventral temporal cortex that grew stronger with Age. Left-lateralized Segregation effects in toddlers are present early and ontogenetically prior to right-hemisphere Integration effects, suggesting a potentially important role for left segregation in language learning.

Title: Structural connectivity of language tracts in 6-week-old infants

Authors: ***J. LIU**[1], C. PONTING[2], T. TSANG[3], S. BOOKHEIMER[2], M. DAPRETTO[4]; [1]Neurosci., [3]Psychology, [4]Psychiatry and Biobehavioral Sci., [2]UCLA, Los Angeles, CA

Abstract: Altered structural connectivity has been reported in several developmental disorders that involve atypical language function such as specific language impairment, global developmental delay, dyslexia, and autism spectrum disorder, suggesting that atypical structural connectivity in the developing infant brain may provide a biomarker of future developmental outcome. White matter tracts connecting language areas in the brain are present very early in

development. These include the arcuate fasciculus (AF) and the superior longitudinal fasciculus (SLF), which are dorsal pathways connecting Wernicke's and Broca's areas, two brain regions which have been found to be activated during speech processing in infants during natural sleep. These early developing white matter pathways are thought to subserve the integration of sensory and motor representations that must precede more advanced language development; indeed, these early structural connections are in place to support language acquisition well before the onset of overt language production. While a number of studies have previously shown that these white matter tracts can be detected in infants as young as 2 days of age, very little is known about how early measures of structural connectivity might relate to later behavioral language outcome.

This study began to address this gap using diffusion tensor imaging (DTI), which provides an index of structural connectivity by measuring the diffusion of water molecules in the brain to reveal white matter anatomy. DTI data were collected in 6-week-old infants who underwent MRI during natural sleep. Deterministic and probabilistic tractography approaches were used to identify the AF and SLF connecting the superior temporal gyrus and the inferior frontal gyrus. Indices of white matter fiber integrity, including average fractional anisotropy and mean diffusivity, were extracted from probabilistic tractography and subsequently related to behavioral indices of language development (including both receptive and expressive language measures). These findings confirm that white matter tracts connecting language regions in the brain can be readily detected in 6-week-old infants using DTI during natural sleep. Furthermore, exploratory correlational analyses suggest that the structural integrity of white matter fibers connecting language regions at 6 weeks of age does relate to subsequent language outcome.

Title: Structural brain correlates of global motion sensitivity in typically developing children: Parietal surface area and TBSS measures of the superior longitudinal fasciculus

Authors: *O. J. BRADDICK[1], J. ATKINSON[2], N. AKSHOOMOFF[3], E. NEWMAN[3], L. B. CURLEY[3], A. M. DALE[3], T. L. JERNIGAN[3];
[1]Univ. Oxford, Oxford, United Kingdom; [2]Div. of Psychology & Language Sci., Univ. Col. London, London, United Kingdom; [3]Univ. of California San Diego, San Diego, CA

Abstract: Impaired sensitivity to global visual motion, but not to global form, has been found as a signature of a range of neurodevelopmental disorders, often associated with spatial and attention deficits and poor mathematical skills ('Dorsal stream vulnerability' - Braddick et al, *Neuropsychologia*, 2003, 41:1769). We have previously reported (Atkinson et al, *J Vision* 2014 14(10): 1324) cerebral correlates of individual differences in global motion in typically developing children, high sensitivity being associated with a relatively enlarged surface area of the parietal lobe (especially around the intraparietal sulcus) and reduced occipital area.
Is this cortical correlate of global motion sensitivity linked to variations of organization in white matter fiber tracts? We analysed fractional anisotropy (FA) within major fiber tracts defined by tract-based spatial statistics (TBSS) in 125 typically developing children aged 5-12 years, from the PLING study (Pediatric Longitudinal Imaging Neurocognition and Genetics). The superior longitudinal fasciculus (SLF) was treated as the main candidate tract, given its connections to parietal areas previously associated with global motion performance.
We found an asymmetrical relation of global motion sensitivity to SLF structure, with higher FA in the right SLF showing a positive association ($p=0.003$) with high sensitivity, while the left SLF showed a negative association ($p=0.02$) (age taken out as a covariate). This relation was not found for overall FA or for other specific tracts, and did not occur for global form. In contrast, our data show that the associations of parietal surface area relative expansion, and occipital area contraction, associated with motion performance while in the same direction in both hemispheres, were stronger in the left than in the right hemisphere.
We conclude that (a) developmental variation in global motion sensitivity is linked to local white matter organization in SLF, as well as to regional differences in parietal area; (b) a complex pattern of hemispheric asymmetry in both fiber tracts and cortical area is associated with the phenotype of high global motion sensitivity. These findings provide pointers for the neuroanatomical investigation of the visual correlates of neurodevelopmental disabilities and of 'dorsal stream vulnerability'.

Title: White matter damage associated with motor, attention and working memory deficits in children with congenital hyperinsulinism

Authors: *G. PITTS[1], K. HUSSAIN[1], A. KUMARAN[1], J. BULLOCK[2], D. GADIAN[1], F. VARGHA-KHADEM[1];
[1]UCL Inst. of Child health, London, United Kingdom; [2]Great Ormond Street Hosp., London, United Kingdom

Abstract: Neonates and infants with congenital hyperinsulinism (CHI) experience severe and recurrent episodes of hypoglycaemia. It is recognised that these infants are at risk of brain damage, and imaging studies of neonates have reported global white matter damage through visual inspection of MRI scans. However little is known about the extent of this damage and its adverse effects on cognition and behaviour during childhood and adolescence.
Twenty-four patients with CHI, but without neurological impairments (mean age 11.2yrs, sd= 2.6 yrs, 14 male) completed a comprehensive neuropsychological assessment (including IQ, academic attainments, memory, attention and motor coordination), and underwent structural MRI scans. Forty-two healthy controls (NC, mean age 11.8yrs, sd=2.5 yrs, 16 male) also underwent MRI scanning. Voxel Based Morphometry (VBM) and Tract-Based Spatial Statistics (TBSS) analyses were performed to assess differences in brain structure.
Compared to the standard population mean (X = 100; SD, 15), the CHI group scored lower on working memory, sustained attention, divided attention, fine motor skills and overall motor proficiency (all comparisons Bonferroni corrected, $p<0.002$), but not on full scale IQ or memory and learning.
Morphometric analyses showed a significant reduction in white matter volume in prefrontal regions ($p=0.05$, FWE corrected), and a reduction in total white matter volume. TBSS analysis revealed decreased Fractional Anisotropy (FA) across almost the entire white matter skeleton ($p=0.05$, corrected for multiple comparisons), and an increase in Mean Diffusivity (MD) across the corpus callosum, and in the left cingulum. In the CHI group, lower FA values were significantly correlated with poor attention and motor scores. Moreover, motor scores were

positively correlated with FA of tracts known to serve motor function, including the cortico-spinal tract, anterior and posterior thalamic radiations, anterior limb of internal capsule, and corpus callosum (p=0.05, corrected). No significant correlation was found between full scale IQ and FA.
Using quantitative neuroimaging analyses, we have shown that school-aged children with a history of neonatal hypoglycaemia show widespread damage to white matter. This is accompanied by specific impairments in working memory, attention and motor skills. These deficits appear to be a function of disruption in specific white matter tracts.

Title: Newborn insula gray matter volume is prospectively associated with early life fat gain

Authors: ***J. RASMUSSEN**[1], S. ENTRINGER[2], F. KRUGGEL[3], D. COOPER[3], M. STYNER[4], J. H. GILMORE[4], S. G. POTKIN[3], P. D. WADHWA[3], C. BUSS[2];

Abstract: Childhood obesity is of great concern as obese children are more likely to be obese as adults, and develop obesity-related diseases at earlier ages and of greater severity. The importance of homeostatic brain circuitry, particularly the insula, is well established through structural and functional imaging in obese adults. In this work, we investigate the association between newborn insula gray matter (GM) volume and rate of fat accrual in the first six months of life, an outcome thought to be among the most reliable, valid, and strong predictors of childhood obesity. 52 neonates were assessed using structural MRI within the first month of life and longitudinal Dual X-Ray Absorptiometry shortly after birth and at six months of age. Bilateral insula gray matter (GM) volume was negatively associated with change in body fat percentage (BF%) from birth to six months postnatal age (Figure; R^2=19%; p=0.001). This finding was replicated using GM concentration (ratio of GM to total insula volume) within the insula, a relative measure of GM volume more independent of age and intracranial volume, as a

predictor of change in BF% (R^2=13%; p=0.009;). Furthermore, the observation was spatially consistent with known gustatory regions within the insula, the direction of effect was in concordance with adult findings, the magnitude of effect was substantial, and the results remained significant after post hoc testing of relevant confounding variables. Taken together, insula GM volume assessed at birth holds significant promise as a brain phenotype predicting childhood obesity risk.

Abstract: Microorganisms inhabiting the human gut play a vital role in health and likely influence neurodevelopment. Differences in microbial diversity impact anxious behavior and cognition in rodents and are associated with temperament in human children. Here we test the association of infant gut microbial composition with cognitive and brain imaging outcomes. 89 typically developing infants were recruited at 1 year of age for structural magnetic resonance imaging, diffusion tensor imaging, and resting state connectivity scans during unsedated sleep. Infant fecal samples were analyzed by 16s rRNA amplicon sequencing for identification and relative quantification of bacterial taxa. Distance metrics and cluster scoring methods were used to identify genus level enterotypes within the sample. We tested for differences in Mullen Scales of Early Learning scores and brain imaging outcomes between clusters. We also investigated associations between alpha diversity and these different outcomes. There was moderate support for clustering subjects into three enterotypes by the relative abundance of different bacterial genera. Many genera showed variation across clusters including *Faecalibacterium*, *Bacteroides*, and a genus of Clostridiales. Mullen cognitive scores at 2 years of age differed significantly between clusters and measures of alpha diversity were predictive of scores. The cluster characterized by Bacteroides abundance showed higher cognitive ability compared to the first cluster. The scores for this cluster were increased by one standard deviation compared to average ability shown in cluster 1. Measures of alpha diversity were negatively associated with cognitive measures. Alpha diversity was significantly different between clusters where higher performing clusters had lower alpha diversity. Analyses of regional grey matter volumes at 1 year of age suggest differences in visual processing and emotion regulation areas. This cross-sectional study shows associations between the gut microbiome and cognitive and brain imaging outcomes during a foundational and vulnerable period in neurodevelopment. Future research on microbiome modulation of the gut-brain axis may allow non-invasive intervention to adjust abnormal developmental trajectories during this critical period of human development.

Title: Added sugar intake is inversely related to creativity among preadolescents

Authors: *K. M. HASSEVOORT[1], A. S. LIN[2], S. E. KHAZOUM[2], C. H. HILLMAN[3], N. A. KHAN[2], N. J. COHEN[2];
[1]The Beckman Inst. of Sci. and Technol., Urbana, IL; [2]Univ. of Illinois at Urbana-Champaign, Urbana, IL; [3]Northeastern Univ., Boston, MA

Abstract: Creativity depends on the ability to combine existing mental representations in new ways and depends, in part, on the hippocampus (Duff *et al.*, 2013). The hippocampus, in turn, is affected by a number of health factors, including aerobic fitness, obesity, and diet. Specifically, in rodent studies, diets high in saturated fatty acids and sugar - hallmarks of a western diet pattern - have been shown to negatively impact hippocampal function. Yet few studies have examined the effects of diet on hippocampal-dependent cognition in children. Therefore, the current study sought to explore the relationship of the intake of dietary lipids (saturated fatty acids and omega-3 fatty acids) and simple carbohydrates (added sugars) with creativity in preadolescent children. Participants (N = 36; mean age = 9.1 years) completed the Verbal Form of the Torrance Test of Creative Thinking (TTCT), a widely used test of creativity. Responses on this task were scored according to their fluency, flexibility, and originality. In addition to cognitive testing, participants completed a 3-day food record with the assistance of a parent. This food record was used to conduct nutrient-level analyses. While saturated fatty acid intake and Omega-3 fatty acid intake were not significantly related to creativity, added sugar intake was negatively related to performance across all three dimensions of the TTCT. These relationships were sustained even after controlling for important covariates including age, sex, socioeconomic status, IQ, aerobic fitness, and abdominal adiposity, factors that are also linked to hippocampal function in this age group. These findings are among the first to indicate a link between added

sugar consumption and cognitive performance during childhood, and implicate western diet patterns in poorer cognitive function among a pediatric population.

Title: Developmental and familial characteristics of top-down inhibitory control networks and performance strategies: ERPs to the Blue Man Stop-Response Task

Authors: *C. BOUCHARD[1], I. SOLIS[1], B. COFFMAN[2], B. SEAMAN[2], J. C. PESKO[3], K. R. CIESIELSKI[1,4];
[1]Dept. of Psychology, Pediatric Neurosci. Laboratory, UNM, Albuquerque, NM; [2]Dept. of Psychology, UNM, Albuquerque, NM; [3]Dept. of Mathemetics & Statistics, UNM, Albuquerque, NM; [4]MGH/MIT AA Martinos Ctr. Biomed. Imaging, Massachusetts Gen. Hosp., Boston, MA

Abstract: RATIONALE**:** Deficits in top-down inhibitory control are one of the major foci of neurocognitive conceptual frameworks in the neuroscience of developmental psychopathological disorders. Since developmental disorders are associated with genetic risk factors, we ask whether the inhibitory performance strategies and activation of the Frontal-Parietal Network (FPN) that is implicated in effortful top-down inhibitory control of behavior, will demonstrate developmental and familial characteristics. Identification of such a marker may have a value for early diagnostics. METHOD: 18 typically developing children (TD) age 7-12, and their biological parents (BP) age 25-50, were examined using neuropsychological tests high on top-down inhibitory control, e.g. WCST and RO-CFT. Brain Event-Related Potentials (ERPs) were recorded to a visual-spatial N-Back stop-response task, The Blue Man T. (BMT, Ciesielski, 2007). BioSemi High Density 64-ch EEG system with a Polhemus digitizer was used. The amplitude, peak-latency and scalp distribution were examined for the frontal ERP P200 and the parietal-occipital N200 during the first 1000 ms of the response-delay window of the BMT

epoch. Spearman r was calculated for amplitude changes in frontal and parietal nodes of FPN within TD and BP. Between-group comparisons (amplitude, peak-latency) were performed using Kruskal-Wallace T. The effect size eta-squared were calculated. RESULTS**:** We predicted that the marker of familial relationship between TD and BP be displayed in similar amplitude changes in FPN and in performance strategies on BMT and neuropsychological tests**.** Some similarity in performance for recall tasks TD vs. BP were found, however the pattern of task-related activation between the FPN frontal P200 and parietal-occipital N200 was determined predominantly by developmental characteristics not by familial. The occipital-parietal N200 (amplitude, scalp distribution) was more similar between TD and BP, however the frontal P200 was not. The N200 amplitude was positively correlated with performance accuracy in BMT. The P200 increased with age to a stop-response task. The reduction in latency of P200 was correlated with reduction of RTs in BMT and neuropsychological tests. CONCLUSION**:** The top-down inhibitory control related FPN activation is determined more profoundly by developmental factors, and particularly by the prolonged development of the frontal brain systems, than by the commonality of familial characteristics. A valid examination of familial factors in brain activation associated with top-down inhibitory control requires a strict match in gender and age of compared family members.

Title: From joint attention to mentalization: beta oscillatory activity predicts theory of mind skill in typically developing children

Authors: P. SOTO-ICAZA[1], L. VARGAS-BECERRA[2], F. ABOITIZ[1], *P. BILLEKE[3]; [1]Psiquiatria, Pontificia Univ. Católica de Chile, Santiago, Chile; [2]Hosp. Luis Calvo Mackenna, Santiago, Chile; [3]Univ. del Desarrollo, Santiago, Chile

Abstract: Early social development involves the capacity to share with another person the perception of an object, namely joint attention. This skill precedes the development of the ability to attribute mental states to others or theory of mind. Nevertheless, the neural mechanism of development of these abilities is still unknown. Since temporo-parietal region in adults participates in both attention and theory of mind, we tested the hypothesis that functional specialization of this region participates in the development from shared attention to theory of mind. To assess this neural mechanism, we study 24 typically developing children between 3 and 4 years old (12 girls) undergone electroencephalographic (EEG) recording. In a real interactive paradigm, children watched a novel stimulus presented in a screen and looking for the interaction with the experimenter (joint attention condition, JA) or not (no joint attention, nJA).Since share attention with another person requires both uncoupling of the stimuli of interest and refocusing of that attention to the social partner, we expect that attentional networks will be involved. Moreover, if JA is a necessary previous step for the explicit theory of mind development, then it involves the activation of a neural network whose specialization leads to the appearance of theory of mind ability (i.e., mentalization network).Event related potential (ERP) analysis showed a significant difference between JA and nJA conditions in right frontal electrodes between 490ms and 560ms (p 0.01 Wilcoxon test, cluster based permutation test). This difference reveals the Nc component (mid-latency negative component) that suggests attentional orienting. Source analysis shows that this activity is placed in right intraparietal sulcus and right inferior frontal gyrus.Time frequency analysis demonstrated a significant difference in beta band (15Hz-25Hz) between JA and nJA conditions over right parietal channels in JA condition (p 0.01). The source of this oscillatory activity was placed in right temporo-parietal region. Interestingly beta activity only in temporo-parietal junction, and not in others attentional areas (e.g., intraparietal sulcus) discriminates children who already have theory of mind ability.The evidence presented here show that through the development of social interactions begin to recruit more specialized brain areas associated to the ability to understand other persons' perspective and preferences. This process coincides with the apparition of explicit theory of mind in children and could reveal neural mechanism of the acquisition of complex social abilities.

Title: Independent components of neural activation during reading and their relationship to behavior

Authors: *M. SIMMONITE[1], C. WENG[2], T. POLK[1];
[1]Dept. of Psychology, Univ. of Michigan, Ann Arbor, MI; [2]Univ. of California San Francisco, San Francisco, CA

Abstract: Visual word recognition is a complex cognitive skill that requires the precise coordination of multiple spatially remote networks in the brain. We used independent components analysis, a data-driven method of assessing functional connectivity, to explore the networks involved in visual word recognition and to investigate the relationship of these networks to observable behavior. Additionally, we analyzed the ability of task-related changes in these networks to predict reading ability compared to structural and functional markers associated with reading ability in previous research. We recruited 68 participants (aged 16-39 years, with mean of 22.4 years) with a wide range of reading abilities (from individuals with dyslexia to very good readers) and assessed their reading skills with a battery of behavioral tasks aimed at tapping constituent parts of the process of reading, such as phonological awareness and lexical processing. We also used functional MRI to estimate neural activity while they matched line orientations (basic visual task), matched letter strings (orthographic task), and determined whether two non-words rhymed (phonological task) (*Brain*, 119: 1221). We used independent component analysis to identify spatially independent networks of brain regions involved in the tasks. We then explored the relationship between task-related modulation of these networks and behavioral performance. The ICA analysis revealed both task-positive and task-negative components that were significantly modulated by the task demands, including networks not previously identified by standard fMRI analysis methods. Additionally, task-related dynamics in many of these networks were better predictors of both dyslexia diagnosis and of reading-related behavioral measures than were previously identified structural and functional markers.

Title: Altered functional connectivity of hippocampus with premotor area in internet gaming disorder

Authors: *J.-Y. KIM;
Addiction Res. Inst., Seoul, Korea, Republic of

Abstract: With the fact that American Psychiatric Association added Internet Gaming Disorder (IGD) to section 3 in DSM-5, it is serious problem that people not only enjoy the Internet gaming but they are addicted to it. So this study aimed to estimate the alteration of the resting-state functional connectivity (rsFC) of the hippocampus as priori region of interest (ROI) in subjects with Internet Gaming Disorder (IGD) compared with healthy control (HC). The sample was comprised of 23 male with IGD and 23 HC. The MRI data were acquired using a 3T MRI system (Siemens, MAGNETOM Verio). For the preprocessing, we use the statistical parametric mapping toolbox (SPM8). In the connectivity analysis, temporal bandpass filtering (0.009-0.08 Hz) to the smoothed data, detrending the globally increasing cerebral spinal fluid are applied. Then, we analyzed the functional connectivity from the bilateral hippocampus using seed based correlation approach. Finally, the differences of the functional connectivity were investigated by performing the two sample t-test between the IGD and HC. The results were considered statistically significant if they exceeded the uncorrected $p<.001$ with an extent threshold of 50 voxels. The rsFC from the bilateral hippocampus to the BA6 especially the premotor region was decreased in subjects with IGD. In addition, the IGD showed increased rsFC of left hippocampus with the right posterior cingulate cortex and also the subjects with IGD showed increased rsFC from right hippocampus to the right precuneus when compared with HC. The observation of decreased rsFC from bilateral hippocampus to premotor cortex may infer that excessive use of Internet gaming causes functional abnormality in spatial memory and movement related to surrounding stimuli. Further study is needed to verify the brain abnormality caused by obsessive use of Internet game. Title: Correlation of cognitive training gains and resting state functional connectivity

Authors: ***C. LEDBETTER**[1], M. FAISON[2], O. HILL[2], J. PATTERSON[1];
[1]LSU Hlth. Sci. Ctr. - Shreveport, Shreveport, LA; [2]Virginia State Univ., Petersburg, VA

Abstract: Background: Cognitive training interventions purport to improve overall cognitive ability by strengthening individual cognitive skills essential to learning. It is presumed that these gains are in part a result of the positive effects of neural plasticity. Functional MRI and analysis of resting state connectivity offers a non-invasive method for investigating underlying changes in functional connectivity associated with cognitive training. Objective: The purpose of this study analysis was to test the hypothesis that completion of an intensive cognitive training program would result in cognitive skill gains, and that changes in functional connectivity would correlate with measured gains. Methods: To test this hypothesis a group of high-school students (n=23) completed 15-weeks of intensive cognitive training. 11 completed the one-on-one ThinkRx program and 12 completed the BrainSkills program (a digital version of ThinkRx). These students, along with a control group (n=7) of students, underwent pre and post cognitive testing and functional MRI imaging. Cognitive tests measured processing speed, working memory, visual memory, auditory memory, short-term memory, long-term memory, visual processing, auditory analysis segmenting, auditory analysis drop, and logic and reasoning. MR imaging was performed on a 1.5T GE MR scanner and a high-resolution T1 anatomical scan and a 5 minute EPI-BOLD resting state functional scan were acquired. Resting state functional connectivity (rs-fc) was calculated and correlated with cognitive testing scores using SPM12 and the CONN toolbox. Results: The most significant gains associated with cognitive training were seen in measures of auditory processing (auditory analysis segmenting, $F=16.34$, $p=0.000$; auditory analysis drop, $F=13.56$, $p=0.001$). Group analysis demonstrated an association between participation in this intensive cognitive training intervention and changes in rs-fc with the auditory cortex that correlated with auditory processing gains (superior temporal gyrus, $p < 0.01$; middle inferior temporal gyrus, $p< 0.001$; inferior temporal gyrus, $p<0.001$). In addition, following cognitive training network global efficiency increased ($T=2.44$, $p=0.02$). Conclusion: Findings from this analysis provide support for the hypothesis that changes in network connectivity underlie gains in cognitive ability resulting from cognitive training intervention. Further, they provide causal support for the hypothesis that intensive cognitive training can positively affect neural plasticity.

Title: Intensive, metronome-based, one-on-one cognitive training improves cognitive skills in children

Authors: *A. L. MOORE[1], C. LEDBETTER[2], D. M. CARPENTER[3];
[1]Gibson Inst. of Cognitive Res., Colorado Springs, CO; [2]Hlth. Sci. Ctr., LSU, Shreveport, LA;
[3]Univ. of Colorado Colorado Springs, Colorado Springs, CO

Abstract: Cognitive skills associated with general intellectual ability predict reading ability, academic achievement, severity of mental health problems, social mobility, obesity, suicidality, early mortality, income potential, and occupational performance. Accelerating the development and remediation of cognitive skills can be accomplished with an intensive training such as ThinkRx, a comprehensive, trainer-delivered intervention that targets multiple cognitive skills. OBJECTIVE: In a 2-phase randomized controlled trial, we examined the differences between two methods of delivering an intensive, metronome-based cognitive training program on IQ, memory, visual & auditory processing, processing speed, reasoning, and attention for children ages 8-14 in a center setting. METHODS: In phase 1, participants (n = 39) were randomly assigned to either an experimental group (n = 20) to complete 60 hours of cognitive training or to a waitlist control group (n = 19). Pre and post training assessments included the Woodcock Johnson III - Tests of Cognitive Abilities. The experimental group attended 40 90-minute sessions delivered one-on-one by a cognitive trainer who modified the intensity of 24 mental tasks using a metronome, stopwatch, manipulatives, and deliberate distractions. In phase 2, the waitlist control group from phase 1 completed 60 hours of the same cognitive training program with 30 hours delivered 1-on-1 by a cognitive trainer and 30 hours delivered through a digital platform. The tasks in the digital version of the program mimicked the tasks in the 1-on-1 program but did not include feedback or modifications. RESULTS: Phase 1 training effects included significant pretest to post-test gains on all measures, and a mean gain of 21 points in IQ for the trained group. MANOVA results indicated an overall significant difference between treatment and control groups (F = 15.83, p = .00, partial η^2 = .83), with pairwise comparisons indicating significant differences on all measures except attention. Phase 2 training effects included significant pretest to post-test gains on all measures, and a mean gain of 22 points in IQ for the second trained group. Although MANOVA results revealed an overall significant difference between the 1-on-1 delivery group and the hybrid delivery group (F = 3.36, p = .008,

partial η^2 = .48), pairwise comparisons only indicated a significant difference on long-term memory. CONCLUSION: The generalized improvements across cognitive skills suggests that two methods of delivering ThinkRx, an intensive, metronome-based, cognitive training, may be viable options for enhancing general intellectual ability and cognition in a center setting.

Title: Assessing the development of episodic memory and future thinking through verbal and behavioral tests

Authors: *K. L. DICKERSON, E. BRYANT, A. M. SEED, J. A. AINGE;
Psychology and Neurosci., Univ. of St Andrews, St Andrews, United Kingdom

Abstract: The ability to mentally recreate past experiences and the ability to imagine future episodes are supported by a common network of brain regions. The explanation for this link at a cognitive level is debated, but it has been suggested that both of these cognitive processes are supported by mental time travel. Through the mental representation and flexible evaluation of future scenarios, we are able to anticipate and plan for events that have not yet come to fruition. Episodic memory and episodic future thinking has been tested in the literature through behavioral and verbal tasks. However, the relationship between functional ability and reporting skill has not yet been evaluated. In order to explore this question, we verbally evaluated differences in memory, planning and imagination in children between the ages of four and seven years. We compared these results to an experimental test of memory and planning (a version of the so-called spoon test) and evaluated differences both within individuals and across development. In the interviews subjects were instructed to remember or create a scene based on word prompts. Trials fell into three language categories: past, present and future. Each interview was transcribed and coded based on the guidelines given by Hassabis, Kumaran and Maguire (2007) with modifications to allow for the decreased age of participants. Across all three conditions scores improved incrementally with age. For four and five-year-olds, the ability to construct rich scenes appears diminished in the future and present tenses as compared to the past tense. This indicates that these verbal tasks possess a unique developmental trajectory, possibly

due to the unique element of construction in present and future scene generation. We also completed a forced-choice task, which are more commonly used in this age group, and found that a correct choice on this task was correlated with higher performance in the future and present tenses during the interview assessment. This may help to validate item-choice tasks as a test of episodic future planning capabilities in non-verbal populations.

Title: Effects of 6 weeks motor-enrichment-intervention to improve math performance in preadolescent children

Authors: *J. WIENECKE[1], M. BECK[2], R. LIND[2], J. LUNDBYE-JENSEN[2], S. GEERTSEN[2]; [1]Univ. of Copenhagen, Copenhanen, Denmark; [2]Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Multisensory learning paradigms can positively affect learning of various cognitive skills (Shams & Seitz, 2008). Furthermore, integrating congruent motor movements (i.e. motor-enrichment) during acquisition can be superior to only audio-visual acquisition in academically related learning (Mayer et al., 2015).
We conducted a six-week cluster-randomized intervention study of motor-enriched mathematics for Danish schoolchildren (n= 148, age= 7.5 ± 0.02). We investigated whether low intensity motor activity congruently integrated during solving of math problems could enhance math performance. Three groups were included:
1) Control group with normal math teaching, CON (used pencil, paper but refrained from additional motor activity).
2) Fine-motor-enriched-group, FM (motor-manipulating LEGO bricks integrated in the lessons).
3) Gross-motor-enriched-group, GM (full-body movements integrated in the lessons).
In FM and GM, all math classes (six lessons pr. week) had motor activity integrated in the math lessons and the teachers of all groups followed a detailed description for the conduction of the lessons. This aimed at ensuring homogeneity between groups concerning the taught themes.
The children were tested pre- (T0) and post- (T1) intervention. We used a standardized 1st grade math test including 2nd grade questions to avoid a potential ceiling effect (50 math questions in total). Additionally, we conducted a phonological- and spatial working memory test and a test of executive functioning to investigate potential mediators of academic performance. Furthermore, electroencephalography (EEG) was measured during mental arithmetic at T1.
All groups improved their numbers of correct answers (CA) from T0 to T1. Interestingly, the improvement in GM from T0-T1 was significantly larger than FM 1.76 ± 0.70 CA ($P = 0.03$). Additionally, a subgroup analysis was performed, extracting data from children with learning difficulties, according to national standards (n= 44). In this subgroup no significant differences was observed in the improvements from T0-T1 between the three groups ($P > 0.05$). Conversely, in normal-achieving children, GM improved significantly more from T0-T1 than CON 1.78 ± 0.70 CA ($P = 0.04$) and FM 2.14 ± 0.69 CA ($P < 0.01$) from T0-T1.
We conclude that gross-motor enrichment can increase math performance and that this effect might be more pronounced for normal-achieving children compared to children with learning difficulties. Future work should seek to investigate the mechanisms behind the observed behavioral differences.

Title: Development of neural stability for four basic arithmetic operations

Authors: *T.-T. CHANG[1], P.-H. LEE[2], A. W. S. METCALFE[3];
[1]Natl. Chengchi University., Taipei, Taiwan; [2]Natl. Chengchi Univ., Taipei, Taiwan;
[3]Sunnybrook Res. Inst., Toronto, ON, Canada

Abstract: Arithmetic problem solving skill is a cognitive domain crucial for academic development. Although neuroimaging studies have well characterized the neural engagement of distinct arithmetic problems, how these skills transit into more stable representations with learning and experience is yet unknown. Here we tackle this fundamental issue by implementing trial-wise multivoxel representational similarity (MRS) analyses (Kriegeskorte, Mur, & Bandettini, 2008) on a cross-sectional fMRI study.

We assessed brain activation of a group of 19-to-29-year-old adults (n=29) and a group of 8-to-10-year-old children (n=21) while they performed the four basic arithmetic operation problems - addition, subtraction, multiplication, and division. We first examined whether each participant demonstrated stable neural representations for each of the four operations by implementing trial-wise MRS analyses. Beta weights of each trial for each operation were extracted from voxels within anatomically-defined bilateral IPS, the regions specialized for numerical processing. For each participant, neural stability index (NSI) was calculated as an average of the pairwise correlation coefficient for each pair within each operation. NSIs were then entered into a 4 (operations)-by-2 (group) ANOVA, with operation as within-subject and group as between-subject factors.

As shown in Figure 1, regardless of age, subtraction and division engaged higher levels of NSIs than addition and multiplication ($F = 6.518$, $p < .001$). Relative to children, adults exhibited higher levels of neural stability in the left IPS when solving problems from all of the four operations ($F = 7.510$, $p = .009$).

Our findings suggest that the development of arithmetic problem solving skills from childhood to adulthood is characterized by more stable neural representations in brain regions crucial for representing numerical quantity. This pattern is more salient in operations associated with quantity manipulation, suggesting that the emergence of arithmetic problem skill has a function-specific developmental progression.

Network, Univ. of Tuebingen, Tuebingen, Germany; [5]Dept. of Psychiatry and Psychotherapy, Univ. Hosp. of Tuebingen, Tuebingen, Germany

Abstract: Arithmetic learning studies in adults suggested reduced activation in the fronto-parietal network and increased activation in the left angular gyrus after learning. This shift has been assumed to be associated to shift from procedural to retrieval strategies. However,

developmental studies indicate that findings are not easily transferable from adults to children. Therefore, in the present study, brain activation changes of arithmetic learning in children have been investigated.
20 fifth-graders received seven sessions of complex multiplication training by using a web-based learning platform. Their performance was tested before training, after one session of training, and after seven sessions of training via functional near-infrared spectroscopy (fNIRS), while children solved multiplication problem.
Behavioral data revealed significantly improved performance in trained complex problems after seven sessions of training, being accompanied by decreased activation of the left angular gyrus and medial temporal gyrus, and also of the right middle frontal gyrus. After one session of training, although no significant behavioral improvement was observed in trained multiplication problems, fNIRS data revealed decreased activation of the left angular gyrus and inferior parietal lobule, along with decreased activation in the right superior parietal lobule and intraparietal sulcus.
In line with multiplication learning in adults and training studies of other operations in children, our findings indicate a decreased fronto-parietal network activation after multiplication training. However, contradictory to the multiplication training in adults, decreased activation of the left angular gyrus and surrounding regions was found. We conclude that strategy shifts from procedural to retrieval strategies in children engage different neural patterns than in adults and that the role of angular gyrus activation changes over the course of development.

Title: Number comparison efficiency mediates the relationship between the linearity of the mental number line and math achievement

Authors: ***N.-R. KIM**, S. CHO;
Dept. of Psychology, Chung-Ang Univ., Seoul, Korea, Republic of

Abstract: Numerical magnitude is believed to be mentally represented as a 'number line' that resembles a ruler, in which relatively smaller vs. larger magnitudes are represented towards the left vs. right side in the order of magnitude (Note, the direction of space-magnitude association may depend on reading direction or culture). Studies of children's number estimation consistently report overestimation of relatively smaller numbers and underestimation of relatively larger numbers manifesting as a logarithmic pattern of estimation. With development, there is a gradual logarithmic-to-linear transformation of number line estimation performance. Many previous studies report that measurements of the linearity of the mental number line correlates with math achievement. On the other hand, number comparison performance has also been reported to be correlated with math ability. Number comparison performance can be thought to reflect how efficiently one can accurately access the semantic meaning of numbers represented on the mental number line. In the present study, we investigated whether number comparison efficiency mediates the relationship between the linearity of the mental number line and math achievement.

Forty-nine first graders (aged 6 to 7, 25 females) participated in the present study. We measured each child's performance on number line estimation, Arabic number comparison and a comprehensive math achievement test (covering calculation, mental arithmetic, etc.). The number range for number line estimation was from 0 to 200 which is more expanded, compared to most previous studies which tested estimation up to 100. In the Arabic number comparison task, two Arabic numbers were presented side by side on each side of the screen. Participants were asked to indicate with a button press which number was larger in semantic magnitude.

A mediation analysis using a bootstrapping method (5000 resamples, 95% confidence interval) was employed. As a result, the relationship between the linearity of the mental number line and math ability was found to be fully mediated by number comparison performance (more specifically, response time). This result supports the idea that children's ability to efficiently access the semantic meaning of symbolic numbers mediates the previously reported relationship between the linearity of the mental number line and math achievement.

Title: Finding the neural correlates of middle childhood "slump" in creativity

Authors: *M. SAGGAR, A. STANKOV, M. SCHREIER, A. REISS;
Psychiatry and Behavioral Sci., Stanford Univ., Palo Alto, CA

Abstract: Little is known about the underlying neurodevelopmental processes that contribute to a child's creative capacity. Of particular interest is the decline in creativity during middle childhood (esp. 4th grade). This decline has been linked to underachievement and an increased risk for mental health problems. Longitudinal neuroimaging studies are, thus, required to understand whether decline in creativity is due to the burden of social norms, educational training, or typical brain development. Here, we present preliminary results from a cohort-sequential semi-longitudinal study using functional Near-infrared Spectroscopy (fNIRS). A total of 56 children (n=24 third-graders and n=32 fourth-graders) were assessed longitudinally at two time points. Creativity was evaluated using the standardized Torrance Test of Creative Thinking (TTCT). The 52-channel fNIRS data, covering bilateral prefrontal cortices, were collected while children engaged in the TTCT and a control-drawing task to connect dots on paper. Additionally, data were collected to assess general intelligence, response inhibition, temperamental characteristics, and family environment. As expected, the examination of average TTCT raw scores indicated a significant grade by time interaction ($p=0.044$), such that 3rd graders scored higher on TTCT during the end of their grade, while 4th graders had a decline in TTCT scores towards the end of their grade. Due to technical difficulties, only a subset of participants (n=15 fourth-graders and n=9 third-graders) had good quality fNIRS data at both assessments. Based on previous work, we hypothesized that the 4th-grade decline in creativity could be associated with a greater need for "conformity" from classroom expectations and peer pressure. We operationalized conformity in terms of variability in task-related functional connectivity (FC). Thus, less variability in FC would imply greater conformity. Significant grade by time interactions were observed for both TTCT and control conditions ($ps < 0.05$), such that 4th graders had reduced variability in FC towards the end of their grade, where as no changes in FC variability were observed for the 3rd graders. Taken together, our data suggest that longitudinal neuroimaging studies could provide better insights about the neural basis for 4th-grade decline in creativity.

Title: The functional brain architecture of own- and other-race face processing in children and adults

Authors: *G. ANZURES[1], C. J. MONDLOCH[3], F. HAIST[2];
[1]Ctr. for Human Develop., [2]Dept. of Psychiatry, UC San Diego, La Jolla, CA; [3]Brock Univ., St. Catharines, ON, Canada

Abstract: Differential experience with different races profoundly affects face perception in children and adults. Understanding this other-race effect can shed light on the development of racial stereotypes and prejudices. However, we know virtually nothing about the functional brain architecture for own- and other-race face processing in children. Here, we administered a passive and an active face perception task during FMRI testing (multi-echo simultaneous multi-slice [MESMS] acquisition with Multi-echo Independent Component Analysis [ME-ICA]) in Caucasian adults (N=16, 18-21 years) and children (N=14, 8-10 years). In the passive task, participants viewed Caucasian and Asian faces and houses (blocked design) and pressed a button indicating the color of the background. In the categorization task, participants pressed buttons to indicate Caucasian and Asian faces (event-related). Behaviorally, adult and child participants showed the classic other-race effect in face recognition ($p < .01$). In the simple viewing FMRI task, all adults produced a reliable fusiform face area (FFA) bilaterally (faces > houses), 12 of 14 children produced bilateral FFAs. Within the right FFAs, other-race faces produced a greater extent of activation than own-race faces in adults and children. Whole-brain analyses of the simple viewing task showed an other-race activation advantage primarily in posterior occipito-temporal regions, including bilateral fusiform gyrus (right > left), lingual gyrus, calcarine cortex, and cuneus. Adults, but not children, also showed greater other-race processing in left amygdala, left lateral inferior occipital gyrus (OFA region), and left inferior frontal gyrus (BA47). We found striking developmental differences in the categorization task. Adults showed greater other-race activation in left insula, left superior frontal gyrus, and crucially, left anterior cingulate gyrus. In contrast, children produced greater other-race activation throughout all regions of cortex with the important exception of the anterior cingulate gyrus. During simple viewing, adults showed greater processing for other-race faces in core and extended face regions that were not observed in children. When categorizing faces by race, children produced widespread hyperactivation to other-race faces throughout cortex, but the anterior cingulate cortex, thought

to be crucial for monitoring and controlling automatic thoughts of prejudice, stereotype, and bias, is not mature during this period of childhood.

Title: The impact of emotional cues on short-term and long-term memory during adolescence

Authors: ***A. COHEN**[1,2], D. V. DELLARCO[2], M. I. CONLEY[2], B. CASEY[2,3];
[1]Weill Cornell Grad. Sch. of Med. Sci., New York, NY; [2]Sackler Inst., Weill Cornell Med. Col., New York, NY; [3]Psychology, Yale Univ., New Haven, CT

Abstract: Emotional information pervades daily life and can influence memory, which affects learning and performance of everyday cognitive tasks. Adolescence is a time of heightened sensitivity to emotional and social inputs, as dynamic changes in brain structure and function take place. In adults, emotional information typically enhances subsequent memory, via consolidation mechanisms involving the amygdala (Beyler et al., 2016); however, the impact of emotional and social content on memory across development, as neural circuitries continues to mature (Casey et al., 2016), remains unclear. The present study implements an emotional n-back task using happy, fearful, and calm faces as well as places in individuals ages 9 to 29 (n = 90, 50 females). Participants are tested for their implicit memory of the stimuli used in the task either immediately after completing the task or 24 hours later, to allow for memory consolidation. Adolescents show better memory for places than faces in the immediate recall condition. However, after 24 hours, we observe linear improvement in corrected recognition memory (correct hits minus incorrect false alarms) for neutral faces across age and non-linear changes in memory for happy and fearful cues. Late adolescence also shows evidence of a novelty bias to faces after 24-hour consolidation. These preliminary results suggest that emotional and social information influence short-term and long-term memory capacity across development. These findings may have implications for learning and for observed developmental differences in behavior.

Title: Neural predictors of educational attainment in adolescence

Authors: *D. FUHRMANN[1], M. SPEEKENBRINK[2], S.-J. BLAKEMORE[3];
[1]Inst. of Cognitive Neurosci., UCL Inst. of Cognitive Neurosci., London, United Kingdom;
[2]Exptl. Psychology, [3]Inst. of Cognitive Neurosci., Univ. Col. London, London, United Kingdom

Abstract: The developmental mismatch hypothesis proposes that, in humans, striatal structures involved in reward processing mature earlier than prefrontal areas involved in cognitive control, leading to a mismatch in maturation in adolescence. Structural mismatch in adolescence has mainly been investigated in relation to risk and sensation seeking behaviors but it may also affect other processes relying on the interplay between reward processing and self-control. One such measure is grit, the ability to sustain efforts towards long-term goals. Grit has been shown to predict changes in grades better than IQ. Here we used magnetic resonance imaging to investigate whether connectivity and activation of frontal and striatal regions as an indicator of structural mismatch predicts grit during adolescence. We scanned adolescent girls to assess fronto-striatal connectivity strength and frontal and striatal activation in an emotional go-no go task. We correlated these neural predictors with grit to assess the validity of structural mismatch in adolescence as a predictor of educational outcomes.

Title: Cognitive functions negatively correlate to the angular gray matter volume in schizophrenia

Authors: ***T. UENO**[1], H. KUGA[1], N. ORIBE[1], K. TAKAO[1], R. HAYASHIDA[1], N. NAKAYAMA[1], H. MIZUHARA[2], T. YUZURIHA[1];
[1]Hizen Seishin Iryo Ctr., Saga-Ken, Japan; [2]Grad. Sch. of Informatics, Kyoto Univ., Kyoto, Japan

Abstract: Background; Several Studies showed that impairment of cognitive function in schizophrenia patients. (Hedman, van Haren et al. 2012) However, little is known about the exact intelligence quotients (IQ) using Wechsler Adult Intelligence Scale (WAIS) in schizophrenia patients. Moreover, there are very few studies about the relationship of brain structure and IQ in schizophrenia. The current study shows the correlation between regional brain gray matter volume and IQ in schizophrenia patients.
Methods; Thirty schizophrenia patients were recruited from Hizen Psychiatric Center. They met to DSM-4 criteria diagnosed by two independent psychiatrists (age 20-65). All participants signed informed consent forms according to the ethical committee of the Hizen Psychiatric Center. The exclusion criteria were alcohol/drug abuse, brain hemorrhage /infarction, or thyroid dysfunction. Independent psychologist tested the patients using WAIS to determine the exact cognitive function. All participants were scanned by 1.5 T MRI machine (Phillips) to get the T1 weighted structural brain images in 6 minutes. Resolution was 1mm x 1mm x 1.2 mm. All the images were segmented to gay matter images and converted to normalized images with the canonical brain image in MNI coordinate with the method of Dartel method in SPM software (Ashburner 2007). General linear model was used to investigate correlation between the regional gray matter volume and the full IQ of WAIS with covariate of age and sex. Cutoff was under 0.001 (P value) of each point of brain, and 0.001 (P value) of spatial extent with Gaussian random field model to exclude the type 1 error.
Result; We found the negative correlation between the regional gray matter volume and full IQ in right angular cortex. No voxel was survived in positive correlation.
Discussion; The angular gyrus was considered to have functions of attention, arithmetic ability, and spatial cognition. Interestingly low volume of this area was negatively correlated to high IQ. A paper showed that more intelligent children demonstrated a particularly plastic cortex. (Shaw, Greenstein et al. 2006) The result might suggest dynamical change of angular cortex along a curing course of schizophrenia.

Title: Hemispheric silencing of phospholipase C-β1 in the right anterior cingulate cortical neurons leads to impaired observational fear learning in mice

Authors: *S.-W. KIM[1], M. KIM[1], J. BYUN[1], T. CHO[1], Y.-S. KIM[2], H.-S. SHIN[1];
[1]Ctr. for cognition and sociality, Inst. for Basic Sci. (IBS), Daejeon-City, Korea, Republic of;
[2]Grad. Sch. of New Drug Discovery & Development, Chungnam Natl. Universit, Daejeon-Si, Korea, Republic of

Abstract: Patients with schizophrenia exhibit significant deficiencies in empathic behaviors, resulting in social dysfunction. Decreased expression of phospholipase C-β1 (PLC-β1) has been detected in some brain regions of patients with schizophrenia. Nonetheless, a causal link between this biochemical change and impaired empathic behaviors has not been demonstrated. In this study, we report that mice with a specific knockdown of PLC-β1 in the anterior cingulate cortex (ACC), but not in the prelimbic or infralimbic cortex, exhibited impaired observational fear learning in mice. On slice recording experiment, neuronal excitability of ACC was decreased in the mutant mice compared with wild-type. Furthermore, a knockdown of PLC-β1 in the right ACC, but not in the left ACC, decreased observational fear learning. These results indicate that PLC-β1 signaling in the right ACC is critical for observational fear learning. Importantly, these results support the notion that the decrease in PLC-β1 expression in the brains of patients with schizophrenia is a pathogenically relevant molecular marker of the disorder.

Title: Perceptual rivalry as bayesian inference : Accumulating evidences towards circular inferences in schizophrenia

Authors: *P. LEPTOURGOS[1], C.- . NOTREDAME[2], R. JARDRI[2], S. DENEVE[1];
[1]INSERM U960 (Laboratoire de Neurosciences Cognitives), GNT, Ecole Normale Superieure, Paris, France; [2]CNRS UMR9193 (SCALab), Lille Univ., Lille, France

Abstract: Probabilistic inference is considered as one of the most promising candidate frameworks to explain
brain function. Similarly, impairments in the mechanics of those inferences have been suggested as the
generative mechanism of various psychiatric illnesses, including schizophrenia. According to the Circular
Inference Framework (CIF), aberrant inferences (circular inferences) implemented in cortical networks
generate a system that overinterprets weak sensory evidence (and / or priors) and might cause psychotic symptoms (Jardri and Denève, 2013). In this project, we used bistable perception to probe
those mechanisms and validate experimentally the CIF in the domain of visual perception.
The Necker Cube is an ambiguous figure, known to induce bistability. We continuously presented such
figures to healthy participants (in a preliminary study) and schizophrenia patients (in an ongoing study)
during 15 consecutive runs. We manipulated sensory evidence by adding shades to the stimuli (in the
last 3 runs) and prior expectations by giving different instructions to 3 different groups (15 – 15 – 20
participants), concerning the presence of an implicit preference. Participants' responses were discretely
and pseudo-regularly collected (according to Mamassian and Goutcher, 2005).
In the preliminary study conducted on healthy participants (N=50), we confirmed the existence of an
implicit prior ($Z=-4.613$, $p<0.001$) and we showed that manipulation of this prior had significant opposite
effects on relative predominance (Kruskal Wallis, $H(2)=9.35$, $p=0.009$), either by exacerbating or
cancelling the intrinsic bias of the system, but also significantly reduced reaction times ($H(2)=10.74$,
$p=0.0047$). The effect of sensory evidence was even stronger ($Z=-3.364$, $p<0.001$), and induced a significant bias corresponding to the direction of the cue. Moreover, we found trends in the correlations

between bistability and psychotic tendencies (measured with the LSHS score). At the theoretical level, a
simple multiplicative rule produced good fits and first order markovian statistics could account very well
for the dynamics of bistability. Finally, we extended the above study by recruiting schizophrenia patients
with prominent psychotic symptoms (ongoing study). Our first results suggest that patients exhibit
important deviations from optimality and their behavior is well predicted by the CIF (higher alternation
rate, weaker effects of the visual cues, instructions).

Title: Lower resilience against surprising information predicts hallucination proneness in healthy individuals

Authors: ***H. STUKE**[1], H. STUKE[2], V. WEILNHAMMER[1], K. SCHMACK[1];
[1]Charité - Universitätsmedizin Berlin, Berlin, Germany; [2]Dept. of Mathematics, Freie Univ., Berlin, Germany

Abstract: Introduction: Sensory information is intrinsically ambiguous and a stable interpretation of the world is only possible through a suppression of unlikely interpretations by prior beliefs. A weakening of the impact of prior beliefs might thus lead to a tendency towards unlikely interpretations and hence contribute to the formation of hallucinations in psychosis. Here, we empirically tested this suggested link between a weakened impact of prior beliefs and psychosis-like symptoms. Methods: Eighty-two healthy human participants with varying hallucination proneness performed a probabilistic reasoning task, in which carps and trouts were sequentially angled from one of two possible lakes. On each trial, participants had to guess from which lake fishes were being angled based on two sources of information: Firstly, the proportion of fishes differed between the two lakes and participants could infer the lake on the basis of the

number of already angled carps and trouts. Secondly, prior information was given in form of a tone that was - dependent on the pitch - more often associated with the one or the other lake. For data analysis, we developed a novel computational learning model that tracks the trajectory of the participants' beliefs about the correct lake. This model allowed us to quantify the impact of prior beliefs in two ways: (1) based on static information learned prior to the experiment (i.e., the tone pitch), and, (2) as the 'resilience against surprising information' of the belief generated during the course of the experiment: This resilience was captured by a non-linear relationship between prediction error and learning that reduces the impact of more surprising information. For cross-validation, participants performed a standard reversal learning task where the number of strategy changes served as a measure for belief instability. Results: The novel model proved to be superior to conventional learning models in explaining the participants' behavior. The parameter encoding the impact of the static information learned prior to the experiment was not associated with neither hallucination proneness nor belief instability. The non-linearity parameter encoding the strength of resilience against surprising information however correlated negatively with hallucination proneness and belief instability. Discussion: Our results suggest that a lowered resilience against surprising information, as implemented by a non-linear relationship between prediction error and learning, might be involved in the formation of hallucinations. Our current findings hence empirically substantiate theories that link psychosis to a weakened stability of prior beliefs.

Title: Test-retest reliability of the MATRICS Cognitive Consensus Battery (MCCB) in persons with schizophrenia and healthy volunteers: A non-interventional study

Authors: *N. SHAAFI KABIRI[1], A. C. COTE[3], B. N. DUPEE[4], P. J. FRIED[5], M. H. KRENGEL[2], K. C. THOMAS[1];
[1]Anat. & Neurobio., [2]Neurol., Boston Univ. Sch. of Med., Boston, MA; [3]Biol., Boston Univ., Boston, MA; [4]Dept. of Biol., Simmons Col., Boston, MA; [5]Neurol., Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: Objective. The MATRICS Cognitive Consensus Battery (MCCB) evaluates cognitive function and change due to treatment in schizophrenia (SCZ) patients. The goals of this study were: (1) Evaluate the Practice Effect (PE) of repeated MCCB scores in SCZ to establish test-retest reliability without intervention (2) Compare baseline scores and PEs between SCZ and healthy volunteers (HV).
Methods. This study, approved by the Boston University School of Medicine Institutional Review Board conformed to the Declaration of Helsinki. Thirty-one HV and thirty SCZ adults provided written consented and the MCCB battery twice (interval: 14±2 days).
Age-normed performance was assessed on all MCCB tests: Trail Making Test (TMT), Brief Assessment of Cognition in Schizophrenia Symbol Coding (BACS), Hopkins Verbal Learning Test-Revised (HVLT-R), Wechsler Memory Scale-III Spatial Span (SS), Letter Number Span (LNS), Neuropsychological Assessment Battery Mazes (NAB), Brief Visuospatial Memory Test-Revised (BVMT-R), Continuous Performance Task-Identical Pairs (CPT-IP); Composite scores: attention/vigilance, speed of processing, working memory, verbal learning, visual learning, reasoning and problem solving, and overall composite score.
Baseline and follow-up data were compared using paired-samples t-tests with PE considered statistically significant ($p<.05$, 2-tailed) with an effect size (Cohen's d) ≥ 0.2.
Results. Incomplete data from two HVs were excluded from CPT-IP, attention/vigilance, and overall composite analyses.
SCZ group displayed medium PEs for BVMT-R and visual learning (*p's < .05, d's =0.54)* and weak PEs for LNS and overall composite score (*p's < .05, d's =0.40-0.48)*. Scores on all other tests and composites remained unchanged.
HV group displayed strong PEs for BACS, speed of processing, working memory, and overall composite (*p's < .001, d's =0.81-1.34*); medium PEs for NAB, LNS, BVMT-R, HVLT-R, reasoning/problem solving, verbal learning, and visual learning (*p's < .05, d's =0.56-0.67)*; and weak PEs for TMT and CPT-IP (*p's < .05, d's =0.38-0.41)*.
Independent two-sample t-tests were used to compare SCZ and HV baseline scores. All tests and composite scores except NAB and reasoning and problem solving showed statistically significant differences (with at least $p<.05$).
Conclusion. In the SCZ group, MCCB had good test-retest reliability with limited PEs except for LNS, BVMT-R, and overall composite score. In contrast, the majority of tests and the composite scores showed small to very large practice effect in the HV group.

Title: Schizophrenia polygenic burden is significantly associated with cognitive performance in nonpsychotic individuals

Authors: *R. SHAFEE[1,3], P. NANDA[4], N. TANDON[5,7], J. PADMANABHAN[6,8], N. ALLIEY-RODRIGUEZ[9], E. GERSHON[10], B. CLEMENTZ[11], G. PEARLSON[12], C. TAMMINGA[13], M. KESHAVAN[2,6], S. MCCARROLL[1,3];

Sch. of Med., New Haven, CT; [13]Psychiatry, UT Southwestern Med. Sch., Dallas, TX

Abstract: Psychiatric disorders such as schizophrenia are frequently accompanied by cognitive deficits. Probands as well as their unaffected relatives show decreased functioning in many cognitive domains. The Brief Assessment of Cognition in Schizophrenia (BACS) is a cognitive battery designed to capture the deficits that are seen frequently in schizophrenia. We used data from the Bipolar-Schizophrenia Network for Intermediate Phenotypes (BSNIP) consortium to investigate the effect of the polygenic burden of schizophrenia common variants (PRS_SZ) on BACS performance as well as on Wide Range Achievement Test (WRAT, often used as a proxy for premorbid IQ) in two groups: psychotic probands (N = 314) and nonpsychotic individuals consisting of healthy controls and non-psychotic relatives (N = 438). Our BACS score consisted

of six components: verbal memory, verbal fluency, digit sequencing, digit symbol coding, token motor task and Tower of London. We found that PRS_SZ is significantly negatively correlated with digit sequencing (DS) and digit symbol (DSC) coding scores in the nonpsychotic group (combined r = -0.21, p<10^-4) but not in the psychotic group (p>0.05). PRS_SZ showed no significant correlation with WRAT in either group. Additionally, the correlation between BACS and PRS_SZ in the nonpsychotic group remained unchanged after regressing out WRAT. We noted that while DS and DSC BACS scores differed significantly between the psychotic and nonpsychotic groups (p<10^-10), WRAT was only nominally different (p~0.05 after controlling for years of education). Additionally, a polygenic score for educational attainment showed significant positive correlation with WRAT (p<10^-3) but not with BACS (p>0.05). Together, these results indicate that in our sample, schizophrenia polygenic burden captures the variability in cognitive functions affected in schizophrenia much better than the variability in overall intelligence. The absence of significant correlation between PRS_SZ and BACS components in the probands could be due to the effects of medication or due to disease pathology altering these cognitive functions in a way that could not be captured by genetic predisposition to schizophrenia.

Title: Behavioral response to LPS treatment in heterozygous Disc1 mutant mice

Authors: *Y.-F. CHANG[1], C.-C. LAI[1], L.-J. LEE[1,2,3];
[1]Grad. Inst. of Anat. and Cell Biol., [2]Grad. Inst. of Brain and Mind Sci., [3]Neurobio. and cognitive science center, Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Both genetic and environmental factors contribute to the pathogenesis of schizophrenia. To study the interaction of the two, we examined the effects of neuroinflammation as an environmental insult in a genetic mouse model of schizophrenia in which the Disc1 gene has been manipulated. In our Disc1 mutant mice, the normal Disc1 gene was replaced by 129S6/SvEv 25-bp deletion variant. In this study, adult male wildtype (WT) and heterozygous Disc1 mutant (Het) mice were used. Neuroinflammation paradigm was induced by

intraperitoneal injection of bacterial endotoxin lipopolysaccharide(LPS; 0.5 mg/kg). One day after LPS or saline injection, mice were subjected to behavioral examinations. The acoustic startle responses were equally reduced in both genotypes after LPS while the ratios of prepulse inhibition were not significantly altered by LPS treatment.In the open field arena, the locomotor activity and explorative behaviors were also largely reduced in both genotypes after LPS injection. The time spent and travelled distance in the central and peripheral area of the open field were further analyzed. No difference was noted between WT and Het mice in saline-treated groups. After LPS injection, the WT mice spent significantly less amount of time in the central region compared with those received saline treatment, indicating a LPS-induced anxiety-like behavioral change.However, in the Het mice, the time spent in the central region was not altered by LPS treatment. Our result indicated the LPS-induced anxiety-like behavior is reduced in heterozygous Disc1 mutant mice.

Title: DISC1 KO as model for bipolar disorders? Correlations of behavior and MR spectroscopy in mice.

Authors: *M. A. VOGT[1], A. SARTORIUS[2], W. WEBER-FAHR[2], A. SAWA[5], A. MEYER-LINDENBERG[3], P. GASS[4];

Sch. of Med., Baltimore, MD

Abstract: *Disrupted-in-Schizophrenia 1* (DISC1) was identified as a gene disrupted in a Scottish pedigree suffering of mental diseases as schizophrenia and depression. Although recent genome-wide association studies failed to identify DISC1 as a main genetic factor of schizophrenia, DISC1 is considered as a valid model used to understand the biological and pathophysiological processes underlying mental diseases. Consequently, a variety of DISC1 mutant mice was used in recent years to model a wide range of psychiatric diseases associated to the field of schizophrenia. Here we analyzed DISC1 mutant mice on a C57BL6 background and littermate

controls in a set of behavioral assays dedicated to locomotion, sensorimotor gating and executive functions. As a second step, the mice were analyzed in MR spectroscopy and fMRI for brain activity and metabolism. We could show that DISC1 mutant mice show a distinct behavioral phenotype with subtle hypo-locomotion, decreased acoustic startle response and prepulse inhibition. Referring to executive functions, the mutant mice demonstrated increased ability to problem solving in the puzzle box task. This behavioral phenotype was correlated to results obtained in the MR spectroscopy and fMRI. Although no basal alterations could be detected in the DISC1 mutants, the altered sensorimotor gating was highly correlated to e.g. levels of GABA in the hippocampus. This is, to our knowledge, the first time that a distinct behavioral phenotype could be clearly linked to a neurotransmitter level in a distinct brain region. The behavioral phenotype observed here is more associated towards bipolar disorders than to an endophenotype of schizophrenia. The findings of the spectroscopy studies and fMRI show that this can be linked to a single specific behavioral characteristic.

Title: A pilot study to assess the effects of gamma neurofeedback on working memory in schizophrenia patients

Authors: F. SINGH[1], A. SMITH[2], N. DUDECK[2], R. CHENG[2], R. GOSLA[2], E. HERRERA[2], Y. QIU[2], Z. YANG[2], *J. A. PINEDA[2];

Abstract: Deficits in working memory are a common and recalcitrant symptom of schizophrenia (SCZ) spectrum disorders and have been associated with reduced gamma (35-50Hz) synchrony in frontoparietal regions of the brain. Neurofeedback (NFB) is an operant conditioning methodology used to train individuals to volitionally control brain oscillatory activity. NFB influences frontoparietal neural circuitry and improves executive control in healthy populations. In this pilot study, we examined 1) whether NFB can be employed to improve gamma synchrony in SCZ patients and 2) if improved synchrony is associated with improvements in working memory (WM). We hypothesized that increased coherence in gamma oscillations over frontal

cortex would correlate positively with increased performance on a working memory task. Three subjects (two male and one female, ages 18-27), who met DSM-V criteria for SCZ were recruited from University of California, San Diego and Veterans' Administration Healthcare System for an open-label pilot NFB study. Subjects remained on their existing medications throughout the study. Pre-treatment assessments included EEG (5 minutes eyes closed, 5 minutes eyes open), performance on the n-back (a WM task), and neuropsychological testing using the Matrics Consensus Cognitive Battery (MATRICs). In a cross-over design, all 3 subjects completed 8 sessions of Gamma-NFB (G-NFB; 2 sessions/week, three 15-min trials/session) followed by 8 sessions of active-placebo (AP-NFB) training over frontal cortex. Assessments were also obtained at the conclusion of G-NFB and AP-NFB. Subjects showed 153% increase in threshold of training during G-NFB indicating training effects, and this training correlated with improved WM. Average threshold increased during AP-NFB by 66%, but there was no change in WM. Thus, the present study indicates that SCZ subjects can undergo NFB to enhance gamma frequency power over the frontal cortices of the brain. Additionally, enhancements in gamma frequency, but not other frequencies are correlated with improved WM. Therefore, the data from this pilot study suggest that NFB may be a successful way to enhance WM and has the potential to be used in a clinical setting to help treat some of the symptoms associated with schizophrenia spectrum disorders.

Abstract: Sleep abnormalities are a common symptom of psychiatric disorders. Upwards of 80% of patients with schizophrenia report abnormal sleep with potential negative effects on quality of life and cognitive function. Abnormal sleep patterns are often reported in the prodromal stages and prior to a psychotic break, suggesting they may be a predictive feature of the illness. Although sleep abnormalities are a significant feature of schizophrenia symptomatology, and may provide insight into its etiology, the biological mechanisms underlying disrupted sleep in schizophrenia are unknown. Changes to the timing and quality of sleep can result from dysfunction of: 1) circadian rhythms, which determine the time-of-day when sleep occurs and/or 2) sleep homeostasis, comprising mechanisms to a) determine and b) alleviate sleep need. The immediate early gene *early growth response 3* (*Egr3*) has been associated with schizophrenia risk in human populations and decreased levels of EGR3 protein have been found in postmortem patient brain tissue. *Egr3*-deficient mice display behaviors associated with schizophrenia pathophysiology including sleep abnormalities. We previously found that male and female *Egr3 -/-* mice slept less than wild type (WT) littermates and that these differences were most profound during light/dark transitions. Compared to WT mice after sleep deprivation, *Egr3-/-* mice also exhibit diminished compensatory responses in non-rapid eye movement sleep (NREM) EEG slow-wave activity during recovery sleep. The potential roles of *Egr3* in both schizophrenia and sleep homeostasis led us to examine the role of *Egr3* in circadian rhythms. Adult female *Egr3 -/-* and WT mice were monitored for 9 weeks including 3 weeks in normal light/dark (LD), constant dark (DD), and constant light (LL) conditions in non-invasive sleep monitoring cages. We found that *Egr3-/-* mice have no circadian disruption and actually display more robust circadian rhythms of locomotor activity compared to WT. For example, *Egr3-/-* mice show increased circadian amplitude and inter-daily stability during LD and DD conditions. Both *Egr3-/-* and WT mice show normal responses to constant light, such as activity suppression and lengthening of their free-running clock. These data suggest that loss of *Egr3* does not disrupt circadian function, but impairs sleep homeostasis. *Egr3* knockouts are a valuable tool to selectively investigate the mechanisms underlying sleep homeostasis independent of circadian rhythms. Elucidation of the mechanisms by which *Egr3* regulates sleep homeostasis should provide insights into a key feature of both the prodromal phase and precipitation of acute episodes of schizophrenia.

Title: Speech-in-noise perception deficits reflect central auditory dysfunction in schizophrenia.

Authors: S. RACKELMANN, 92093[1], *M. TARASENKO[2], A. SHILUK[1], W. ZHANG[1], S. T. PIANKA[3], A. W. BISMARK[2], M. L. THOMAS[1], J. SPROCK[1], C. KAUFFMAN[4], G. A. LIGHT[1];
[1]UCSD, La Jolla, CA; [2]VA San Diego Healthcare Syst. / UCSD Dept. of Psy, LA Jolla, CA; [3]UCLA, Los Angeles, CA; [4]Alpine Special Treatment Ctr., Alpine, CA

Abstract: Auditory Targeted Cognitive Training (ATCT) has shown great promise for remediating cognitive deficits in schizophrenia (SZ) by producing neuroplastic changes within the neural substrates underlying verbal memory. However, nearly half of chronic SZ patients fail to derive a meaningful benefit from the intervention, underscoring the need to identify early predictors of therapeutic response. Speech-in-noise (SIN) perception, or the ability to decipher a "target" speech signal in the presence of irrelevant background noise, is deficient in other disorders of central auditory processing, including autism and learning disorders, but no research has yet examined SIN perception in SZ. The present study thus utilized two established measures (Words-in-Noise [WIN] and Quick Speech-in-Noise [QuickSIN]) to determine whether SIN perception deficits are present in SZ, whether such deficits reflect illness-related central auditory dysfunction, and the potential utility of these measures to serve as predictive treatment biomarkers. Participants were 28 adults diagnosed with SZ at a residential transitional care facility. For both WIN and QuickSIN, speech stimuli were presented in varying intensities of background conversation noise (four-talker babble); WIN utilized one-word stimuli whereas QuickSIN utilized sentence stimuli. Participants were instructed to repeat the words or sentences aloud, and their responses were scored based on repetition accuracy of the single word (WIN) or five "key" words (QuickSIN). Cognitive functioning was assessed using the MATRICS Cognitive Consensus Battery (MCCB). On average, participants performed in the "mildly impaired" range on both the WIN (M = 5.3, SD = 2.6) and the QuickSIN (M = 3.9, SD = 3.8). WIN performance was significantly associated with MCCB Attention/Vigilance only (r = 0.43, p = 0.03). QuickSIN performance was significantly associated with MCCB Working Memory, Verbal Learning/Memory, and Global Cognition (r's $\geq$ 0.40, p's $\leq$ 0.04) and marginally associated with MCCB Reasoning/Problem Solving (r = 0.34, p = 0.08). For people with SZ, WIN performance appears to reflect peripheral auditory processing (i.e. auditory attention),

whereas QuickSIN indexes functioning of the central auditory processing network underlying the cognitive domains targeted by ATCT. QuickSIN thus appears to be a promising measure for predicting and monitoring ATCT response in SZ.

Title: Cognition predicts treatment engagement among inpatients with schizophrenia

Authors: ***A. SHILUK**[1], M. L. THOMAS[1], S. RACKELMANN[1], W. ZHANG[1], S. T. PIANKA[2], C. KAUFFMAN[3], J. SPROCK[1], A. W. BISMARK[4,1], M. TARASENKO[4,1], G. A. LIGHT[4,1];
[1]Psychiatry, UCSD, San Diego, CA; [2]UCLA, Los Angeles, CA; [3]Alpine Special Treatment Ctr., Alpine, CA; [4]VA San Diego Healthcare Syst., San Diego, CA

Abstract: Facilitating treatment engagement from people with schizophrenia has long been problematic for mental health providers, with treatment failures contributing to elevated rates of poverty, homelessness, and incarceration. Consequences of inadequate treatment include symptom exacerbation, rehospitalization, as well as the detrimental neural sequelae of disease progression. Inpatient settings present a valuable opportunity for intensive rehabilitation and thus continue to be an important locus of long-term care and support for many with psychotic acuity and chronic disability. It is not clear, however, which patient factors are associated with adherence to treatment. The aim of the present study was to determine whether neurocognition predicts treatment engagement in chronic schizophrenia.
Schizophrenia patients (n = 28) recruited from an ongoing longitudinal study within an inpatient transitional care facility were evaluated following acute stabilization. The MATRICS Consensus Cognitive Battery (MCCB) was administered to assess global cognition. Psychosocial treatment engagement was defined by the standardized total number of attended group therapies, structured social activities, self-care, and vocational rehabilitation sessions. Subjects were tracked over a

period of 20 weeks. Data were analyzed using linear mixed-effects models.
MCCB global scores significantly predicted baseline treatment engagement ($\beta = 0.49$; $p = .003$) but not change over time ($\beta = -0.01$; $p = .92$); patients with higher cognition showed greater engagement. Using stepwise regression with specific MCCB cognitive domains, the strongest predictor of engagement was MCCB Visual Learning (Brief Visuospatial Memory Test – Revised) followed, in order, by Working Memory, Attention and Vigilance, Reasoning and Problem Solving, Verbal Learning, and Speed of Processing.
Neurocognition is a robust predictor of treatment engagement in schizophrenia inpatients. These results suggest that cognitive impairments prevalent in this population interfere with patients' adherence to treatment and are therefore barriers to successful outcome. Findings from this study underscore the necessity of targeted interventions enhancing functioning within specific cognitive domains.

Title: Genome-wide gene expression analysis reveals molecular phenotypes related to schizophrenia in Neurogranin knockout mice

Authors: *S. HATTORI[1], H. HAGIHARA[1], T. KAMEYAMA[1], Y. OUCHI[1], H. INAGAKI[1], H. KURAHASHI[1], F. L. HUANG[2], K.-P. HUANG[2], T. MIYAKAWA[1];
[1]Inst. for Comprehensive Med. Sci., Fujita Hlth. Univ., Toyoake, Japan; [2]NICHD, NIH, Program of Developmental Neurobiology, MD

Abstract: Large-scale genome-wide association studies have identified susceptibility loci for schizophrenia in the gene encoding neurogranin (*NRGN*). Neurogranin is a neuron-specific calmodulin binding protein abundantly expressed in the hippocampus and cortex. Nrgn knockout (KO) mice exhibit a series of behavioral abnormalities relevant to schizophrenia, including

hyper-locomotor activity, cognitive deficits, and impaired sensorimotor gating (Hattori et al., abstract for SfN meeting 2015). We have reported that dentate gyrus (DG) granule cells in adult but not in young (<10 weeks old) mutants are in pseudo-immature state, which has been proposed as an endophenotype of schizophrenia, at molecular levels (Hagihara et al., abstract for SfN meeting 2015). In this study, we measured genome-wide gene expression levels in the DG and prefrontal cortex (PFC) of adult (>20 weeks old) *Nrgn* KO mice by mRNA sequencing (RNA-seq). Bioinformatics analyses of transcriptome data revealed that the gene expression patterns of the DG in adult mutants are significantly similar to those of several other strains of mutant mice, including *Schnurri-2* (*Shn-2*) KO mice, an animal model of schizophrenia with remarkable face validity (Takao et al., *Neuropsychopharmacology*, 2013). Based on the gene expression patterns of the DG, adult *Nrgn* KO mice could be divided in 2 groups: mutant mice with immature DG and those with mature DG, suggesting that deficiency of *Nrgn* results in progressive and age-dependent "dematuration". Additionally, the transcriptome pattern of the DG in *Nrgn* KO mice was similar to that of animal models of epilepsy, which is caused by excessive neuronal excitability implicated in the mechanism for induction of immature DG. The gene expression patterns of the mutant PFC showed slight but significant similarity to those of post-mortem cortex from patients with schizophrenia. Collectively, these data indicate that *Nrgn* KO mice have a high degree of face validity as an animal model for schizophrenia. Moreover, *Nrgn* KO mice might be an animal model recapitulating the fact that typical onset of schizophrenia occurs during late adolescence or early adulthood. The late onset of these phenotypes would provide unique opportunity for studying molecular mechanisms underlying the pathogenesis of schizophrenia and its related disorders.

Title: Predicting cognition in schizophrenia patients using novel reverse-translated tasks

Authors: *A. W. BISMARK[1], A. SHILUK[2], S. RACKELMANN[2], W. ZHANG[2], S. T. PIANKA[3], C. KAUFFMAN[4], M. TARASENKO[1], M. L. THOMAS[2], J. W. YOUNG[2], G. A. LIGHT[2];

Abstract: Despite a growing appreciation of the contribution of attention, motivation and reward learning impairments to the disabling global cognitive deficits in schizophrenia patients, there are no available medications that alleviate these deficits. This dearth of effective procognitive agents may be driven in part by a lack of reverse-translated cognitive tasks with domain pure metrics for screening promising compounds across preclinical and clinical investigations. Here, we address this translational gap by examining the relationships among novel reverse-translated tasks of attention, motivation, and reward learning to well-established cognitive tests used in schizophrenia trials.
Schizophrenia patients (n=30) recruited from an inpatient transitional care facility were tested in the 5-choice continuous performance task (5C-CPT: Attention), progressive ratio breakpoint (PRB: Motivation), and probabilistic learning (PL: Reward Learning) tasks. The MATRICS Consensus Cognitive Battery (MCCB) was administered to assess global cognition with the attention (CPT-IP) and working memory subtests used as benchmark comparisons for the 5C-CPT.
Initial correlation between the 5C-CPT and CPT-IP ($r=.65$, $p<.001$) indicate overlapping, but distinct measures of attentional functioning. Although both measures significantly correlated with global cognition (5C-CPT: $r=.72$, $p<.001$; CPT-IP: $r=.86$, $p<.001$), the CPT-IP displayed a much stronger relationship with working memory (5C-CPT: $r=.49$, $p<.010$; CPT-IP: $r=.68$, $p<.001$), suggesting the 5C-CPT is a more domain-pure measure of attention, likely driven by its lack of reliance on working memory. Multiple regression indicated attention (5C-CPT) ($\beta=.611$, $p<.001$) and motivation ($\beta=.334$, $p<.022$) significantly predicted global cognition and accounted for 51% and 10% of the variance respectively. In contrast, reward learning did not significantly predict global cognition ($\beta=-.012$, $p<$*ns*), accounting for <1% of variance.
Reverse-translated measures of attention and motivation are robust predictors of established measures of cognitive functioning in schizophrenia patients, demonstrating their convergent validity. Since these reverse-translated 5C-CPT and PRB appear to be more “domain-pure” tests of attention and motivation, their use in therapeutic development may facilitate translation from preclinical to clinical trials. Future studies will determine whether these novel tasks are sensitive to and predict pharmacologic and cognitive interventions in schizophrenia patients.

Abstract: Difficulty to switch from an existing response set to a new one is called perseverative errors, which can be measured using the Wisconsin Card Sorting Test (WCST). Perseverative errors are consistently seen in animals with prefrontal lesions, indicating the critical role of the region in attention control, task switching and context updating. Using electroencephalogram simultaneously administered with WCST, studies with healthy human subjects captured weaker P300 evoked potential around the prefrontal area during error trials. This finding confirmed P300 as an endogenous task-switching marker in addition to its modality-independent salience detection properties, making it a powerful ERP component to assess the neural correlates of cognitive response in different populations. Psychosis cases are known to have elevated perseverative errors, but the electrophysiological profiles of psychotic probands in relation to task-switching are less understood. In the present study, 628 clinically stable subjects from the Bipolar and Schizophrenia Network on Intermediate Phenotypes consortium (B-SNIP) underwent Penn Conditional Exclusion Test (PCET), a computerized analog to WCST. These participants were divided into high, medium, and low-performing groups based on their perseverative error rates in PCET, then each group's ERP components to an auditory oddball task, a standard paradigm to consistently evoke P300, were examined. Principle component analysis of the pooled ERP recordings condensed the data into two components, accounting for

about 90% of P300 variability in the sample; 1-way ANOVA showed marked difference in P300 and N200 amplitudes between high, medium, and low performance groups (p=0.0047 and p=0.01, respectively). This analysis provided direct evidence that perseverative error rates are associated with strength of prefrontal response to novel information, regardless of disease load.

Title: Tapered and nano-patterned optical fiber for customized light delivery geometries *In vivo*

Authors: ***M. PISANELLO**[1,2], L. SILEO[1], A. DELLA PATRIA[1], B. L. SABATINI[3], M. DE VITTORIO[1,2], F. PISANELLO[1];
[1]Ctr. for Biomolecular Nanotechnologies, Inst. Italiano Di Tecnologia, Arnesano, Italy; [2]Ingegneria dell'Innovazione, Univ. del Salento, Lecce, Italy; [3]Neurobio., Harvard Med. School, Howard Huges Med. Inst., Boston, MA

Abstract: It is well recognized that important advances in optogenetic modulation of neural activity can be achieved using structured light illumination into the living mouse brain, with the goal of better matching spatio-temporal stimulation patterns with the complex structural topology of different brain areas. This can be obtained with sub-cellular resolution by using multiphoton microscopy in the superficial cortical layers, while structured illumination of deep-brain regions can be obtained through microendoscopes [Neuron 84, 1157 (2014)] or micrometer-sized light emitting diodes arrays [Neuron, 88, 1136 (2016)]. These approaches, however, can produce severe tissue damage due a to pronounced implant cross section or induce tissue heating when used for long stimulation periods [Front. Neurosci., 10:70 (2016)].
Here we exploit advanced nanostructuring of tapered and metal-coated optical fibers to allow for user-customized light delivery patterns in deep-brain regions. The technological process to realize such devices flow as follows. First, a low-angle taper profile is obtained by heat-and-pull

process, leading to sub-micrometer tips for reduced tissue damage during implantation. A thin metallic layer is then deposited by thermal evaporation, with the goal to shield light emission (otherwise arising almost all-along the taper). Next, focused ion beam milling is used to realize optical apertures to allow for out-of-axis light emission at well-defined sections along the taper. Apertures position, size and shape can be designed to match with the specific spatial distribution of the cellular groups to be controlled: small windows with size from 5μm to 50μm can allow for high accuracy and precision in spatial light delivery, while larger aperture of more than 100μm can be used to shine light over larger brain structures. The fabrication technology allows for the realization of emission sites along the whole conical surface of the taper, making possible to obtain two different light delivery patterns placed back-to-back around the waveguide or with a 360° rotational symmetry.
Moreover, a simple optical strategy can be used to tune the light injection angle of the laser beam into the optical fiber. This, combined with the modal demultiplexing properties of the taper, allows for the activation of a fraction of the light delivery sites [Neuron 82, 1245 (2014), Biomed. Opt. Express 6, 4014 (2015)]. Such approach can therefore be exploited to dynamically reconfigure the spatio-temporal light delivery pattern, paving the way toward structured light delivery in deep-brain regions with reduced invasiveness.

Title: In-vivo characterization of excitatory opsins in different regions of the mouse brain

Authors: ***J. TEGTMEIER**, K. JANITZKY, K. TAKAGAKI, F. W. OHL, M. T. LIPPERT; Leibniz Inst. For Neurobio., Magdeburg, Germany

Abstract: Since the discovery of ChR2 and its application in optogenetics, a large number of advanced excitatory optogenetic probes have been developed. However, most studies to date have used stimulation parameters derived from *in vitro* measurements, which cannot be directly translated to *in vivo* applications. It is therefore often unclear what exact neuronal effect a particular stimulation paradigm might have *in vivo*. For example, *in vivo*, opsins may not be able

to follow high stimulation frequencies, or inadvertent overstimulation might result in silencing rather than stimulation. We therefore characterized responses of two commonly used opsins in various brain structures in mice *in vivo*: the most commonly used excitatory opsin mutant ChR2(H134R) and the advanced fast opsin Chronos. We determined the attainable stimulation frequencies, necessary light levels, and effective pulse lengths in the neocortex, VTA and LC. We also compared the promoters hSyn and CamKIIa in terms of their influence on *in vivo* stimulation results and tested different expression durations. For the two monoaminergic areas, we employed cell type specific expression in Th-Cre and Dat-Cre mice to selectively stimulate dopaminergic and noradrenergic cells. In VTA and LC we found only small differences between opsins and expression schemes, indicating a direct limiting effect of the targeted cells. In cortex, however, we found both longer term expression of ChR2(H134R) as well as Chronos to permit substantially higher stimulation frequencies. Furthermore, in the cortex, Chronos enabled significantly higher stimulation frequencies compared to ChR2(H134R). Our results highlight the importance of characterizing the opsin of choice in the target brain structure *in vivo* and provide guidelines for using the opsins in cortex, VTA and LC.

Title: Optogenetic tools with varying kinetics differentially engage intrinsic network resonance *In vivo*.

Authors: *N. JUN[1], J. A. CARDIN[2];
[1]Dept. of Ophthalmology and Visual Sci., [2]Neuroscience: Kavli Inst. for Neurosci. / Swartz Program in Theoretical Neurobio., Yale Univ., New Haven, CT

Abstract: Channelrhodopsins (ChRs) are light-gated ion channels that enable cell type-specific activation of neurons or neural circuits. Channelrhodopsin-2 has been widely used as a tool to probe circuit function in vitro and in vivo. Two additional recently developed ChR variants,

Chronos and Chrimson (Klapoetke et al 2014), are characterized by faster kinetics and a red-shifted excitation spectrum, respectively. However, because these variants have largely only been tested in vitro, little is known about their efficacy and utility in the intact brain. In addition, variations in the kinetics of optogenetic tools may regulate the degree to which they engage local network dynamics. Such variation may affect the utility and optimal use of next-generation optogenetic tools in circuit dissection. We compared ChR-evoked patterns of multi-unit (MU) activity and local field potentials (LFPs) in primary visual cortex of lightly anesthetized mice expressing Chronos, Chrimson, or ChR2 in pyramidal neurons (PNs). We assessed overall activation of PNs by measuring mean MU firing rates, as well as the temporal progression of firing rates. Previous work has found substantial increases in gamma oscillations (30-80Hz), an emergent resonant activity pattern that relies on interactions between excitatory and inhibitory neurons, upon ChR2 activation of PNs (Adesnik and Scanziani 2010). Using this evoked pattern as an assay for local network engagement, we examined the effects of ChR variant activation on the power of gamma oscillations (30-80 Hz) in the LFP. While activating all three ChR variants caused light-evoked increases in PN firing in vivo, we observed variant-dependent differences in inter-spike interval distributions and the relative power of gamma oscillations. Chronos and Chrimson did not enhance gamma oscillations, whereas ChR2 more than doubled power in the gamma band. These findings suggest that variations in kinetics of optogenetic tools can substantially affect their efficacy in neural networks in vivo, as well as the manner in which their activation engages circuit resonance.

Title: Chloride indicator protein for non-invasive functional bioluminescence imaging

Authors: *K. BERGLUND[1], J. K. TUNG[2], R. E. GROSS[2];
[1]Neurosurg. and Anesthesiol., [2]Neurosurg., Emory Univ., Atlanta, GA

Abstract: Although fluorescence imaging has vastly advanced our knowledge of how the brain works, its invasive nature limits its usage: the brain has to be exposed so that excitation light, a prerequisite for fluorescence, can penetrate the brain tissue. In contrast, bioluminescence

imaging can be conducted in a non-invasive manner because the substrate required to generate biological light can be delivered to the brain systemically via the bloodstream. However, in its current form, bioluminescence does not provide any information on the brain's activity unlike commonly used fluorescent calcium indicator proteins.
We developed a functional imaging probe based on a relatively unexplored imaging modality - bioluminescence. Specifically, we rationally designed and tested novel bioluminescent proteins that change their emission spectra according to the intracellular chloride ion concentration ($[Cl^-]_i$) - an important determinant for normal and pathological neuronal activity - using blue-light emitting luciferase, GLuc, and Cl^--dependent variant of yellow florescent protein, Topaz. When expressed in an *in vitro* heterologous protein expression system, we observed expected emission changes according to manipulated $[Cl^-]_i$. As a proof-of-principle, primary neurons from rat embryos in culture were transfected with the probe and well-characterized down-regulation of $[Cl^-]_i$ during development was measured. We hope that the new probe can be utilized to detect a similar change in $[Cl^-]_i$ in the developing brain in the whole, live animals, using a small animal bioluminescence imager.
Neuronal Cl^- is involved in many normal neurophysiological activities, such as development, synaptic inhibition, pH and volume regulations. In addition, changes in neuronal Cl^- levels have been implicated in the pathological mechanisms underlying various neurological diseases (*i.e.* pain, stroke, and epilepsy). Thus, the new bioluminescence Cl^- indicator protein will be a valuable tool to non-invasively assess Cl^- fluctuations in normal and pathological neuronal processes *in vitro* and *in vivo*.

Title: Bioluminescent control of optogenetics in acute brain slices

Authors: *R. ST. LAURENT[1], C. I. MOORE[1], D. LIPSCOMBE[1], B. W. CONNORS[1], U. HOCHGESCHWENDER[3,4], J. A. KAUER[1,2];
[1]Neurosci. Grad. Program, [2]Mol. Pharmacology, Physiology, and Biotech., Brown Univ., Providence, RI; [3]Neurosci. Program, [4]Col. of Med., Central Michigan Univ., Mt Pleasant, MI

Abstract: Recent expansions in the optogenetic toolbox, luminopsins, are fusion proteins of light-activated ion channels or pumps (channelrhodopsin or *Leptosphaeria maculans*) and *Gaussia* luciferase (a bioluminescent enzyme) which bypass the need for an external light source. In the presence of a corresponding luciferin, the luciferase emits cold light sufficient to open the actuator. The ability to manipulate membrane potential in excitable cells has many potential benefits for neuroscience research. For example, dopamine release is essential in processes pertaining to reward, learning, and motor control. Optogenetic studies are able to manipulate these cells on a fast time scale. However, until now we have been unable to manipulate membrane properties on a longer time scale of minutes without the use of DREADDs, which rely on endogenous signaling pathways. Here we seek to demonstrate the ability of luminopsins to alter the membrane potential and firing rate of VTA dopamine neurons using luminopsins.
We virally transduced AAV9-hSyn-LMO3 (LMO3; channelrhodopsin fused to *Gaussia* luciferase) into the VTA of C57BL/6 mice and characterized transduced cells using whole-cell patch clamp recordings in acute midbrain slices. Bath application of the luciferin, coelenterazine (CTZ), resulted in detectable bioluminescence in 100% of slices expressing luminopsins. Dopamine neurons depolarized after CTZ application (4 min after CTZ mean = 1.5 ± 2.5 mV, 8 min after CTZ mean = 8.5 ± 5.5 mV; n = 9). Bioluminescence was no longer observed at 10 min after CTZ, however, in most neurons the membrane potential did not return to baseline values. Control experiments without luminopsin viral expression showed that CTZ alone does not induce depolarization (4 min after CTZ mean = -3.5 ± 3.2 mV, 8 min after CTZ mean = -1.5 ± 4.3 mV; n = 10). Preliminary results suggest that dopamine neurons voltage clamped at -70 mV have a slow inward current (176 ± 132 pA; n = 5) that corresponds with the onset of bioluminescence and persists for tens of minutes. Although brief current injections are sufficient to increase firing rate in VTA dopamine cells, the long sustained inward current achieved through luminopsin activation did not increase firing rate (LMO3: 0.18 ± 0.10 Hz, control: 0.14 ± 0.07 Hz; n = 9-10). Our results indicate that we are able to manipulate dopamine neuron membrane potential using luminopsins.

Title: Bioluminescence activated optogenetic stimulation in a rat model of spinal cord injury.

Authors: P. OTERO[1], E. D. PETERSEN[1], A. PAL[1], J. ZENCHAK[1], *U. HOCHGESCHWENDER[1,2];
[1]Neurosci., [2]Col. of Med., Central Michigan Univ., Mt Pleasant, MI

Abstract: Current methods used to treat spinal cord injury with electrical stimulation include functional electrical stimulation and intrathecal electrical stimulation. Both of these methods offer potential quality of life improvements for patients but are not entirely effective. Importantly, both approaches have the drawback of rapidly fatiguing the stimulated motor units. Optogenetics provides a method of stimulation that can be executed at the neuronal level and does not result in the same rapid fatigue as electrical stimulation. The current drawback of traditional optogenetic stimulation is its invasiveness, as this approach requires an implanted light source. Bioluminescence-driven optogenetics avoids fiber implants by providing light via a luciferase fused to the opsin (luminopsin, LMO), with the luciferase substrate applied intravenously or intrathecally. In one approach, LMO3, a fusion of a mutated version of Gaussia luciferase and Volvox channelrhodopsin 1, is expressed locally, by injection of adeno-associated virus (AAV) immediately caudal to the site of injury (T9). The reasoning is that neuronal stimulation below the lesion will make it more likely for dormant neurons to regenerate and promote formation of new connections, potentially leading to a gain in function. In another approach, LMO3 is expressed in neuronal precursor cells grafted into the damaged spinal cord. Here, stimulation of neuronal progenitor cells is expected to increase functional integration of transplanted cells into host circuitry. Both approaches have the potential to improve behavioral deficits and injury pathology and will broaden our understanding of spinal cord injury recovery and synaptic remodeling.

Title: Split Gaussia luciferase based genetically encoded calcium indicator.

Authors: *A. PAL[1], Z. ZAIDI[1], W. E. MEDENDORP[1], J. A. KAUER[3,4], B. W. CONNORS[3], C. I. MOORE[3], D. LIPSCOMBE[3], U. HOCHGESCHWENDER[1,2];
[1]Neurosci. Program, [2]Col. of Med., Central Michigan Univ., MT Pleasant, MI; [3]Dept. of Neurosci., [4]Dept. of Mol. Pharmacology, Physiology, and Biotech., Brown Univ., Providence, RI

Abstract: The detection and imaging of calcium flux in live cells provides useful insight about cellular physiology. Genetically encoded calcium indicators (GECIs) based on fluorescent proteins (GCaMPs) have been employed extensively to report calcium flux in neurons. In GCaMPs, the calmodulin-M13 protein complex is employed as a calcium sensing unit that undergoes a conformational change in the presence of calcium. However, fluorescence-based GECIs have their own set of disadvantages such as requiring external, invasive light delivery for excitation. We have employed the same calcium sensing calmodulin-M13 protein complex, but switched out the fluorescent reporter with a *Gaussia* luciferase (GLuc) enzyme reporter that is split in half. By inserting the CaM-M13 peptide between the N- and C-terminal catalytic domains of GLuc, the luciferase is inactive in the absence of calcium. Influx of calcium into the cell contracts the calmodulin-M13 complex and brings the two halves of the luciferase back together to form an active enzyme, which in the presence of its substrate (coelenterazine, CTZ) emits light. We call this split luciferase-based GECI LumiCaMPsin, or LMC. By varying locations of the split site in the GLuc molecule, sequences of the CaM-M13 peptide, length of polyG linkers between split GLuc and the CaM-M13 module, and placement of 5' and 3' targeting signals, we arrived at version LMC4. This version has low background luminescence in the absence of calcium and high light emission in its presence, making it a good candidate for a bioluminescence calcium reporter.

Title: Bioluminescent optogenetics (BL-OG): A systematic investigation of the neurophysiological effects of BL-OG in-vivo

Authors: ***M. GOMEZ-RAMIREZ**[1], A. I. MORE[1], B. W. CONNORS[1], J. A. KAUER[1], D. LIPSCOMBE[1], U. HOCHGESCHWENDER[2], C. I. MOORE[1];
[1]Neurosci., Brown Univ., Providence, RI; [2]Foundational Science, Col. of Med., Central Michigan Univ., Mount Pleasant, MI

Abstract: Recently, several genetic-based solutions for studying underlying neural circuits mediating perceptual processes have been developed. The most widely used tool has been optogenetics, a method that regulates neural activity of genetically-specific cell populations by controlling neurons' light-sensitive ion channels with light. The spatiotemporal precision of optogenetics and its rapidly expanding toolkit have made this technique highly useful for basic research. However, a major limitation of optogenetics is the use of invasive external devices to deliver light into tissue. Recently, our lab and others have been developing less invasive, but highly precise, approach for activating and/or deactivating genetically-specific neural circuits. Our method, termed Bioluminescent OptoGenetics (BL-OG), tethers an optogenetic component to a luciferase. The light emitted from the luciferase/luciferin interaction activates the optogenetic element, which in turn regulates neural membrane potential without the need for a physical light-emitting device. Systemic administration of a luciferin can in turn generate bioluminescence. Tethered versions of this configuration linking the bioluminescent luciferase to the optogenetic element are referred to as luminopsins (Berglund et al., 2015) and have shown efficacy in initial studies in vivo. To build on these initial demonstrations to systematically characterize the optimal use of luminopsin in vivo, we performed concomitant bioluminescent and neurophysiological recordings in anesthetized mice, with luminopsin expression in the granular and superficial layers of primary somatosensory cortex (SI). Preliminary studies show

robust bioluminescent activation with direct intracortical application. High CTZ doses caused a strong transient response followed by a slow decay. In contrast, responses to lower CTZ concentrations failed to reveal a sharp peak response and a slow decay. These preliminary data further our understanding of the BL-OG technique by providing an estimate of the temporal dynamics of bioluminescent responses as a function of CTZ dosage.

Abstract: Studies involving neural activity readouts in humans, primates, and rodents have highlighted the involvement of orbitofrontal cortex (OFC) in diverse reward-related tasks including feeding and social behavior. Distinct OFC neurons show different responses to various

facets of reward including anticipation, consumption, and initiation of reward seeking, but it remains unknown if these subpopulations defined by unique activity patterns functionally give rise to discrete behaviors related to reward. To dissect the individual contributions of activity-specific OFC neuronal populations to behavior, we coupled genetically encoded Ca^{2+} indicators with engineered microbial opsins to both optically monitor and manipulate the activity of OFC neurons at the single cell level with two-photon microscopy. Employing this all-optical tactic in head-fixed mice, we found that 40% of targeted OFC neurons were excited by reward-related stimuli (calorie-dense liquid), while 15% of the cells were inhibited during reward presentation and consumption (n = ~200 neurons per animal, n = 10 mice). The majority of these identified neurons also reliably responded to 6s pulse trains of single-cell resolution two-photon optogenetic stimulation, opening the door to examining whether optogenetic single-cell stimulation of these activity-specific subpopulations reproduces reward-related behaviors even in the absence of reward; these investigations are also designed to be compatible with CLARITY-based circuit tracing and multi-fiber photometry (MFP) to dissect the anatomical wiring and activity dynamics of OFC reward circuits. Together, this approach may help elucidate how individual circuit elements within neocortex can individually and collectively contribute to reward evaluation and behavior, and to what extent specific activity patterns, connectivity patterns, and/or molecular gene expression patterns help determine causal links between neural circuits and behavior.

Abstract: Background: MRI-histology correlation studies provide unique opportunities into understanding MRI signatures of disease state, and hence predicting pathological substrates of disease progression from *in-vivo* imaging. Clearing methods, such as CLARITY, are superior to standard histological techniques as they allow the investigation of three dimensional, intact biological systems. Combining MRI and CLARITY is a novel, powerful tool in discovering imaging correlates of pathology.
Methods: 15 Thy1-YFP mice were scanned *in-vivo* on a 7T MRI with high-resolution T1 and T2 mapping, weighted images and diffusion tensor imaging (DTI). They were then perfusion fixed with PFA, the brains were extracted and then imaged ex-vivo using contrast-enhanced CT. Afterwards, intact whole brains were cleared passively using a 1% hydrogel solution and imaged with native fluorescence using a light-sheet microscope. The brains were also cut into 3 consecutive coronal sections and imaged with a confocal microscope at a higher resolution.
Results and Discussion: We developed a pipeline for the registration, segmentation and analysis of multimodal imaging with CLARITY and the Allen mouse brain atlas. Our pipeline provides accurate registration between in-vivo, ex-vivo imaging data and CLARITY. It also warps all datasets into the Allen atlas space to make use of their extensive labels and genetic information. In addition, our tool enables unbiased brain-wide quantification of CLARITY morphological features (cell loss, size). It also enables performing structural tensor analysis and comparison with tractography from DTI. Our MIRACL pipeline can be applied in numerous neurological disorders and mouse models to uncover underlying tissue changes responsible for *in-vivo* MRI relaxometry and diffusion parameters.

Title: Crystal structure of a light gated anion channel

Authors: *Y. KIM[1,2,5], H. E. KATO[3], A. BERNDT[2,5], S. LEE[2,5], D. HILGER[3], B. KOBILKA[3], K. DEISSEROTH[2,5,4];

Abstract: Fast and reversible neuronal inhibition is an important experimental approach in optogenetics, and recent structure-guided opsin-engineering and opsin-discovery efforts have expanded the inhibition toolbox to include robust and efficient chloride-conducting channelrhodopsins. The first high-resolution structure of a cation-conducting excitatory channelrhodopsin was described in 2012, and became rapidly instrumental for developing and confirming a predictive model for light-gated pore selectivity, as well as for the initial engineering of chloride-conducting channelrhodopsins in 2014. However, a structure has not yet been obtained for any anion-conducting channelrhodopsin, which if obtained would greatly deepen insight into the operation and selectivity of the channel pore, and facilitate further design. Here we report at 3.1Å resolution the first X-ray crystallographic structure of a light-gated anion channel. This closed-state structure of the iC++ channelrhodopsin reveals a markedly distinct electrostatic surface potential lining the pore conduction pathway, compared with that of the cation-conducting C1C2, consistent with the fundamental predictions of the pore selectivity model. Although the pore constriction site revealed similar architecture compared with the cation-conducting channelrhodopsin (suggesting conserved gating properties, consistent with

electrophysiological characterization), a strikingly altered pattern of key amino acid side chain orientation was observed in the extracellular vestibule, ion pore, and cytosolic gate. Intriguing additional features included a substantially enlarged extracellular pore, which could be occupied by chloride ions and play additional roles in channel ion selectivity. This initial atomic structure of an anion-selective channelrhodopsin further illuminates the mechanism of channelrhodopsin ion selectivity and conductance, and provides a roadmap for further opsin engineering.

Title: Pathways to clinical CLARITY: Quantitative methodologies for transparent-volume analysis of irregular, soft, and heterogenous tissues in development and disease

Authors: ***B. HSUEH**[1], V. BURNS[1], P. PAUERSTEIN[1], L. YE[1], K. ENGBERG[1], A.-C. WANG[1], X. GU[1], H. CHAKRAVARTHY[1], E. ARDA[1], G. CHARVILLE[1], K. HOLZEM[2], I. EFIMOV[2,3], H. VOGEL[1], S. KIM[1], K. DEISSEROTH[1];

Abstract: Volumetric tissue structural relationships are not well captured by typical thin-section histology, posing challenges for the study of tissue physiology and pathology given the natural and fundamental importance of three-dimensional structures in tissue function and dysfunction,

particularly in the nervous system. Moreover, while recent progress has been made with intact (non-sectioning-based) methods for clearing, labeling, and imaging whole organs such as the mature brain, these approaches are generally unsuitable for soft, irregular, and heterogeneous tissues that represent the vast majority of clinical samples and biopsies. Here we develop a novel two-phase hydrogel methodology with clearing speeds 25-fold greater than previously published methods ($p < 0.005$), along with a dedicated automated imaging/analysis computational platform, for high-throughput quantitative volumetric interrogation of intact soft tissue structures. We have validated and applied this platform in the examination of a variety of organs, with specific focus on the dynamics of pancreatic innervation, where automated computational analysis generated image feature datasets of several thousand mouse pancreatic islets and revealed multiphasic pruning of islet innervation through a 4-fold reduction in neural signal during the first week of life ($p < 0.005$). After characterizing islet innervation dynamics spanning pre- and post-natal development in mouse, we identified and quantified the same islet innervation measures in whole pre-natal human samples and tissue-banked juvenile pancreata (from healthy and type-I diabetic subjects), linking multiple rounds of molecular labeling using registration of the multiple labeling datastreams across entire intact samples. Finally, we develop *in silico* models and simulations to quantitatively evaluate advantages of this intact-tissue approach compared with conventional thin-section histology, revealing that traditional 2D approaches underestimate islet volumes by 20% or more ($p < 0.0005$), and have reduced statistical power due to smaller sample sizes. A human islet age classifier built using generalized linear models is sufficient to achieve >90% accuracy with as few as four 3D image features, but does not perform better than chance when using the equivalent features in 2D. Taken together, these tools and results point to a broad application domain of volumetric histology in both research and clinical settings.

Title: Probing large-scale network dynamics at high speed in the brain of behaving flies

Authors: *S. AIMON[1], T. KATSUKI[1], L. GROSENICK[2], M. BROXTON[2], K. DEISSEROTH[2], T. SEJNOWSKI[3], R. J. GREENSPAN[1];

Abstract: Our goal is to record and characterize fly brain activity at the scale of the whole network and close to the speed of the fastest neuronal computations, while a head-fixed fly is behaving (typically walking, grooming, or resting) and responding to various stimuli. Fast calcium or voltage sensors are expressed, either pan-neuronally, or in subsets of neurons broadly distributed in the brain (e. g. acetylcholine or dopamine neurons). We image the fly brain fluorescence using light field microscopy, which captures large volumes in a single camera exposure, albeit at reduced lateral resolution compared to the normal 2D diffraction limit of the microscope. 3D stacks are then reconstructed offline from the light field images using wave optics to model point spread functions, before applying 3D deconvolution. This technique makes it possible to image the whole brain at a frame rate of 200 Hz. We then use statistical techniques (PCA and spatial ICA) to extract maps of spatially distinct sources of activity as well as their time series. Even though PCA and ICA are mathematical algorithms that make minimal assumptions about the brain (ICA assumes spatial sparsity), most component's maps correspond to well-known anatomical structures. In some cases, neuron types can be inferred from the combination of sub-neuropile regions present in the map. The time series for each component is also extracted. With voltage sensors, the method permits the capturing of both graded potentials and spikes. The time series and the maps permit the identification of sub-neuropile areas and sometimes specific neurons involved in processing stimuli and behaviors, along with the dynamics of their activity. Patterns of spontaneous activity specific to some brain structures are also detected and help characterize the fly's internal state.

Title: Methods for comparison of MRI and CLARITY data in human tissue specimen

Authors: *C. LEUZE[1], M. GOUBRAN[2], M. ASWENDT[3], Q. TIAN[2], B. HSUEH[4], M. ZEINEH[2], K. DEISSEROTH[4,5,6], J. MCNAB[2];

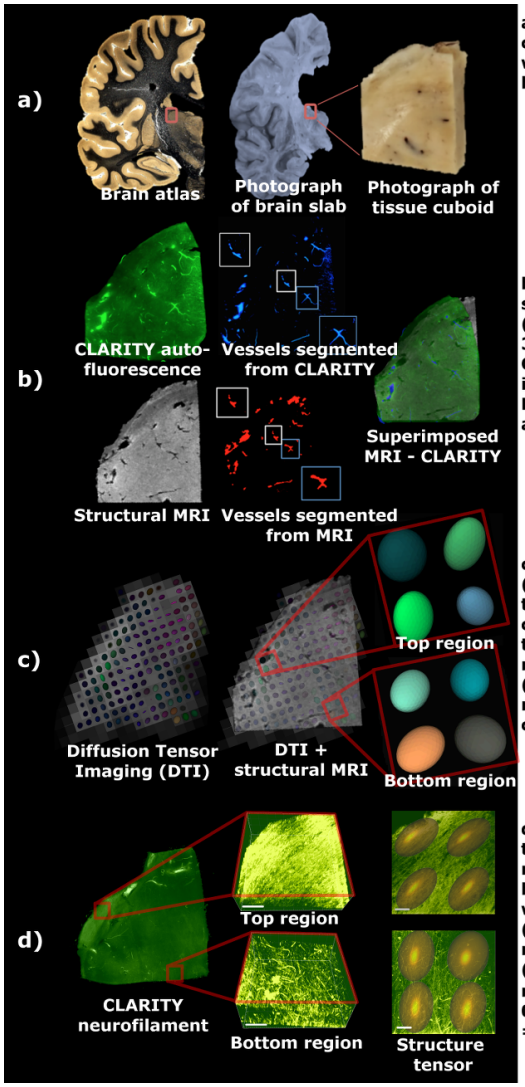
Abstract: Introduction: Relating diffusion MRI (dMRI) measurements to the underlying tissue structure through histology can help to improve the accuracy and reliability of structural connectivity measurements. In order to capture the complete nature of 3D elements such as cellular projections in both modalities, we devised a method to align MRI data with 3D histological CLARITY data and and we present a way to quantitatively compare fiber orientations within both MRI and CLARITY data.
Methods: We acquired a structural MRI scan at (FIESTA-C sequence, 350x350x300μm resolution) and a diffusion MRI scan (Diffusion-weighted EPI-sequence, $1mm^3$ resolution, $b=2000s/mm^2$, 450 diffusion directions) of a $1cm^3$ cuboid of human brain tissue containing part of the thalamus (Fig.1-a). After MRI scanning, a 200μm thin section was cut off the sample, cleared with CLARITY as described in [2] and stained for neurofilaments.
Results & Conclusion: The high resolution structural MRI scan showed a detailed visualization of the blood vessels. Since blood vessels retained their shape after tissue clearing and were well visible in the auto fluorescence image, they allowed precise alignment of MRI and CLARITY data (Fig. 1-b). For the diffusion MRI data, we measured the diffusion tensor in the aligned region (Fig.1-c), which showed an anisotropic region running along the side of the sample (Fig.1-c, top region, FA=0.30±0.10) and a less coherent region towards the bottom of the sample (Fig.1-c, bottom region, FA=0.25±0.09). Regions at corresponding locations within the the cleared, neurofilament-stained samples were analyzed by measuring the structure tensor (Fig.1-d). A similar behavior to the diffusion measurement could be observed with coherently running fiber pathways in the top region (FA=0.30±0.03) and reduced coherence in the bottom region (FA=0.21±0.05). The next steps will involve clearing of larger specimen so that the CLARITY data covers larger regions within the MRI data, which will allow for a more precise comparison

of individual voxels.
[1] Tomer, R. et al. Nat Protoc 9, 1682-1697 (2014).



a) A tissue cuboid (1cm^3) covering part of the thalamus was excised of a fixed brain human brain slab.

b) The cleared specimen and a structural MRI scan (resolution 350 x 350 x 300um) of the same region. Corresponding vessels were identified in both CLARITY and MRI dataset and used for aligment of the data.

c) Diffusion tensor imaging (resolution 1mm isotropic) of the same sample before clearing. The green tensors in the top region represent fibers running parallel to the surface (FA=0.30±0.10). The bottom region shows slightly less coherence (FA=0.25±0.09).

d) Structure tensor analysis of the neurofilament stain in that region showed a similar behaviour like the DTI scan with a higher anisotropy (FA=0.30±0.03) in the top region and reduced anisotropy (FA=0.21±0.05) in the bottom region. (CLARITY resolution 0.25 x 0.25 x 1.3 um, scale bar = 70um)

Title: Stable, chronic two-photon imaging in awake, behaving rhesus macaque.

Authors: *X. SUN[1], E. TRAUTMANN[2], D. O'SHEA[2], S. RYU[1], J. MARSHEL[1], W. ALLEN[1], I. KAUVAR[1], C. RAMAKRISHNAN[1], K. DEISSEROTH[3], K. SHENOY[4];
[2]Neurobio., [3]Bioengineering, [4]Electrical Engin., [1]Stanford Univ., Stanford, CA

Abstract: Optical functional imaging, such as 2-photon (2P) calcium imaging, have become powerful tools for investigating functions of neural circuits *in vivo*. Translating these techniques to non-human primates enables recording hundreds or thousands of neurons simultaneously with single-neuron resolution, tracking the same neurons across multiple sessions, combining functional recordings with high resolution structural imaging, and identifying cell types using genetic labeling.
We have developed a platform for performing 2P imaging in awake, behaving rhesus monkeys and have demonstrated: 1) dense expression of GCaMP across PMd, M1, and S1, 2) stable imaging of neurons during a motor behavioral task, 3) imaging neurons 500 microns below the surface in highly-scattering primate cortex, and 4) tracking the same neurons across multiple days and sessions. While encouraging, the vast majority of the thousands of neurons imaged via 2P exhibited bright, filled processes and somas and did not modulate in intensity, consistent with reports of GCaMP overexpression in rodent imaging (e.g. Harvey et al., 2012). We achieved these imaging goals by addressing experimental and engineering translation challenges unique to monkey research. To screen for GCaMP constructs that express in primates, we injected 8 viral constructs at 32 sites in PMd, M1 and S1. To align with long-term monkey research timescales, the imaging chamber must maintain clarity for several months to years. We developed an imaging chamber that incorporates a transparent replaceable silicone window, which is sealed from the external environment to minimize risks of infection and opacification. Another challenge to stable imaging are the brain pulsations induced by cardiac and respiratory rhythms. To restrict brain motion, we developed a stabilization system that uses gentle pressure to restrict total XY motion to 5-10 μm for prolonged experiments. To prevent the experimental task itself from generating movement of the brain while imaging, we developed a novel rigid three-point

head restraint system. Finally, to maximize the imaging depth, we used a dichroic and light guide at the back aperture of the imaging objective to collect scattered photons and maximize the photon collection efficiency. Our results demonstrate the feasibility of two-photon imaging that can facilitate a new class of systems neuroscience experiments in behaving monkeys, complementary to electrophysiological studies.

Title: Focused ultrasound facilitates non-invasive aav delivery for optogenetics

Authors: **S. WANG**, T. KUGELMAN, A. BUCH, S. HUSSAINI, M. HERMAN, M. KARAKATSANI, Y. HAN, K. DUFF, *E. KONOFAGOU;
Columbia Univ., New York, NY

Abstract: Optogenetics is a recently developed technique that has been widely applied in the field of neuroscience. Light-sensitive protein channels such as Channelrhodopsins (ChR), are introduced into neurons either by viral transduction or transgenic manipulations. Recent advances in focused ultrasound (FUS) offer a non-invasive approach to carrying out viral transduction in the brain as shown by our group and others. In the presence of microbubbles, the blood-brain barrier (BBB) can be temporarily opened, and we have demonstrated the feasibility of non-invasive AAV delivery to the targeted brain region. Taking advantage of the FUS-mediated BBB opening, we propose a FUS-based, non-invasive adenoviral delivery scheme suitable for non-invasive optogenetic applications. The ability of FUS to facilitate AAV9-ChR-mcherry delivery was first demonstrated in wild-type mice. Caudate-Putamen and hippocampus were selected to be the targets for FUS and contrast-enhanced MRI was used to reveal the BBB opened regions. For mice receiving FUS, the following parameters were used: frequency 1.5 MHz, peak-rarefactional pressure 0.45 MPa, pulse length 10 ms, pulse repetition frequency 5 Hz,

and a duration of 120 s. Mice were allowed to survive for ten days and the ChR expression was examined with confocal imaging of the brain slides (40 μm). In addition, the region of transduction was compared with mice receiving direct infusion of the same viral particle. The bioactivity and efficiency of FUS delivered AAV was examined by performing optogenetic stimulation. Both pulsed stimulation (2s on and 2s off) and long pulse stimulation (10 s) were carried out while the animals were fully functional. Finally, the safety of the proposed technique was tested via histological analysis. Fluorescence images revealed that FUS-facilitated AAV delivery successfully transduced targeted brain regions. Furthermore, the level of transduction was comparable to that from direct infusion. When stimulated with the blue light, a higher number of spikes was observed indicating an increased level of neuronal activity. Compared to resting state, the number of spikes was significantly higher ($P<0.001$) upon stimulation. Ten-second long pulsed stimulation showed an initial increase of spike frequency followed by a gradual decrease to the baseline. These results were comparable to mice receiving direct viral infusion. Therefore, the successful non-invasive AAV delivery can provide an alternate and safer route for Channelrhodopsin neuronal transduction for optogenetic stimulation.

Title: Tailoring light-delivery depth for optogenetic control of neural activity in deep-brain structures with tapered optical fibers

Authors: ***F. PISANELLO**[1], G. MANDELBAUM[2], M. PISANELLO[1,3], L. SILEO[1], A. DELLA PATRIA[1], I. A. OLDENBURG[2], T. HAYNES[2], M. S. EMARA[1,3], B. SPAGNOLO[1,3], B. L. SABATINI[2], M. DE VITTORIO[1,4];
[1]Inst. Italiano Di Tecnologia, Arnesano, Italy; [2]Dept. of Neurobio., Harvard Med. School, Howard Hughes Med. Inst., Boston, MA; [3]Ingegneria dell'innovazione, [4]INgegneria dell'innovazione, Univ. del Salento, Lecce, Italy

Abstract: In vivo optogenetic experiments in deep structures of the mouse brain are still limited by the use of flat-cleaved optical fibers, whose illumination is restricted to a small and fixed volume close to fiber facet [Neuron 86, 106 (2015); Front. Neurosci. 10:70 (2016)]. Here we exploit modal demultiplexing properties of tapered optical fibers (TOFs) to adapt light delivery

depth to the size of functional structures and to obtain spatial-resolved optogenetic control of neural activity in deep-brain regions.
A very small taper angle is designed to gradually lose the total internal reflection along the taper and therefore to deliver light along a taper segment that can be tuned from L~0.4mm to L~2mm. The same device allows for two operation modalities: (i) when light is injected into the fiber through the whole numerical aperture, light is delivered homogeneously along the whole segment; (ii) when light is coupled with an angle into the fiber, the user can instead select a well-defined sub-portion of L that emits light. The approach was tested in motor cortex and in striatum, in both head-restrained and free-moving animals.
For the motor cortex experiment we used the *VGAT-ChR2* mouse line (ChR2 in all inhibitory interneurons). Experiments with modality (i) show that the light emission geometry of TOFs permits sustained inhibition of neural activity at delivered powers 5-times smaller than the threshold recorded for standard flat-cleaved fibers. The experiments in striatum were instead carried out in mice expressing ChR2 in the indirect spiny projection neurons of the striatum (*Ador2a-Cre; Ai32*). Immunohistochemistry for c-fos (protein product of an immediate early gene whose expression is regulated by neuronal activity) after TOF-based light delivery (in modality (i)) revealed a more uniform c-fos induction across ~2 mm of the dorsal ventral axis of the striatum, with respect to the ~0.5mm obtained with standard fibers, for the same delivered light power.
In both motor cortex and striatum, coupling light at different angles into the fiber (modality (ii)) [Neuron 82, 1245 (2014); Biom. Opt. Exp. 6 4014 (2015)] allows for obtaining site-selective light delivery in three independently addressable subregions of these structures by using a single implant. This property can also be used with multiple lasers at multiple wavelengths and different input angles to obtain multicolor light delivery at different depth.
The simplicity of this technique, together with its versatility, reduced invasiveness and compatibility with both laser and LED sources, indicate this approach can greatly complement the set of existing methods for light delivery in optogenetic experiments.

Title: Comparison of network effects of optogenetic and electrical stimulation on the synchronized oscillations in a computational model of parkinsonian basal ganglia

Authors: S. RATNADURAI-GIRIDHARAN[1], C. C. CHEUNG[1], *L. L. RUBCHINSKY[2,1]; [1]Indiana Univ. Purdue Univ. Indianapolis, Indianapolis, IN; [2]Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Deep brain stimulation (DBS) is used as a therapeutic procedure to treat symptoms of several neurological and neuropsychiatric disorders by controlling electrical activity of neural circuits. In particular it is used to treat motor symptoms of Parkinson's disease (PD), associated with excessive oscillatory synchronized activity in the beta frequency band. An alternative way to stimulate neural circuits is an emerging technology of optogenetics. It is not clear if optogenetics will eventually be possible to implement in clinical practice. However it is emerging as a widely used experimental tool to control brain networks. Thus the goal of his study is to explore how effective an optogenetic stimulation in comparison with electrical stimulation in their network effects on elevated synchronized oscillatory activity. We use a computational model of subthalamic and pallidal circuits, which was developed to reproduce experimentally observed beta-band activity patterns. We model electrical stimulation as well as optogenetic stimulation of two types (excitatory via channelrhodopsin and inhibitory via halorodopsin). All three modes of stimulation can decrease beta synchrony. The actions of different stimulation types on the beta activity differ from each other. Electrical DBS and optogenetic excitation have somewhat similar effects on the network. They both cause desynchronization and suppression of the beta-band bursting. As intensity of stimulation is growing, they synchronize the network at higher (non-beta) frequencies in almost tonic dynamics. Optogenetic inhibition effectively reduces spiking and bursting activity of the targeted neurons. We compare the stimulation modes in terms of the minimal effective current delivered to basal ganglia neurons in order to suppress beta activity below a threshold. Optogenetic inhibition usually requires less effective current than electrical DBS to achieve beta suppression. Optogenetic excitation, while as not efficacious as optogenetic inhibition, still usually requires less effective current than electrical DBS to suppress beta activity. Our results suggest that optogenetic stimulation may introduce smaller effective currents than conventional electrical DBS, but still achieve sufficient beta activity suppression. Thus optogenetic stimulation may be more effective than electrical stimulation in control of synchronized oscillatory neural activity.

Title: Opto-panx1: engineering a new, optically-controlled pannexin 1 channel

Authors: *A. W. LOHMAN[1], W. ZHANG[2], R. E. CAMPBELL[2], R. J. THOMPSON[1];
[1]Cell Biol. and Anatomy; Hotchkiss Brain Inst., Univ. of Calgary, Calgary, AB, Canada; [2]Dept. of Chem., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Pannexin 1 (Panx1) forms a large pore ion channel that regulates several cellular and (patho)physiological processes including ATP release, phagocyte chemotaxis, inflammasome assembly and neuronal excitotoxicity. Characterization of Panx1 has expanded over the past decade, but pharmacological and genetic manipulations of the channel have been enigmatic due to overlapping targets for antagonists and the potential for compensation by other Panx isoforms. As a result, ascribing specific contributions of Panx1 signalling in health and disease has proved difficult. Here, we have developed a new optogenetic tool for the isolation and study of Panx1 signalling, called opto-Panx1. Opto-Panx1 consists of a two-protein system. We first engineered an optically-activated Hepatitis C Virus protease (HCVp) by inserting a photocleavable protein (PhoCl) between HCVp and an inhibitory peptide which blocks the protease active site. Next, we mutagenized the caspase cleavage site in the Panx1 C-tail to a consensus HCVp motif ($Panx1^{HCV}$). Proteolytic truncation of the Panx1 C-tail opens the channel pore. We assessed the functional status of opto-Panx1 by TO-PRO-3 dye uptake and electrophysiology. Photostimulation of opto-Panx1 with 380nm light promoted dye uptake and increased whole cell currents in transfected HEK293T cells, but not cells expressing a non-cleavable mMaple-HCVp variant. Chronic photoactivation induced cell blebbing, consistent with reported Panx1 activities in apoptotic cells and ischemic neurons. These responses were not observed in cells solely expressing PhoCl-HCVp or $Panx1^{HCV}$ or cells co-expressing PhoCl-HCVp and $Panx1^{WT}$, indicating specificity of the system. For *in vivo* applications, we generated a bi-cistronic AAV vector for dual expression of PhoCl-HCVp and $Panx1^{HCV}$ with a proximal floxed DsRed-STOP codon element allowing Cre recombinase-driven expression. Transfection of this construct in HEK293T cells along with Cre recombinase revealed a loss of DsRed fluorescence and induction of opto-Panx1 expression, as evidenced by increased green fluorescence (from PhoCl). This new optogenetic tool provides sensitive spatio-temporal control over Panx1 activity for examining cell type specific contributions of these channels across a broad range of scientific disciplines.

Title: Comparison of optogenetic and electrical intracranial self-stimulation of the mouse VTA

Authors: ***T. C. WEIDNER**, D. VINCENZ, M. J. BROCKA, J. TEGTMEIER, A. KOLODZIEJ, K. TAKAGAKI, F. W. OHL, J. GOLDSCHMIDT, M. T. LIPPERT;
Systems Physiol. of Learning, Leibniz Inst. for Neurobio., Magdeburg, Germany

Abstract: Optogenetic methods have become a mainstay of systems neurophysiology and have replaced electrical stimulation in many fields of basic research. However, there are numerous experimental contexts where optogenetic methods cannot be used yet. For example, optogenetic stimulation is currently not feasible in human patients. In addition, one must also relate new optogenetic findings to the large body of neurophysiological research that has been performed before the invention of optogenetics. However, it is often difficult to relate findings using optogenetics to findings from electrical stimulation. In this study, we compare electrical and optogenetic stimulation of the ventral tegmental area (VTA) in mice. The VTA and its dopaminergic circuitry are both important from a clinical point of view as well as an area of high interest in optogenetic research. While indirect comparisons of optogenetic and electrical VTA stimulation have been done previously, matching of stimulation intensity between the electrical and optical modality has not been reported yet. Here, we matched the intensity of electrical and optogenetic stimulation by the strength of self-stimulation behavior evoked by different current strengths and light levels. We used two different transgenic mouse lines which are typically used in optogenetic VTA studies, TH::Cre and DAT::Cre mice. In both groups, we transduced 10 male animals with AAV-EF1a-DIO-hChR2(H134R)-eYFP-WPRE-pA and implanted a custom-made optrode into the left VTA. Following a three week expression period, the mice were tested in a lever-pressing task for optogenetic and electrical intracranial self-stimulation (ICSS) at various intensities. The resulting responses were fitted with a Gompertz-model and two behaviorally equivalent intensities were chosen for imaging with electrical and optogenetic stimulation. The mice were passively stimulated at these intensities and the spatial patterns of neural activity measured using SPECT-imaging of regional cerebral blood flow. Our results show that the application of behaviorally equivalent optogenetic and electrical stimuli resulted in

surprisingly similar activity patterns in the Nucleus accumbens (Nacc), medial prefrontal cortex (mPFC), Raphe nuclei (DRN) and dorsal striatum. Previously described differences in brain activity between electrical and optogenetic stimulation of the VTA may therefore be related to unequal intensities of stimulation rather than to a fundamental difference in the stimulation modalities.

Title: Coupling optogenetic stimulation and microdialysis *In vivo* to investigate how distinct stimulation patterns regulate dopamine levels

Authors: *M. SKIRZEWSKI, I. KARAVANOVA, A. BUONANNO;
Section Mol. Neurobio., NIH/NICHD, Bethesda, MD

Abstract: Optogenetics has been widely used to investigate electrophysiological synaptic function and circuits *in vitro* and *in vivo*, and to correlate them to behaviors. However, relatively little is known about how distinct optogenetic stimulation paradigms regulate the release and accumulation of neurotransmitters and neuromodulators in the brain. These parameters are important because, as has been reported previously at corticostriatal synapses, the release of low concentrations of dopamine during pacemaker or irregular firing leads to long-term depression, whereas the release of high concentrations of dopamine during bursting induces long-term potentiation (Williams et al, Neuroscience 39:1-16, 1990; Reynolds et al, Nature 413:67-70, 2001). Importantly, these dopamine-dependent forms of synaptic plasticity provide the basis for context-dependent changes underlying reward-related learning in primates and rodents. Because presently it is not clear how different protocols of optogenetic manipulations (tonic vs. phasic) widely used to modulate dopamine-dependent behaviors affect dopamine levels, particularly in brain areas such as prefrontal cortex or hippocampus where microdialysis is the only suitable method sensitive enough to detect extracellular dopamine levels (0.5 - 1.5 nM), we have set-out to combine these two experimental approaches. Preliminary findings indicate that tonic vs. phasic optogenetic stimulation on dopaminergic processes in dorsal striatum leads to different locomotor activity behaviors in mice, supporting the idea that distinct optogenetic stimulation

paradigms differentially regulate the accumulation of dopamine. Here, we provide direct evidence of how *in vivo* extracellular dopamine levels in prefrontal cortex and dorsal striatum are regulated during tonic vs. phasic optogenetic stimulation of midbrain dopaminergic neurons. The combined optogenetic-microdialysis approach is allowing us to investigate the properties of dopamine accumulation, and provide a complementary functional study in support for electrophysiological and behavioral analysis to determine the direct relevance of extracellular dopamine levels to behaviors. *This work was supported by the Eunice Kennedy Shriver NICHD Intramural Research Program, NIH.*

Title: Transparent microelectrodes eliminating light-induced artifacts for simultaneous optogenetics and electrophysiology.

Authors: H. LYU[1], X. LIU[2], *D. KUZUM[2];
[1]Univ. of California San Diego, San Diego, CA; [2]Univ. of California San Diego, La Jolla, CA

Abstract: Emerging light and optic-based methods, such as optogenetics and multiphoton microscopy, have revolutionized neuroscience research. However, light-induced artifacts in metal-based microelectrodes significantly limit simultaneous use of these tools. Due to Becquerel and photo-thermal effects, these artifacts appear as transients in recordings and can interfere with local field potentials or spike recordings, depending on the frequency and duration of the light stimulus. In this work, light-induced artifacts in Au and transparent graphene electrodes fabricated in the same batch are systematically investigated. Graphene and Au electrodes were fabricated on transparent polyimide (Fig. 1a,b). Monolayer graphene was transferred onto patterned metal contacts. Standard optical fiber with 200 μm diameter was used to apply light pulses on the electrode to study light-induced artifacts during optogenetic stimulation (Fig 1c). The recordings by the Au electrode exhibit severe light-induced artifacts, while no light-related artifacts were observed for the graphene electrode. Rhythmic square pulse stimulation with 20 ms pulse duration at 10 Hz and was applied to both graphene and Au electrodes (Fig 1d). Power spectrum density analysis on the recording of the graphene electrode did not reveal any features at 10 Hz and its harmonic frequency components. However, Au electrode recordings showed fundamental frequency component, and harmonic peaks at 20 Hz,

30 Hz and 40 Hz. In summary, we have demonstrated that transparent graphene electrodes can enable artifact free optogenetics and electrophysiology while conventional metal electrodes drastically suffer from light-induced artifacts. With its other superior properties, such as high mechanical strength, good conductivity, transparency and biocompatibility, graphene electrodes are extremely promising for studies involving electrical recordings and optical stimulation or imaging.

Title: Vision restoration - neuronal imaging of red-shifted channelrhodopsin responses in the living eye

Authors: *S. K. CHEONG[1], J. M. STRAZZERI[1,2], D. R. WILLIAMS[3,1], W. H. MERIGAN[2,1]; [1]Ctr. for Visual Sci., [2]Flaum Eye Inst., [3]Inst. of Optics, Univ. of Rochester, Rochester, NY

Abstract: ***Purpose:*** The rate of progress in developing new approaches to vision restoration is limited by the inability to troubleshoot each approach at the level of individual neurons in the living eye. Here we describe the application of an *in vivo* method to record and track the response of retinal neurons in a study of optogenetic vision restoration in blind mice. We used a red-shifted channelrhodopsin (ChrimsonR) and stimulated the eye using red light, outside the activation spectra of mouse photoreceptors and melanopsin. We recorded ChrimsonR mediated light response directly from retinal neurons using *in vivo* adaptive optics imaging of a genetically encoded calcium indicator (GCaMP6s) in a mouse model of photoreceptor degeneration (*rd10*). ***Methods:*** Transgenes GCaMP6s and/or ChrimsonR-tdTomato were transfected into retinal neurons using adeno-associated viral vectors. *In vivo* functional calcium imaging of GCaMP6s, excited by 488 nm over a 5 x 6.7° field of view, was performed using a custom built adaptive optics scanning light ophthalmoscope to measure cell responses to light stimulation. Uniform field, 8.6° diameter, 0.2 Hz square wave stimuli were presented in Maxwellian view using two LEDs: 365 nm to drive S-opsin, and 620 nm to drive ChrimsonR. Response amplitude and phase were computed at the stimulus frequency (f1). Responses were also recorded from wild-type (C57BL/6J) mice transfected with only GCaMP6s. ***Results:*** Robust coexpression of GCaMP6s and ChrimsonR-tdTomato was observed in many neurons following serial injections. In *rd10* mice without ChrimsonR, no cells showed light evoked activity to 620 nm or 365 nm stimulation. In rd10 mice with ChrimsonR, cells showed robust responses to 620 nm stimulation (that activates ChrimsonR) but not to 365 nm stimulation (that activates S-opsin); responses to 620 nm were recorded in mice up to 119 days of age, 90 days post injection. In wild-type mice without ChrimsonR, many cells showed light evoked activity to 365 nm but none responded to 620 nm stimulation. ***Conclusions:*** ChrimsonR allows study of optogenetic vision restoration using stimulating light outside the activation spectra of mouse photoreceptors. *In vivo* calcium imaging of retinal neurons allows recording of restored visual responses directly at the site of therapy in the eye and may be applied to multiple methods of vision restoration.

Abstract: Multifunctional devices for optogenetic stimulation and neural recording may offer benefits to the basic study of the nervous system. Since optogenetic experiments typically rely on viral delivery of opsin genes and require visible light, an invasive two-step surgery is often employed. As the majority of optogenetic studies still rely on silica fibers outfitted with metallic electrodes, the modulus mismatch between these devices and the brain tissue lead to profound foreign-body response posing a barrier to long-term opto-electrophysiology. Consequently, there remains a need for flexible and multifunctional neural probes that combine viral delivery with optogenetic stimulation and electrophysiological recording in freely moving rodents. Here we introduce an all-polymer probe that integrates an optical waveguide, 6 electrodes, and 2 microfluidic channels. This device produced via a thermal drawing process has a cross sectional diameter of 200 μm, and connectorized with optical, electrical and microfluidic interfaces weighs <0.5g. The choice of materials enabled low-loss optical transmission, and the development of a custom conductive polyethylene (CPE) composite with graphite (5% by weight) yielded electrodes whose impedance is comparable to that of metallic microwires (100s kΩ) enabling electrophysiological recordings of isolated action potentials with high signal to noise ratio

(SNR). The utility of our devices was confirmed by recording the optically-induced neural activity 2 weeks following the delivery of the adeno-associated virus carrying a gene for channelrhodopsin 2 (AAV5-CaMKIIα::ChR2-EYFP) into medial prefrontal cortex (mPFC) of wild type mice. Optical stimulation in the premotor area resulted in increase of locomotor activity consistent with ChR2-facilitated excitation. Multiple implantations were also performed to allow optogenetic studies of projections from the basolateral amygdala to the mPFC or the ventral hippocampus (vHPC). These circuits exhibited distinctly different latencies of optically evoked signals, and furthermore the activity was correlated to the behavioral response. Consistent with prior studies, stimulation of the BLA inputs into the vHPC resulted in a decreased time spent in the center during a standard open field test. Finally, the flexibility of our probes was manifested in their enhanced biocompatibility as corroborated by reduced glial response and blood-brain barrier breach following up to 90 days of implantation. As our device allowed for minimally-invasive optogenetics in freely moving mice with a one-step surgery, we anticipate its future applications in systems neuroscience studies.

Title: Selective optogenetic control of Purkinje cells in monkey cerebellum

Authors: ***Y. EL-SHAMAYLEH**[1,2], Y. KOJIMA[1,2], R. SOETEDJO[1,2], G. D. HORWITZ[1,2]; [1]Physiol. & Biophysics, Univ. of Washington, Seattle, WA; [2]Washington Natl. Primate Res. Ctr., Seattle, WA

Abstract: A central goal of systems neuroscience is to understand how distinct cell types contribute to brain function. The ability to manipulate gene expression in specific cell types in

small animals (e.g. flies and mice) has already revealed key principles of neural coding and the neural basis of behavior, but these animals are poor models for higher brain function. Primates are a superior model in this respect, but achieving cell type-specific manipulations in primates (e.g. through optogenetics) have been challenging. Here, we report robust Purkinje cell-specific expression of channelrhodopsin-2 in the primate cerebellum. We injected the cerebellar cortex of three rhesus monkeys with recombinant AAV vectors. Vector constructs contained a 1 kb L7 promoter fragment which targets Purkinje cells in rats and mice but, to our knowledge, has not been tested in monkeys. Physiological recordings confirmed potent optogenetic activation of transduced cerebellar neurons (N = 3 monkeys). Optical stimulation of the oculomotor vermis increased the probability of both simple and complex spikes, and was sufficient to perturb saccade trajectories with a latency of ~13 ms. Sustained optical stimulation caused horizontal saccade hypometria in one direction and hypermetria in the opposite direction. Histological examination of cerebellar sections via immunohistochemistry and fluorescence microscopy confirmed the specificity of viral vector-mediated opsin expression (N = 3 monkeys). In contrast, control injections of a vector containing the ubiquitous CMV promotor transduced a broad range of cerebellar cell types (N = 1 monkey). Thus, AAV vectors containing a 1 kb L7 promotor fragment provide an effective tool for the causal interrogation of Purkinje cell contributions to cerebellar function in primates. More broadly, this study highlights the promise of cell type-specific promoters in conjunction with viral vector-mediated gene delivery to manipulate the activity of targeted neural populations in macaques.

Title: Efficient ArchT-mediated optogenetic inhibition by red-shifted off-peak 594-nm light *In vivo*

Authors: *R. SETSUIE[1], K. TAMURA[1], M. TAKEDA[1,2], K. MIYAMOTO[1], Y. MIYASHITA[1,2];
[1]Dept. of Physiol., The Univ. of Tokyo Sch. of Med., Tokyo, Japan; [2]Grad. Sch. of Medicine, Juntendo Univ., Tokyo, Japan

Abstract: Manipulation of a large number of neurons is a prime requirement for optogenetic intervention to behavior in mammals with large brain sizes, such as primates. The spatial volume effectively illuminated by a single optical fiber is restricted by attenuation of the emitted light due to distance as well as scattering and absorption by brain tissue. In many *in vivo* studies, a proton pump ArchT has been driven by 532-nm light according to *in vitro* cellular studies that reported the excitation peak in the 530~550-nm range. The 532-nm light, however, can be strongly absorbed by hemoglobin, and may not be the most effective for large brain volume inhibition. One of the alternative approaches is to use a longer wavelength to avoid the tissue absorption. Thus we examined the efficacy of red-shifted 594-nm light in ArchT-mediated large-volume inhibition of neuronal activity in comparison with 532-nm light.
ArchT was expressed in the primary somatosensory cortex of Wistar rats by injecting a virus vector (AAV5-CaMKIIa-ArchT-GFP; 2 μl; titer, 0.5~2.0×10^13 GC/ml). To measure the efficacy of photoinhibition at different distances from the optical fiber, we designed an optical device with one tungsten microelectrode surrounded by four non-overlapping side-emitting optic fibers at horizontal distances of 250, 500, 700, and 1000 μm from the electrode. Light-responsive single-/multi-unit activities were recorded under urethane anesthesia (1.2 g/kg) as described previously (Tsubota et al, 2015). The decreases in the spontaneous firing rate during illumination were measured with 532-nm or 594-nm DPSS lasers. In each unit, the light power, matched between 532-nm and 594-nm, was optimized for different optic fiber distances so that changes in the firing rate could be measured accurately without floor or ceiling effects (within the linear range) by considering the inverse square attenuation of light with distance. We found that the off-peak 594-nm and on-peak 532nm light suppressed the firing with a comparable efficacy at 250 μm (e.g., 60% at 0.6mW). At each distance, 594-nm light showed a suppression efficacy consistent with the prediction of inverse square attenuation. On the other hand, with distance, suppression by 532-nm light became lower than the inverse square attenuation. Correspondingly, at 1000 μm, its suppression was approximately half that of 594-nm light.
Thus our results suggest that 594-nm light is more effective than commonly used 532-nm light for ArchT-mediated large volume silencing in mammalian cortices *in vivo*. We propose that red-shifted off-peak 594-nm light is beneficial for behavioral intervention in primates.

Title: *In vivo* all-optical electrophysiology of neuronal structures via two-photon microscopy of genetically-encoded calcium indicators and optogenetics

Authors: *J. R. MESTER[1,2], P. BAZZIGALUPPI[4,3], P. L. CARLEN[4,3], J. G. SLED[5,2], B. STEFANOVIC[1,2];
[1]Physical Sci., Sunnybrook Hlth. Sci. Ctr., Toronto, ON, Canada; [2]Med. Biophysics, [3]Univ. of Toronto, Toronto, ON, Canada; [4]Toronto Western Hosp., Toronto, ON, Canada; [5]Hosp. for Sick Children, Toronto, ON, Canada

Abstract: Simultaneous optogenetic stimulation of individual neurons and recording of fluorescent calcium indicators emission in vivo has been made possible by the development of red-shifted opsins such as C1V1, Chrimson, and ReaChR. As reported recently, C1V1 and GCaMP variants can be excited simultaneously with minimal cross-excitation. This is advantageous for in situ two-photon fluorescence microscopy (2PFM) for the purpose of all-optical electrophysiology. In this work, we used a transgenic mouse line expressing GCaMP6f in cortical pyramidal neurons (Jackson Labs) transfected with an adeno-associated virus (AAV) driving expression of C1V1(t/t) in these neurons (AAV9.CamKIIa.C1V1(E122T/E162T).TS.eYFP.WPRE.hGH, University of Pennsylvania vector core, AAV-eSYN-C1V1(E122T/E162T)-TS-mCherry, Vector biolabs). AAV injections were performed 2-3 weeks prior to 2PFM imaging. Prior to imaging, mice were anesthetized under isoflurane (5% induction, 1% maintenance) and implanted with a cranial window. 2PFM was done using a twin FV1000MPE microscope (Olympus). C1V1 and GCaMP6f were simultaneously illuminated with 1040nm and 900nm pulsed light using two Ti:Sapphire lasers (Mai Tai DeepSee, Newport) so as to photostimulate C1V1 while exciting GCaMP6f, respectively. The dual wavelength 2P illumination was enabled by beam combining via a custom 950nm low-pass dichroic filter (Chroma Technologies). GUI-based galvanometer control (Fluoview, Olympus) was used to raster scan or to follow a spiral trajectory with 1040-nm illumination. We imaged GCaMP6f and C1V1 reporter (YFP/mCherry) to localize co-expressing cells. By investigating soma, dendrites, axons, and axonal boutons, we found that the primary cellular expression of C1V1 with our transfection protocol was non-somatic. Interrogation of these cellular compartments resulted in increased frequency of GCaMP6f spiking events (spike

sizes 25-100% dF/F) in a broader spatial region than that spanned by photostimulation trajectory during stimulus paradigm. Furthermore, the spikes were not always time-locked with the stimulus paradigm, suggesting either delayed responses, postsynaptic events, or unrelated spontaneous activity. However, with current anesthesia protocol, the baseline level of spontaneous activity is very low when no stimulus is delivered, so it is unlikely that these spikes are unrelated to the stimulus. Further work on this methodology is warranted to enable its use as a viable alternative to invasive electrophysiology methods.

Title: Simultaneous two-photon calcium imaging and optogenetics using GCaMP6 and ChrimsonR

Authors: *E. M. GOLDBERG;
Neurol., Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Two-photon microscopy of calcium-sensitive probes facilitates optical imaging of the activity of many neurons at high speed and with cellular-level resolution, including relatively deep in the light-scattering environment of brain tissue. Optogenetics utilizes light-sensitive molecules to manipulate neuronal activity, also with cellular-level resolution, and with millisecond temporal precision. Recent and rapid advances in the ability to combine these techniques has expanded the tools available to investigate mechanisms of neural circuit function. Here, we demonstrate the simultaneous combination of two-photon calcium imaging of the genetically-encoded indicator GCaMP6f with one-photon photostimulation of the red-shifted channelrhodopsin variant ChrimsonR in cultured neurons and in acute brain slices *in vitro*. This was accomplished with simple modifications to a commercial two-photon microscope system. Photostimulation with 660 nm light of primary rat hippocampal neurons in culture, as well as granule cells and parvalbumin-positive interneurons in the hippocampal dentate gyrus in acute

brain slices, expressing GCaMP6f and ChrimsonR.tdTomato, produced robust GCaMP6f-mediated signals. Imaging:photostimulation did not require use of a shutter (and hence avoids sequential imaging:photostimulation) or post-hoc correction of photostimulation artifact. Severe light scattering and lack of single neuron precision will limit the broad applicability of this approach, but it may nevertheless have narrow applications for specific research questions *in vitro* and perhaps *in vivo*.

Title: Integration of optogenetic stimulation with neuronal and neurotransmitter recordings

Authors: *D. A. JOHNSON, E. NAYLOR, S. GABBERT, D. V. AILLON, D. A. JOHNSON; Pinnacle Technology, Inc, Lawrence, KS

Abstract: The integration of optogenetics and *in vivo* brain responses requires researchers to coordinate disparate tools and timing issues. Standardized techniques and turn-key systems will allow researchers to focus on the experiment and not system design. Pinnacle has developed an LED-based light delivery method small enough to reside on a rodent's head yet powerful enough to deliver sufficient light for opsin activation (> 100 mW/mm^2 for most wavelengths) and combine this with biopotential and neurotransmitter detection. Pinnacle's system includes LED fiber probes, precise timing, TTL I/O, various recording headstages (EEG/EMG, sleep, seizure, biosensors, etc.) and synchronized video. No optical commutator is required. In validation experiments, wild-type control mice (C57BL6/J) and transgenic mice expressing channelrhodopsin in the hippocampus and cortical regions [(Thy1-COP4/EYFP)9Gfng - Jackson Laboratory] were stimulated in the hippocampus for 20 s with blue (445 nm) or deep red (660 nm) light at 20 Hz, 10% duty cycle, (intensity > 100 mW/mm^2) while measuring EEG via a depth electrode in the hippocampus and a cortical electrode in each hemisphere. The same experiment was also performed with the addition of a glutamate biosensor implanted in the prefrontal cortex (40 s stimulation). All surgical procedures were approved by the University of Kansas IACUC. Control mice (C57BL6/J) showed no response to optical stimulation including no Becquerel effect. In response to blue light stimulation, all transgenic mice expressing

channelrhodopsin had EEG frequency changes in the hippocampus corresponding to the timing of the stimulation pulse. In 70% of the trials, the response propagated to both hemispheres resulting in large-amplitude, cortical seizure-like, activity lasting 20 – 30 s after stimulation. Glutamate in the prefrontal cortex consistently declined (0.17 +/- 0.02 uM) during periods of blue light stimulation. As an additional control, stimulation at 660 nm (deep red) did not result in any measurable response in either EEG or extracellular glutamate concentration.

Title: Two-photon holographic control of single neurons expressing somatic opsins

Authors: ***O. A. SHEMESH**[1], D. TANESE[2], V. ZAMPINI[2], C. LINGHU[1], E. PAPAGIAKOUMOU[2], E. RONZITTI[2], K. D. PIATKEVICH[1], V. EMILIANI[2], E. S. BOYDEN[1];

Abstract: Optogenetics, the use of light-driven microbial opsins to mediate optical control of neuronal activity, is in widespread use for the activation and silencing of populations of neurons. Natural neural codes, however, vary from neuron to neuron even within a single class of cells, with the firing of even single neurons capable of altering behavior or brain state. Thus, an intriguing question is whether it is possible to drive individual neurons. In recent years, two-photon (2P) photostimulation of individual neurons expressing optogenetic proteins has begun to be explored. 2P activation is essential for selective targeting of single neurons because it excites opsins precisely where the light is aimed, unlike single photon stimulation wherein the stray light would activate opsin-bearing neurons away from the targeted cell. Of the different 2P stimulation approaches, computer generated holography (CGH) stands out since it enables precise sculpting of the illumination volume and simultaneous illumination of an entire cell or even multiple cells at the same time. Holography also enables millisecond temporal resolution and even sub-millisecond temporal jitter of action potential generation, meaning that CGH could support single cell, sub-millisecond optogenetic control. Despite recent advances in 2P stimulation, there remains a major problem. In a neuronal network, cell bodies are densely surrounded by neurites of neighboring cells. Thus, if neurons within a region are bearing densely expressed opsins, even 2P stimulation of a single neuron's cell body may excite opsins on dendrites or axons that are passing by, causing artifactual activation of nearby neurons. To avoid this crosstalk, we designed a soma-targeted opsin, which is selectively expressed in the cell body. We screened for soma targeting proteins and found a protein fragment that could limit GFP expression to the cell body of neurons. We termed this fragment 'SomaTag', and fused to it the powerful channelrhodopsin CoChR. We found SomaTag-CoChR to localize to the cell body of neurons in the mammalian cortex, and in combination with holographic 2P stimulation, could support optogenetic stimulation of single cells in mammalian brain slices with millisecond temporal resolution. This new SomaTag-CoChR, in conjunction with optimized 2P optics, may enable a diverse set of neural codes and computations to be probed in a causal fashion in systems and circuit neuroscience.

Title: Quantitative analysis of phosphoproteome in hippocampal neurons from mouse model of developmental delay

Authors: S.-H. LIM, S. CHOI, J. MOON, *J.-R. LEE;
KRIBB, Daejeon, Korea, Republic of

Abstract: Lack of synaptic formation is one of the common phenomena emerging in neurons of developmental delay. Protein kinases and protein phosphatases regulate many neuronal functions, so the balance between the activities of protein kinases and protein phosphatases is very important in the neuron. Although many synaptic proteins have been known to be phosphorylated or dephosphorylated by synaptic functions, a systematic analysis of phosphoproteins has not been performed about neuronal development. Here we carried out the extensive analysis of phosphopeptides in the hippocampal neurons from a mouse model of developmental delay using Orbitrap MS/MS system. Synaptic proteins were extracted from hippocampal neurons with anionic detergent and the filter-aided sample preparation (FASP) was adopted to remove the residual anionic detergent for full activity of trypsin. After enrichment of phosphopeptides was carried out, labeling with iTRAQ isobaric tag was employed for the quantitative analysis of phosphopeptides. Among phosphopeptides of hippocampal neurons more than 30,000, phosphopeptides more than 600 were significantly increased and decreased in hippocampal neurons of developmental delay compared to wild type. With western blotting the phosphorylation of synaptic proteins were confirmed, and the effects of their phosphorylation and dephosphorylation on synaptic formation were examined. Thus, through the extensive analysis of neuronal phosphopeptides, new signal pathways and unique functions of protein kinases and phosphatases could be elucidated for neuronal development and synaptic formation.

Title: Multi-dimensional characterization of the brain's immune populations

Authors: *B. KORIN, T. BEN-SHANNAN, T. DUBOVIK, A. ROLLS;
Technion - Israel Inst. of Technol., Haifa, Israel

Abstract: Immune cells play a crucial role in brain regulation and malfunction. Yet, we are still limited in our understanding of the complexity and variability of the brain's immune populations and the vast majority of research has been focused on resident microglia and infiltrating monocytes/macrophages. To cope with this gap we adapted mass cytometry (CyTOF), an emerging technology that revolutionizes immunology research, to analyze multiple cell populations in the brain, providing a bird's eye view of the system. CyTOF is a variation of flow cytometry in which antibodies are labeled with heavy metals, rather than fluorophores, and analyzed by their time of flight in a mass spectrometer. This overcomes the overlap in emission curves evident in fluorescent labeling, enabling the use of tens of markers to analyze simultaneously multiple cell populations. Using this strategy, we detected a wide range of immune cell subsets present in the naïve brain, including two subsets of resident microglia, several subsets of infiltrating monocytes/macrophages, granulocytes, dendritic cells (DCs), B cells, natural killer (NK) cells, CD4 and CD8 T cells. By isolating the meninges and choroid plexus from the parenchyma, we determined the relative distribution of those cells between these compartments. Analysis of the expression of cytokine receptors (e.g. IL-1R, IL-2R, IL-4R, IL-6R, TNF-αR and IFN-γR) on various immune populations in the brain revealed the differential expression of receptors across the resident and infiltrating immune cells. This characterization is especially relevant for understanding the effects of cytokines on brain activity. Finally, we examined the changes in the brain following peripheral bacterial infection (with *E. coli*), demonstrating the differential outcomes in the brain and the blood as a result of the peripheral manipulation. Taken together, such multidimensional characterization of the brain's vibrant immune environment provides a new perspective and a valuable tool for our understanding of brain-immune communication.

Title: Explore the exocytotic proteins that interact with Synapsin Ia in a phosphorylation-dependent manner

Authors: *H.-J. YANG[1], C.-T. WANG[2,3,4,1];
[1]Genome and Systems Biol. Program, Natl. Taiwan Univ. and Academia Sinica, Taipei, Taiwan; [2]Inst. of Mol. and Cell. Biol., [3]Dept. of Life Sci., [4]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Synapsins (Syns), a family of evolutionarily conserved phosphoproteins, are widespread in the nervous system and localize to synaptic vesicles (SVs). Syns are encoded by three distinct genes (*syn I*, *syn II*, and *syn III*) and consist of ten homologous proteins by alternative splicing, i.e., Syn Ia-b, IIa-b, and IIIa-f. Among all homologous proteins, Syn Ia is the best studied in regulating the dynamics of SVs by controlling their storage and mobilization in a phosphorylation-dependent manner. These physiological functions of Syn Ia are mainly mediated by interaction with certain presynaptic proteins (such as cytoskeleton) through phosphorylation of Syn Ia. To date, only a few of exocytotic proteins are found to directly interact with Syn Ia in a phosphorylation-dependent manner. In this study, we explore new exocytotic proteins that interact with Syn Ia through phosphorylation of Syn Ia. To begin with, we performed Bioinformatics approaches. First, we conducted systematic database search to find the proteins that can interact with Syn Ia. Second, we performed the sequence-based protein-protein interaction (PPI) prediction with the software MirrorTree. Based on the results from database search and PPI prediction, we selected the candidate proteins that are exocytotic proteins and likely affect SV release. Furthermore, we performed endogenous co-immunoprecipitation for these candidate proteins. We found that the interaction between Syn Ia and Synaptophysin (Syp) was changed after overexpression of the Syn Ia phosphodeficient mutant, suggesting that the Syn Ia-Syp interaction may be regulated by phosphorylation of Syn Ia. Our results suggest that Syp may potentially involve in Syn Ia's regulation of SV exocytosis in a Syn Ia phosphorylation-dependent manner.

Stock Ctr., Texas State Univ., San Marcos, TX

Abstract: Aged garlic extract (AGE) is widely used as a dietary supplement on account of its protective effects against oxidative stress and inflammation. But less is known about specific molecular targets of AGE and its bioactive components, including *N*-α-(1-deoxy-D-fructos-1-yl)-L-arginine (FruArg). Our recent study showed that both AGE and FruArg significantly attenuate lipopolysaccharide (LPS)-induced neuroinflammatory responses in BV-2 microglial cells. This study aims to unveil effects of AGE and FruArg on gene expression profiles due to LPS-stimulated neuroinflammatory responses by conducting a genome-wide search. In the present study, RNA-Seq analysis by Illumina HiSeq 2500 was used to assess the global gene expression in the mouse immortalized microglial BV-2 cells to investigate the protective effects of AGE and FruArg on the transcriptional responses in LPS-induced cells. Results showed that LPS treatment significantly altered 2563 genes. AGE repressed 67% of the transcriptome alteration induced by LPS, whereas FruArg accounted for the protective effect by reducing expression of 54.8% of total genes altered by LPS. Key pro-inflammatory canonical pathways induced by the LPS stimulation included toll-like receptor, IL-6 signaling, and Nrf2-mediated oxidative stress pathway, along with elevated expression levels of genes, such as *Il6, Cd14, Casp3, Nfkb1, Hmox1,* and *Tnf*. These genes could be modulated by both AGE and FruArg treatment. These findings suggest that AGE and FruArg are capable of alleviating oxidative and neuroinflammatory responses stimulated by LPS in BV-2 cells by modulating gene expression in the key pro-inflammatory canonical pathways. Inhibition of the expression of multiple immune- and inflammation-related genes suggested that AGE and FruArg could serve as candidates for the prevention of inflammation-mediated neurodegenerative diseases.

Sci., UCSD, La Jolla, CA; [5]Howard Hughes Med. Inst., [6]Computat. Neurobio. Lab., The Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: The growing number of studies focusing on dissecting cell-type specific transcriptional patterns in brain highlights the community effort to profile the molecular signatures of brain cells. However, research on epigenetic signatures, which are closely related to gene regulation and more directly impacted by disease-associated genetic variants, has only recently started. Especially, the temporal and spatial epigenetic changes in brain cells remain far under-explored.

In this study we have characterized the genome-wide DNA methylation (DNAm) patterns of neurons from two distinct brain regions during postnatal maturation. NeuN+ nuclei were isolated from frontal cortex and hippocampus of mice at postnatal weeks 1, 4 and 10 and their DNA methylation and transcription landscape were profiled using MethlC-seq and RNA-seq. NeuN+ nuclei from both brain regions showed dramatic global accumulation of non-CG methylation and a slight increase in genome-wide CG methylation as the brain matured, which is consistent with previous findings in whole frontal cortex in both mouse and human. Despite the similar global DNAm dynamics, hundreds of thousands CG differentially methylated regions (CG DMRs) were identified, marking regulatory elements responsible for the distinct transcriptional patterns of neurons from different brain regions. Interestingly, a subset of CG DMRs was clustered forming thousands of hypomethylated regions stretching more than 2 kilobases. These regions strongly overlapped with genes that are region specific transcriptional markers, implying DNAm as a unique signature for spatial distribution of cells in brain. In addition, the large block of hypomethylation correlated with gene up-regulation, as well as lower level of non-CG methylation. Consistent with this, hundreds of genes showed cell-type specific intragenic non-CG methlyation. To expand our scope, we generated methylome data for pyramidal neurons and

the underrepresented inhibitory Parvalbumin (PV) interneurons and further dissect the methlyation patterns observed in these cell types. Lastly, the data generated in this study provides a valuable resource for the community to understand the epigenetic differences between neurons, as well as regions, and its functional implications, especially in cell identity determination. This work is supported by NIMH grant MH094670.

Title: A novel electrochemical detection method for aptamer biosensors of thrombin

Authors: ***H. YOO**[1,2], W. SUN[2], S. YANG[3], J. PARK[2], C.-H. JI[2], S. JUN[2];
[1]Ewha Womans Univ., Seoul-City, Korea, Republic of; [2]Dept. of Electronics Engin., [3]Convergence Inst. of Art and Sci., Ewha Womans Univ., Seoul, Korea, Republic of

Abstract: Aptamers are single-stranded DNA or RNA molecules which can bind to specific target analytes. Aptamers are known to be able to detect a variety of analytes with high stability and high sensitivity. However, there are still several challenges for the realization of aptamer-based biosensors. One of the challenges to overcome is how to transduce the chemical binding between aptamers and target analytes. An aptamer-based detection of analytes was analyzed using electrochemical impedance spectroscopy (EIS). After thrombin-specific aptamers were coated on the gold electrode, EIS data showed that the binding between the aptamers and thrombin increased the impedance magnitude. The EIS data was also used to model the electrode-electrolyte interface to precisely examine the effect of thrombin-aptamer binding. As a result, it was shown that resistance is the most feasible component for aptamer-based thrombin detection. Based on this, this study has proposed a new simple aptamer detection method using a current source device. This approach is to obtain the resistance value by observing the voltage values to be measured between the two electrodes in particular the current pulse caused to put the voltage pulse as a function generator to a current source device. As a result, the value of voltage applied to the both end electrodes was increased, as the thrombin concentration increases. It

showed the potential for use of aptamer-functionalized gold electrodes in biosensors for in-field detection of proteins.

Title: Complex microbiota targeted rederivation: a method to study effects of gut microbiota on model phenotypes

Authors: ***M. L. HART**[1], A. C. ERICSSON[2], C. L. FRANKLIN[3];
[1]Vet. Pathobiology, [2]Univ. of Missouri Metagenomics Ctr., [3]Mutant Mouse Resource and Res. Centers, Univ. of Missouri, Columbia, MO

Abstract: Recent studies indicate that the gut microbiota (GM) can significantly impact both local and systemic host physiologic processes. With the rising concern to optimize experimental reproducibility and translatability, it is essential to consider the GM in study design. To assess the role of microbiota on model phenotypes, complex microbiota targeted rederivation (CMTR) can be used. With CMTR, mice of the desired model are rederived using surgical embryo transfer into surrogate dams with one or more desired GM profiles. Unfortunately, differing GM are often present in inbred strains of mice which can complicate the use of CMTR as these strains frequently have poor reproductive indices and variations in maternal care. To overcome these limitations, we exploited the benefits of outbred mice as surrogates by establishing colonies of CD1 mice with differing GM profiles. CD1 embryos were transferred into CD1 or C57BL/6 surrogate dams that varied by GM composition and complexity to establish three separate colonies. Using targeted 16S rRNA amplicon sequencing, female offspring were found to have similar GM profiles to surrogate dams. Furthermore, breeding colonies of CD1 mice with distinct GM profiles were maintained for four generations, demonstrating stability of GM profiles within these colonies. We then compared changes in the phenotype of B6 IL-10$^{-/-}$ mice rederived by CMTR using either CD1 colonies or the inbred strains from which the colonies were derived. Cecal and colonic histologic lesion scores differed significantly between groups, but no differences were seen when surrogate source of GM (CD1 vs inbred strain) was

compared. These findings underscore that CMTR using outbred CD1 colonies is an invaluable experimental resource in the assessment of GM effects on model phenotype with applicability to virtually any model. With the emerging interest in the gut brain axis, the effect of the GM on systemic disease models such as neuroscience models are a priority for further investigation at the MU MMRRC.

Title: Transcriptional identities of major cell types in the human brain

Authors: *K. W. KELLEY[1], M. C. OLDHAM[2];
[1]Neurology, The Eli and Edythe Broad Ctr. of Regeneration Med., [2]Dept. of Neurolog. Surgery, Univ. of California San Francisco, San Francisco, CA

Abstract: Understanding the molecular basis of cellular identity in the human brain is essential for ascertaining the functions of different cell types and their susceptibilities to pathologies that underlie neurological diseases. However, acquiring this information has been difficult due to pragmatic and technical challenges. By analyzing gene coexpression relationships in 62 datasets representing over 7000 non-pathological adult human brain samples spanning all major neuroanatomical regions and technology platforms, we identified consensus transcriptional signatures of astrocytes, oligodendrocytes, microglia, and neurons. We developed a new metric to describe cellular identity called gene expression 'fidelity', which ranks genes according to their sensitivity and specificity of expression for a given cell type and provides a mathematical bridge between the analysis of gene expression data from bulk tissue samples and single cells. Predictive gene expression modeling using high-fidelity genes revealed that nearly half of the variation in gene expression levels measured from bulk tissue samples can be explained by variation in the abundance of major cell types. Furthermore, we show how predictive modeling can be used to identify cell type-specific transcriptional differences in disease, among brain regions, and between species. Our work provides a broad foundation for understanding the molecular basis of cellular identity in the human brain and offers a generalizable strategy for defining cell types as vectors of genes ranked by expression fidelity.

Title: A customized comparative genomic hybridization array for the analysis of copy number variations and exon-dosage anomalies in neurological disorders.

Authors: *V. LA COGNATA[1,2], G. MORELLO[1], G. GENTILE[1], V. D'AGATA[2], S. CAVALLARO[1];
[1]Inst. of Neurolog. Sciences, Catania, Natl. Res. Council, Catania, Italy; [2]Dept. of Biomed. and Biotechnological Sciences, Section of Human Anat. and Histology, Univ. of Catania, Catania, Italy

Abstract: Neurological disorders are a highly heterogeneous group of pathological conditions characterized by multifactorial etiology relying on genetics, epigenetics and/or environmental contributions. The very complex nature of this group of diseases makes the investigation of their genetic basis rather difficult, mostly if performed gene by gene through traditional methodological approaches. For this reason, high-throughput genotyping technologies are increasingly replacing the classical detection methods, providing higher resolution and a complete window of candidate genomic anomalies. Among the advanced biotechnologies, microarray-based comparative genomic hybridization (aCGH) represents a powerful molecular tool to explore the pathogenetic role of unbalanced structural rearrangements, also in a diagnostic setting. Here, we report the design strategy, development, validation, and implementation of *NeuroArray*, an exon-centric customized aCGH tailored to detect single/multi-exon deletions and duplications in a large panel of multi- and monogenic neurological disorders. This targeted design allows a focused evaluation of structural imbalances in clinically relevant genes at exon-level resolution. An increasing use of the *NeuroArray* platform may offer new insights in investigating potential overlapping gene signatures among neurological conditions and defining genotype-phenotype relationships.

Title: Profiling serotonergic neurons from donors at different states of satiation with single-neuron transcriptomics.

Authors: *E. C. DABE[1,2], A. B. KOHN[2], R. GILLETTE[3], L. L. MOROZ[2];
[1]Univ. of Florida Whitney Lab., Saint Augustine, FL; [2]Neurosci., Univ. of Florida McKnight Brain Inst., Gainesville, FL; [3]Mol. and Integrative Physiol., Univ. of Illinois Urbana-Champaign, Urbana, IL

Abstract: The giant serotonergic metacerebral cells MCCs of *Pleurobranchaea californica* are intrinsic neuromodulators of the well-studied feeding network in *P. californica* and are conserved across opistobranchs. Serotonin (5HT) is a critical factor in both behavioral arousal and appetite. Analysis of indole metabolites has previously shown that satiated animals have reduced levels of serotonin (5-HT) and its metabolite 5-HT-SO_4 (but not of its precursor tryptophan or the metabolite 5-hydroxyindole acetic acid) 24 hrs post-feeding, compared to unfed controls. This suggests reduction in synthesis and possibly in release of serotonin in satiated animals. To evaluate these changes and their regulation at the genomic level, we isolated MCC neurons from satiated and unfed *P.californica* 24 hours post-feeding and processed them for single-neuron RNA-seq (min. n=6). Other groups of 5-HT neurons (min. n=3), neurons of other neurotransmitter phenotypes (min. n=3) and whole CNS ganglia or specific regions were also sequenced on Illumina Next-Seq to form the first *P. californica* hybrid reference transcriptome. Normalized RNA expression levels in transcripts per million (TPM), and differential transcript expression were calculated using RSEM and DESEQ2. Overall, we observed a significant decrease in transcript expression of tryptophan hydroxylase and an increase in expression of serotonin transporter (SERT) in satiated animals. Changes in other 5-HT pathways genes were not detected. This finding matches with the observed decrease in 5-HT levels and further suggests that there is a potential increased re-uptake of 5-HT during satiation. We also analyzed homologous MCC transcriptomes from four opistobranch species and discerned several potential transcription factors that could be regulating the 5-HT gene cohort in molluscs.

Title: Perinatal Inflammatory imprinting in a neonatal animal model of white matter injury: a DNA methylation study

Authors: *S. MCGRAW[1,2], W. C. PIERRE[1,2], L.-M. LEGAULT[1], V. BERTRAND-LEHOUILLIER[1], I. LONDONO[1], G. A. LODYGENSKY[1,2];
[1]Ctr. De Recherche Du CHU Ste-Justine, Montreal, QC, Canada; [2]Univ. de Montréal, Montreal, QC, Canada

Abstract: **Introduction:** Preterm infants are vulnerable to inflammation-induced white matter injury (WMI) which is associated with neurocognitive impairment and neuro-psychiatric manifestation in adulthood. Epigenetic mechanisms play a role in normal development and pathological adaptation in response to environmental challenges. DNA methylation is considered the most stable and well-characterized epigenetic modification. We hypothesize that perturbations in normal profiles following inflammation-induced WMI in the neonatal period could be implicated in the processes leading to known neuropsychiatric diseases in adulthood. **Objective:** The aim of this study was to assess DNA methylation profile in the brain of neonatal rats subjected to WMI compared to controls at 24h (P4) and 21 days (P24) post-injury. **Methods :** We injected LPS (1mg/kg) or sterile saline in the left side of the corpus callosum of P3 rat pups. Brains were collected at P4 (n=8) and P24 (n=8). We extracted genomic DNA from ipsilateral brain hemisphere and produced multiplex libraries of reduced representation bisulfite sequencing to establish genome-wide quantitative DNA methylation profiles. Genomic regions (100bp, 2 CpG min, 15x sequencing) with a ±≥10% average CpG methylation differences between groups of replicates (Ctrl vs LPS) were designated as differentially methylated tiles (DMTs). Functional enrichment analyses of genic associated DMTs were generated using Metascape (http://metascape.org). **Results:** A total of 1590 and 1838 DMTs were observed at P4 and P24 respectively. At P4 and P24, inflammation induced hypermethylation in genes related to nervous system development and developmental growth, respectively and hypomethylation in genes associated with inflammatory pathways. (see table). **Conclusion:** Neonatal WMI resulted in perturbed brain DNA methylation profiles of genes promoting inflammatory pathway at P4

that remained at P24. It also altered brain DNA methylation profiles inhibiting pathways related to normal development of nervous system (P4) and developmental growth and morphogenesis (P24). Further analysis of target genes through qPCR will be performed to determine if alterations in DNA methylation are associated with aberrant gene expression regulation.

Table 1:Pathways affected by changes in DNA methylation profile following neonatal WMI

Conditions	Pathways	Gene names	Methylation Difference %	Annotation
P4 hypermethylated	Nervous system development	RELN	13.06	Intron
P4 hypomethylated	Inflammation	TNF	-19.21	5' UTR
			-10.48	3' UTR
P24 hypermethyled	Developmental growth	TGFBR2	10.33	Intron
P24 hypomethyled	Inflammation	PIK3R1	-10.14	Promoter-TSS
		C3	-11.68	Intron

Title: Discovery proteomics for small neuronal populations using mass spectrometry: toward single cell proteomics

Authors: *P. NEMES[1], S. B. CHOI[1], M. ZAMARBIDE[2], M. MANZINI[2];
[1]Dept. of Chem., [2]Dept. of Pharmacol. and Physiol., George Washington Univ., Washington, DC

Abstract: Characterization of gene expression is central to understanding how molecular processes orchestrate development and function of the nervous system. To address vast cell-to-cell differences (heterogeneity) in the brain, new instruments are needed, particularly those capable of single-cell analysis. High-resolution electrospray ionization mass spectrometry (HRMS) is able to characterize the proteome, but requires averaging hundreds of thousands to millions of cells at the expense of potentially losing information specific to small populations of neurons or individual neurons. Here we present an ultrahigh-sensitivity HRMS approach that enables the identification of a substantial number of proteins in limited populations of neurons. The HRMS instrument integrates a custom-built microanalytical capillary electrophoresis platform and HRMS to achieve trace-level detection capability. For example, angiotensin II was detected at a ~350-zeptomol lower limit of detection. Next, this platform was used analyze ~500 picogram protein digest from neurons that were isolated from the mouse hippocampus. With 10,000-to-100,000-times higher volumetric sensitivity than feasible by traditional HRMS technology, microanalytical HRMS allowed us to simultaneously characterize the expression of 350+ non-redundant protein groups without knowing their neuronal presence ahead of time. The identified proteins included many gene products that have been ascribed to neurons, such as synaptic proteins (e.g., synapsin 1 and 2) and the neural cell adhesion molecule (NCAM). Trace-level detection of the neuron proteome by microanalytical HRMS opens new avenues to study gene expression in small populations of neurons in the brain. Additionally, refinement of this technique will open the road to mapping gene expression also in single neurons, so to help better understand basic molecular processes underlying normal brain development and function.

Title: Single-cell RNAseq of human cerebral cortical neurons reveals transcriptional heterogeneity

Authors: G. E. KAESER[1], *J. J. CHUN[2], Y. C. YUNG[1], B. B. LAKE[3], R. AI[3], N. S. SALATHIA[4], A. CHEN[1], X. SHENG[1], J.-B. FAN[4], W. WANG[3], K. ZHANG[3];

Abstract: The well-known diversity of human brain neurons underlies myriad aspects of neural function. Does the transcriptional landscape within single neurons reflect this diversity as well? Here we report efforts from a NIMH U01 supported team to develop a scalable pipeline to sequence and quantify the transcriptome of over 3,200 single neurons from post-mortem human brain, analyzing six Brodmann Areas (BAs) of the cerebral cortex. Single neuronal nuclei were sorted and processed for total RNA sequencing, followed by use of an iterative, unbiased clustering and classification method that identified 16 neuronal subtypes. These subtypes were further annotated using known gene markers and cortical cytoarchitecture. Neuronal clusters were identified based upon differentially expressed genes (DEGs) that first divided excitatory and inhibitory neurons expressing classical neurotransmitter and transporter genes. Further analyses split neurons according to cortical layer, developmental origin, and BA. These analyses demonstrated a robust and scalable method for identifying and categorizing single neuron transcriptomes, while identifying expressed genes sufficient to distinguish novel and orthologous neuronal subtypes as well as transcriptionally defined BAs within the human brain. The remarkable heterogeneity identified in single neuronal transcriptomes may further reflect activities of complex neuronal networks that vary with time and function. In addition, previous studies from our group have identified increased genomic mosaicism in normal and Alzheimer's disease cortical neurons; the transcriptomic heterogeneity is consistent with normally occurring genomic mosaicism, which may be altered in diseased conditions.

Title: The endogenous disrupted in schizophrenia 1 (DISC1) interactome in human neural progenitor cells

Authors: *B. J. WILKINSON[1,3], M. P. COBA[2,3];
[2]Dept. of Psychiatry and Behavior, [1]USC, Los Angeles, CA; [3]Zilkha Neurogenetic Inst., Los Angeles, CA

Abstract: Disrupted in Schizophrenia 1 (DISC1) was originally identified as contributing to schizophrenia and bipolar disorder through a balanced translocation in a Scottish family. Since its discovery, the role of DISC1 in psychiatric disease along with many of its biological functions, including its proposed function as a scaffolding molecule, have been explained through its protein interactions. Although multiple binding partners have been described, these have been identified through yeast-two hybrid screens or protein-over expression systems using non-stoichiometrical protein ratios. Moreover, there has been controversy about the specificity of DISC1 commercial antibodies, therefore making it difficult to validate and interpret the context of DISC1 interactomes. Here, we show human *in-vivo* protein-protein interactions of endogenous DISC1 in human neural progenitor cells for the first time. We introduced a 3X-FLAG tag coding sequence at the C-termini of the endogenous DISC1 coding sequence using the CRISPR-Cas9 genome engineering system in human pluripotent stem cells. Following differentiation to neural progenitors, we isolated DISC1 protein interactions via immunoprecipation followed by tandem mass spectrometry, enabling the identification of the endogenous human DISC1-interactome. We then expanded the DISC1 interactome by immunoisolation of DISC1 protein interactors including AKAP9, PDE4DIP, and TNIK and determined their respective interactomes. This expanded network allowed for the mapping of cellular localization and the clustering of psychiatric disease risk candidates in common signaling pathways.

Abstract: Epigenomic marks such as cytosine DNA methylation (mC) have highly diverse patterns across brain neuronal and non-neuronal cell types. Human and mouse brains accumulate high levels of non-CG methylation (mCH) at locations throughout the genome that are inversely correlated with gene expression. In addition, more than 200,000 regions showing differential CG methylation were identified between three cortical excitatory and inhibitory neuron types. Approximately 16% of the mouse genome contains differential mC signatures that allows neuronal cell types to be distinguished by low coverage single cell WGBS (whole-genome bisulfite sequencing). We are developing single cell methylome techniques for the classification of mammalian brain cells types using mC patterns, and to explore the epigenomic heterogeneity of neurons with single-cell resolution. To meet the need of large-scale single cell methylome profiling of thousands of cells, we developed a new method for the preparation of single cell methylome libraries with improved complexity using the Adaptase™ technology. Single cell methylomes are generated from single neuronal nuclei isolated from mouse frontal cortex using FACS coupled to a mouse INTACT (isolation of nuclei tagged in specific cell types) strategy. We demonstrated robust neuron type classification using single cell methylomes, readily separating excitatory and inhibitory populations and also identifying distinct inhibitory cells that are similar to PV+ or VIP+ inhibitory cells. The data further allowed an accurate classification of pyramidal neurons in superficial versus inner layers of mouse frontal cortex. The single cell methylome method will enable unbiased characterizations of brain epigenomic diversities without the need of isolating specific cell populations.

Title: Fast recording of whole mouse brains with aspheric light sheet microscopy

Authors: *H.-U. DODT[1,2], S. SAGHAFI[1], C. HAHN[1,2], K. BECKER[1,2], M. PENDE[1,2], I. SABDYUSHEVA-LITSCHAUER[2], M. WANIS[1];

Abstract: Visualization of complete neuronal networks in the brain is an important goal of neuroscience. To this end chemical clearing and recording of mouse brains with light sheet microscopy has become increasingly popular in recent years. Several microscopic setups have been developed for light sheet microscopy but often it is difficult to view preparations like whole mouse brains with different magnifications and to exchange easily objectives.
We developed therefore a setup where microscope objectives are dipped from above in the clearing solution and can be exchanged in less than a minute. As no low magnification objectives for clearing solutions are available on the market we developed correction devices for existing air objectives (2X, 4X, 20X). These devices correct for spherical aberration and allow dipping of objectives into all clearing solutions described in the literature.
Gaussian light sheets for large fields of view have to be rather thick throughout their extension. If made thin in the center they deviate strongly in axial direction towards the edges of the field of view. We thus developed a completely new light sheet generator using aspherical optical elements. It generates a very thin long light sheet with a vastly extended field of view. This light sheet generator allowed us to image whole mouse brains using a single stack of images with a corrected 2X objective and additional demagnification showing clearly neuronal dendrites and axons. For imaging with higher resolution we could easily switch to higher power objectives in our setup. As clearing we used sDISCO, a stabilized version of our 3DISCO clearing, which allows the storage and imaging of GFP labelled preparations for long times. Apart from brains we also imaged adult GFP labelled drosophilae and cm large pieces of human cancers in autofluorescence.
We believe that the development of a light sheet generator for very long thin light sheets is a crucial step towards the imaging of very large samples with microscopic resolution.

Title: Adaptive correction of defocus in light sheet microscopy of cleared mouse brains

Authors: *L. SILVESTRI[1,2], M. MÜLLENBROICH[1], A. DI GIOVANNA[1], L. SACCONI[1,2], F. PAVONE[1,3,2];

Abstract: Light sheet microscopy, coupled with chemical clearing of the sample, is raising as a major tool to reconstruct brain anatomy across large areas - even entire mouse brains - with micron-scale resolution. Indeed, the selective illumination of the sample in the focal plane of the detection objective allows obtaining three-dimensional resolution with a wide-field detection scheme. On the one hand, the uncoupling between illumination and detection speeds up image acquisition by several orders of magnitude with respect to point-scanning techniques like confocal or two-photon microscopy. On the other hand, separation of illumination and detection optical paths renders the system sensitive to low-order optical aberrations, like defocus, which are self-corrected in confocal microscopy. Thus, albeit in theory light sheet microscopy can achieve high resolution imaging in whole cleared mouse brains, in practice specimen-induced defocus degrades image quality in different regions of the sample.
Here, we describe an optical method to measure defocus in a light sheet microscope in real time, allowing fast defocus correction via closed-loop motion of detection objective. With the proposed autofocus system image contrast and resolution are kept high across the entire sample, allowing reliable tracing of small structures, like small capillaries.

Title: Integrated dual approach for 3D reconstruction of myelinated fibers orientation: combination of polarized light imaging and two-photon fluorescence microscopy

Authors: I. COSTANTINI[1], L. SILVESTRI[1], M. AXER[2], M. MENZEL[2], D. GRÄßEL[2], K. AMUNTS[2,3], *F. S. PAVONE[4,5,6];

Inst. of Optics, Florence, Italy; [6]Univ. of Florence, Dept. of Physics, Sesto Fiorentino, Italy

Abstract: Connectomics aims at defining the interactions existing among brain regions through the reconstruction of the neuronal fiber network. 3D-Polarized light imaging (3D-PLI) allows to assess fiber orientation and inclination angles in histological brain sections thanks to the birefringent properties of the myelin sheaths. This optical method enables a fast analysis of fixed mouse and human brains without any exogenous labeling. A single 3D (fiber) orientation vector is obtained for each voxel and reflects the net effect of all comprised fibers. In this work, we employ an integrated dual approach that combines 3D-PLI with two-photon fluorescence microscopy (TPFM) to study the mixture of various fiber orientations within the sample (and voxel) of interest. We exploit the higher axial and radial resolution of TPFM optical sectioning in combination with myelin autofluorescence to perform the 3D reconstruction of fiber orientation within each brain section. We demonstrate that the correlation between the two methods permits to reconstruct areas of the brain with the possibility of characterizing a specific sector of the sample at high resolution, below micrometer level. Our study shows that the integration of different techniques allows an improved analysis of brain connectomics, providing a novel tool for an implemented 3D reconstruction of nerve fiber orientations in fixed samples.

Title: 3D reconstruction of mouse white matter tracts in a Common Coordinate Framework with a combined approach

Authors: *S.-L. DING, J. ROYALL, P. LESNAR, Y. LI, B. FACER, Q. WANG, N. DEE, A. BERNARD, J. PHILLIPS, C. KOCH, S. SUNKIN, H. ZENG, J. A. HARRIS, L. NG;
Data analysis and Annotation, Allen Inst. For Brain Sci., Seattle, WA

Abstract: 3-D reconstruction of white matter (WM) tracts allows more accurate targeting of individual fiber tracts for lesion, stimulation and fiber tracing studies. We aimed to reconstruct about 90 WM tracts in the mouse brain, including some left undefined in commonly used brain atlases using our average 3D template derived from serial two-photon tomography of 1675 mice brains. The delineation of the WM tracts was made with a 3D drawing tool, ITK-SNAP, on the basis of inherent contrast features in the anatomical common template in combination with myelin basic protein, neurofilaments (SMI-32 and NF-160), parvalbumin (PV), and calbindin reference stains. Although WM tracts generally exhibited lower signal intensity (darker) than gray matter structures (brighter) in the anatomical template, these features were not necessarily homogenous between different WM tracts or along individual WM tracts themselves. In the case of isolated and solid WM bundles such as the anterior commissure, fornix, fasciculus retroflexus, and mammilothalamic tract, contours and trajectories were easily defined without the need of additional data. In most other cases, however, WM tracts adjoined, merged (mix) or intersected other bundles and/or portions of gray matter structures at particular locations, leading to complex signal intensities along their paths, thus necessitating the correlation of template signal intensity with reference data for accurate delineation of boundaries and trajectories. For example, the medial lemniscus travels through the medulla, pons, and midbrain on its way to the thalamus, exhibiting significant changes in shape, size, location, topography, and signal intensity throughout. The trajectory and contour of the medial lemniscus was confirmed by analysis of sequential PV-stained sections, which revealed strong staining and a distinct fiber orientation pattern. In certain cases, other stains were used, as were tracer experiments from the Allen Mouse Brain Connectivity Atlas. This data set was especially useful when an anterograde tracer (rAAV) was injected in a desired anatomic structure restrictively (e.g. red nucleus). In this scenario, trajectories of a fiber bundle (e.g. rubrospinal tract originated from the red nucleus) were confidently traced with modest adjustments according to contours exhibited in other

reference data. Finally, the lateral, third, and fourth ventricles as well as the cerebral aqueduct and central canal were also delineated based on low signal intensity (dark), with the exception of the regions occupied by the choroid plexus, which display higher signal intensity (less dark) and were included in the corresponding ventricles.

Title: Ribbon imaging: high-speed scanning of specialized 3d rois fitted to neuronal structures using an electrical tunable lens

Authors: *M. S. SMIRNOV, L. YAN, R. YASUDA;
Max Planck Florida Inst., Jupiter, FL

Abstract: During high-resolution imaging of subcellular live neuronal activity, rapid image acquisition is often critical to capture the structural and biochemical changes which occur in sub-second timescales. However, the process of raster scanning is poorly adapted to the complex morphological structure of neuronal processes, resulting in a large amount of scanned 'dead space'. We introduce Ribbon Imaging: a low-cost method to selectively scan only the labeled regions in fluorescent biological tissue during live, two-photon excitation without relying on a motorized stage. By manually selecting custom, non-uniform regions of interest, or ribbons, the galvanometer scanning path is reshaped, significantly reducing acquisition time by ignoring non-fluorescent dead space. With the use of an electrically tunable lens in the excitation path, we are able to further increase our scanning efficiency by rapidly and precisely altering focal distance during the acquisition of each ribbon, allowing us to image structures spanning multiple Z planes in a single frame. The ability to quickly image *in vivo* along the Z axis allows for high time-resolution experiments which would otherwise be prohibitively time-consuming due to the vertical orientation of cortical neurons. By combining ribbon imaging with FRET-FLIM, the lifetimes of molecular sensors can be imaged for the first time in 3D over long distances and without the need to collect Z stacks. I will present data showing rapid changes in subcellular molecular activity measured using FRET-FLIM spanning along curved dendrites in hippocampal slices. Furthermore, I will show structural changes in dendritic spines imaged along neurons *in*

vivo at speeds over 20x faster than allowed by standard two-photon microscopy. All hardware and pixel mapping is controlled through a user-friendly interface and accessible MATLAB code built into Scanimage.

Title: Helmholtz phase tomography for label-free imaging of neuronal intracellular transport

Authors: M. E. KANDEL[1], H. SHAKIR[2], C. A. BEST[2], *G. POPESCU[3];
[1]Electrical and Computer Engin., [2]Bioengineering, [3]Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: Neuron growth and development is guided by the transport of intracellular cargo, providing a quantifiable measurement of growth and development. It is nevertheless cumbersome to simultaneously assay the intracellular traffic along with the complete 3D geometry of the extension. Where confocal imaging systems are used, strong optical sectioning is achieved at the expense of photobleaching and phototoxicity. Recent improvements in light sheet microscopy have provided decreased exposure compared to point scanning methods, but such systems are expensive and still suffer from problems associated with fluorescent tags. Often the assay of intracellular traffic is not performed simultaneously with the structure of the neuron, and instead intracellular traffic is measured using a widefield fluoresce technique, while the structure is acquired using a confocal system after fixation.
In order to overcome these obstacles, we show that conventional widefield microscopes can be augmented with phase sensitive modules to provide sub-nanometer sensitivity. The resulting phase map is a measurement of the intrinsic structural information which enables the direct application of the physical equations governing mass transport. In this work we propose and validate a new method for tomographic reconstruction that relies on inverting the 3-dimensional deterministic signal associated with the object's structural informational, namely we directly invert the Helmholtz equation. Crucially, owing to the sectioning capabilities of Spatial Light Interference Microscopy (Wang et al, Opt Express, 2011), we find that our approach does not require the use of a point-spread function, avoiding numerical and physical artifacts typical of

nonlinear structures.
To validate our new found approach, we acquire time-lapse tomograms and apply our method to calculate surfaces areas over which we track mass flow rates, yielding a flux through the neuron's processes. We believe this new analysis scheme is widely applicable to quantifying neuron transport and is particularly well suited to imaging fine structures such as synapses.

Abstract: Rett Syndrome (RTT) is a pervasive, X-linked neurodevelopmental disorder that predominantly affects girls. It is mostly caused by a sporadic mutation in the gene encoding methyl CpG-binding protein 2 (MeCP2).The clinical features of RTT are most commonly reported to emerge between the ages of 6-18 months and implicating RTT as a disorder of postnatal development. However, a variety of recent evidence from our lab and others demonstrates that RTT phenotypes are present at the earliest stages of brain development including neurogenesis, migration, and patterning in addition to stages of synaptic and circuit development and plasticity. We have used RTT patient-derived induced pluripotent stem cells to

generate 3D human cerebral organoids that can serve as a model for human neurogenesis *in vitro*. We aim to expand on our existing findings in order to determine aberrancies at individual stages of neurogenesis by performing structural and immunocytochemical staining in isogenic control and MeCP2-deficient organoids. In addition, we aim to use Third Harmonic Generation (THG) microscopy as a label-free, nondestructive 3D tissue visualization method in order to gain a complete understanding of the structural complexity that underlies human neurogenesis.
As a proof of concept, we have performed THG imaging in healthy intact human cerebral organoids cleared with SWITCH. We acquired an intrinsic THG signal with the following laser configurations: 400 kHz repetition rate, 65 fs pulse width laser at 1350 nm wavelength. In these THG images, nuclei are clearly delineated and cross sections demonstrate the depth penetration capacity (> 1mm) that extends throughout the organoid. Imaging control and MeCP2-deficient human cerebral organoids in 2D sections reveals structural and protein expression-based alterations that we expect will be clearly elucidated via both THG and three-photon fluorescence microscopy.

Title: Algorithmic optimization of DIC microscopy images for electrophysiology and neuronal-tissue reconstruction

Authors: ***B. COLLYER**[1], M. G. THOMAS[2], M. J. WALL[2], P. BANIUKIEWICZ[1], T. BRETSCHNEIDER[1], A. SHMYGOL[3], M. J. E. RICHARDSON[1];

Abstract: Differential interference contrast (DIC) microscopy is a standard technique for imaging transparent biological specimens that are problematic to observe under traditional bright-field illumination. DIC microscopes use the interference of coherent parallel light-beams with slightly differing optical paths to form sharply defined images of the specimen that show an artificial light-shadow effect. Though this shadowing facilitates visual identification of tissue

components, it complicates tissue reconstruction as it is phase and not intensity related. During electrophysiological experiments DIC microscopy video is used to find and identify cells; however, the continuous feed of images is rarely retained or exploited algorithmically to aid the experimentalist in cell identification or reconstruction of the local tissue environment. Here we present preliminary results from a study aimed at extracting useful experimental information from this under-utilized resource. We automated the acquisition of large data sets comprised of multiple DIC images at dense submicrometre intervals in the xyz-planes from neocortex, hippocampus and uterine endometrium. Using deconvolution methods and phase-to-intensity conversion algorithms, the extent to which these data can be used to generate 3D models of tissue was investigated.

Title: High-throughput whole mouse brain vasculature imaging with micrometric resolution using light sheet microscopy

Authors: ***A. P. DI GIOVANNA**[1], A. TIBO[2], L. SILVESTRI[1,4], M. C. MÜLLENBROICH[1], L. SACCONI[1,4], P. FRASCONI[2], F. S. PAVONE[1,4,3];

Abstract: Cerebral blood vessels are charged with the fundamental task of insuring and regulating blood supply depending on neuronal demand, which is known as “neurovascular coupling”. However, in spite of its essential role, we still miss a complete map of brain vasculature network on a brain wide scale, which it is referred to as “angiome”. Moreover, mainstream functional imaging methods like BOLD-fMRI rely on the level of blood oxygenation for indirect measure of neuronal metabolism. A greater understanding of vascular organization

would then also provide a better interpretation of these methodologies. Methods based on micro-optical sectioning tomography (MOST) have shown the possibility to label and image the entire mouse brain vascular system with high resolution and contrast. On the other hand, these approaches still provide a moderate throughput (about 1 week to image a single sample) and use a staining protocol designed for transmission imaging rather than fluorescence, preventing simultaneous imaging of blood vessels and fluorescently-labeled neurons. We describe an approach enabling high throughput *ex vivo* whole mouse brain vasculature imaging using light sheet microscopy in combination with CLARITY technique and a specialized blood vessels labeling. The procedure preserve endogenous fluorescence, allowing for simultaneous imaging of vessels and neurons in transgenic animals. Contrary to serial sectioning techniques, the samples is preserved during imaging acquisition, allowing for successive analysis. Noteworthy, the fast whole brain image acquisition of the method proposed foster a proper characterization of morphological variability both in physiological and pathological conditions. We speculate that the high-contrast provided by our staining and imaging protocol will also be beneficial for the development of segmentation algorithms, which should be fully automatic and capable of dealing with datasets exceeding one TeraByte.

Abstract: Optical tissue clearing has revolutionized researchers' ability to perform fluorescent measurement of individual cells, protein patterning, and structural features within intact tissue samples and organs. However, one complication shared by all optical clearing methods is a spatially inconsistent refractive index, leading to light scattering and focal plane shifts that limit the application of high-resolution fluorescence microscopy to ideal samples, specialized microscope designs, or limited imaging depths. To overcome these technical limitations and lack of flexibility in current light-sheet fluorescence microscope designs, we implemented C-DSLM (cleared tissue digital scanned light-sheet microscopy), a method that utilizes electrotunable lenses (ETL) inserted in both the excitation and detection arms to generate volumetric images without mechanical manipulation of the sample while simultaneously correcting for shifts in focal plane due to spatial heterogeneity of refractive index. C-DSLM has sub-micron in-plane and micron axial resolution, compensates for inhomogeneous refractive index, reduces background using HiLo background subtraction, allows imaging deep within large samples without sectioning, eliminates mechanical drift as well as physical distortion for small deformable samples, and is compatible with any clearing protocol. These advancements enable high-resolution fluorescent imaging without complicated refractive index matching, custom microscope objectives, computationally expensive deconvolution, or destructive sample sectioning. In addition, we have developed a computational analysis pipeline to reconstruct and filter volumetric images to aid researchers in identification of key features within these extremely large imaging datasets. We demonstrate the flexibility and power of our methodology by quantifying features in tissue from multiple animal models, including two unique measurements: 1) quantification of individual oligodendrocyte cells and myelin networks within intact optically cleared mouse brain and spinal cords; and 2) quantification of changes in the vascular and neuronal networks due to experimental retinopathy of prematurity within intact optically clear albino rat eyes.

Title: An integrated photonic probe for light sheet microscopy

Authors: ***F. YE**[1], B. AVANTS[1], J. ROBINSON[1,2,3];
[1]ELECTRICAL AND COMPUTER ENGINEERING, Rice Univ., Houston, TX;
[2]Bioengineering, RICE UNIVERSITY, Houston, TX; [3]Neurosci., Baylor Col. of Med., Houston, TX

Abstract: The ability to record the neural activity from many individual cells in three dimensions in the living brain is a major technological challenge. Optical techniques that measure changes in calcium or voltage provide a promising route toward this goal, but delivering light to specific regions deep within the brain is limited by the scattering of neural tissue. By focusing light to a single illumination plane, researchers can perform high-speed volumetric imaging or optically stimulate cells within specific layers of tissue. Typically, selective plane illumination relies on macroscopic cylindrical lenses that are not compatible with integrated microdevices which can be implanted into the body or arrayed on a chip. To overcome this limitation, we use planar metallic lenses combined with integrated photonic devices to create a microscale probe capable of producing planar illumination. Our results show that a single metallic slit is an efficient nanophotonic element for light sheet illumination. Further, we have integrated the microlens onto the AlN resonant waveguide gratings that radiate vertically from a planar chip. To scan this plane without moving the probe, we implemented three gratings with resonant ring filters tuned to unique resonant wavelengths within the absorption band of GCaMP. We can thus illuminate individual planes at specific depths within the tissue by tuning the excitation wavelength. This combination of radiating photonic elements and planar metallic lenses enables us to achieve light sheet illumination that can be used for deep brain imaging with an integrated probe that does not require a large-footprint pulsed laser needed for multiphoton microscopy.

Title: Design and implementation of multi-signal, time-lapse digital reconstructions of neuronal morphology

Authors: *S. NANDA[1], H. CHEN[2], R. DAS[3], H. PENG[4], D. N. COX[3], G. A. ASCOLI[1]; [1]Krasnow Inst. For Advanced Studies, Fairfax, VA; [2]Dept. of Computer Sci. and Bioimaging Res. Ctr., The Univ. of Georgia, Cortical Architecture Imaging and Discovery Lab., Athens, GA; [3]Neurosci. Inst., Georgia State Univ., Atlanta, GA; [4]Allen Inst. for Brain Sci., Seattle, WA

Abstract: Mature neuronal arbors develop from growth processes regulated by complex molecular interactions. The convergence of extracellular, intracellular, and activity-dependent molecular events on the cytoskeletal effectors, primarily actin filaments and microtubules, facilitates neural development as well as maintenance of mature morphology. Several effective techniques to digitally reconstruct and analyze neuronal morphologies exist, but the quantification of their structural dynamics remains challenging. Current descriptions of neuron morphology are static and do not contain precise representations of intracellular components. Recent advances in tissue labeling and imaging techniques necessitate the co-evolution of the standard SWC format for representing digital arbor tracings. Generation of time-varying reconstructions is required, co-registering subcellular information with neuronal morphology. Additionally, large numbers of augmented reconstructions are required to develop data-driven mechanistic models of neuronal development and of structural plasticity.
Here we present the definition of a new multichannel file structure and a new Vaa3D plug-in to handle this new type of data. We also introduce a design to tag dynamic structural changes in a time-coded manner. Next, we illustrate ongoing progress in using the multichannel/time-lapse system on developing neurons in the *Drosophila* larva. Time-varying images of overall neuronal morphology along with fluorescently labeled subcellular cytoskeletal components are digitally traced into the aforementioned file structures. These new reconstructions enable complete statistical analysis of the structural changes and the underlying molecular processes. Lastly, we will demonstrate how stochastic computational simulations of neuronal growth, statistically constrained by and validated against these novel reconstructions, can help select the most

experimentally promising genetic alterations to gain additional biological insight.
The designed data structure and research approach are also broadly applicable to other types of multichannel/time-lapse neuronal imaging, such as quantification of voltage changes or tracking the arbor-wide movement of any subcellular component of interest.

Title: Automated 3D analysis of confocal microscopy images by 3D-ACE reveals widespread molecular and cellular adaptions in the spinal nociceptive circuitry of monoacylglycerol lipase knockout mice

Authors: *C. I. PONGOR[1], S. G. WOODHAMS[1], B. BENJAMIN[1], B. DUDOK[2], L. BARNA[2], M. KANO[3], K. SAKIMURA[4], M. WATANABE[5], I. KATONA[2];

Sch. of Med., Univ. of Tokyo, Tokyo, Japan; [4]Brain Res. Inst., Niigata Univ., Niigita, Japan; [5]Dept. of Anat., Hokkaido Univ. Sch. of Med., Sapporo, Japan

Abstract: Immunofluorescence staining and confocal microscopy are widely used to study specific molecular alterations underlying physiological or pathophysiological processes. However, changes in fluorescence intensity levels can either directly reflect up-or downregulation of the target protein or be indirectly caused by the appearance or disappearance of subcellular profiles harbouring the target protein. Due to the limited resolution and sensitivity of confocal microscopy, reliably distinguishing between these two possibilities in a high yield manner is often difficult and laborious. To circumvent this obstacle, we developed 3D-ACE; an open-source, easy-to-use analysis tool with a graphical user interface.
The 3D-ACE plug-in for Fiji enables unbiased, object-based 3D analysis of co-expression of

target proteins on large batches of confocal microscopy images, thereby facilitating automatized analysis of large sample sizes. We chose to write 3D-ACE in Python, a language widely in the scientific community, and utilized the plugin "3D Objects counter" for the image processing platform Fiji and ImageJ. In short, the plug-in first segments the images, then finds objects in the two channels and determines which objects overlap. A database of properties of objects, such as their volume, intensity, and overlapping ratio is created. Quantitative data can be attained by setting filters for this database.
As a proof of principle, we applied 3D-ACE to reveal the molecular and cellular adaptations following deletion of monoacylglycerol lipase (MGL), the predominant degrading enzyme of the endocannabinoid messenger 2-AG. Unexpectedly, our data uncovered a remarkable cell-type-specific reorganization of the local excitatory, but not inhibitory, circuits in the superficial laminae of the spinal dorsal horn. These extensive molecular and cellular adaptation mechanisms may explain the lack of the expected analgesic phenotype in MGL knockout mice, and therefore the failure of chronic complete blockade of MGL, a theoretically promising treatment for chronic pain via elevation of 2-AG signalling at CB_1 receptors. . Finally, to test the validity of the workflow, results from the automated analysis were compared to a manual method for two of the sample sets. Importantly, both methods yielded similar results, but the automated analysis was far more efficient. 3D-ACE analyzed an order of magnitude more structures in a fraction of the time (200x faster), producing stronger statistical significance and removing selection bias when compared to the manual analysis.

Title: VividSTORM: a novel open-source software for super-resolution and confocal microscopy images

Authors: *V. MICZÁN[1,2], L. BARNA[1], B. DUDOK[1,3], A. HORVÁTH[2], J. R. GLAVINICS[1,2], Z. I. LÁSZLÓ[1,3], I. KATONA[1];
[1]Momentum Lab. of Mol. Neurobio., Inst. of Exptl. Medicine, HAS, Budapest, Hungary; [2]Fac. of Information Technol. and Bionics, Pázmány Péter Catholic Univ., Budapest, Hungary; [3]Sch. of Ph.D. Studies, Semmelweis Univ., Budapest, Hungary

Abstract: Super-resolution light microscopy techniques can visualize the nanoscale molecular composition of brain circuits with similar localization precision of target proteins such as immunogold electron microscopy. Moreover, the possibility to simultaneously visualize multiple proteins, together with the faster tissue processing protocols and the higher immunolabeling density represents potential major advantages over electron microscopy in several neuroscience applications. Indeed, we have recently shown that combining Stochastic Optical Reconstruction Microscopy (STORM) with confocal microscopy allows rapid and efficient nanoscale molecular imaging within morphologically and neurochemically defined cellular and subcellular context in intact brain circuits (Dudok et al., 2015, Nature Neuroscience, 18:75-86). To further facilitate the correlated visualization and data analysis of super-resolution and confocal images, we have developed the open-source software VividSTORM, and recently implemented multiple new features not yet available in any other microscopy software packages. VividSTORM offers the simultaneous, correlated visualization and analysis of both pixel-intensity-based (such as widefield, TIRF, confocal, STED or SIM) and coordinate-based (such as STORM or PALM) microscopy data. By using the graphical user interface of VividSTORM, the key steps of the correlated analysis of the two different imaging modalities are: i) to overlay the pixelated image and the single-molecule localization coordinates; ii) to outline the labelled target cell or subcellular structure on the conventional microscopy image as region-of-interest (ROI); iii) to filter those specific single molecule localization points which belong to the identified target profile; iv) to perform coordinate-based analysis of the super-resolution imaging data. We implemented several novel tools in VividSTORM in order to facilitate this process including: manual and automatic, fiducial-marker-based or image-based alignment methods; an unbiased ROI selection feature by automated 2D or 3D segmentation of the pixelated image using a modified Morphological Active Contours Without Edges (MACWE) algorithm; and the analysis of molecular clustering by using multi-scale Bayesian or DBSCAN methods. The batch analysis of pre-selected ROIs is also supported to further facilitate high-throughput correlated confocal and super-resolution data analysis and functional interpretation of quantitative molecular observations within identified cellular and subcellular structures.

Title: HeadLight: plug & play tool for visualization andanatomical analysis of whole brain datasets

Authors: K. U. VENKATARAJU, 11724[1], *P. OSTEN[2];
[1]Cold Spring Harbor Lab., COLD SPRING HARBOR, NY; [2]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Today whole-brain imaging in multiple modalities enables neuroscientists to acquire brain datasets of different animal models at various developmental stages. Here we present a toolchain called “HeadLight” (a cross-platform GUI application built using CMake, C++, ITK, VTK and matlab) that can be used to process and analyze large image-based datasets. Using this plug & play tool, the neuroscience community can register whole-brain datasets to reference brain volumes linked to available atlases, as well as build their own atlases for different types organisms based on data acquired by different imaging modalities. As an example, we demonstrate the use of Headlight for co-registration of two mouse brain atlases, one generated by magnetic resonance imaging (MRI) and the second created by serial two photon (STP) tomography that is linked to the Allen mouse brain atlas. We also use the reference STP (RSTP) framework to register brains imaged by light-sheet fluorescent microscopy (LSFM), demonstrating a cross imaging-platform versatility. The datasets registered in Headlight can be browsed alongside a view of hierarchical anatomical structures. In addition, a built-in cell-counting module, based on Graphical Processing units (GPU), allows for fast detection of fluorescently labeled cells. The cell count-based data can be used to generate unbiased cell density maps across the entire mouse brain, as well as to create 2D “flat” maps of cortical cell distribution in different layers. Headlight thus provides a versatile whole-brain registration and viewing platform that can be easily used by many neuroscience laboratories.

Abstract: Fast and accurate quantification of morphology is a critical challenge in determining neuronal cell types in the brain. To address this challenge, we introduce SmartScope2, the first open source, automated neuron reconstruction machine that integrates automated bioimage analysis and rapid multiphoton imaging. The system integrates a commercially-available microscope with open-source software control for rapid 3D visualization and analysis. We show that SmartScope2 can automatically image and digitally reconstruct neuronal morphology with reduced imaging, storage and analysis loads by leveraging on-line data analysis and sparse neuronal geometry.

(Pharmacology), North-West Univ., Potchefstroom, South Africa; [7]Dept. of Pharmacology, Karolinska Inst., Stockholm S-11281, Sweden; [8]Dept. of Mathematics, Aarhus Univ., Aarhus, Denmark

Abstract: Background: Superimposed effect of early life adversity, namely maternal separation is known as one of the possible risk factors for the development of the neuropsychiatric disorders. Quantitative investigation of the structure of cerebral cortex in preclinical studies could help to increase our knowledge about the neurostructural underpinnings of the early life stress. Therefore, in the present study, we aimed to investigate the superimposed effect of maternal separation as an environmental factor in a genetic rat model of depression (Flinders Line rats) on the neurostructural components of medial prefrontal cortex (mPFC).
Methods: The degree of neuronal minicolumnarity was tested by a newly developed cylinder *K*-function, in layer III of medial prefrontal cortex of rats. The acquisition of 3D coordinates of neurons was performed by optical disector in a well-defined region using optical microscopy. Alteration in shape, orientation and volume of neurons in layer III of mPFC between three groups of rat models: Flinders Sensitive Line (FSL) as depressed rats, FSL with maternal separation (FSL-MS) and Flinders Resistant Line (FRL) rats as a control group were tested by a newly developed estimator of volume tensors.
Result: Findings of this study related to the degree of neuronal columnarity in three animal groups demonstrated a subtle anisotropy in parallel to mPFC layers in the FSL-MS but not significant difference. Volume tensor estimation showed no significant alteration from sphere shape in neurons obtained from the FSL-MS ($p>0.05$) while the obtained results of other groups indicated a prolate shape ($p<0.05$).
Conclusion: Our results suggest that the interaction between the environmental factor (maternal separation as an early life adversity) and genetic factor (genetic animal model of depression) is reflected in a quantifiable structural alteration of mPFC including neuronal shape factor.

Title: A high volume throughput of 3D morphometrics of the CNS

Authors: *M. C. WU[1], J. HO[2], D. D. QUACH[1];
[2]Neuroinformatics, [1]Neurodigitech, San Diego, CA

Abstract: 3D visualization is essential to disclose both cytoarchitecture and the morphology of the CNS. With the advanced microscopy, the immunofluorescence method can further examine biochemical property of individual neurons. Nevertheless, using this protocol is unable to achieve the goal of a high volume, high throughput imaging and morphometrics at multiple ROIs (Regions of Interest) of the brain, mainly due to signal degradation. Thus, this method is only able to characterizie morphological features of a small population of neurons within one or limited number of ROIs of the brain. We have developed a high-throughput protocol added to the current imaging platform that combines Golgi-Cox/IHC and Nikon Eclipse microscopy to produce 3D profiles of multiple neuron populations at multiple ROIs of the brain. In brief, a series of Golgi-stained sections (200 um thick) of the brain will be digitized using pre-set imaging parameters to register x, y, z coordinates of the ROIs, then screened through internal morphological features of the neuron, such as 1) apical or basal dendrites of pyramidal cells in the cortex or hippocampus, and 2) the dendrites of medium spiny neurons in the striatum, etc. With precisely registered 3D coordinates of sampled neurons of the entire brain, the rigorous high magnification digitization is proceeded under 100x (oil immersion) lens using the customized high-powered computing desktop system. Thus, we are able to digitize 5 to 7 neurons per day, which generates thousands of Gigabytes storage. This throughput will be accelerated by improved computing powered system. With the 3D automatic image analysis software, we are able to generate a large-scale 3D morphometric data bank eventually that can be complementary to current leading brain bank, i.e., Allen Brain Atlas, Human Connectome and Blue Brain projects.

Title: Wireless control of cellular function by activation of EPG, a novel gene responsive to electromagnetic fields

Authors: *J. BANERJEE[1,2], S. PARK[1,2], M. SORRELL[1,2], J. PEVSNER[1], W. GUGGINO[3], A. GILAD[2], G. PELLED[1,2];
[1]Kennedy Krieger Inst., Baltimore, MD; [2]Radiology, [3]Physiol., Johns Hopkins Univ., Baltimore, MD

Abstract: Major advances in molecular and synthetic biology have revolutionized the capability to control cell excitability in living organisms. Yet, the majority of the technologies that manipulate cellular function in a cell-spatio-temporal-specific manner demand the use of optics, drugs, radio-wave or ultrasound. Identification of genes responsible for controlling cellular function by non-invasive electromagnetic fields (EMF) is still in its infancy. In the present study we investigated the potential of an alternative and novel method to wirelessly control cellular function through the transmission of non-invasive EMF.
Various aquatic species use electromagnetic fields for orientation and navigation, but the cellular mechanism by which this is accomplished remains unknown. One of these species is the *Kryptopterus bicirrhis* (glass catfish). Using expression cloning in *Xenopus laevis* oocytes, we identified a single gene from *K. bicirrhis* that, once expressed in the oocytes, produces changes in the oocyte's membrane current when activated by EMF. We termed this gene the *electromagnetic perceptive gene (EPG).* Bioinformatic analysis of EPG showed that this previously uncharacterized gene encoded a putative membrane associated protein. The encoded protein possesses a highly conserved UPAR_LY6 domain that may interact with the beta subunits of voltage gated sodium channels. We expressed EPG in HEK293T mammalian cells and confirmed its expression in the membrane. To examine whether remote activation of EPG can modulate neuronal function, neuronal cultures were transduced using adeno-associated virus expressing EPG under the excitatory neuron specific promoter, Ca^{2+}/calmodulin-dependent protein kinase II (pAAV2-CaMKIIprom::-EPG-IRES-hrGFP). The cultured neurons were loaded with the calcium indicator Fura 2-AM. 10 s long EMF pulses (250 mT) induced an average of 21 ± 9% increase in intracellular calcium in EPG-expressing neurons (n=9; $p<0.0005$), but no responses in control or non-infected neurons. Thus, the data demonstrates that wireless activation of EPG in neuronal culture results in significant changes in neuronal activity. Furthermore, stereotaxic injections of AAV expressing EPG in the rat hippocampus have resulted in location specific EPG expression suggesting that EPG can be expressed in a specific cellular population and in a specific location in the rodent brain.
We anticipate that this discovery has the potential to transform the neuroscience field, by providing a tool that offers non-invasive, cellular-specific, temporal-specific and region-specific stimulation.

Title: Neuromodulation of hippocampus function by EPG, a novel gene responsive to electromagnetic fields, decreases seizure activity in the kainic acid rat model of epilepsy

Authors: *B. E. THEISEN[1,2], G. BAR-KLEIN[3,4], H. DIETZ[3,4], A. FATEMI[1,2], A. GILAD[5], G. PELLED[1,5];
[1]Kennedy Krieger Inst., Baltimore, MD; [2]Dept. of Neurol., [3]The Howard Hughes Med. Inst., [4]Inst. of Genet. Med., [5]Dept. of Radiology, Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Epilepsy is a common chronic neurological disorder effecting 0.5-1% of the population. Evidence from patients and animal studies suggest that neuromodulation can reduce seizure occurrences. For example, studies have shown that deep brain stimulation can inhibit seizure development and optogenetics approaches have shown to modify seizure-onset in epilepsy. However, these invasive technologies could lead to unpredictable and undesirable side effects.
We have recently discovered and cloned a new gene from the *Kryptopterus bicirrhis* (glass catfish) that is sensitive to electromagnetic fields. We term this gene electromagnetic perceptive gene (EPG). Once expressed in cultured neurons, wireless induction of electromagnetic fields leads to increases in intracellular calcium concentrations. Furthermore, immunohistochemistry confirmed that the EPG can be expressed under cell-specific promoters in specific brain location. Here, we tested whether the EPG technology could be used as a neuromodulation approach in the kainic acid (KA) rat model of epilepsy.
Six adult rats were treated with KA (i.p.) to induce spontaneous recurrent seizures. Two to three months after KA administration, telemetric ECoG electrodes were implanted in the cortex allowing continuous recordings. Two weeks following electrode implantations, the baseline number of seizures was determined for each KA rat as the average number of seizures per day over a six days period. Then, bilateral stereotaxic injections of virus containing the EPG (pAAV2-CMVprom::-EPG-IRES-hrGFP) into the rats' hippocampus were performed. A viral vector containing only GFP reporter was used as control. Two weeks following stereotaxic viral injections, the average number of seizures was reevaluated. KA rats that have been injected with virus containing the EPG showed significant reduction in the number of seizures (17.12±4.3 initially to 9.12±3.8 seizures per day, 46.86±9.7% decrease; $p<0.05$; $n=4$). KA rats that were

injected with the virus containing only GFP (control) did not show significant reduction in the number of seizures (12.67±2.6 to 10.25±4.6, 15.96±4.8% decrease; n=2). Four weeks following initial viral injections, electromagnetic activation of the EPG in the KA rats was performed, which led to further decreases in seizure activity (3.6±1.23 seizures per day, 80.35±4.2% decrease).
This preliminary data suggests that wireless activation of EPG by external electromagnetic fields, or possibly, by electromagnetic changes induced by the seizure themselves, leads to suppression of seizures. Further investigation could lead to a new, non-invasive alternative to current clinical standards.

Title: Wireless ultrasonically-powered neurostimulators with bioimpedance measurement capacity

Authors: *D. CELINSKIS[1], B. C. TOWE[2];
[1]Sch. of Engin., Brown Univ., Providence, RI; [2]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: Despite the immense improvement in the quality of life achieved using the state-of-the-art neurostimulation devices, existing neurostimulators suffer from important limitations of size, battery life, and tissue damage due to lead placement and implantation. To address these limitations, we have been developing a platform for tetherless sub-millimeter size neuroelectric devices that rely on ultrasonic energy harvesting. Our present work focuses on passive neuroelectronic devices that in addition to neurostimulation, report tissue impedance to provide a sensitive indicator of blood flow for the conditions involving changes in tissue perfusion, such as a peripheral vascular disease. We demonstrate an improved microscale implantable impedance measuring system that employs the transit time nature of ultrasound to achieve much higher dynamic range and improved tissue impedance characterization. Experiments using tissue models allowed us to characterize device impedance measurements in the range of physiological tissue conductivities to an accuracy of 10%. Changes in tissue blood flow can translate to the changes of tissue impedance as high as hundred percent and thus this suggests a high sensitivity.

We discuss our results in terms of their potential to serve as a completely integrated feedback control system that would allow both neurostimulation control of a physiologic response such as vasodilation, and then immediately and locally monitor tissue impedance as an indicator of the achieved result and the efficacy of treatment. The ability to wirelessly stimulate and record its effect from the same tissue using scalable passive implantable devices will enable dynamic control over treatment protocols and paves a way towards adaptable, personalized neuroelectric medicine.

Title: Studying the effects of focal 3mhz ultrasound on neural activity in transgenic mice

Authors: *T. SATO, D. WU, M. FLANNERY, M. SHAPIRO, D. TSAO;
Caltech, Pasadena, CA

Abstract: Transcranial focused ultrasound (tFUS) is a highly promising tool for non-invasive neuromodulation. Studies have shown the potential for modulating and inducing sensations in the human somatosensory cortex (Legon et al. 2014, Lee et al. 2015). However, the mechanisms for how ultrasound affects neurons and what parameters are critical are unknown. Human studies have shown large variability within subjects, and it is very difficult to optimize parameters in humans. A refinement of our understanding is needed to apply ultrasonic neuromodulation in humans in a safe, systematic manner. Many of the studies so far *in vivo* and *ex vivo* in animal models have utilized electrophysiological means or coarse imaging methods (BOLD, PET) requiring intensive labor with invasive probes that could affect how ultrasonic energy interacts with neurons or offering poor spatial and temporal time scales. In transgenic mice with widespread cortical GCaMP6 expression, calcium imaging of neural activity provides a non-invasive means of studying large populations of neural activity with high temporal and spatial resolution. The long wavelength of low-frequency (500kHz or lower) ultrasound that is normally used in neuromodulation studies, however, precludes the use of simple means to deliver ultrasound to small target regions of the mouse brain with a high dynamic range in power. In this study, we apply 3MHz ultrasound, with a focal size of <800um, while observing responses to

both baseline signals and responses to visual stimulation. In addition, we use a fiber-optic hydrophone to directly measure *in vivo* the pressure and temperature changes in this preparation to account for the complexities of reflections and interference patterns, instead of simply using measurements of the ultrasound field in water or using computational methods to estimate the ultrasound field in a preparation.

Title: High-frequency deep brain stimulation of the fornix improves memory consolidation and causes network-level neuroanatomical remodelling in an Alzheimer's mouse model

Authors: *D. R. GALLINO[1], G. A. DEVENYI[3], J. GERMANN[2], S. FREY[4], A. P. MATHIEU[2], M. CHAKRAVARTY[5];
[1]Cerebral Imaging Ctr., Douglas Mental Hlth. Univ. Inst., Verdun, QC, Canada; [2]Cerebral Imaging Ctr., Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada; [3]Dept. of Psychiatry, Douglas Mental Hlth. Univ. Institute, McGill Univ., Montreal, QC, Canada; [4]Rogue Res., Montreal, QC, Canada; [5]Psychiatry, Biomed. Engin., Cerebral Imaging Center, Douglas Mental Hlth. Univ. Institute, McGill Univ., Montreal, QC, Canada

Abstract: Deep brain stimulation (DBS) involves the targeted delivery of high-frequency electrical stimulation to brain regions affected by neuropsychiatric disorders using a surgically implanted electrode. Recently a clinical trial has been initiated to determine the utility of DBS of the fornix for the treatment of Alzheimer’s disease. Here we study the longitudinal effects of

DBS on brain structure and behaviour using a mouse model of Alzheimer's disease. We overcome MRI-compatibility issues of traditional metal electrodes using carbon fibre-based electrodes for delivery of DBS.
10 week-old male and female 3xTg mice received bilateral electrode implantion +/- 0.75 mm bilaterally, perpendicular to the skull plane at bregma, and at a depth of 3.25 mm to target the body of the fornix. Sham (n = 2M/6F) or monophasic stimulation (n = 3M/4F) was delivered for 1 hour at settings homologous to those used in humans: 100 Hz, 100 μA, ~1.5 V with pulse width of 100 μs. Memory and cognitive flexibility was assessed weekly in water maze with changing platform positions. MRI image acquisition occurred 3 days before stimulation, 3 days and 6 weeks post stimulation. Animals were imaged in a 7T Bruker Biospec 70/30 USR using a T2 weighted 3D FLASH acquisition with 100 μm isotropic voxels.
Latency and pathlength in the water maze did not significantly differ between sham and stimulated animals. However, during weeks 3-4 post stimulation, animals showed a significant (P=0.013) bias to return to the previous week's platform position (fig.1). Deformation-based morphometric analysis revealed significant (FDR 5%) relative growth of the anterior thalamus after 6 weeks in stimulated animals (fig.1).
Our findings suggest that acute DBS of the fornix enhances memory consolidation and makes memories harder to extinguish 3-4 weeks post stimulation. This may be mediated by remodelling of the anterior thalamus and hippocampus. The innovative use of carbon fiber electrodes allowed animals to be imaged with minimal invasiveness due to MRI acquisition artifacts and lend themselves well to preclinical longitudinal designs.

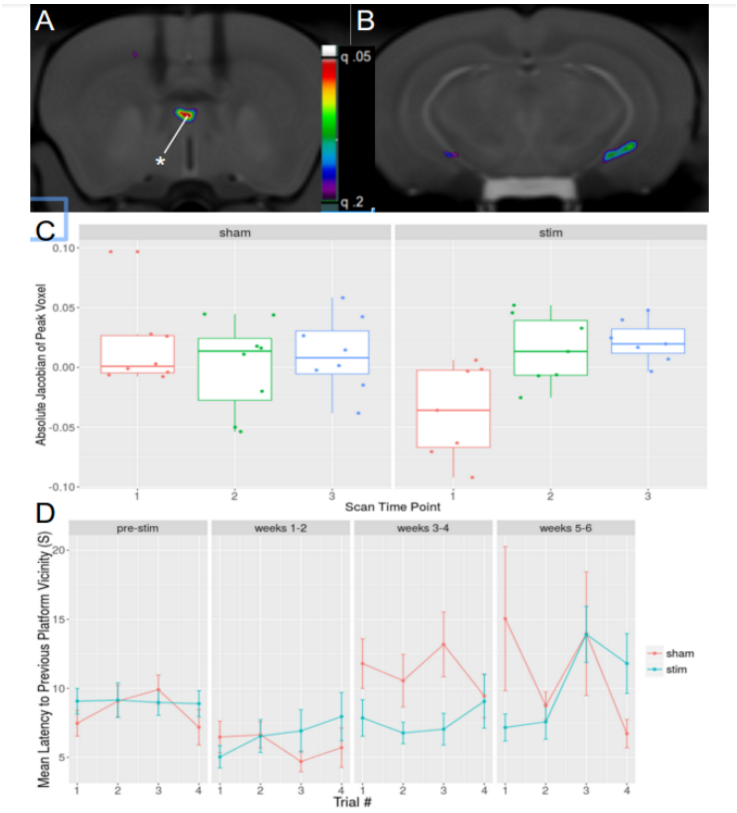

Figure 1. A&B. T statistic maps of relative deformation in stimulated animals when compared to sham with respect to time. Anterior thalamus and ventral hippocampus shown. FDR from 20% to 5% displayed in color. Underlays are coronal views of final registration. C. Absolute deformation values from peak voxel (denoted in A by asterisk) in anterior thalamus plotted by scanning time point (3 days prior, 3 days and 6 weeks post-stimulation). D. Latency to the previous week's platform position in water maze, displayed as mean +/- SE. During weeks 3 and 4, stimulated mice return in significantly less time.

Title: A new paradigm for neural restoration: low level random electrical stimulation can enhance vibration perception in diabetic neuropathy

Authors: *E. GIOKAS[1], K. MIGDAL[2], J. MICHALIK[2], L. REYES[2], P. BREEN[3], J. M. SERRADOR[4,2];

[1]New York Col. of Podiatric Med., New York, NY; [2]War Related Illness and Injury Study Ctr., Dept of Veteran Affairs, East Orange, NJ; [3]Biomed. Engin. and Neurosci., Western Sydney Univ., Kingswood, Australia, Australia; [4]Pharmacology, Physiol. & Neurosci., Rutgers, Newark, NJ

Abstract: Peripheral sensory loss is a common problem in patients with diabetes. Loss of feeling in the foot can lead to chronic foot problems and amputations. Reversing this sensory loss could greatly improve quality of life and prognosis. A novel paradigm that has been shown to improve sensory perception is the use of stochastic noise applied at the sensory receptor. Our hypothesis was that applying stochastic noise to the conduit nerve, rather than the sensory receptor, would improve neural traffic and vibration perception threshold.
Twelve healthy controls (1 Female, Age: 50±13 yrs; Height: 173±9 cm; Weight: 83.8±12.9 kg; BMI: 28.2±5.2) and five participants with Diabetes (Age: 59±9 yrs; Height: 174±1 cm; Weight: 94.7±15.6 kg; BMI: 30.8±5.1; HbA1c: 7.7±0.9) volunteered for the study. Electrodes were placed proximally to the medial and lateral malleoli such that the tibial nerve was stimulated. We evaluated the vibration perception threshold (VPT) of the plantar side of the hallux (big toe) using a Neurothesiometer. Stimulation was randomly applied, with two control conditions (no electrical stimulation) and four stimulation conditions (0±15μA, 0±30μA, 0±45μA, 0±60μA, 0±75μA, 0±90μA, 0±105μA). Participants were unable to perceive stimulation. Both participants and experimenter performing the VPT measures were blinded to stimulation condition. Assessment of sensory function in the big toe of participants demonstrated that healthy controls had significantly lower VPTs (Mean: 12.2; Range 2.5-21 V) than participants with diabetes (Mean: 28.5; Range 6-50 V, P=0.011). Application of the low levels of subsensory random stochastic electrical noise resulted in significant improvement in VPT. Effects of stimulation on VPT was different for each individual with overall 60.3% of the trials resulting in improvements in VPT (Range 14.3-100% for each participant) while 23.8% resulted in impairment of VPT. There was no difference between baseline and sham (0 μA) conditions. Stimulation resulted in significant improvements in VPT ($P<0.001$) in both controls (Baseline: 12.2±6.5 vs Optimal Level: 9.5±5.5 V) and diabetics (Baseline: 28.5±17.5 vs Optimal Level: 23.1±15.8 V) with greater absolute improvement in diabetics. However, examining percent improvement, effects were similar between controls (+25.8±19.4%) and diabetics (+19.9±11.7%).
These findings represent a novel method to treat sensory loss in diabetic neuropathy. Since participants cannot feel the stimulation, it could provide an effective treatment with no side effects. This work was supported by the War Related Illness and Injury Study Center within the Department of Veteran Affairs.

Title: Modulation of body mass composition using galvanic vestibular stimulation.

Authors: *J. MCKEOWN, P. D. MCGEOCH, H. PETERSON, V. S. RAMACHANDRAN; Ctr. for Brain & Cognition, UC San Diego, LA Jolla, CA

Abstract: In a series of experiments participants consumed high calorie diets for prolonged periods, in some cases up to 10,000 calories a day, while at the same time refraining from physical exercise. In most cases the subjects gained a surprisingly modest amount of weight. This observation supports the concept that there is a "set-point" for body mass composition as modulated by the hypothalamus. Deviation too far in either direction from this set-point is restricted by ill-understood mechanisms.

It has been known for some time that animals living in a state of chronic centrifugation show a marked change in their body mass composition. In particular, they go through a process of "de-fatting", with their total body fat dropping from in excess of 20% to around 5%. Experiments using a type of mutant mouse that is missing the otolith organs from its inner ear have shown that, rather than being a non-specific effect of hypergravity, this change in body mass composition appears to be mediated by a specific vestibulo-hypothalamic pathway.

We attempted to replicate its effect by stimulating the otolith organs using galvanic vestibular stimulation (GVS). This technology involves passing a small electric current into the skin overlying the mastoid process, and has been shown at currents less than 3mA to preferentially activate the otolith organs.

In a pilot study we recruited 10 overweight (BMI 25-30) or obese (BMI >30) subjects. Three were randomly selected as blinded control subjects and 7 were given between 20 and 40 hours of binaural GVS in a 0.5 Hz sinusoid as tolerated up to 2mA. All the participants had their body mass composition measured at the start and end of the study period using dual energy X-ray absorptiometry. We found that in contrast to the control group, the GVS group had up to a 16% reduction in their total body fat. This observation was supported by an analysis of secretion of leptin, the "satiety hormone", in the saliva of subjects undergoing GVS.

We postulate that prolonged vestibular stimulation most likely acts via the parabrachial nucleus in the pons which is known to integrate vestibular, sympathetic and parasympathetic afferent activity. Via this pathway GVS modulates the function of the dorsomedial hypothalamus. We suggest that repeated GVS acts to alter the set-point for body mass to lower the proportion of body fat.

Title: Blood pressure and heart rate responses to vestibular stimulation in aged and young-adult male and female rats.

Authors: ***G. P. MARTINELLI**[1], G. R. HOLSTEIN[2];
[1]Dept. Neurol., [2]Depts. of Neurology, Neuroscience, and Anat., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Acute changes in blood pressure (BP) are regulated by the baroreflex, which conveys baroreceptor signals initially to the solitary nucleus and ultimately to presympathetic neurons in the rostral ventrolateral medulla (RVLM). This pathway maintains homeostasis through negative feedback. In contrast, the vestibular system can modulate BP through a more direct and feed-forward mechanism, the vestibulo-sympathetic reflex (VSR), which is activated during movement and changes in posture re:gravity (e.g. when rising from a seated or lying position). The VSR assures adequate cerebral perfusion during these postural adjustments, allowing humans to stand up without fainting due to blood pooling in the lower body. VSR dysfunction has been postulated to underlie neurogenic orthostatic hypotension in some individuals, and orthostatic hypotension is significantly more prevalent and severe in the elderly.
The present study compared BP and heart rate responses to tilt and sinusoidal galvanic vestibular stimulation (sGVS) in isoflurane-anesthetized young adult (4-6 mo) and aged (24-26 mo) male and female F344 rats obtained from the NIA Aged Rodent Colonies. At least one week prior to stimulation, animals were implanted with an intra-aortic telemetric device (DSI Technologies) that transmitted physiological data including HR, BP (systolic, diastolic and mean arterial pressure), HR variability, body temperature and other relevant parameters. These data were analyzed offline using proprietary Ponemah software (DSI). For tilt stimulation, anesthetized rats were placed prone on a servo-controlled tilt table, and raised in the pitch plane from horizontal to 70° nose-up (0.91g). Animals remained in that position for 5 min before being returned to the prone position for 10 min. This sequence was repeated 5 times per session per rat. For sGVS, single 3 mA and 0.05 Hz sinusoids were presented 10 times at 4 min intervals. Testing was

repeated 3 times in each session with a 45 min rest period between each stimulus sequence. Each animal was tested at least twice with each stimulus.
To identify the vestibular neurons activated by these stimuli, rats were perfused with mixed aldehydes 90 min after the stimulation and the brainstems were sectioned serially. One set of tissue sections was stained for c-Fos protein to map the locations of the vestibular neurons activated by pIRs of the individual end organs. Other sets of sections were used for immunofluorescence detection of glutamate, GABA and PACAP in activated vestibular neurons. We found marked differences in the physiological responses of aged vs young adult animals, and corresponding alterations in the activated VN neurons.

Title: Vestibular nuclear neurons of the vestibulo-sympathetic reflex (VSR) activated by pulsed infrared stimulation of vestibular end organs.

Authors: *G. R. HOLSTEIN[1], G. P. MARTINELLI[2], R. D. RABBITT[3], S. M. RAJGURU[4]; [1]Depts Neurol, Neurosci, Anat/Cell Bio, [2]Dept. Neurol., Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]Univ. of Utah, Salt Lake City, UT; [4]Univ. of Miami, Miami, FL

Abstract: Studies in humans and experimental animals show that vestibular system activation can modulate blood pressure (BP). In humans, otolith stimulation using linear acceleration causes BP changes that are attenuated in patients with bilateral vestibular dysfunction. Off-vertical-axis rotation, a specific otolith stimulus, produces increases and decreases in muscle sympathetic nerve activity (SNA) that are in-phase with the head-up and head-down tilt components of the stimulus, respectively. Linear acceleration, head/body-up tilt and electrical stimulation of the vestibular nerve increase SNA and/or raise BP in experimental animals as well. These responses are mediated by a VSR pathway from the vestibular end organs to the vestibular nuclei (VN), which in turn project to presympathetic neurons in the rostral

ventrolateral medulla (RVLM). We previously demonstrated in rats that the VSR pathway can be activated by tilt and sinusoidal galvanic vestibular stimulation and that activated VSR neurons in VN and RVLM accumulate c-Fos protein. Maps of cFos-positive activated vestibular neurons that were also backfilled following a retrograde tracer injection in RVLM showed that VN neurons of the VSR are located in the caudal half of the medial and spinal VN. More recently, we found that pulsed infrared stimulation (pIRs) can also be used to activate the VSR.
In the present study, pIRs (1863nm, 100-250pps, 250μs) was directed through the round window toward the vestibular end organs in rats using customized optical fibers. Changes in BP and heart rate were recorded in response to pIRs of semicircular canal cristae and otolith maculae. Eye movements evoked by vestibular stimulation were measured using a video-based eye tracking system (ISCAN Inc, Woburn, MA) and a custom MATLAB program was used for analysis. These experiments documented the contributions of individual end organs in modulating BP through the VSR pathway. To identify the vestibular neurons activated by these stimuli, rats were perfused with mixed aldehydes 90 min after the pIRs and the brainstems were sectioned serially. One set of tissue sections was stained for c-Fos protein to map the locations of VN neurons activated by pIRs of individual end organs. Other sets of sections were used for immunofluorescence detection of glutamate, GABA and PACAP in pIRs-activated VN neurons. Taking advantage of the high spatial and temporal specificity of the stimulus, this study demonstrated the locations of central vestibular neurons specifically activated by pIRs of individual vestibular end organs.

Title: Pulsed infrared stimulation of the vestibular system evokes vestibulo-ocular and vestibulo-sympathetic reflex responses.

Authors: *S. RAJGURU[1], W. JIANG[2], G. R. HOLSTEIN[3], G. P. MARTINELLI[3], C.-P. RICHTER[4], R. D. RABBITT[5];
[1]Biomed. Engin. and Otolaryngology, [2]Biomed. Engin., Univ. of Miami, Coral Gables, FL; [3]Icahn Sch. of Med. at Mount Sinai, New York, NY; [4]Northwestern Univ., Chicago, IL; [5]Univ. of Utah, Salt Lake City, UT

Abstract: Bilateral vestibulopathy in patients leads to postural instability and chronic disequilibrium. Infrared neural stimulation (INS) has been investigated as an alternative neurostimulation modality that does not require direct contact with neural tissue and has been shown to produce significant post-synaptic afferent responses in the vestibular system. In the present study, we have investigated the physiological effects of pulsed infrared stimulation of the vestibular system in a rat model and carried out histopathological analysis. The animals were placed in a custom-designed modified stereotaxic frame that allows delivery of head rotations in pitch, roll, and yaw planes tracked using rotary potentiometers. A head post was cemented to the skull to secure the animal's head during stimulation and recording procedures. Pulsed infrared radiation (IR: 1863nm, 100-250pps, 250μs) was directed through the round window toward the vestibular end organs. Evoked vestibulo-ocular and vestibulo-sympathetic reflex responses were measured. Eye movements were measured using a video-based, two-channel eye tracking system (ISCAN Inc, Woburn, MA) and analyzed in MATLAB. We observed significant in-torsion followed by sinusoidal movements of the ipsilateral eye by frequency modulated infrared pulses. Depending upon the modulation frequency of IR, amplitude of oscillating eye movement ranged from 1 to 7º. At lower modulation frequencies (0.05-0.25Hz), an increase in the stimulation frequency was matched by a corresponding increase in the magnitude of the eye movement. The eye movements continued in response to IR after 30+ minutes of continuous stimulation. Simultaneously, a drop in blood pressure (BP) and heart rate (HR) was recorded during pulsed infrared stimulation of the vestibular system. The results compared well with previous observations of HR and BP following galvanic stimulation of the vestibular system. To identify the vestibular endorgans activated by infrared stimuli, histology and micro-computed tomography were used. Following the experiments, the radiation energy was increased to a level that would induce tissue damage. The cochlea and vestibular end organs were harvested to quantify the damage and determine the beam path. Alternatively, high-resolution microCT was used to image the structures as well as the location of the optical fiber fixed in place following experimentation. Overall, the results demonstrate selective activation of vestibular endorgans by pulsed IR and suggest its potential applications in inner ear research.

Title: An automatic method for segmenting brain nucleus boundaries on cell-resolution cytoarchitectural image sequence

Authors: ***Z. FENG**, A. LI, H. GONG, Q. LUO;
Britton Chance Ctr. for Biomed. Photonics, Wuhan Natl. Lab. For Optoelectronics, Hubei, China

Abstract: It has always been a manual way to delineate the brain region and nuclei of brain tissue on cell-resolution 3D image dataset, which was time-consuming as well as error-prone. The key problem of automation of nucleus segmentation on cytoarchitectural image is to recognize the blurry boundaries formed by isolated neurons. We propose a new method that could extract the blurry boundaries of brain nuclei on cell-resolution dataset automatically. This method parameterizes the boundaries of nuclei with closed cubic spline and guides the evolution of parameterized boundaries using the cytoarchitectural information around the nodes of boundary. It takes the nucleus boundary on the first image of the image sequence as the initial value, and calculates the boundaries of nucleus on the remaining images of the sequence. We applied this method to the cerebellum area and olfactory area, segmented the mitral layer of Main Olfactory Bulb, granular layer of Lobule II and the molecular layer of Lobule II on consecutive 100 coronal sections automatically and precisely.

Title: Unbiased automated phenotyping of rodent behavior in nonsocial and social contexts

Authors: *Y. KWON, G. K. ADAMS, G. J. BERMAN, R. C. LIU;
Dept. of Biol., Emory Univ., Atlanta, GA

Abstract: Animal behaviors are complex, yet our methods for quantifying them have been relatively simplistic. This has limited how well we can meaningfully phenotype animals to establish behavioral differences whose neural mechanisms may be of interest. Traditional methods to assess behaviors generally look only at the timing or quantity of specific events that have been predefined for an observer or apparatus to identify. However, for a given animal model, it may not always be known ahead of time what behaviors are most important to track to reveal functional distinctions. Hence, it is essential to develop unbiased methods to phenotype behavior. Such tools have begun to be used in model systems such as Drosophila and C. elegans, but less has been done to analyze rodent behavior. Pursuing such methods for rodents could help elucidate behaviors that have thus far escaped careful quantification, such as natural social behaviors, which are of increasing interest from a neuropsychiatric perspective. We exploit algorithms developed to identify behaviors based on their degree of stereotypy (Berman et al, 2014) to create a behavioral state map.Behavioral mapping employs unsupervised machine learning algorithms to learn behaviors from video recordings. Starting with the underlying structure of postural movement data, animal images undergo postural decomposition via PCA. A spectogram for postural modes are created from wavelet transforms, and then via t_SNE, video time points are mapped into a two-dimensional plane. Here, for the first time, we apply these mapping methods to identify stereotyped behavioral states in individual rodents in both social and nonsocial contexts. Our preliminary data suggests that the rodent behavioral repertoire can coarsely be clustered into 20 different behavioral states. Animals traverse these states differently depending on the social context. This proof-of-principle demonstration now lays the groundwork to begin quantifying subtleties in natural social interactions between individuals, which is often difficult to define a priori. Our methods could have application for phenotyping rodent models of autism spectrum disorder (ASD). ASD is characterized by deficits in social communication/interaction and by restricted, repetitive patterns of behavior. Current mouse models of ASD largely focus on phenotypes such as social interaction, ultrasonic vocalization

production, and repetitive self-grooming (Crawley, 2012), but these behaviors represent only a small subset of ASD characteristics. Unbiased behavioral phenotyping may be useful to delineate more robust representations of ASD phenotypes.

Title: Template-based interactive registration, segmentation and quantification workflows for light microscopy images

Authors: ***I. BOWMAN**[1], K. COTTER[1], M. BAY[2], M. ZHU[1], M. Y. SONG[1], N. N. FOSTER[1], M. S. BIENKOWSKI[1], S. YAMASHITA[1], A. W. TOGA[1], H. HINTIRYAN[1], H. DONG[1]; [1]USC Stevens Neuroimaging and Informatics Inst., Los Angeles, CA; [2]Broad CIRM Ctr. and Dept. of Stem Cell Biol. and Regenerative Medicine, USC Keck Sch. of Med., Los Angeles, CA

Abstract: Within the Mouse Connectome Project (MCP) group, we developed a new image processing workflow to aid in the collection and analysis of long-range neural network data. A typical MCP study involves dozens of C57Bl/6J mouse brains. Each animal (case) is injected with two anterograde (PHA-L & BDA) and two retrograde (CTb & FG) chemical tracers to respectively establish the input and output connections of each injection site. Animals survive a few weeks following the injections to allow tracer transport time before euthanization, fixation, and brain excision. Individual brains are cut into 50 μm coronal sections, which undergo fixation and immunostaining before being mounted onto slides for imaging under 10x objective magnification. Epifluorescent scans of a single section comprise five channels (one channel for each tracer plus one channel for cytoarchitectural background), each stored at up to 2 GB. Opening, viewing, and editing a single 2 GB scan is non-trivial even on state of the art equipment -- manually annotating the connectivity of hundreds of scans is intractable and can take a team of researchers months. We created our new image processing workflow to overcome the annotation obstacles. Workflow interaction is performed via a novel interface for image registration: the user observes correspondence point templates to evaluate and provide feedback to the image warping algorithm, and evaluate output of subsequent processing. After warping, the user sets and observes threshold values using an interactive segmentation interface. The

values are applied to the image scans to extract labeled axons, terminals (output connections), and cells (input connections) from tissue background. The segmented images provide graphical reconstructions of labeling registered to a common spatial frame. A final annotation stage employs an overlap indexing method to the segmented images. This comprehensive annotation output of our registration workflow spans multiple cases, and quantifies connectivity from numerous injection sites to their corresponding upstream or downstream regions of interest. Analyzing this data allows the user to identify clusters, hubs, motifs and other graph analysis metrics as well as visualize connectivity information. Applying our registration workflow to the MCP brain data has significantly expedited our analysis of brain connectivity, as well as furthered our ability to present these findings to the neuroscientific community.

Title: Circuitry profiling in the *Drosophila* brain through machine learning

Authors: *R. ARMANANZAS, S. NANDA, G. A. ASCOLI;
Krasnow Inst. For Advanced Study, George Mason Univ., Fairfax, VA

Abstract: Recent and accelerating advances in experimental neuroscience, bioengineering, and information technology are rapidly pushing Cajal's "neuron doctrine" to the verge of empirical and computational testability. Prominent research efforts are unveiling how circuits constitute the basic functional units of nervous systems. Among them, *Drosophila* is currently the species with more promising results in mapping brain-wide connections at the individual neuron level. The pioneering FlyCircuit Database has already traced and co-registered the neurite wiring corresponding to approximately 10% of the cells in female *Drosophila* brain.
Here, we first assigned each of the 16,206 FlyCircuit v1.0 neurons to one of 58 brain regions by

determining the geometrical memberships of the somata within 3D meshes of the neuropil structures. A multi-label classification method (ML-KNN) allowed us to establish regions for those cells located outside of the meshes' boundaries due to imperfect registration. Next, using axonal and dendritic terminal data from the morphological reconstructions, we algebraically computed potential pre- and post- synaptic connectivity based on spatial co-occurrences. This resulted in a largely sparse matrix of connectivity likelihoods that was subsequently filtered to discard isolated cells.
For the detection of distinct circuits, we applied the Large Average Submatrix (LAS) co-clustering method. LAS was able to identify a total of 20 separate biclusters, i.e. sets of pre- and post- synaptic neurons connected through differentiated patterns. Each bicluster connectivity signature was profiled using an outlier detection algorithm based on Kolmogorov-Smirnov statistic and bootstrapping. Finally, to reveal the hub neurons in each profile, we fitted the individual connectivity scores to different logistic distributions. The core cells and connections forming the circuitry motif were those whose inverse cumulative distribution function was equal to or greater than 0.90.
The continuously increasing comprehension of the functional importance of circuitry brings the challenge to develop and select the most suitable, powerful, and practical approaches for quantitative analytics. Applying machine learning techniques to the elucidation of canonical circuits may yield important connectivity patterns that can help explain at least some of the observed behavioral mechanisms.

Title: A fine-grained parallel method for reformatting terabyte-scale volumetric images into hierarchical data

Authors: *Y. LI, A. LI, H. GONG, Q. LUO;
Wuhan Natl. Lab. for Optoelectronics, Huazhong Univ. of Sci. and Technol., Hubei, China

Abstract: Techniques for three-dimensional imaging of whole mammalian brains at single-neuron resolution have generated image data easily exceeding the terabyte size. The image data generated are too large to be processed by usual computers. The common practice is to reformat the image dataset into lots of blocks and stored in a hierarchical structure with multi-resolution levels. So the computers could process small parts of dataset at a time. However, existing tools are time-consuming, or use too much computational memory when reformatting. Here, we present a fine-grained parallel reformatting (FPR) method to solve this critical problem in the processing of terabyte-sized image data. We tested its performance and demonstrated its applicability to various computing platforms. The results suggested that FPR was faster with low memory usage than existing tools during reformatting. It has ability to handle up to one petabyte of image data.

Title: Modulating the hippocampal functional connectivity using real-time optimization of distributed microstimulation

Authors: *B. MAHMOUDI[1], M. CONNOLLY[2], R. GROSS[2];
[1]Emory Univ., Alpharetta, GA; [2]Emory Univ., Atlanta, GA

Abstract: Introduction: Modifying the pattern of neural activities is at the core of neurostimulation therapies for neuropsychiatric disorders. One of the key problems to maximize the effectiveness of these therapies is optimization of neurostimulation parameters. The optimization of neuromodulation requires: (1) identifying biomarkers that can be effectively modulated by electrical stimulation, (2) developing algorithms for optimizing these biomarkers, and (3) verifying that optimizing these biomarkers has the desired effect. We found that the correlation coefficient (CC) between CA3 and CA1 in the rat hippocampus could be effectively modulated by distributed microelectrical stimulation. In this study we address the second requirement by developing an optimization algorithm to modulate this biomarker in real-time. Methods: A rat was implanted with a 16 channel microelectrode array in the hippocampus with 8

electrodes each recording and stimulating CA3 and CA1. A TDT RZ2 BioAmp processor and custom software platform was used to run the optimization. The target of this optimization was to identify the stimulation frequency that enhanced the functional connectivity between CA3 and CA1, in the form of the CC between the local field potential recordings between those two regions. Using the cross-entropy method we implemented a real-time closed-loop optimization algorithm that started with an initial Gaussian distribution over stimulation frequencies. 100 stimulation frequencies were randomly sampled from the distribution and applied sequentially. The CC after each stimulation was calculated. The mean and STD of the 10 frequencies with the greatest effect were used to define a new distribution. Each stimulation was a biphasic symmetric, 2V, 1ms width and 1s duration. The initial distribution had a mean of 100Hz, and a standard deviation of 70Hz
Results: The optimization performed 11 cycles (1100 stimulations). The average CA3-CA1 CC was 0.601 during the first cycle and 0.72 during the final cycle. Over the 11 cycles, the distribution changed from a mean of 100 to 193Hz and a standard deviation of 70 to 28Hz.
Discussion: This study demonstrates a novel approach to modulating neural state and investigating the way the brain responds to stimulation. Our initial study found that a stimulation frequency of 100Hz increased the CA3-CA1 CC more than 5, 20, 50, or 200Hz. However, this optimization converged on a frequency that was previously not tested in our parameter sweep.
Conclusion: Neural state biomarkers can be effectively modulated by electrical stimulation using real-time optimization, and may provide a new approach to improving neural modulation therapy.

Abstract: Synaptic stochasticity methods inspired by neurobiology have been shown to improve performance in spiking artificial neural networks resulting in greater than 95% classification accuracy on a benchmark handwritten digit recognition task. Taking cues from neurobiological research we further analyze the effect of various methods of synaptic pruning on the performance of these spiking networks as well as showing links between biological data and modeled data.

Title: GeNN: Accelerated spiking neural network simulations on GPUs

Authors: ***T. NOWOTNY**, J. P. TURNER, E. YAVUZ;
Univ. of Sussex, Brighton, United Kingdom

Abstract: When simulating models of neural networks in the brain, the size of the simulated networks matters. The speed of neural network simulators and their capacity for simulating large networks therefore remains an important issue. Here we present the GPU enhanced neuronal networks (GeNN) framework [1,2] that we have created to gain the most from GPU accelerators. The use of GPU accelerators has increased explosively over the last 10 years, with many of the main actors in the area of machine learning now relying heavily on this technology (e.g. Amazon, Facebook, Google Deep Mind). One of the first applications for GPU accelerated computing were indeed neural networks. However, using GPU accelerators has become less

mainstream in computational neuroscience because of difficulties with optimizing computational neuroscience model code for the particular architecture of GPUs.
GeNN is offering an elegant solution to the most common problems, using an approach of automatic code generation from minimal descriptions provided by the user. The generated code will automatically be optimized for the detected GPU accelerator and the user-defined model. At the same time, GeNN remains very flexible and expert users can manipulate virtually every aspect of the simulation. GeNN supports all typical computational neuroscience models by allowing users to define their own equations for the model elements, such as neuron dynamics, synapse updates and learning rules. GeNN has been used for networks of Hodgkin-Huxley neurons, with Hebbian learning, STDP and 3-factor learning rules, as well as for more simple models such as networks of Izhikevich, integrate-and-fire and Rulkov map neurons.
For less expert users we have created additional interfaces to the SpineCreator graphical model definition interface [3] and to the popular Brian 2 simulator [4]. With the latter, it is as simple as issuing the command set_device('genn') to take advantage of GPU acceleration.
Acceleration compared to CPU-based solutions varies by model and GPU accelerator hardware and can be as high as 200X but also as low as none. GeNN is available as open source software under GPL v2 [2].

Title: Automatic detection of putative contacts between in-vivo labelled neurons

Authors: *M. M. SEETHARAMA;
Computat. Neuroanatomy, Max Planck Inst. For Biogical Cybernetics, Tuebingen, Germany

Abstract: Understanding the structural organization of the neural networks requires reconstruction of the underlying neural circuitry in anatomical detail and mapping of the synaptic contacts. A typical in-vivo labeled axon innervates a large volume and imaging such in-vivo labeled pairs of neurons at high resolution yields a large set of images, typically in the order of Tera Bytes. Manual mapping of synaptic contacts between such cell pairs would be labor intensive and error prone. Here, we present a software pipeline that automatically detects putative synaptic contacts between the Boutons and Spines of in-vivo labeled pairs of neurons. The pipeline has three phases. Firstly, the regions where the skeletons of axon and dendrites of different neurons come close to each other are detected. Secondly, in these proximity regions, the Boutons along the axons and spines along the dendrites are detected. Thirdly, the overlaps between Boutons and Spines along with their locations are detected. The resulting putative contacts are visualized on the original image stack using a visualization tool and can be verified by the user. This semi-automated approach reduces the number of sites to be manually inspected for putative contacts from tens of thousands to tens of putative contact sites. Hence achieving about three orders of magnitude reduction in the manual effort required.

Title: A neurobehavioral evaluation system using 3d depth tracking and computer vision: the case of stroke-kinect

Authors: *V. RAMESH, S. RICK, K. AGRAWAL, B. MEYERS, G. CAUWENBERGHS, N. WEIBEL;
UC San Diego, La Jolla, CA

Abstract: Due to the subtlety of their symptoms - slight tremors, blurred vision, and loss of mobility, for example - many neurological diseases are challenging to diagnose. As such, a computational tool that can identify and analyze these symptoms accurately will be of immense use to neurologists. We aim to characterize human motor and cognitive abilities through a multimodal approach that will lead to signatures for neurological disorders, based on patterns in

relevant identifiers. We focus here on stroke. Stroke is the 4th leading cause of death and the leading cause of disability in the United States. But Recombinant Tissue Plasminogen Activator (rt-PA), the only FDA-approved treatment currently available, is administered in less than 5% of acute stroke cases. The decision to prescribe rt-PA is based on the National Institute of Health Stroke Scale (NIHSS), a combination of multiple tests conducted by a neurologist to assess visual fields and motor and sensory impairments. Stroke evaluation with the NIHSS is inherently subjective. An inexperienced evaluator may miss key or almost imperceptible tells, misdiagnose the severity of a stroke, forego rt-PA prescriptions, and crudely predict long term outcomes. If this gap in objective and reliable stroke diagnosis is not addressed, stroke survivors will endure an arduous rehabilitation process. We are therefore developing Stroke-Kinect, a new system for automatic eye motion and body motion analysis to assist in the diagnosis of stroke. We obtain high-definition images and the spatial and temporal positions of 25 body joints in stroke and healthy control patients with the Microsoft Kinect v2. We employ machine learning classification algorithms and computer vision techniques to replicate the subjective NIHSS test computationally. Furthermore, we develop new tests for identifiers not captured by the NIHSS that are difficult to detect by the human eye: joint angles and thus body posture, velocity of gestures, twitches and jerks, and center of mass. Our analysis of depth data collected from stroke patients indicates accurate testing for the synchronicity of movements and reliable eye gaze tracking. The data also identifies posture as a key indicator of left side versus right side weakness. These results suggest that larger data sets will permit identification of only the vital indicators in stroke diagnosis, to simplify the NIHSS and mitigate the risk of false negatives and erroneous prescriptions of rt-PA. Stroke-Kinect also paves the way for the computational diagnosis of other neurological disorders, furthering the health sciences and ultimately aiding patients in their recovery.

Title: Real-time reconfigurable event-driven emulation of integrate-and-fire neural networks with STDP

Authors: B. PEDRONI[1], *F. D. BROCCARD[2], S. SHEIK[1], G. CAUWENBERGHS[2,1]; [1]Bioengineering, Univ. of California San Diego, La Jolla, CA; [2]Inst. Neural Computation, UCSD, La Jolla, CA

Abstract: Simulations of spiking neural networks (SNNs) on conventional serial hardware suffer from a lack of scalability for embedded systems that must interact in real-time with complex and dynamic environments.
This limitation can be overcome with the implementation of SNNs on dedicated parallel hardware, making large-scale networks suitable for various real-time applications in autonomous robotics and neuroprosthetics.
However, developing custom application specific integrated circuit and neuromorphic devices for SNNs is both time consuming and expensive. Furthermore, some of these devices are limited in the types of spiking neuron model that can be implemented.
Here, we present a set of open-source software tools for the automation of spiking neural network models mapping on Field-Programmable Gate Arrays (FPGAs). FPGAs are compact, low-cost, reconfigurable integrated circuits that allows the parallel implementations of SNNs for low-power embedded applications.
We show a FPGA implementation of a SNN designed with the Brian simulator, using different neuron models. We also present preliminary results of the effect of coupling on the synchronization of two different SNNs implemented on the same FPGA.

Title: Simultaneous state and parameter estimation with coupled data assimilation for tracking state of vigilance in rats

Authors: *F. BAHARI[1,2], M. W. BILLARD[3,2], C. R. TULYAGANOVA[3,2], K. D. ALLOWAY[4,2], B. J. GLUCKMAN[3,2,5];
[2]Ctr. for Neural Engin., [3]Engin. Sci. and Mechanics, [1]Pennsylvania State Univ., University Park, PA; [4]Neural and Behavioral Neurosciences, [5]Dept. of Neurosurg., Pennsylvania State Univ., Hershey, PA

Abstract: There is extensive clinical and experimental evidence that links state of vigilance to seizure generation (Langdon-Downs et al. 1929; Dinner 2002). Sleep-wake regulation is also altered in epileptic brain (Sedigh-Sarvestani et al. 2014). In order to understand this bi-directional coupling we need to further investigate the underlying neurophysiological interactions of brainstem sleep-wake regulatory system in normal and epileptic brain.
We have been using physiologically-based mathematical models of sleep-wake regulatory network synchronized with experimental measurements to reconstruct and predict the state of sleep-wake regulatory system in chronically implanted animals. Our objective is to assimilate sparse noisy measurements from the system - such as EEG and behaviorally measured state of vigilance as well as unit recordings from the represented cell groups- into these mathematical models (Sedigh-Sarvestani et al. 2012), and thereby both validate or improve the models and detect changes in physiology.
Critical to applying this technique to real biological systems is the need to estimate the underlying model parameters. Here, we present an estimation technique capable of simultaneously fitting and tracking multiple model parameters to optimize the reconstructed system state. Performance is gauged by reconstruction and forecasting of state from noisy observations of model-generated data, and compared to other conventional parameter tracking methods (Voss et al. 2004). In addition, we have extended our data assimilation methodology based on discretized observations of state of vigilance (Sedigh-Sarvestani et al. 2012) to assimilate these indirect observations into the optimized model dynamics to track and reconstruct the state of vigilance in normal and epileptic rats.

Title: SciBot and Hypothes.is: a method for pulling properly cited key biological resources, RRIDs, from the literature

Authors: *A. E. BANDROWSKI, M. MARTONE, J. GRETHE, T. GILLESPIE, G. PINE; UCSD, La Jolla, CA

Abstract: Hypothes.is is an open web annotation tool, which allows users to annotate any web content they come in contact with within user defined groups, such as a class or a laboratory, or in public to leave a public note for others about a particular web page in the W3C open annotation format. SciBot is a text algorithm written in Python, which detects the presence of properly cited antibodies, cell lines, organisms and tools within scientific methods sections. SciBot uses the scicrunch resolver at scicrunch.org/resolver to gather information from the antibodyregistry, cellosaurus, scicrunch tool registry and ~25 model organism stock centers and databases bringing that information into the hypothes.is overlay of any article from any publisher, allowing any user to link back to the authoritative record about a biological resource from the article. Currently, curators have found 820 journal articles, from 112 different journals (http://bit.ly/1VLu0yd), that contain at least one RRID, Research Resource IDentifier, for an antibody, organism, or tool and we ran SciBot on all of the papers. SciBot detected 7068 total annotations and curators have checked 780 papers for their validity. Of these, 465 annotations are for organisms, predominantly mice, 2031 are for tools such as ImageJ, and 4572 are made for antibodies. Cell lines have just become available to use as RRIDs and as of this writing no paper cited a cell line via the RRID syntax yet. The accuracy rate for authors reporting research resources in the first 820 papers remains at 97%, though syntax errors account for about 30% of the total RRIDs, these are predominantly from publishers that do not typeset the RRID syntax.SciBot and Hypothes.is are useful tools for robot assisted curation of the scientific literature, with freely and openly available code bases that can be used for other purposes (https://github.com/SciCrunch/scibot).

Title: Tablet based virtual reality system for research purposes

Authors: ***L. A. MOLINA**[1,2], M. A. NEEDHAM[1], M. H. MOHAJERANI[1], B. L. MCNAUGHTON[1];

[1]Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; [2]Interphaser Ltd., Lethbridge, AB, Canada

Abstract: There is an increasing demand for virtual reality (VR) systems for research purposes, specifically in neuroscience. Implementing VR and neuroimaging or electrophysiology can be challenging due to limitations in the size or mobility of the data acquisition system, the behavioral apparatus or the subject. Here we describe a tablet-based VR system of easy implementation and maintenance, aimed at data collection, and allowing real-time interaction with the configuration of the virtual world and its state variables. Furthermore, we demonstrate its use in a goal oriented task in which mice learn to navigate towards cues associated with rewarding stimuli and avoid those associated to aversive stimuli. Lastly, we present a mechanism to synchronize this VR system with other data acquisition systems and use it to look at neuronal correlates of navigation.

Title: Curating central injection studies from the literature using a general-purpose knowledge management strategy.

Authors: *G. A. BURNS[1], A. E. HERNANDEZ[2], A. M. KHAN[2];
[1]Intelligent Systems Div., Information Sci. Inst., Marina Dl Rey, CA; [2]Dept. of Biol. Sci., Univ. of Texas at El Paso, El Paso, TX

Abstract: The heterogeneity of neuroscience work and lack of consistent methods to model and curate experimentally-derived neuroscientific knowledge has led to a complex landscape of neuroinformatics data and knowledge repositories. We here describe a simple, well-defined knowledge modeling and curation methodology for experimental data and instantiate it with a systems-level neuroscience pilot study based on central (intracranial) injection studies. Experimental work involving central injections has involved injecting or infusing bioactive agents directly into the brain of awake behaving animals in order to observe behavioral effects of the infusion. These methods are now complemented by optogenetic approaches that provide more accurate methods of artificially stimulating or inhibiting genetically-defined neuronal populations. Importantly, we anticipate that for some neuroscience sub-domains, as the experimental focus of active researchers moves away from the central injection methodology, the details of the research findings from that body of work will likely no longer be actively incorporated into current research. We therefore seek to curate and preserve this referenced literature into an electronic resource rapidly and efficiently for future reference. We present several innovations to accelerate and ease the curation process: (A) the use of a PDF-based digital library with information retrieval methods to manage literature fragments supporting claims from the literature; (B) the application of general-purpose knowledge engineering methods (KEfED) that use descriptions of the protocols used in experiments templates to

generate spreadsheets for data entry; (C) the use of semantic web standard methods for storing, presenting and querying the data. We also investigate the use of machine reading techniques to further accelerate knowledge extraction from these papers and establish methods of practice to incorporate student training and involvement in this effort. All data and software gathered in this effort are provided as open source resources.

Title: Neurogpu, a gpu framework for neuron-based simulation

Authors: R. BEN-SHALOM[1], N. S. ATHREYA[1], C. S. KI[1], H. SANGHVI[1], *K. J. BENDER[2,1];

Abstract: Computational models, including compartmental models of individual neurons, are an important component of modern neuroscience. The NEURON simulation environment is one of the most common platforms for compartmental modeling, with an intuitive interface and broad user base. NEURON, like many simulation environments, relies on central processing unit (CPU) computation. Neuronal models can be computationally intensive, especially for large or complex simulations, and often models must be compromised in scale given available CPU-based resources. In our recent work, we developed a simulation environment, NeuroGPU, that relies on graphics processing units (GPUs) rather than CPUs. NeuroGPU is 150 times faster than traditional single core CPU processors, and offers a high level of computational power at low cost. Here, we developed new tools based on NeuroGPU processing that will allow for broad access to GPU-based modeling across the neuroscience community. First, we implemented NeuroGPU in the Python coding language, which allows one to run NEURON simulations via NeuroGPU. Second, previously NeuroGPU supported only Hodgin Huxley based ion channels mechanisms, recently we incorporated Markov ion channel models and point process such as

synapses and extracellular stimulation to NeuroGPU, allowing one to incorporate such models from ModelDB. These improvements to NeuroGPU will make it possible to support most of NEURON compartmental model capabilities and will make it possible for neuroscientists to take advantage of the computational power that low-cost GPU technology offers.

Title: A neurally inspired spiking temporal processing unit computational architecture

Authors: *C. M. VINEYARD[1], J. B. AIMONE[1], M. R. SMITH[1], S. J. VERZI[1], J. DONALDSON[1], G. POPOOLA[1], F. WANG[1], D. R. FOLLETT[2], C. D. JAMES[1], J. H. NAEGLE[1];
[1]Sandia Natl. Labs., Albuquerque, NM; [2]Lewis Rhodes Labs, West Concord, MA

Abstract: Computational neural models are developed to help understand the brain and give insight into its functionality. Prior work modeling non-deterministic neuronal connectivity, brain plasticity, and spike timing have identified key differentiating operating principles from that of conventional von Neumann computation. Unlike general purpose computer architectures, which are based upon complex processor cores and sequential computation, the brain is innately parallel and comprised of simple computational units. Key to the architecture of the brain is a functionality encoded neurally by the combined effect of sparsity with unique variable efficacies and temporal latencies. Utilizing these neuroscience principles, we have developed a Spiking Temporal Processing Unit (STPU) architecture well suited for computational neural modeling and neural network instantiation by executing complexity and computation in the time domain. We implemented the neural inspired STPU architecture in a software simulator as well as on a field programmable gate array (FPGA). Here we show the results of implementing a variety of neural networks and algorithms including: circuits based upon early visual system and hippocampus, Liquid State Machine, SpikingSort, deep neural networks, and the SVM Game. The STPU architecture yields empirical evidence of the efficiency of cortically-inspired computation and provides a framework for a possible paradigm shift in problem solving from conventional computer architecture and processing.

Title: Open science at the montreal neurological institute - LORIS & CBRAIN

Authors: *S. DAS;
McGill Ctr. for Integrative Neurosci., Montreal Neurolog. Inst., Montreal, QC, Canada

Abstract: As technologies mature and global research collaborations intensify, researchers are looking for practical solutions, not only to share large amounts of data, but also to manage, query and process datasets from complex multimodal studies, often well beyond the project's life cycle. In many cases, acquisition realities present a significant burden, therefore gaining access to public data allows for more robust analyses and greater exploratory data mining. To answer this demand, the Montreal Neurological Institute (MNI) has launched "Open Science", serving the public good by making both clinical and research data available to the world (Owens, 2016). The MNI ecosystem currently consists of two principal and complementary platforms, LORIS (www.loris.ca) and CBRAIN (www.cbrain.ca) (Das et al., 2015). Together, they will consolidate and be adapted for the following functionalities for a new implementation at an institutionallevel of public data sharing: 1) Comprehensive multimodal data linking: clinical, genomics, imaging, phenotypic, demographic. 2) Robust Quality Control mechanisms usable as covariates in analysis. 3) Long term storage (and web access) of collected data. 4) Enhanced, multimodal web visualization with realtime viewing and manipulation. 5) Secure, confidential encryption specifically designed for institutional data sharing. 6) Configurable pipelines and flags to facilitate acquisition and analysis 7) Access to High Performance Computing clusters for immediate processing. 8) Configurable modular functionality (filtering, summary statistics, personal dashboards). 9) Multimodal querying with full access control for all consented public data sharing. 10) Mobile access capabilities with responsive viewing. LORIS was first implemented at the MNI in 1999 to organize acquisition and analysis for the multisite MRI Study of Normal Brain Development (Evans and Brain Development Cooperative Group, 2006). It has since proliferated to more than 130 sites worldwide, with greater than 30,000 collection time points and 200,000 imaging scans. In complement, CBRAIN has been developed since

2009 as solution for reproducible distributed computing and tool sharing, serving over 420 users across 50 cities in 22 countries, with an allocation of approximately 6 million CPU hours/year from Compute Canada (www.computecanada.ca). Open Science at the MNI will be a concerted undertaking, leveraging years of experience from MNI platforms to facilitate data sharing on a global scale.

Title: A high performance computing web service for the analysis of local field potentials in Neurodata Without Borders-fomatted datasets

Authors: *S. MACKESEY[1], P. PRABHAT[2], F. SOMMER[3];
[1]Univ. of California Berkeley, Oakland, CA; [2]Lawrence Berkeley Natl. Lab., Berkeley, CA;
[3]Univ. of California, Berkeley, Berkeley, CA

Abstract: Advances in recording technology driven by large-scale neuroscience projects (e.g. BRAIN initiative, Human Brain Project) promise to deliver unprecedented high-resolution recordings of brain activity. This flood of data is already straining both traditional methods of analysis and the existing neuroinformatics infrastructure. Analysis techniques requiring human intervention, such as manual editing of clusters in spike-sorting, do not scale to high-dimensional data. More promising are data mining techniques that reveal structure without human intervention. Unsupervised learning algorithms (e.g. sparse coding, independent component analysis) can extract features from both neural and behavioral signals. However, these methods are often computationally intensive and may require sophisticated implementations. The lack of any widely accepted common data format means that costly parallelized code is likely to be coupled to ad-hoc, idiosyncratic formats. This reduces the reuse potential of the code and disincentivizes development. In the past year, a consortium of large data producers operating under the name Neurodata Without Borders (NWB) have advanced an HDF5-based common data format. We are building a free web service on top of NWB that (1): exposes HDF5-based NWB datasets over an HTTP JSON API; (2): allows users to execute computationally intensive data analyses at scale; (3) provides job management and visualization capabilities. The service will leverage the co-location of data and high-performance computing resources at the National Energy Research Scientific Computing Center (NERSC). A library of analysis algorithms will be

made available for processing NWB-formatted datasets at CRCNS, visualizing the results, and sharing them with other users. At present, we are using convolutional sparse coding as a pilot algorithm.

Title: NSG-R: seamlessly integrating neuroscience tools with high performance computing

Authors: ***N. T. CARNEVALE**[1], P. GLEESON[2], R. A. SILVER[2], S. SIVAGNANAM[3], K. YOSHIMOTO[3], A. MAJUMDAR[3];
[1]Yale Univ. Sch. Med., New Haven, CT; [2]Univ. Col. London, London, United Kingdom; [3]Univ. of California, San Diego, CA

Abstract: The recent trajectory of neuroscience research has been toward development and adoption of methods and tools that pose ever greater computational burdens. Examples include: powerful open-source neural simulators that enable creation of empirically based models of unprecedented complexity; neuroscience community projects (NCPs) that enable collaborative model development and promote data and model sharing; fMRI, high resolution light microscopy, and other imaging methods that generate large data sets that require numerically intensive processing and analysis. For growing numbers of neuroscientists, these advances have produced a critical need to use high performance computing (HPC) resources in their research and teaching--a need that the BRAIN Intitiative is likely to make more acute. That led us to develop the Neuroscience Gateway (NSG), the first and only science gateway that provdes neuroscientists convenient access to HPC resources. NSG's browser-based interface shields them from tedious technical and administrative details, enabling performance of tasks that exceed local hardware capabilities. However, users must first leave their familiar work environments and carry out numerous step-by-step actions that are potentially error prone. This motivated our next step in refining and extending NSG, which we present here: creation of a software

infrastructure that allows seamless access to HPC resources whether from the familiar environment of widely used NCPs or from the existing work environment on neuroscientists' own laptop or desktop computers. Called NSG-R, this infrastructure is implemented as a RESTful web services interface to the NSG. It will allow neuroscientists to access HPC resources in order to analyze data, run simulations, and retrieve results, all within the context of their familiar workflows. NSG-R will also allow running models directly on HPC from their own laptop or desktop computers. Open Source Brain is the first NCP that will integrate NSG-R, making HPC resources transparently available to its users. NSG-R will subsequently be integrated with other projects, e.g. ModelDB, the Neuroscience Information Framework, and OpenWorm, and made available to developers of neural simulators and neuroscience data analysis software. By enabling seamless, ubiquitous access to HPC, the NSG-R project is likely to have a transformative impact on research, catalyzing progress in neuroscience and widening opportunities for educational and career advancement regardless of the institutional affiliation of those who benefit from it. This project levels the playing field for all students and researchers by democratizing access to HPC.

Abstract: Sharing of experimental data is of critical importance in neuroscience allowing a close inspection by the research community and facilitating the use of experimental data for modeling. However, with a few exceptions, data from individual studies conducted by regular size neuroscience labs are not shared. Previously, we provided an example of seamless and low-cost solution for sharing of such data. Specifically, we created a MATLAB® based Graphical User Interface (GUI) engine called Neurovascular Network Explorer 1.0 (NNE 1.0) to interact with a database of 2-photon measurements of sensory stimulus-induced diameter changes of rat cortical arterioles in vivo [1]. NNE 1.0 and the associated database can be downloaded from http://nil.ucsd.edu/index.php?menu=data and then runs either as a MATLAB script or as a standalone program on a Windows platform. The GUI allows browsing the database according to parameters specified by the user, simple manipulation and visualization of the retrieved records (such as averaging and peak-normalization), and export of the results. Further, we provided NNE 1.0 source code. With this source code, the user can database their own experimental results, given the appropriate data structure and naming conventions, and thus share their data in a user-friendly format with other investigators. Here, we present a second generation of this sharing engine called Neurovascular Network Explorer 2.0 (NNE 2.0). In addition to all previous functionalities, NNE 2.0 provides 3D structural vascular data and supports localization of individual measurements within the vascular network. NNE 2.0 operates on two independent databases from the mouse primary sensory cortex. The first one is analogous to that associated with NNE 1.0 and contains sensory stimulus-induced arteriolar diameter changes. The other one contains arteriolar diameter changes in response to selective optogenetic activation of cortical inhibitory neurons. The experimental data corresponding to these databases have been presented previously in the abstract form [2,3]. The new feature of the structural images may be utilized by the user for computational reconstruction of the microvascular network. Such reconstructions can provide a realistic foundation for bottom-up modeling of the vascular/hemodynamic responses, which are important for understanding cerebral blood flow regulation and physiological underpinning of functional Magnetic Resonance Imaging signals [4]. Abstract: Mental health disorder has become a problem in many developed countries and in order to cope with it, a screening technology that will help to check depression and stress is being sought. Self-administered psychological tests and biomarkers have been used in the past, but these are beset by problems such as reporting bias and inspection costs and they also impose a burden on those who conduct the tests. Previous research includes studies that estimate depression and stress state using voice data. The advantage with analysis using voice data is that, besides being non-invasive, it does not require special and exclusive equipment and therefore can be easily carried out remotely. In this research, we focus on the everyday speech sounds of the call voice over the phone and develop a system of monitoring the health condition using the smartphone voice. Additionally, we evaluate the algorithm implemented in this system. For voice evaluations we used the Disordered Voice Database and Program, Model4337 from KayPENTAX, a division of Pentax Medical Inc. This database contains recordings of voices from about 700 persons (healthy individuals and patients) of read speech of "Rainbow passage" (approximately the first 12 seconds). We compared the implemented method with other indices such as jitter, shimmer, and HNR, we have used the speech read of "Rainbow passage" to closely resemble natural free form speech. To evaluate the performance of each index in discriminating between patients and healthy individuals, we used area under the curve (AUC) in the receiver operating characteristic (ROC) plot, sensitivity, and specificity. With respect to jitter, the AUC was 0.827. With respect to shimmer, the AUC values was 0.706. With respect to HNR, the AUC values was 0.655. In contrast, implemented method, the AUC values was 0.852, demonstrating better discriminability between healthy individuals and patients compared to the conventional indices. Consequently, the system has been found to be consistent from speech input on the smartphone, through the analysis up to the output of result. Thereby, the mental health state of the user can now be easily measured on a daily basis.

Title: Psychological impact of Kumamoto earthquake by voice analysis using a smart phone application

Authors: *S. TOKUNO[1], Y. OMIYA[2], S. SHINOHARA[1], M. NAKAMURA[1], N. HAGIWARA[2], S. MITSUYOSHI[1];
[1]Verbal analysis of pathophysiology, The Univ. of Tokyo, Tokyo, Japan; [2]PST Corporation, Inc., Yokohama, Japan

Abstract: We developed an application that is measuring the health of the mind using the voice to call on smartphone which call MIMOSYS (mind monitoring system). This application determines the extent the depressive tendency by voice emotion recognition technology. The user does not need to be aware after once installed, can monitor the health of his/her mind by using the smartphone as a normal mobile phone.
We showed that this application has a sensitivity comparable to the self-administered questionnaire which is commonly used in past studies.
This application published on July 20, 2015 for research, to obtain about 1800 download until April 25th. We carried out a questionnaire about the user's attributes at the time of the first start-up of the application, and compared the results of questionnaire and the health score of mind by voice analysis. Additionally, there is a big earthquake in Kumamoto, the west part of Japan, thus we investigate the effect of the disaster on the mind of residence.
In comparison with the questionnaire, some interesting relationship between user's attributes and mind health score were observed. In the difference between men and women, women shows more depressive tendency compared with men. This is consistent with the male-to-female ratio of depression morbidity. In comparison with the body mass index (BMI), mild obesity is the most favorable, both of obesity and leanness showed depressive tendency. This also does not conflict with other health indicators. In addition, several results were obtain, such as the mind health correlates of income.
In the comparison of before and after earthquake, different reaction depending on the region has been observed.
The largest swing areas which close to the epicenter, initially, the mind health score is inclined to depressive tendency strongly, then it tends to be somewhat recovery was seen. In a little remote

areas from the epicenter, it was mutated to gradually depressive tendency from after the earthquake. In areas affected by the disaster in the Great East Japan Earthquake five years ago, tendency to gradually become high was observed after the earthquake. It might be affected by flashback of post-traumatic stress disorder (PTSD). In other areas, there was no particularly significant change.
As we show above, this application has big potential for health monitoring.

Title: Improvements to automatic detection and classification of dendritic spines

Authors: *S. TAPPAN, A. RODRIGUEZ, M. A. A. KARIM, D. HOPPES, P. J. ANGSTMAN, J. R. GLASER;
R&D, MBF Biosci. - MicroBrightField Inc., Williston, VT

Abstract: The role of dendritic spines is one of the most significant and important areas of neuroscience research. Plasticity of dendritic spine morphology plays a crucial role in development, aging, as well as in learning and memory. Also, many complex brain diseases, including autism spectrum disorders, schizophrenia, Alzheimer's disease, and Parkinson's disease are characterized by dendritic spine pathology including abnormal dendritic spine density and morphology, dendritic spine loss, and aberrant dendritic spine plasticity. In order to develop robust methods for quantifying three-dimensional (3D) dendritic spine morphology at repeated time points imaged *in vivo*, we improved upon existing methods to provide greater precision and accuracy.
Improvements were made to isolate spines in complex, high density regions. Elucidating individual dendritic spines in close proximity is difficult to do, particularly in the Z-dimension. Improved clustering utilizing whole clump branch assignment substantially improved correct branch assignment. Using morphological characteristics such as spine shape and size along with spatial constraints (e.g., their proximity to a dendrite), spines are more accurately identified and

assigned to correct dendritic branches that are in close proximity such as near bifurcations. Additionally, we developed a modified implementation of the Rayburst Sampling algorithm for diameter estimation for cases where spines are in direct contact. Within Neurolucida 360, spine detection can be restricted to individual branches and tools for splitting and merging spines, and manual reassignment to adjacent branches are provided. Preliminary results with manual validation demonstrate that these new methods are a substantial improvement as compared to prior implementations.
To improve dendritic spine shape classification, we compared our current method against a new method of length estimation rather than shortest path distance. By modeling a spine backbone that traces the length of the spine, and by positioning the head and neck of the spine along the backbone, we are able to more accurately characterize the spine shape. In cases where automatic determination is not sufficient, manual adjustment of the backbone points is permitted. The increased accuracy provides a more reliable means to classify the spines based on their morphology.
Together, these methods represent a substantial improvement over currently available automated methods. Furthermore, they open the possibility of improved automated comparison of dendritic spine morphology on 3D images acquired with *in vivo* multiphoton fluorescence microscopy at different time points.

Title: SwarmSight: Open-source software module for real-time, paint-free tracking of insect appendage movements using commodity hardware

Authors: *J. BIRGIOLAS[1], C. M. JERNIGAN[2], R. C. GERKIN[2], B. H. SMITH[3], S. M. CROOK[4];
[1]Neurosci., Arizona State Univ., Phoenix, AZ; [2]Sch. of Life Sci., Arizona State Univ., Tempe, AZ; [3]Sch. of Life Sci., Arizona State Univ., Phoenix, AZ; [4]Sch. of Mathematical and Statistical Sci., Arizona State Univ., Tempe, AZ

Abstract: Machine vision methods can greatly improve the efficiency of assessing animal behavior. In previous work, we described the open-source SwarmSight software (Github.com/JustasB/SwarmSight) for assessing animal group activity from videos [1]. Here we extend SwarmSight to analyze antenna movement from videos, with real-time speed processing (~30 fps). In the past, antenna movement analysis has required high-speed cameras and painting of the antenna tips [2], or lengthy (7.5 sec/frame) processing times [3].
We demonstrate the approach by obtaining the x, y and dominant angle sector locations of flagellar tips from conventional camera videos of restrained bees (Fig. 1A). We validate the software accuracy by comparing the tip locations found by two humans to the locations found by the software in several hundred video frames. Inter-human disagreement was 10.9 pixels (px) on average and within 30 px in 90.3% of the frames. The software was a mean of 8.5 px - and within 30 px in 99.2% of the frames - from the closest human location (Fig 1B).
We presented two odors to 23 restrained female bees (*Apis mellifera*) to assess the software's ability to measure temporal changes in innate antennal movement patterns. Videos of bees presented with pure and 35x diluted versions of heptanal and heptanol were analyzed with SwarmSight to track the dominant sectors (Fig 1C) and tip x, y locations (Fig 1E). For both odorants, dominant sector and angle means at both concentrations were significantly different (Holms adj. t-tests $p < 0.01$, Shapiro tests N.S.) from pre-odor-presentation means (Fig 1D).
Overall, SwarmSight enables efficient and accurate tracking of bee antenna tips without requiring special animal preparations or equipment. This approach can also be used to automate behavior assessment of appendage movements for bumblebees, crickets, ants, and other insects.

Title: T-sne as a visualization step in the spike sorting pipeline

Authors: J. NETO, *G. DIMITRIADIS, A. KAMPFF;
Sainsbury Wellcome Ctr., London, United Kingdom

Abstract: Systems neuroscience is entering an era of 'Big Data' where recordings from multiple brain regions will be made with probes containing hundreds to thousands of individual electrodes. One of the problems introduced by these technologies is the transformation of the data into physiologically meaningful signals. Deriving the spiking information of neurons from such spatiotemporally dense sets is a problem that has attracted attention but is still far from resolved. Methodologies solely based on human input are becoming less appealing as the data sets increase in size and complexity. In tandem, as the feature space of the automated algorithms explodes, the previewing and manual correction of their results becomes impossible to achieve. Here we introduce the t-student stochastic neighbor embedding (t-sne) dimensionality reduction method as an extra step in the spike sorting pipeline. We position this step after the reduction of the signal with PCA of the detected spikes and before any further clustering. T-sne allows the embedding of the n-dimensional spike (n = Nchannels*Mpcs) into a low dimensional space. We show that this embedding creates obvious clusters of spikes that can be previewed and manually delineated with little effort and a high degree of confidence. We propose that these clusters represent single units and test the quality of this assertion by running our algorithm on labeled data sets both from hybrid and paired juxtacellular/extracellular recordings. Finally, we develop a GPU based extension to the algorithm that allows for fast embedding of millions of spikes. at <http://biorxiv.org/lookup/doi/10.1101/037937>

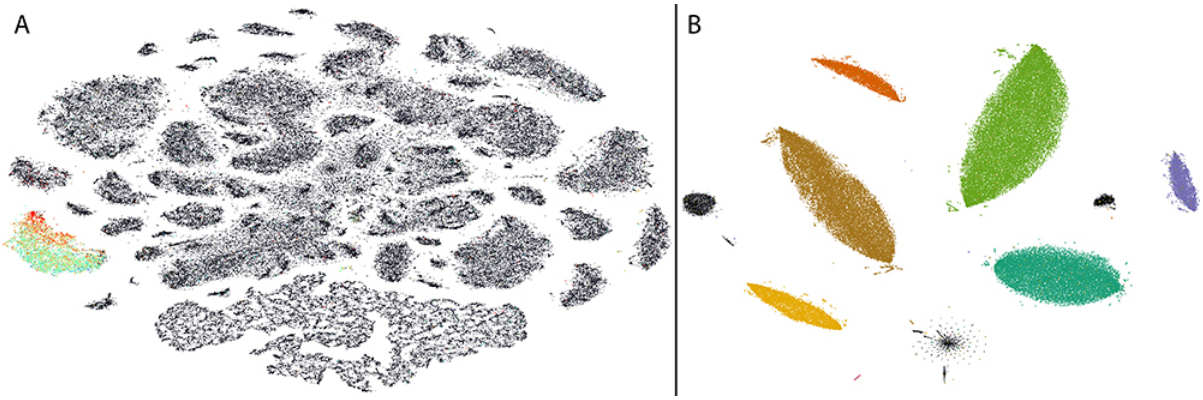

Figure 1. Spikes embedded in t-sne space. A) Paired recordings with one cell labeled by a parallel juxtacellular recording (color indicates size of juxtacellularly recorded spikes). B) Hybrid data with 7 units labelled (color indicates the units, black is unlabeled spikes).

Title: Efficient and accurate extraction of *In vivo* calcium signals from microendoscopic video data

Authors: *P. ZHOU[1], S. RESENDEZ[2], G. STUBER[2], R. E. KASS[1], L. PANINSKI[3]; [1]Carnegie Mellon Univ., Pittsburgh, PA; [2]The Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [3]Columbia Univ., New York City, NY

Abstract: Monitoring the activity of large-scale neuronal ensembles during complex behavioral states is fundamental to neuroscience research. Continued advances in optical imaging technology are greatly expanding the number and depth of neuronal populations that can be visualized. Specifically, in vivo Ca2+ imaging through microendoscopic lenses and the development of miniaturized microscopes have enabled deep brain imaging of previously inaccessible neuronal populations within the brains of freely moving mice. While these techniques have been widely used in studies of brain-behavior relationships, automatic methods

for extracting cellular signals from this data are currently limited and suboptimal.
Constrained Nonnegative Matrix Factorization (CNMF) is a recently proposed method that has shown great advantages in simultaneously denoising, deconvolving, and demixing of calcium imaging data (Pnevmatikakis et al, Neuron 2016). This method was optimized for 2-photon and light sheet data, where the background is relatively weak and has a simple spatiotemporally separable structure. However, microendoscopic data suffer from high levels of background fluorescence from multiple sources as well as an increased potential for overlapping neuronal signals. The standard CNMF approach does not successfully isolate neural signals from the very strong fluctuating background in these experiments.
Here we extend the CNMF approach to better subtract strong background activity, using Singular Value Decomposition (SVD) together with low spatial frequency constraints. The spatial low-pass feature of the background is due to the large blurring effect of the out-of-focus fluorescence. We validate our method using 1-photon imaging data collected from freely behaving mice and find empirically that it is able to remove background signals that can be an order of magnitude larger than the individual neuronal signals of interest. Compared with the widely used PCA/ICA approach, the proposed method is much faster and extracts neurons with improved localized spatial structure and denoised temporal traces without negative events. Our analysis yielded fast, reliable, and high quality signal extraction under a wide variety of imaging parameters. We plan to release the code as open source software.

Title: Reliable identification of the same neurons across multiple days in calcium imaging data

Authors: *L. SHEINTUCH, A. RUBIN, N. GEVA, Y. ZIV;
Neurobio., Weizmann Inst. of Sci., Rehovot, Israel

Abstract: Recent advances in optical imaging and genetically encoded Ca^{2+} indicators converged to enable chronic, cell-type specific recordings of neuronal activity from large neuronal populations in various brain structures of freely behaving rodents. The capability to repeatedly image populations of the same neurons over periods of time that range from days to months is important for longitudinal studies of neuronal dynamics, e.g., in learning and long-

term memory. Such longitudinal studies necessitate correct identification ("registration") of the same neurons across multiple imaging sessions. Accurate registration of the same neurons becomes challenging as the number of active cells in a session and the number of imaging sessions are increased. In previous work, cells were registered as the same if they were located within a certain distance threshold determined by the distribution of within-session nearest neighbor distances. Such an approach, however, does not always guarantee that the optimal registration threshold is being used and furthermore, it fails to take into account the morphology of the cells, which could provide critical additional information relevant to the registration decision. Previous work also lacked quantitative estimation of registration errors (i.e. false positives and false negatives), crucial for addressing coding stability and dynamics issues. Here we present a probabilistic method for registration of cells across multiple sessions based on the similarity in the spatial footprint of cellular activity. Our method inherently estimates the uncertainty associated with the registration of each cell-pair across sessions, allowing for the exclusion of uncertain registered cells from longitudinal studies. We have found morphology based cell registration to be superior to distance based registration, and that a high fraction (>85%) of the cell-pairs can be reliably registered ($p<0.05$) over periods of weeks. We validated the performance of our cell registration method using place cells in the CA1 of the hippocampus: over intervals of days–weeks, cells with high registration certainty levels had higher place field correlations compared to cells with lower certainty levels. Overall, our method allows for reliable cell registration to be performed across multiple sessions of Ca^{2+} imaging, facilitating longitudinal studies of neuronal dynamics.

Title: Detection of repetitive spike sequences in neural ensemble based on edit similarity

Authors: ***K. F. WATANABE**[1,2], T. HAGA[3], T. FUKAI[3];
[1]Riken BSI, Saitama, Japan; [2]Grad. Sch. of Frontier Sci., The Univ. of Tokyo, Kashiwa, Japan; [3]RIKEN BSI, Wako, Japan

Abstract: Recent technological advances enable us to record the activity of hundreds and thousands of neurons simultaneously in awake animals. However, mathematical methods available for analyzing large-scale neural data are still limited. Accumulating evidence suggests that sequences of neural firing play a role in various behavioral tasks such as spatial navigation, sensory discrimination and decision-making. In this study, we propose a novel method to detect the repetition of similar but noisy spatiotemporal patterns of firing in a large neural ensemble. Novel methods for sequence detection has to be developed since the conventional analysis methods, such as template matching, are neither efficient nor robust when applied to large-scale data in the presence of biological noise, which may induce strong fluctuations in the temporal order of neuronal firing, and eliminate some spikes from or add additional spikes to repeated sequences. To overcome the difficulties, our method extended a concept of edit similarity to determine similarity between two different temporal segments of neuronal activities. We will verify the proposed method by using artificial and experimentally obtained neural activity data.

Title: Improvements to information theory analysis techniques throughout neuroscience with matlab support

Authors: ***N. TIMME**, D. N. LINSENBARDT, M. MYROSHNYCHENKO, C. C. LAPISH; Psychology, IUPUI, Indianapolis, IN

Abstract: Understanding how neural systems integrate and encode information is central to understanding brain function. An explosion in the availability of approaches that can be used to examine interactions across varying levels of brain function brings with it new challenges and opportunities. Information theory is well suited to the wide array of experiments and the

challenging nature of data analysis typical to neuroscience. Frequently, data from neuroscience experiments are multivariate, the interactions between the variables are non-linear, and the landscape of hypothesized or possible interactions between variables is extremely broad. Information theory is well suited to address these types of data as it possesses multivariate analysis tools, it can capture non-linear interactions, and it is model independent (i.e. it does not require assumptions about the structure of interactions between variables). Methods currently exist to apply information theory analyses to many different types of data, including discrete data, continuous data, single trial data, trial based data, and aggregate data that result from dimensionality reduction techniques (e.g. principle component analysis). In total, information theory is a powerful tool for highlighting and detecting complex interactions in large systems with many types of variables. To reduce barriers to the use of information theory analyses, we have created a free MATLAB software package that can be applied to a wide variety of typical neuroscience data analysis scenarios. In addition to utilizing established analysis routines, this software package also includes several improvements to analyses of continuous data and trial based data. As demonstrations, we applied the software package to numerous model systems, including models of large Izhikevich networks, sensory habituation in Aplysia, location encoding in hippocampal place cells, movement direction encoding in primary motor cortex, and light stimulus encoding by center selective retinal ganglion cells. Among other things, analyses of these models showed time dependent information flow through networks, synergist and redundant encoding by neurons, and encoding schemes modulated by inhibition, background activity, and stimulation correlation.

Title: Alyx: an open-source database for efficient data organisation and collaboration in neurophysiology

Authors: *M. L. HUNTER, C. P. BURGESS, K. D. HARRIS;
Univ. Col. London, London, United Kingdom

Abstract: Data management is a major and growing challenge in experimental neurophysiology. Many different types of information need to be stored, managed and shared, from animal husbandry, through many kinds of experimental data and metadata, to human-curated results and conclusions, as well as the relationships between these different data ontologies.
Current solutions are generally specific to individual experimenters or groups, and target only a subset of these data types. Not only does this take time in maintaining multiple systems and training users, but it also severely limits collaboration and sharing, and causes particular problems in experiments where many different data types need to be managed and linked together. Such an ad-hoc arrangement can also make it very difficult to reuse old datasets where crucial metadata is missing or unclear.
We developed 'Alyx', an open-source, extendable solution to the challenge of storing metadata and managing large neurophysiology datasets. An online, intuitive "electronic lab notebook" allows users to manage, view and share data with little to no training when performing an experiment or other procedure. The database links these records to the location of raw data files; multiple types of data acquired simultaneously can also be linked together. Software performing data acquisition or processing (such as automated weighing, spike sorting or two-photon ROI detection) uses a developer-friendly REST API, accessible from Python, MATLAB, and many other languages, to retrieve raw data files and store the associated results automatically. Sharing of data can be achieved by exposing the database API and relevant data files over the Internet, or exporting the files and metadata into a ZIP archive.
The system is based on mature, tested, and well-documented technologies. An SQL-backed data model, written in Python, is based on the Neurodata Without Borders specification. It currently incorporates standardized modules for managing experimental subjects and equipment, as well as data from electrophysiology, two-photon and widefield imaging experiments, behavioural data and arbitrary other files. Additionally, the data model allows for experiment-specific hierarchical data in the open JSON format with no need for a centrally agreed standard. Alyx can be hosted locally on a private server, cluster, or on commercial cloud hosting solutions. It integrates with network fileservers and can be easily adapted to use existing file storage structures. It efficiently deals with the problem of simultaneously storing data in multiple locations, including offline tape or disk archives.

Title: NDIO: Neuroscience discovery input and output

Authors: *J. MATELSKY[1], S. BERG[5], A. EUSMAN[2], K. LILLANEY[2], J. T. VOGELSTEIN[3,4], G. D. HAGER[2], R. BURNS[2], W. R. GRAY RONCAL[2,6];
[2]Computer Sci., [3]Biomed. Engin., [4]Inst. for Computat. Med., [1]Johns Hopkins Univ., Baltimore, MD; [5]Howard Hughes Med. Institute, Janelia Res. Campus, Ashburn, VA; [6]Res. Exploratory Develop., JHU Applied Physics Lab., Laurel, MD

Abstract: While neuroimagery datasets continue to grow, our methods for accessing them remain relatively disparate and inaccessible. Researchers have developed a rich set of tools to help reach neuroscientific conclusions. However, in order to store, retrieve and analyze data, it is often necessary to understand many different data specifications, and develop ad-hoc tools to standardize data formats and retrieve the data subvolumes of interest. This has the potential to impede scientific progress, especially across laboratories and datasets, and currently results in science that is difficult to reproduce or extend.

We present ndio, a toolkit that implements a neuroscience API in a simple and easily approachable software package. ndio is extensible and offers easy-to-use wrappers for RESTful calls to get and put image and annotation data using NeuroData, DVID, and S3 — enabling data access and sharing across many neuroscience research labs. ndio provides a common vocabulary for big data neuroscience and allows researchers to focus on scientific discovery, abstracting many of the problems associated with big data. We also implement RAMON (Reusable Annotation Markup for Open Neuroscience), an existing data standard providing common metadata for annotations across modalities, research groups and projects. An illustration of ndio operations from an end-user perspective is shown in Figure 1.

ndio is stable and is in active use by several teams across a variety of modalities, including Electron Microscopy, MRI, Array Tomography, and CLARITY. It is publicly developed under a permissive, open-source license and can be installed from PyPI using a single command line call. We demonstrate the utility of ndio through a series of claims that reproduce many of the scientific discoveries in the recent high-profile Kasthuri 2015 Cell Paper entitled: “A Saturated Volume of Neocortex.” Additional functionality and features are planned and the community is invited to contribute via our github repository at: github.com/neurodata/ndio.

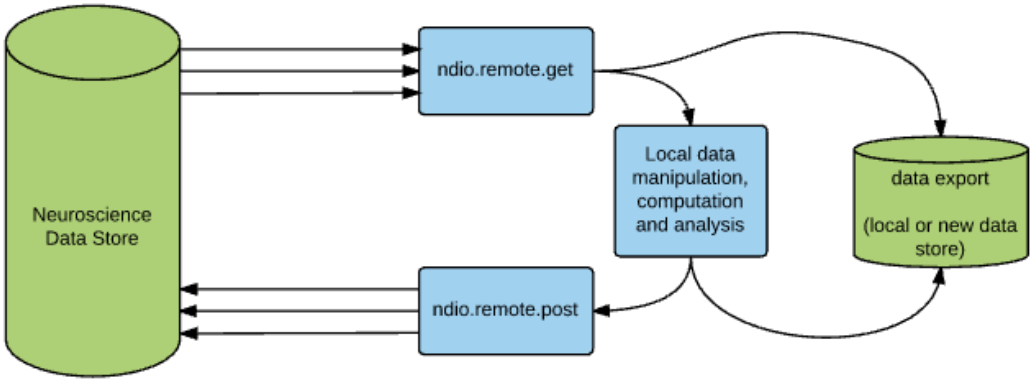

Figure 1: A high-level view of ndio being used for scientific discovery. Large data requests (gets and puts) are divided into smaller subvolumes in a process that is transparent to the end user. Data may be exported to common formats (e.g., numpy, hdf5, nifti) at any point using the ndio tools.

Title: Quantitative tract integrity profile (q-tips) as a novel toolbox for assessing tract-based white matter integrity

Authors: *S. YOUNAS[1], S. M. COURTNEY[3], M. MARTIN[4], C. R. FIGLEY[2];
[1]BioMedical Engin., [2]Dept. of Radiology, Univ. of Manitoba, Winnipeg, MB, Canada;
[3]Psychological and Brain Sci., Johns Hopkins University,, Baltimore, MD; [4]Dept. of Physics, Univ. of Winnipeg, Winnipeg, MB, Canada

Abstract: Quantitative approaches for diffusion tensor imaging (DTI) and other advanced white matter imaging methods have typically fallen into one of two categories: region-of-interest (ROI)

or voxel-wise analyses. ROI analyses extract data from relatively large, pre-determined regions, thereby facilitating the investigation of global white matter differences at the expense of sensitivity to small, localized changes. On the other hand, while voxel-wise analyses maintain high spatial resolution (i.e., by performing point-by-point analyses), sensitivity can suffer in group analyses if, for example, lesion sizes/locations vary across subjects. In order to address these limitations, a few recent studies have proposed tract-based analyses that extract quantitative imaging values along white matter tracts to combine the benefits of ROI and voxel-wise approaches.

However, although promising, existing tract-based analysis approaches have several limitations: 1) they currently use complicated, in-house software that requires multiple steps and command line inputs; 2) they are platform (Linux) dependent and therefore cannot be run on Windows-based workstations; 3) they require tractography to be performed in order to extract quantitative values, and are therefore exclusively for DTI data (i.e., cannot be used to create tract profiles from other quantitative white matter imaging modalities); and 4) most of them rely on visual examination of these curves and have not implemented more advanced methods to quantify the white matter integrity profiles (e.g., by comparing each subject's tract profile to a normative profile).

To address these issues, we have developed the *Quantitative Tract Integrity Profiles (Q-TIPs)* toolbox, which is purely MATLAB-based (making it compatible with any OS), has a flexible and user-friendly interface, and will be distributed as a standalone toolbox for the popular SPM software package. This toolbox extracts the orientation of any user-defined ROI mask by calculating its medial axis using Voronoi and Delaunay algorithms, and then cross-sectional segments along the medial axis are used to create profiles for any quantitative white matter imaging metric (e.g., DTI, myelin water imaging, magnetization transfer imaging, etc.). For final quantification, curve-fitting methods are then implemented to compare each individual tract to normative or group-averaged tract profiles.

This toolbox can be used to investigate structure-function or structure-behavior correlates as a function of neural development, healthy aging, or white matter disease, and is therefore expected to have broad research and clinical implications.

Title: Automatic anatomic orientation from the atlas to histological sections and back

Authors: *N. J. O'CONNOR[1], B. S. EASTWOOD[1], S. J. TAPPAN[1], M. FAY[1], K. E. DAY[1], P. J. ANGSTMAN[1], C. GERFEN[2], J. R. GLASER[1];
[1]MBF Biosci., Williston, VT; [2]Lab. of Systems Neurosci., Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Determining position in brain images can be a difficult task even for experienced neuroanatomists and usually involves comparing images in a microscope, or on a monitor, to structures in a paper or digital reference atlas. Here we present a novel software platform that facilitates whole brain analysis of anatomy and function by combining automated methods for reconstructing whole brain images from serial sections, aligning those sections to a reference atlas, and annotating both sections and 3D brain images with atlas delineations. The registration of brain images to a common reference atlas allows researchers to objectively make and compare measurements across brains and even across laboratories.
The components we developed for this platform include an automated alignment method for creating full-resolution 3D brain images from serial sections. This method corrects for translation, rotation, and flipped between sections as it compiles 3D images. The platform also includes alignment methods for matching individual experimental sections and 3D brain images with the Allen Institute for Brain Science's average mouse brain and its atlas (http://mouse.brain-map.org/). This matching process creates transforms that are used to maps the atlas's delineated brain structures onto a section or 3D brain. The transforms also enable the tabulation of cell counts obtained from experimental images into distinct brain regions.
To test these methods we analyzed fluorescent mouse brains comprised of over one-hundred coronal sections from mice injected with an AAV-Cre-dependent expression vector, counterstained with fluorescent Nissl stain and imaged by fluorescent whole slide imaging (Neurolucida). Sections from these images were automatically extracted, aligned, and compiled into full resolution 3D whole-brain images, and Cre-positive cells were marked using Laplacian of Gaussian automated detection methods (BrainMaker). The brain images were then matched to the Allen average brain and atlas to create annotation overlays, and mapped cell tabulated by brain region. The accuracy of mapping the atlas's delineations onto experimental sections was assessed by eye.
Here we introduce new technology to reconstruct whole brain images from serial sections, map annotations from a standard atlas onto experimental data, and determine anatomically partitioned cell counts in 3D brain images. The benefits of this new platform for neuroscience research include improved objectivity when identifying brain regions in images, the ability to analyzing more brain regions than is currently done, and the generation of data that can be compared across brains or laboratories.

Title: Digital imaging library of brain CRF distribution in serial sections

Authors: *H. J. KARTEN[1], N. O'CONNOR[2], T. KAWAMURA[3], P. E. SAWCHENKO[4], P. SANNA[3];
[1]UCSD, Del Mar, CA; [2]MBF Bioscience, Inc., Williston, VT; [3]Mol. and Cell. Neurosci., The Scripps Res. Inst., La Jolla, CA; [4]Lab. of Neuronal Structure and Function, Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: Whole Slide Imaging (WSI) is a powerful tool for comprehensive viewing and mapping of complete sets of serial sections of histological material at a resolution of 0.5 um/pixel. WSI enabled us to generate detailed histological image databases that allow users to independently assess the distribution and density of molecular markers, using genetically encoded fluorescent markers, immunohistochemistry, *in situ* hybridization, and autoradiography in bright field and fluorescent material. These image databases will be freely shared over the Internet, thereby circumventing the subjective nature of most journal reports with regard to the localization and density of molecular markers. Corticotropin-releasing factor (CRF) is a neuropeptide that was isolated from the hypothalamus on the basis of its capacity to initiate the neuroendocrine stress cascade. In addition, its broad central distribution includes aspects of the limbic forebrain associated with affective behaviors, placing CRF in a position to participate in complementary modes of stress adaptation. Here, to provide a comprehensive resource of the brain CRF distribution, we used Crh-IRES-Cre transgenic mice (B6(Cg)-Crhtm1(cre)Zjh/J) that express Cre recombinase under the control of the endogenous CRF promoter crossed with a floxed td-Tomato reporter line (B6.Cg-Gt(ROSA)26Sortm14(CAG-TdTomato)Hze/J) in which a *loxP*-flanked STOP cassette prevents transcription of a CAG promoter-driven red fluorescent

protein variant (tdTomato). In these mice, TdTomato is expressed following Cre-mediated recombination in CRF neurons to visualize CRF-expressing cells with high fidelity (Chen Y. et al 2015). To generate a database of histological images of CRF-expressing neurons, we developed software to automatically detect, order, and align serial sections from whole slide images. Anatomic regions in aligned sections, scored for the density of CRF-expressing cells and hyperlinked to a list of their anatomical structures within section images, are compiled into a web-based, interactive anatomical structure hierarchy. The sections, scores and hierarchy published to an image server can be made available for public viewing and searching.

Title: Disseminating Vaa3D and its high-performance, open-source, cross-platform neuron image toolbox

Authors: ***Y. WANG**[1,2], Z. ZHOU[2], X. LIU[2], A. BRIA[3], Y. GUO[4], H. PENG[2];

Abstract: Vaa3D (http://vaa3d.org) is a widely used image visualization and analysis software system in recent years. Vaa3D has a number of powerful functions such as visualization, interaction, computation, analysis, and management of multidimensional terabyte-level image data [1,2,3].
However, whereas Vaa3D is a cross-platform (Windows, Mac OS, and Linux) software package and is quickly becoming one of the most advanced software systems for neuroscience applications, building Vaa3D from source code is sometimes a cumbersome process. For instance, while 80% of the downloaders of Vaa3D are Windows users, it is not trivial to

successfully build a Windows Vaa3D distribution from source code due to various recent upgrades in Windows operating system, the underlying Qt libraries, and the C/C++ compilers. In this study, we improve the cross-platform compatibility of Vaa3D. We have updated the GitHub documentation for the Vaa3D Windows building procedures for several often-used building tools, which can be easily followed and reproduced. In our latest release of Vaa3D, we have produced more than 100 plugins on top of the core Vaa3D platform (version 3.2) for various neuroscience applications including displaying, filtering, comparison, segmentation, stitching, fusion, 3D geometry representation generation, quantitative calculation and analysis, heterogeneous image and surface data processing, automatic and interactive neuron morphology tracing and analysis, terabyte image processing and annotation, and so on.

Title: Baseline drift detrending techniques for fast scan cyclic voltammetry

Authors: *M. DEWAELE[1], Y. OH[1], C. PARK[1], Y. KANG[1], H. SHIN[1], I. KIM[1], K. BENNET[2], K. LEE[3], D. P. JANG[1];
[1]Grad. Sch. of Biomed. Engin., Hanyang Univ., Seoul, Korea, Republic of; [2]Engineering, Neurosurg., [3]Neurosurg., Mayo Clin., Rochester, MN

Abstract: Removing baseline drift from fast scan cyclic voltammetry (FSCV) is essential for accurate data analysis. While FSCV is useful because of its ability to track short term changes in

metabolite concentration, accurate analysis of concentration changes in vivo is difficult because of the large changes in background signals over extended time. The drifting background signals can obscure the much smaller signals from metabolites such as dopamine. During brain surgery, while using FSCV to track metabolites such as dopamine, which can take hours, the background must be stabilized, so that it can be subtracted, which can take valuable time. Current limitations of FSCV analysis include needing to move the background reference point often because of changes over long times. In this paper, we will investigate three techniques to attempt to remove the baseline drift and accurately display phasic changes in dopamine concentration both in vitro and in vivo. Using time polynomial regression, shape component regression, and a high pass filter, we will compare and contrast these methods to detrend the data series. When comparing the three detrending techniques, high pass filtering significantly showed the best performance. Both the time polynomial regression and shape component regression techniques failed to produce a stable baseline, resulting in significant variance from the desired baseline of zero. Using a high pass filter, the low frequency baseline drift was removed, and only the signals due to phasic changes in dopamine concentration remained. Thus we conclude that this filtering technique is preferable to the aforementioned alternatives. Keywords: Fast-scan cyclic voltammetry (FSCV); Detrending; Dopamine; Baseline drift. **Acknowledgement:** This research was supported by the NIH 1U01NS090455-01 award.

Title: Optimizing cage-based training for non-human primates

Authors: ***M. D. CURRY**[1], M. PARSA[2], A. CILKER[3], L. VIOLETTI[3], M.-R. A. DEHAQANI[4], B. NOUDOOST[1];

[1]Cell Biol. and Neurosci., [2]Computer Sci., [3]Montana State Univ., Bozeman, MT; [4]Sch. of Cognitive Sci., Inst. for Res. in Fundamental Sci., Tehran, Iran, Islamic Republic of

Abstract: Non-human primates (NHPs) are widely used experimental models in neurophysiological studies. Training on cognitive tasks prior to collecting neurophysiological data is an inseparable part of much of the research conducted using NHPs. Any improvement in the training method that reduces stress to the animal, increases the speed of training or improves performance on the task is of great potential value. Nevertheless, training procedures vary greatly from lab to lab and are likely far from being optimized. We have designed, built and successfully utilized a fully portable cage-mountable system to train NHPs. Although this system has been developed using Rhesus monkeys (*Macaca mulatta*), it could be used to train a variety of monkey species. Here we describe the technical specifications, construction, and operation of the system. The flexibility and portability of both the animal interface (AI) and the control unit (CU) of this system would allow it to be used for a large variety of behavioral paradigms. This method has been used to train rhesus monkeys on two different behavioral paradigms including the delayed match-to-sample (DMS) task and a change detection task. Utilizing the in-cage training system allows the animal greater control over when and how long it chooses to work, rather than imposing a training schedule based on the availability of the experimenter. Using this method the animal learned to perform both behavioral tasks in a short amount of time; based on our experience, learning of the DMS task was faster with in-cage training than with traditional methods. In some cases the animal would use the training system without the need for any water restriction. In addition to allowing voluntary, self-paced engagement with the task, this method has the advantage of being less disruptive to the monkey's social interactions, and presumably eliminating some of the stress occasioned by relocating for chair training. This system has the potential to ease and expedite the behavioral training of non-human primates on a variety of tasks.

Title: Feeding Experimentation Device Pus (fed+): an open-source behavior device for monitoring rodent home cage feeding in real-time

Authors: *J. A. LICHOLAI[1,2], K. P. NGUYEN[1], A. V. KRAVITZ[1,3];

Abstract: To study obesity and related disorders, researchers need to accurately measure food intake. The most common method for monitoring food intake involves manual periodic weighing of food, which is time consuming, labor intensive, and produces data with a low temporal resolution. Several excellent commercial systems exist that can capture high-resolution information about food intake, but these cost thousands of dollars. Previously, our lab made the Feeding Experimentation Device (FED) that (1) is low-cost, (2) is home cage compatible, and (3) can measure food intake and feeding patterns over multiple days (Nguyen et al., J Neurosci Methods, 2016). FED is packaged within a 3D printed case and equipped with technology to detect and record the removal of food pellets. With this project, we upgraded FED to provide more flexibility in conducting food intake and operant experiments, with the ease and security of online data management. The new modifications includes an output connector allowing integration of FED+ with other equipment, such as data acquisition systems for electrophysiology or photometry, by synchronizing time points from the two systems via TTL signals. We also added an ability to stream data to an open-source phant server, where the data can be accessed and graphed in real-time. Lastly, FED+ has two additional sensors for training rodents on operant tasks. This permits operant tasks to be learned in a home-cage environment and with extended training sessions. FED+ continues to be made from easily accessible hardware components and all of its code and hardware are open-source. Altogether, FED+ monitors feeding behavior and operant learning in real-time, with easy synchronization with other scientific equipment.

Title: The neuroscience lexicon: return of the STD

Authors: *T. GILLESPIE[1], M. E. MARTONE[2], A. E. BANDROWSKI[1], J. S. GRETHE[2]; [1]Neurosci., [2]Neurosciences, UCSD, LA Jolla, CA

Abstract: Scientific communities communicate using shared language. Communication between subfields of neuroscience, which all have their own partially overlapping technical vocabularies, is especially challenging due to the fantastic diversity of their methodologies and subjects of research. Given this diversity of perspectives on the nervous system, formal vocabularies, terminologies, lexicons, and ontologies are vital for enabling effective communication between experts in different subfields of neuroscience. To this end, the Neuroscience Information Framework (NIF) has built and maintains the NIF standard ontology (NIFSTD) and NeuroLex, a community lexicon for neuroscience. Since the start of the NIF ontology in 2008, tooling for working with ontologies has improved enormously. In addition, a suite of new tools for online collaboration has achieved wide adoption and provides better ways for individuals to contribute to formal ontologies. We have migrated the NIF ontology to GitHub at https://github.com/SciCrunch/NIF-Ontology to make it easier for individuals and organizations to contribute, and have participated in the development of SciGraph, a new tool for deploying ontologies at scale which vastly simplifies integration of ontologies into other information systems. We have restructured the layout of the NIF ontology and converted all internal ontology files to Turtle format (ttl, terse triple language) to improve human readability and simplify change tracking. We are curating the community contributed information contained in NeuroLex and integrating it into the NIF ontology so that the knowledge can be used to tag and search neuroscience data sources via the NIF data federation. Finally, we have updated and streamlined the process by which community contributions are reviewed and incorporated into the formal NIF ontology and built a new tool, InterLex, for managing community terminologies. Here we will present a detailed overview of the new architecture for the community and formal ontologies, as well as details on how to contribute to and make use of them.

Title: EEG as an imaging tool: which inverse method can successfully disentangle sources in proximity?

Authors: *K. KALOGIANNI[1], J. C. DE MUNCK[3], G. NOLTE[4], A. VARDY[2], A. C. SCHOUTEN[1,5], F. C. T. VAN DER HELM[1], A. DAFFERTSHOFER[6];

Ctr., Amsterdam, Netherlands; [4]Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [5]MIRA Inst. for Biomed. Technol. and Tech. Medicine, Univ. of Twente, Enschede, Netherlands; [6]Fac. of Behavioural and Movement Sci., MOVE Res. Institute, VU Univ. Amsterdam, Amsterdam, Netherlands

Abstract: The accuracy of EEG source localization depends on the choice of the inverse method, the resolution of the forward model, and the signal to noise ratio (SNR) of the recordings. Since we are interested in disentangling sources in proximity, the goal of our study is to examine the sensitivity of spatial resolution of EEG source reconstruction to a wide variety of factors like reconstruction method, SNR, orientation, inter-dipole distance and depth of the simulated dipoles, etc.
We simulated time series to resemble waveforms of somatosensory evoked potentials. Inter-dipole distances and different dipole orientations were investigated as well as the effect of (realistic) noise. We employed both spherical and realistic head models. Source reconstruction was realized using a conventional stationary dipole model, MUSIC, self-consistent MUSIC (SC-MUSIC) algorithm, and e-LORETA. In addition to the above mentioned methods, a new approach is tested building upon the e-LORETA solution: the topography of the maximum of the e-LORETA distribution is projected out of the data before calculating the next e-LORETA inverse solution in a iterative process.
The quality of fit (or localization) was defined as the distance between the simulated point-sources and either the estimated point-sources or the activity distributions by means of the Euclidean distance or of the Earth Mover''s Distance, respectively.
As expected, inter-dipole distances played an important role in the ability of every method to disentangle the simulated sources. Overall, SC-MUSIC appeared best suited for disentangling the two simulated sources even at high-noise simulations.

Title: Label free capillary velocimetry in mouse cerebral cortex using dynamic laser speckle

Authors: *A. SAFI[1], C. YEON[2], J. HONG[2], E. CHUNG[3];
[1]Sch. of Mechanical Engin., [2]Biomed. Sci. & Engin., [3]Sch. of Mechanical Engin. and Biomed. Sci. & Engin., Gwangju Inst. of Sci. and Technol. (GIST), Gwangju, Korea, Republic of

Abstract: Many brain disorders including Alzheimer's disease or stroke are known to be correlated with blood flow. Label free assessment of blood flow in capillaries under normal and diseased conditions could be helpful for diagnosis and therapeutic treatments. Laser speckle contrast imaging (LSCI) is a simple wide-field imaging tool and has been widely used for flow analysis. However, quantitative information from LSCI has been restricted due to the presence of static scattering from tissue without *a priori* knowledge of the flow behaviour. Here we suggest a method for blood flow estimation in capillaries using full field time varying speckle. We use temporal demodulation to distinguish the dynamic speckle from its stationary counterpart, based on which we perform temporal autocorrelation to estimate the blood flow in capillary vessels. The results obtained from flow phantom experiment are in good agreement with the calibrated values. We also showed our method in case of *in vivo* experiment on mouse brain. Our results show dynamic laser speckle is an indicative of dynamic red blood cell (dRBC) content and our proposed method combined with qualitative perfusion map may prove to be a powerful tool to investigate the heterogeneities of capillary velocities.

Title: A novel method for automated cytoarchitectonic parcellation of the rhesus monkey neocortex

Authors: *A. NAZARAN[1], J. J. WISCO[2,4], N. K. BANGERTER[3];
[2]Dept. of Physiol. and Developmental Biology, Neurosci. Ctr., [3]Dept. of Electrical and Computer Engineering, Neurosci. Ctr., [1]Brigham Young Univ., Provo, UT; [4]Dept. of Neurobio. and Anat., Univ. of Utah Sch. of Med., Salt Lake City, UT

Abstract: INTRODUCTION
Validation of commonly used MRI techniques for in-vivo cytoarchitectonic analysis with respect to histology is crucial for assessing the reliability and accuracy of cytoarchitectural differences seen with the progression of the disease. In this work, we present an algorithm for the semi-automated parcellation of cytoarchitectonic areas from a high-resolution histological image of one thionin-stained coronal section of the Rhesus monkey (macaca mulatta) brain through the level of the hippocampus and pulvinar nucleus from Brainmaps.org. The algorithm first creates a binary mask of neurons from histological sections, and then measures the density, size, and number of neurons in a specific radial distance in the binary masked image. After that, a map including all the aforementioned features is constructed. The algorithm finally segments the map into cytoarchitectonic areas.
METHODS
The slice number 0721 from the dataset number RH04 from Brainmaps.org was acquired at the resolution 0.05 mm. An ROI over the left side of the monkey brain was defined. Partitioning the cortex into homogeneous sub-regions involved a multi-step, semi-automated process of 1) making a binary mask of the neurons based on Otsu's thresholding, 2) acquiring neuron centroids from the binary masked image, 3) defining a radial distance over each neuron centroid, 4) calculating the *density*, *size*, and *number* of all the neurons with a centroid inside the radial distance, and 4) dividing the cortex into sub-regions based the similarity of texture and content extracted from the features. The reference map for this histological slice has also provided at Brainmaps.org. An expert neuroanatomist evaluated the determined sub-regions in comparison with visually inspected sub-regions from the same ROI.
RESULTS: Our semi-automated method agrees with that of the expert visualization, but also differentiates slight changes in the cytoarchitecture. For example, in area TEO, neither anatomists from BrainMaps.org, nor our group found changes in the cytoarchitecture. However, our algorithm demarcated TEO into three different areas. The algorithm finds more parcellations

that are difficult to see by eye alone.
CONCLUSION
The evaluation of the algorithm by our expert neuroanatomist based on visual inspection indicates that the semi-automated technique is identifying what the neuroanatomist would consider sub-regions, in addition to correctly identifying major cytoarchitectonic areas.

Title: Accurate detection of muscle activation onset based on surface EMG using a maximum profile likelihood approach

Authors: E. S. SUVISESHAMUTHU[1], *D. ALLEXANDRE[1], G. H. YUE[1,2];
[1]Kessler Fndn., West Orange, NJ; [2]Physical Med. & Rehabil., Rutgers New Jersey Med. Sch., Newark, NJ

Abstract: Background: Myoelectric signals recorded with surface electromyography (sEMG) electrodes provide valuable information for understanding muscle function and neuromuscular diseases especially under human movement conditions. However, investigators working with sEMG for this goal often face a challenge of precisely estimating the onset of muscle activation as this requires detection of the smallest muscle activity at the earliest time based on the sEMG recordings that typically vary from trial to trial and subject to subject. The current study attempted to address this challenge by employing a robust statistical approach to treat the sEMG data for accurate detection of muscle activation onset (MAO) in an unsupervised fashion. **Objective:** To design and evaluate the performance of an algorithm relying on the maximum profile likelihood (MPL) [Zhu and Ghodsi, 2006] for predicting the MAO of a handgrip contraction. **Methods:** The sEMG data were collected from the Flexor Digitorum Superficialis (FDS) and Extensor Digitorum (ED) muscles of a healthy individual (male, 24 years) while performing 100 intermittent handgrip contractions at 20% maximum voluntary contraction (MVC). The acquired sEMG signals were first preconditioned with the Teager-Kaiser energy

operator [Kaiser, 1990], and then supplied to the MPL and wavelet change detection (WCD) [Lavielle, 1999] algorithms. The performance of the algorithms was evaluated by mean errors between the MAO time (in ms) estimated by each of the algorithms and MAO time derived from manual detection based on independent demarcation of the MAOs on the raw sEMG signals by five motor control/sEMG experts. The MAO detection accuracy of the MPL algorithm was then compared to that of the WCD algorithm, a widely accepted and used approach.
Results: The MPL-based approach detected the FDS and ED activation onset with a mean accuracy of ±20 and ±32 ms, respectively, whereas, the conventional WCD algorithm produced a mean accuracy of ±30 and ±76 ms, respectively.
Conclusions: The statistical approach based on the MPL is capable of more accurately detecting the MAO from the FDS and ED muscles in a voluntary handgrip. This unsupervised approach obviates the need for parameter tuning, which is a unique advantage over other popular methods such as the WCD and those based on threshold detection. Research is underway to further validate this technique subject to various experimental conditions.

Title: Minimizing ROI crosstalk in neuronal activity data from miniature microscope calcium imaging.

Authors: *A. LUCHETTI, A. BOTA, Y. HAYASHI;
RIKEN BSI, Wakoshi, Japan

Abstract: One of the most exciting neuroscience innovations in the last decade has been the development of techniques for imaging neuronal activity in the living, freely behaving animal. These techniques potentially allow the recording of several hundred neurons simultaneously by using a single-photon epifluorescence mini microscope and a GRIN lens implanted in the animal's brain. The next challenge is finding optimal ways to analyze this data by identifying individual neurons in the recording and transforming image data into neuronal activity data. Due to light scattering generated in single-photon epifluorescence, the crosstalk between nearby neurons becomes a significant issue when imaging tissue expressing densely expressed calcium

indicator. Here, we propose a novel approach to solving this difficulty, by using an algorithm that evaluates how bright-pixels are distributed within the Region of Interest (ROI) area, rather than the average brightness of the ROI itself. The technique first determines a local area around each ROI, then evaluates the distribution of the brightest pixels within this local area and assigns a score to the ROI based on how the brightest pixels are clustered within it. We test this technique on experimental data from both sparsely and densely expressed CA1 in vivo samples and measure the number of errors by comparing automatically detected spikes against manual analysis. We find that this technique can keep the number of false positives low without sacrificing the sensitivity of detection, thus also preventing accumulation of false negatives.
