Abstract: The American alligator (*Alligator mississippiensis*) and domesticated chicken (*Gallus gallus domesticus*) are both archosaurs, derived from a common evolutionary ancestor about 240 Mya (Green et al. 2014). By comparing retinal cellular organization in these two species, we can test whether retinal structure has diverged in association with two different ecological niches: an aquatic predator (alligator) and a terrestrial prey (chicken). To investigate this, we have employed immunohistochemistry and confocal microscopy to identify key cell populations from frozen sections of paraformaldehyde-fixed retinas. We used the following primary antibodies known to recognize proteins expressed by specific cell types in the chicken retina: bipolar cells (α-PKCα, Caminos et al. 1999), Müller cells (α-glutamine synthetase, Norenberg et al. 1980), amacrine cells (α-syntaxin-1, Barnstable et al. 1985), target amacrine cells (α-parvalbumin, Weller et al. 2009), starburst amacrine cells (α-ChAT, Millar et al. 1985), and dopaminergic amacrine cells (α-tyrosine hydroxylase, Fauquet and Ziller 1989). The α-PKC antibody did not label bipolar cells in the alligator retina. The α-glutamine synthetase antibody labeled Müller cells in both species, but labeling in the inner plexiform layer (IPL) was less extensive in the alligator retina. Antibodies raised against syntaxin-1 gave a similar labeling pattern in both species with labeling of amacrine cell bodies in the inner nuclear layer (INL) and their processes in the IPL as well as labeling of presumed horizontal cell processes in the outer plexiform layer. Parvalbumin antibodies labeled target amacrine cells, which are confined to the ventral half of the chicken retina. In the alligator, these antibodies labeled morphologically distinct populations of amacrine cells in both the dorsal and ventral retina. The antibodies raised against ChAT labeled starburst amacrine cells in both species with labeling localized to cell bodies in the INL and in the ganglion cell layer and processes confined to two bands in the IPL. Interestingly, the density of α-ChAT-positive cell bodies was higher in the chicken retina. The α-tyrosine hydroxylase antibodies labeled morphologically distinct populations of amacrine cells in the chicken and alligator retinas. These results support the hypothesis that the chicken and alligator have evolved specializations that might tailor retinal signal processing to suit the lifestyle of each species.

Title: Effects of light luminance level on retinal dopamine metabolism and lens induced myopia susceptibility

Authors: *E. LANDIS[1], H. PARK[2], C. SIDHU[2], K. STOUT[3], G. MILLER[4], M. IUVONE[2], M. PARDUE[5];
[1]Neurosci., [2]Ophthalmology, [3]Mol. and Systems Pharmacol., [4]Envrn. Hlth., Emory Univ., Atlanta, GA; [5]Biomed. Engin., Georgia Inst. of Technol., Atlanta, GA

Abstract: Purpose: The purpose of this study is to determine how varied ambient light impacts dopamine activity in the mouse retina and alters susceptibility to lens induced myopia. High and low light levels decrease myopia susceptibility but intermediate light increases susceptibility. We hypothesize that this occurs through different dopamine related mechanisms. To determine the role of dopamine, we analyzed dopamine signaling in the retinas of mice housed in varied ambient light for acute or chronic durations.
Methods: Wild-type C57BL/6J mice (Jackson Labs) were housed individually in scotopic (0.005 lux), mesopic (50 lux) and photopic (15,000 lux) light beginning at the start of a light phase. A subset of mice were housed under each light level for 3 hours and were sacrificed for retina collection 3 hours (acute response) after light onset (ZT 3). A second group of mice were housed under each light level for 10 days (chronic response) and sacrificed for retina collection 4 hours after light onset. Retinas were analyzed for dopamine (DA) and its primary metabolite DOPAC via high performance liquid chromatography.
Results: Results were normalized to mean levels under mesopic light to compare relative light responses across exposure periods. The acute response to scotopic light showed the highest levels of DA (1.11 normalized to mesopic) and the lowest level of DOPAC (0.48 normalized), relative to the other light levels. The acute response to photopic light had the lowest level of DA (0.86 normalized) and the highest of DOPAC (1.48 normalized). Chronic response retinas showed higher levels of DA and DOPAC in both scotopic (DA: 1.27, DOPAC: 1.18 normalized) and photopic (DA: 1.13, DOPAC: 1.50 normalized) housed mice. The DOPAC/DA ratio, a measure of DA turnover, increased with light level regardless of exposure period but was higher in acute exposure scotopic light in comparison to chronic exposure; the opposite was true under photopic light.
Conclusion: The acute response to various ambient light shows that early in light adaption DA metabolism is modified to varied ambient light. With chronic exposure to the different luminances, scotopic and photopic light lead to increased DA activity relative to mesopic light. DA metabolism increased with longer exposure to scotopic light but decreased with exposure to photopic light. This finding could indicate different DA mechanisms in the response to luminance levels, which could further alter lens induced myopia in mice. How these differences

lead to changes in myopia susceptibility will be investigated by measuring changes in retinal DA release and uptake by fast-scan cyclic voltammetry.

Title: Inhibition within starburst amacrine cell network localizes SAC dendritic signaling and sharpens direction selectivity

Authors: *H. DING, J. S. DIAMOND;
NIH, Bethesda, MD

Abstract: Directionally-tuned inhibitory signals from starburst amacrine cells (SACs) play a key role in the direction selective circuit in the mammalian retina. Past studies have shown that different regions of the SAC dendritic arbor can respond independently to visual stimuli and exhibit distinct directional tuning. By using two-photon calcium imaging, we study how individual branches within a single SAC dendritic arbor transform excitatory and inhibitory inputs to produce directionally tuned output signals. We examined the angular tuning properties of individual presynaptic varicosities on SAC dendrites by measuring calcium signals evoked by bars moving across the visual field in eight different directions. We found that outputs could be separated into clusters based on their response correlations and that the clusters corresponded to outputs arising on the same parent dendrite. The correlation between outputs from the same parent dendrite was much higher than between outputs from other parent dendrites. We also mapped the visual receptive field properties of each varicosity to determine the spatial relationship between light-evoked inputs and outputs. As predicted by recent studies, we found that the centers of mapped receptive fields lay over parent dendrites located more proximal to the soma.
Blocking SAC-SAC inhibition with GABAzine broadened the tuning width of individual outputs and decreased the separability of responses among outputs from different parent dendrites. GABAzine decreased the difference in output correlations of branches within the same parent dendrite and branches from different parent dendrites. GABAzine expanded the receptive field

size of individual varicosities by increasing the overall amplitude of responses, but did not change the receptive field shape. This effect was primarily due to blockade of SAC-SAC inhibition rather than feedback inhibition onto bipolar cell terminals, because GABAzine did not dramatically increase responses or receptive field sizes in type 5 cone bipolar cells, which provide excitatory input to ON SACs. Taken together, these results indicate that SAC-SAC inhibition compartmentalizes DS signaling within smaller regions of SAC dendrites, enabling finer discrimination of motion direction.

Title: Optogenetic interrogation of synaptic computation in the retina

Authors: *J. POTTACKAL[1], G. E. PERRIN[2], J. H. SINGER[2], J. B. DEMB[1];
[1]Dept. of Ophthalmology and Visual Sci., Yale Univ., New Haven, CT; [2]Dept. of Biol., Univ. of Maryland, College Park, MD

Abstract: Synapses perform complex transformations of presynaptic voltage into postsynaptic current. However, the extent to which functional properties of synaptic transmission differ between specific cell types in the central nervous system remains largely unknown. The mouse retina presents a tractable system in which to address this problem due to significant recent progress in the identification and characterization of its ~100 types of neurons. Here, we describe a novel optogenetic approach that enables quantitative analysis of synaptic transmission between identified cell types in the retina. We use the Cre-Lox conditional expression system to drive expression of the light-gated ion channel channelrhodopsin-2 (ChR2) in genetically identified subsets of retinal interneurons, including bipolar cells and amacrine cells (ACs). Under

pharmacological blockade of photoreceptor-mediated visual responses, whole-cell current clamp recordings from ChR2-expressing ACs in the wholemount retina demonstrate that ChR2 stimulation provides rapid, faithful modulation of membrane potential in graded (i.e. non-spiking) neurons over a physiologically relevant range of temporal frequencies up to ≥30 Hz. We find that ChR2-mediated depolarization of CRH-1 ACs evokes robust inhibitory postsynaptic currents (IPSCs) in ON α retinal ganglion cells (RGCs) voltage-clamped at 0 mV. Subsequent linear-nonlinear cascade analysis of ChR2-evoked IPSCs in ON α RGCs rules out a gain control mechanism of variance adaptation at the CRH-1 AC—ON α RGC synapse. Finally, this approach complements existing techniques for interrogating synaptic transmission in the retina while offering improved stability and signal-to-noise ratio compared to paired whole-cell recording.

Title: Mechanisms of surround inhibition in the object motion sensitive circuit of the mouse retina

Authors: *T. KIM, D. KERSCHENSTEINER;
Washington Univ. In St.Louis, Saint Louis, MO

Abstract: Object motion is first detected in the retina. In mice, W3-retinal ganglion cells (W3-RGCs) respond robustly to movements of small objects, but remain silent during global image motion. We previously showed that object motion sensitive responses of W3-RGCs are driven by excitatory input from vesicular glutamate transporter 3-expressing amacrine cells (VG3-ACs). Both VG3-ACs and W3-RGCs receive strong inhibitory input from their receptive field surrounds, which suppresses responses to global image motion. Here, we use transgenic mouse lines expressing Cre recombinase in a candidate cell type to identify and characterize the source of surround inhibition in the object motion sensitive circuit of the retina. In 2-photon guided patch clamp recordings, we characterize responses of the candidate cells, test their functional

connectivity with VG3-ACs and W3-RGCs using optogenetics, and evaluate the contribution of candidate cells to the feature-selective responses of VG3-ACs and W3-RGCs using conditional knockouts of the vesicular inhibitory amino acid transporter (VIAAT).

Title: GABA-induced chloride gradients in cone bipolar cells of the mammalian retina

Authors: *S. L. STELLA, Jr., D. S. MCDEVITT;
Neural and Behavioral Sci., Penn State Univ. Hershey-College of Med., Hershey, PA

Abstract: In mammalian retina, photoreceptor signals are segregated into ON and OFF pathways, rods contact a single class of bipolar cell, the rod ON bipolar cell, whereas cones contact both ON and OFF cone bipolar cells. Little is known about GABA's action at cone bipolar cells, and the ability of GABA to regulate their excitability through intracellular chloride ion (Cl^-) changes. Ionotropic GABA receptor expression is well documented in rod bipolar cells, but the spatial distribution and pharmacological profile is not known in cone bipolar cells. The goal of this project was to characterize GABA-mediated $[Cl^-]_i$ changes in cone bipolar cells of the mouse retina using yellow fluorescent protein (YFP) as a Cl^- biosensor. Mice expressing YFP under the Thy-1.2 promoter were used for this study. YFP fluorescence is sensitive to quenching by many anions, of which Cl^- is the most physiologically relevant. This provides a way to monitor $[Cl^-]_i$ changes in real-time. To address ionotropic GABA receptor function on cone bipolar cells, two techniques were employed: real-time Cl^- imaging using YFP fluorescence confocal microscopy and immunocytochemistry. Currently, we have identified both ON and OFF cone bipolar cell types expressing YFP. We discovered that changes in YFP fluorescence were correlated with increasing GABA concentrations (0.001 to 1 mM). Changes in YFP fluorescence were observed at the dendrites and soma. These YFP fluorescence changes to GABA were suppressed by replacing $[Cl^-]_o$ with gluconate. In addition, the YFP fluorescence changes were independent of changes in pH, suggesting $[Cl^-]_i$ changes were induced by GABA. We also observed different responses in the soma and dendrite to both GABA and the Cl^- transport inhibitor, furosemide, suggesting that there is a unique spatial Cl^- gradient in some cone

bipolar cells. $GABA_A$ and $GABA_C$ receptors were expressed at the dendrites, soma and terminals of cone bipolar cells. This distribution of GABA receptors on cone bipolar cells is in agreement with the Cl^- imaging of GABA-induced changes in $[Cl^-]_i$, suggesting that YFP expressing neurons provide an elegant way to monitor spatial and temporal Cl^- gradients in real time.

Title: VIP-expressing amacrine cells comprise different cell types in mouse retina

Authors: *L. PEREZ DE SEVILLA[1], H. TE HAPUKINO[2], N. BRECHA[2];
[1]Neurobio., [2]UCLA, Los Angeles, CA

Abstract: Amacrine cells consist of a heterogeneous group of inhibitory interneurons that form distinct microcircuits and participate in visual information processing in the inner retina. This study has focused on defining and characterizing the vasoactive intestinal peptide (VIP) expressing amacrine cells in the mouse retina using a VIP-Cre recombinase mouse line. **Methods:** VIP-tdTomato and VIP-Brainbow mouse lines were generated by crossing a VIP-Cre transgenic mouse line (JAX #10908) with a Cre-dependent tdTomato (JAX #7909) and a Brainbow2.1 (JAX #13731) reporter mouse line. Fluorescent cell bodies in retinal whole-mounts were imaged and reconstructed using a Zeiss LSM 710 confocal microscope. VIP-tdTomato fluorescent cell bodies in the INL and GCL were injected with Neurobiotin in retinal whole-mounts to define their general morphology, stratification patterns and to test their gap junction connectivity with other cells. **Results:** TdTomato fluorescent cell bodies in the INL and their processes were distributed to laminae 1, 3, 4 and 5 of the IPL. Brainbow2.1 fluorescence and tracer injections revealed three types in the INL and four types in the GCL, based on the ramification of their processes in the IPL, general morphology, dendritic field sizes and coupling patterns. Neurobiotin injections of tdTomato fluorescent cells in the INL revealed VIP-2 amacrine cells coupling to VIP-2 amacrine, non-VIP amacrine and ganglion cells. The remaining VIP amacrine cells in the INL and GCL exhibited no tracer coupling. **Conclusion:** We have

identified a novel amacrine cell population consisting of 4 main types and 3 other types; four of them located in the GCL. All types are characterized by VIP expression and they differ in their general morphology, stratification patterns and gap junction coupling.

Title: Spectral-spatial mapping by primary photoreceptors organized in a somatotopic array

Authors: T. K. H. GROVES[1], *J. A. JELLIES[2];
[1]Biol. Sci., [2]Western Michigan Univ., Kalamazoo, MI

Abstract: We wondered how animals with simple, non-image-forming eyes can extract and use image features (such as spectral contrast across a visual field). Our overarching hypothesis is that 2-dimensional pixel arrays of simple eyes can be used to extract low-resolution image features. The medicinal leech, *Hirudo verbana* is endowed with a visual system composed of "simple" eyes in 2 discrete arrays. *Hirudo* collects visual information using 5 pairs of pigmented cephalic eyecups at the margin of the anterior sucker, and a second distributed and segmentally iterated array of 7 pairs of dermal sensilla arranged dorsal to ventral along the central annulus of each mid-body segment (for a total of at least 294 sensilla). Because these eyespots sample different spatial domains of the external environment we propose that they comprise a type of low-resolution somatotopic retinal surface. *Hirudo* can discriminate green and near ultraviolet (UV) light (Jellies. 2014. J. Exp. Biol. 217:974), and they rotate away from ventrally, but not dorsally presented UV light. Furthermore, a visually-sensitive interneuron (the S-cell) integrates spectral contrast in that it responds best to UV only when presented ventrally, and best to green light when presented dorsally (Jellies. 2014. J. Comp. Physiol. A 200:923). We have suggested that the array of dermal sensilla can act as a “spectral statocyst” to inform 3-D body position. We predicted that the primary sensillar photoreceptors may be responsible for comparing wavelengths across the visual field, information that is then projected into the CNS. Adult leeches were dissected to expose discrete sensillar nerves from ventral, dorsal, and lateral sensilla. We used extracellular recording in combination with light stimulation (using previously developed LEDs, red, green, blue, UV) to characterize complex trains of light-evoked action potentials from sensilla across 4 wavelength ranges and luminosity, and under light-adapted conditions. Ventral sensilla were strikingly preferentially responsive to UV light, while dorsal

sensilla were more broadly responsive to green light. Furthermore, the unique ventral UV response had distinctly tonic components while the dorsal sensillar responses to green light resembled the phasi-tonic responses seen in posterior cephalic eyes. We suggest that spatially relevant spectral contrast information is established at the primary sensory level. Thus, synaptic interactions between sensillar axons and interneurons in the CNS may underlie previously described UV evoked behaviors and provide the substrates for synaptic computation for visual feature extraction by a system lacking image-forming eyes.

Title: Nitric oxide promotes neurotransmitter release by activating a voltage-independent Ca^{2+} influx pathway in amacrine cells

Authors: *J. W. MADDOX, E. GLEASON;
Biol. Sci., Louisiana State Univ., Baton Rouge, LA

Abstract: Nitric oxide (NO) synthase is localized to amacrine cell (AC) presynaptic terminals (Cao and Eldred, 2001) suggesting that NO synthesis might affect neurotransmitter release. We have previously shown that NO elevates cytosolic Ca^{2+} (Ca^{2+}_{Cyt}), enhances GABAergic evoked postsynaptic currents, and increases GABAergic spontaneous postsynaptic current frequency ($sPSC_{Fq}$). These effects are independent of soluble guanylate cyclase, and NO does not alter Ca_v currents. Here, we test the hypothesis that NO increases $sPSC_{Fq}$ by eliciting a voltage-independent Ca^{2+}_{Cyt} elevation. Cultured chick ACs (Gleason et al., 1993) contacting other ACs were voltage clamped at -70 mV and exposed to the NO donor *S*-Nitroso-*N*-Acetylpenicillamine (SNAP, 500 µM), which increased $sPSC_{Fq}$ by 63% ($p < 0.01$). To determine if the NO-dependent Ca^{2+} elevation is action potential-dependent, the Na_v channel blocker TTX (300 nM) was included in the external solution, but NO still increased $sPSC_{Fq}$ by 68% ($p = 0.03$). However, preloading the cells with the fast Ca^{2+} chelator BAPTA-AM (10 µM, 1 hr) prevented the NO-dependent increase in $sPSC_{Fq}$ ($p = 0.6$). To determine the contribution of Ca^{2+} stores, ACs were pre-treated with the SERCA pump inhibitor thapsigargin (TG, 2 µM, 1 hr) then loaded with the Ca^{2+} indicator Oregon Green BAPTA-AM (2 µM, 1 hr). In the presence of external Ca^{2+}, NO

increased Ca^{2+}_{Cyt} from baseline in control ($p < 0.01$) and TG treated cells ($p < 0.01$). In the absence of external Ca^{2+}, NO was unable to increase Ca^{2+}_{Cyt} from baseline in control and TG treated cells ($p = 0.06$). NO was still effective at increasing $sPSC_{Fq}$ after Ca^{2+} store depletion ($p < 0.01$). These results indicate that NO activates a Ca^{2+} influx pathway exclusively. The Ca^{2+} permeable cation channel TRPC5 can be activated by S-nitrosylation (Yoshida et al., 2005), and antibody labeling suggests that TRPC5 is expressed by these cells. To determine the involvement of TRPC5, the TRPC5 inhibitor clemizole (10 μM) was applied prior to and during application of SNAP. Clemizole prevented the NO-dependent increase of Ca^{2+}_{Cyt} ($p = 0.5$) and the increase in $sPSC_{Fq}$ ($p = 0.97$). Additionally, 2 mM La^{3+} prevented the NO-dependent increase in $sPSC_{Fq}$ ($p = 0.5$), whereas 10 μM La^{3+} potentiated the NO-dependent increase of $sPSC_{Fq}$ ($p = 0.02$), an effect consistent with TRPC5 activity. TRPC5 can be activated by PLC (Svobodova and Groschner, 2016). Consistent with this, the PLC inhibitor U-73122 (10 μM) reduced the NO-dependent increase in $sPSC_{Fq}$ ($p = 0.02$), but was not affected by the less active U-73343 ($p = 0.9$). These results suggest that presynaptic NO signals can increase inhibitory output of GABAergic ACs in the absence of depolarization.

Title: Extrasynaptic $GABA_A$ receptor Gabra6 and Gabra4 are expressed in mouse outer retina

Authors: *A. A. HIRANO[1,2], A. SOLOMON[1], S. A. BARNES[3,1], N. C. BRECHA[1,2];
[1]David Geffen Sch. of Med. At UCLA, Los Angeles, CA; [2]VAGLAHS, Los Angeles, CA;
[3]Dalhousie Univ., Halifax, NS, Canada

Abstract: Horizontal cells possess the molecular machinery for vesicular release, including VGAT/VIAAT, which accumulates inhibitory amino acids (IAA) into synaptic vesicles, and horizontal cell VGAT/VIAAT knockout eliminated inhibitory feedback to photoreceptors (Hirano et al., 2016). To determine the possible targets of horizontal cell GABA/IAA release, we investigated the expression of GABA receptors in the mouse retina. Immunohistochemistry on vertical sections of mouse retina with Gabra6 antibodies (Synaptic Systems) produced hotspots of labeling deep within the outer plexiform layer (OPL) and faint outlines of bipolar cell bodies. Staining with PNA to label cone pedicles demonstrated Gabra6-like immunoreactivity was concentrated beneath cone pedicles. Staining of Cx57-channelrhodopsin (ChR2)-tdTomato, which outlines the cell membrane of horizontal cells, retinas indicated that Gabra6-like immunoreactivity is on horizontal cell processes and runs up the stalks of horizontal cell endings innervating rods. Rod bipolar cells, identified by PKC immunostaining, showed Gabra6-like immunoreactivity concentrated on the dendrites running along the same horizontal cell stalk-like regions. ON bipolar cell dendrites, immunolabeled for $Galpha_o$, showed a similar pattern of Gabra6 immunoreactivity, which did not seem to reach the very tips. RT-PCR using multiple sets of primers designed from Gabra6 cDNA sequence(s) produced amplicons of the predicted sizes from retina, although the intensity was much less than those from cerebellum, indicating a low level of mRNA expression in retina. Immunolabeling with Gabra4 antibodies (PhosphoSolutions, Inc.) labeled putative cone photoreceptor and bipolar cell bodies. In addition, there was strong Gabra4-like immunolabeling of the distal calbindin band in the inner plexiform layer (IPL). Double label experiments with Gabra4 and vAChT antibodies confirmed this OFF ChAT band co-localization. Extrasynaptic $GABA_A$ receptor expression in the outer retina suggests tonic inhibition by GABA/IAA of bipolar cells and photoreceptors and that these receptors may be targets of horizontal cell signaling.

Title: ATP-induced changes in intracellular Ca^{2+} levels and extracellular H+ concentration from retinal Muller (glial) cells

Authors: *B. K. TCHERNOOKOVA[1], C. HEER[3], M. YOUNG[3], D. SWYGART[3], R. KAUFMAN[3], M. KREITZER[3], R. MALCHOW[2];
[1]Biol. Sci., [2]Univ. of Illinois at Chicago, Chicago, IL; [3]Indiana Wesleyan Univ., Marion, IN

Abstract: Adenosine 5'-triphosphate is believed to be co-released with neurotransmitters and can act as a signaling molecule via the activation of ATP-sensitive ionotropic and metabotropic receptors. In the present work, we examine changes in extracellular H^+ concentrations and intracellular Ca^{2+} rises triggered by ATP application onto isolated Müller cells and slices prepared from retinae of tiger salamanders. Recordings of H^+ concentration were obtained via the self-referencing technique and Ca^{2+} levels were imaged with the Ca^{2+} dye Oregon Green. All recordings were performed with 1mM HEPES as the extracellular pH buffer. ATP causes a robust extracellular acidification from isolated Muller cells. This acidification is reduced in the presence of the ATP receptor blockers suramin and PPADS, as well as by the anion transport blocker DIDS. ATP application also causes intracellular calcium rises in Müller cells. Both the calcium rise and the extracellular acidification are reduced when the reuptake of calcium into the endoplasmic reticulum is inhibited with thapsigargin and when PLC-IP3 signaling is disrupted with the inhibitors U-73122 and 2-APB. Bath-applied ATP causes a robust extracellular acidification from retinal slices when the H^+-selective microelectrode is positioned in close proximity to the outer plexiform layer. Suramin and PPADS reduce the acidification measured from slices. ATP-induced extracellular acidification is also observed from Müller cells of other species, including human, rat and lamprey. This work emphasizes the role of ATP as an intercellular signaling agent in the retina, which can induce intracellular calcium rises in Müller glia, which in turn lead to robust changes in extracellular acidity. The fact that the ATP-induced responses occur in Müller cells of a variety of species suggests a highly evolutionarily conserved response that is likely to play an important role in regulating responses of retinal neurons.

Abstract: For acetylcholine synthesis in the presynaptic terminal of cholinergic neurons, choline uptake by the high affinity choline transporter is essential. In a previous study, we have reported that $P2X_2$-purinoceptors are densely expressed in OFF-cholinergic amacrine cells of the mouse retina. When $P2X_2$-purinoceptors are expressed at high density in the expression system, they acquire permeability to large cations such as N-methyl-D-glucamin. In the present study, we examined whether $P2X_2$-purinoceptors densely expressed in OFF-cholinergic amacrine cells can acquire a permeability choline in the mouse retina. An application of ATP produced detectable choline currents in OFF-cholinergic amacrine cells but not in ON-cholinergic amacrine cells in retinal slice preparations. In dissociated preparations of cholinergic amacrine cells, ATP-induced choline current were carried by $P2X_2$-purinoceptor-mediated cation channels. In HEK293T cells, ATP induced choline current and facilitated the choline uptake into the cell in the $P2X_2$-purinoceptor expressing cells. High-affinity choline transporters are distributed at higher levels in ON-cholinergic amacrine cells than in OFF-cholinergic amacrine cells. These findings support the hypothesis that $P2X_2$-purinoceptors function as a novel choline uptake pathway and may regulate the synthesis of acetylcholine in the OFF-cholinergic amacrine cells in the mouse retina.

Title: Retinal dopaminergic function after 6 weeks of diabetes.

Authors: *M. FLOOD;
Physiological Sci., Univ. of Arizona, Tucson, AZ

Abstract: Previous studies have shown dysfunction of amacrine cells in the rod pathway early in diabetes. Dopamine is involved in light adaptation, and several studies have also found a deficit in total retinal dopamine content and dopaminergic amacrine cell number in diabetes. This suggests a disruption in the dopaminergic system underlies the signaling changes we see in the diabetic retina. Here we examined the effects of dopamine Type 1 Receptor (D1R) activation on inhibition to rod bipolar cells in a mouse model of diabetes, and quantified total dopaminergic amacrine cell number, in order to determine whether the dopaminergic signaling pathway is compromised. Diabetes was induced in C57BL/6J mice at 5 weeks of age by i.p. injections of streptozotocin (STZ, 75 mg/kg) or citrate buffer control. Diabetes was confirmed by blood glucose levels > 200 mg/dL. Six weeks post injections, whole-cell voltage clamp recordings of light-evoked (L) and spontaneous (s) inhibitory post synaptic currents (IPSCs) were made from rod bipolar cells (RBCs) by holding at 0 mV, the reversal potential for Cl^- ions. D1Rs were activated with the selective agonist SKF-38393 (20 μM). Light responses were elicited at multiple intensities by a 30ms full field LED stimulus (λ = 525 nm). The peak, charge transfer (Q), rise time and 37% decay time (D37) were measured for all evoked responses. Amplitude, frequency and decay constant were measured for sIPSCs. All light response data was analyzed by 2-way repeated measures ANOVA. sIPSC data was analyzed by paired t-tests. Dopaminergic amacrine cells were identified by staining for tyrosine hydroxylase (TH). Retinas were costained with α-caspase to identify apoptotic cells. Cell number, soma size and mean intensity of TH immunoreactivity were measured in ImageJ and analyzed by one way ANOVA. We found that in STZ treated and control mice, SKF treatment significantly reduced L-IPSC Q and peak (n=7 cells, $p < 0.05$) with no significant changes in response rise time or D37. Although on average responses were larger in control than STZ mice, there were no significant differences between the two groups. In both control and STZ groups, sIPSCs showed significant decreases in

frequency ($p < 0.05$) but no significant differences in amplitude or decay constant. No significant differences were found in dopaminergic amacrine cell number, apoptotic cell number, soma size or mean intensity of TH immunoreactivity between STZ and control animals. Our data suggests that at 6 weeks of diabetes, there is no significant impairment of D1R modulation of RBC inhibition and no significant change in the number or viability of dopaminergic amacrine cells.

Title: Simultaneous modeling of neural phenomena from multiple time scales

Authors: *R. RAMEZAN[1], D. WYNNE[2];
[1]Dept. of Mathematics, California State University, Fullerton, Fullerton, CA; [2]Dept. of Mathematics, California State Univ., Fullerton, CA

Abstract: A large portion of our knowledge about the brain relies on the statistical models developed for the analysis of neuronal data. In this research, we show how our conclusions based on neural spike trains depend on the time scales in which the data is analyzed. Two flexible models within the inhomogeneous Poisson process framework are discussed. Both of these formulations account for simultaneous biological phenomena, from multiple time scales, such as refractory period, bursting, brain rhythms, and learning.
Analyzing a data-set from LGN and retina, we compare the fit of these models with the Bayesian adaptive regression splines (BARS) method and discuss the strengths and limitations of the methodology. Computational efficiency, which is usually a challenge, is one of the highlights of these new models. The reconstruction quality of a complex intensity function demonstrates the power of this new multiscale methodology.

Title: Synaptic transfer between ON and OFF visual channels mediated by AII amacrine cells in mouse retina

Authors: *C. W. GRAYDON, J. S. DIAMOND;
Synaptic Physiol. Section, NINDS, Bethesda, MD

Abstract: The mammalian retina is a model system for studying how information travels through neural circuits. In vertebrate retinas, visual information is split into ON and OFF channels (signifying response to the onset and offset of light, respectively) at the first synapse between photoreceptors and bipolar cells. In the mammalian retina, an interneuron called the AII amacrine cell sits at the confluence of rod (night, ON only) and cone (day, ON and OFF) pathways. In the mouse, the AII receives ribbon synapse inputs from rod bipolar cells (RBCs, ON) and one type of OFF cone bipolar cell (CBCs), provides glycinergic output to OFF CBCs and ganglion cells, and connects to other AIIs and multiple types of ON CBCs through gap junctions. However, the characteristics of AII output synapses onto OFF CBCs and whether the AII processes incoming RBC information before passing it onto OFF CBCs are poorly understood topics. We made paired electrophysiological recordings in mouse retina slices to characterize the synaptic inputs and outputs of the AII (e.g. RBC -> AII and AII -> CBC), as well as the filtering that occurs as a signal flows through the AII (e.g. RBC -> CBC through unpatched AIIs). Similarly to ribbon synapses, the glycinergic output of the AII (AII -> CBC) was observed to exhibit a large transient release component following the onset of a stimulus (thought to encode contrast information), followed by a sustained component of ongoing release throughout the duration of the stimulus (thought to encode luminance). Curiously, we found that the RBC information flowing through the AII to OFF CBCs maintained the same synaptic transfer function as the immediately connected pairs within the circuit. In other words, there was no gain or loss in sensitivity when information flowed through the AII - responses in a CBC when stimulating an RBC exhibited the same transfer function as the responses of the AII when stimulating an RBC, despite traveling through an additional, sign-inverting (glycinergic inhibitory) synapse. While this transfer function was the same for the transient synaptic component occurring at the onset of a stimulus, the sustained component that persists throughout the duration of the stimulus was completely filtered out and not transmitted by the AII. This filtering can be explained by basic biophysical properties of the AII and synaptic release

probabilities. These results indicate that the AII acts as a temporal filter in the mammalian retina, passing transient signals with great sensitivity while eliminating sustained information.

Title: Temporal progression of retinal, cognitive, and motor deficits in a rat model of Type II diabetes

Authors: *R. E. ALLEN[1], A. FEOLA[3], C. MOTZ[2], A. L. OTTENSMEYER[2], L. HE[4], P. IUVONE[4], P. M. THULE[1], M. T. PARDUE[2,5];

Abstract: Diabetic retinopathy is the leading cause of blindness in working age adults and is likely closely related to other diabetic complications, such as cognitive deficits and vascular changes in the brain. The Goto-Kakizaki (GK) rat is a spontaneously occurring, polygenic, non-insulin-dependent, non-obese model of Type II diabetes that develops impaired glucose-induced insulin secretion at 2 weeks and fasting hyperglycemia at 4 weeks. Retinal, cognitive, and motor deficits have been reported in the GK rat. However, the temporal appearance of these deficits

and the relationship between them has not been studied. We hypothesize that Goto-Kakizaki rats exhibit retinal dysfunction prior to cognitive and motor dysfunction. The following assessments were performed at 4 and 8 weeks of age in male and female GK rats and Wistar (W) controls: electoretinogram (ERG, retinal function), rotarod (motor function), and glucose and insulin tolerance tests (hyperglycemia and insulin resistance). Spatial alternation (cognitive function) and exploratory behavior were assessed using a Y-maze task at 5, 6, 7, and 8 weeks. By 4 weeks of age, GK rats exhibited significant glucose intolerance ($p < 0.001$), insulin resistance ($p < 0.001$), and retinal deficits, including delays in ERG implicit times (flicker, $p < 0.01$; b-wave, $p < 0.001$; oscillatory potentials, $p < 0.001$). Additionally, greater ERG amplitudes for a-wave, b-wave, oscillatory potential, and flicker were observed in GK rats at 4 weeks ($p < 0.001$ for each), though amplitudes began to approach Wistar levels by 8 weeks. Beginning at 6 weeks, GK rats showed cognitive function deficits ($p < 0.05$) and exploratory behavior deficits ($p < 0.05$). However, no motor function deficits were observed using rotarod, even by 8 weeks. Interestingly, male GK rats had higher levels of hyperglycemia ($p < 0.05$), but female GK rats showed greater delays in flicker ERG implicit time ($p < 0.001$). Retinal function deficits in GK rats presented by 4 weeks, with deficits in cognitive and exploratory behavior presenting at 6 weeks and motor deficits not presenting during the 8 week testing period. Future studies will investigate dopamine loss as a common mechanistic link, assess long term changes in function and retinal vasculature, and determine if retinal deficits can predict cognitive dysfunction and late stage retinal disease.

Title: Revisiting cannabinoid receptor 2 expression and function in murine retina

Authors: N. MURATAEVA[1], J. BOROWSKA-FIELDING[2], A.-M. SZCZESNIAK[2], B. SMITH[2], C. HILLARD[3], J. ROMERO[4], M. KELLY[2], *A. STRAIKER[1];

Abstract: Cannabinoid receptor 2 (CB_2) plays a significant role in the regulation of the immune function, and is mainly expressed by cells of the immune system. CB_2 expression has been reported on activated microglial cells and astrocytes, while neuronal expression remains a subject of contention. CB_2 has been reported in retina along with evidence that CB_2 contributes to retinal visual processing. The purpose of this study was to revisit CB_2 expression using a CB_2 reporter model and to examine in detail the consequence of CB_2 deactivation on the retinal responses to light using both transgenic and pharmacological approaches.
In CB_2 receptor knockout mice we observed increases in the a-wave of the ERG in scotopic conditions, as well as dark adapted cone-driven ON bipolar cells and to a lesser extent cone-driven ON bipolar cells early in light adaptation. Significantly however, acute block of CB_2 with the antagonist AM630 did not mimic the results observed in the CB_2 KO mice while chronic (7 days) block did. Consistent with this we find that the staining for the CB_2 antibody previously used to show retinal CB_2 protein expression is also present in CB_2 knockout tissue. Separately, using CB_2 reporter mice we do not observe CB_2 reporter (GFP) expression under baseline conditions, though we do see ocular expression under inflammatory conditions.
We conclude that chronic but not acute loss of CB_2 function modulates retinal visual processing. However the lack of retinal CB_2 expression or response to acute CB_2 blockade suggests that this occurs as a result of developmental or adaptive changes rather than acute CB_2 deactivation.

Title: Dendritic plasticity of deafferented cone bipolar cells

Authors: *C. BEIER[1], A. HOVHANNISYAN[1], D. V. PALANKER[2], A. SHER[1];
[1]UC Santa Cruz, Santa Cruz, CA; [2]Ophthalmology, Stanford Univ., Stanford, CA

Abstract: The adult retina is well known to be destructively plastic in response to injury or disease. However, recently we showed that deafferented adult rod bipolar cells in rabbit retina actively restructure their dendrites to make connections with healthy photoreceptors. Here we test if the deafferented cone bipolar cells in the ground squirrel retina undergo similar restructuring. We also investigate if the deafferented S-on bipolar cells make new connections exclusive to S-cones in both ground squirrel and rabbit retina.
Line-shaped lesions were produced in ground squirrels and rabbits with a 532nm laser, using beam diameter of 100μm, scanned at speeds and powers titrated to destroy photoreceptors, leaving bipolar cells intact. Ground squirrel blue bipolar cells were labeled with the HCN4 antibody (Puller, et al. J Comp Neurology, 2011). Additional immunohistochemistry (IHC) was performed to identify photoreceptors and synaptic proteins found at outer plexiform layer (OPL) synapses and other cone bipolar cell types (PNA, S-Opsin, CtBP2, iGluR5, CD15, secretagogin). Subsequent analyses were performed on Z-stacks of IHC data. To selectively label blue bipolar cells in the rabbit retina we injected biocytin intravitreously and enucleated 40-50 hours later (MacNeil and Gaul, J Comp Neurology, 2008).
In the ground squirrel PNA and S-Opsin staining is lost in acute lesions, matched by the reduction in the number of photoreceptor ribbons. Dendrites of HCN4, CD15, and secretagogin stained cone bipolar cells are not noticeably altered in acute lesions though iGluR5 staining is reduced. 1 month after photoreceptor ablation, dendritic tree changes in deafferented bipolar cells are apparent but differ between cell types. CD15 stained cells prune their dendritic trees in response to deafferentation. Dendrites of secretagogin stained cells remain with no signs of drastic restructuring. Deafferented HCN4 stained cells maintain a vertical dendritic stalk that either terminates near the OPL or turns at the OPL and then continues laterally within the plexiform layer.
Cone bipolar cells types in the ground squirrel retina respond uniquely to deafferentation suggesting the structural plasticity mechanisms available to adult cone bipolar cell types are different.

Title: Probing selectivity and connectivity in *Drosophila* visual projection neurons

Authors: *M. MORIMOTO, A. NERN, A. M. WONG, M. B. REISER;
Howard Hughes Med. Inst. Janelia Farm Res. Campus, Ashburn, VA

Abstract: What information of the external world is extracted by the sensory system and used to produce behavior? To approach this question, we are studying the visual projection neurons in the *Drosophila* visual system. These neurons project from the third optic neuropil (lobula) to the central brain, and have been proposed to carry behaviorally relevant visual features to higher brain regions. It was recently shown that optogenetic activation of individual visual projection neuron types could induce distinct behaviors such as takeoff and backward walking, linking these visual neurons to specific behavioral programs downstream.
Using *in vivo* two-photon GCaMP imaging, I recorded visually evoked Ca^{2+} responses from several of these cell types. Cell types that showed induced takeoff and backward walking preferentially responded to dark looming stimuli or fragmented expanding local features, which suggests their role in behaviors triggered by object approach. I plan to determine whether directional selectivity (DS) underlies the mechanism for this approach sensitivity.
To explore how this visual information is transformed in the downstream circuit, we identified several candidate neurons that receive input from this cell type by anatomical overlap, then validated their connections using optogenetic activation and GCaMP imaging. I am currently investigating the response properties of these downstream neurons, with the hypothesis that visual information becomes more selective downstream. We hope this work will detail how behaviorally relevant information is extracted across several layers of a neural circuit.

Title: Real-time characterization of dmp 543-mediated elevations in acetylcholine release in porcine retina

Authors: B. SINCOX, D. LINN, *E. RAMSSON;
Biomed. Sci., Grand Valley State Univ., Allendale, MI

Abstract: Glaucoma, among other retinal diseases, is believed to be caused by excitotoxicity in the nervous system of the eye. Evidence suggests that acetylcholine is linked to neuroprotection, and inducing the release of acetylcholine can possibly reduce the excitotoxicity caused by elevated intraocular pressure. Therefore, the regulation of the release of acetylcholine may prevent the loss of eyesight associated with glaucoma. Using Fast-Scan Cyclic Voltammetry and an acetylcholine biosensor, acetylcholine release in response to both light and DMP 543 was identified and characterized. Since acetylcholine does not participate in carbon-based redox reactions, the electrodes could not directly detect it. Instead, we measured the release of hydrogen peroxide which is a product of the breakdown of acetylcholine and subsequent choline breakdown. A recording electrode was placed within the inner plexiform layer of pig retina, where acetylcholine is released, and optimized according to release profiles. Using light stimulation as a control, preliminary results indicate both light and DMP 543 caused an increase in the release of acetylcholine. Since acetylcholine release was found to be elevated in response to DMP 543, it may be a useful drug in the treatment of glaucoma.

Title: The impact of sensory uncertainty on maximally informative adaptive dynamics in neural populations

Authors: *W.-M. HSU[1,2], D. B. KASTNER[3], S. A. BACCUS[4], T. O. SHARPEE[1]; [1]CNL-T, Salk Inst., La Jolla, CA; [2]Physics, UCSD, La Jolla, CA; [3]Psychiatry, UCSF, San Francisco, CA; [4]Neurobio., Stanford Univ., Stanford, CA

Abstract: Sensory neural populations are optimized to transmit information about the sensory environment. This optimization has occurred through the course of evolution in the creation of

different cell types, and also occurs dynamically to adapt neural responses to the current stimulus environment. Recent experimental and theoretical work has shown that when encoding a particular stimulus feature, the existence of multiple neuronal types with different thresholds increases information transmission when sensory noise drops below a certain level. This prediction across an evolutionary timescale simultaneously explains the existence of adapting and sensitizing Off retinal ganglion cells (RGCs), which have high and low thresholds for spiking, respectively, as well as the absence of comparable types among On that have higher effective noise level. However, the difference in thresholds between adapting and sensitizing cells is systematically lower than the one that would yield maximal information in an environment of stationary contrast. Yet, to achieve the optimal threshold for the current environment, ganglion cells must dynamically measure the contrast. Here we show that smaller differences in thresholds are optimal in the case where the stimulus contrast is not known but is estimated from sensory inputs. In some cases, we find evidence of a hysteresis where coordination between thresholds lags behind changes in sensitivity that are induced by contrast adaptation. This causes neural populations to follow locally optimal but globally suboptimal solutions in terms of information transmitted. Further, we find that sensory uncertainty increases both the average firing rate and information transmission, but only in the regime of low firing rates. At high firing rates, sensory uncertainty increases the average firing rate but decreases information. Our findings reveal the relationship between sensory uncertainty and maximal information transmission in neural populations, and provide additional arguments for sparse coding in the brain.

Title: Asymmetric distribution of melanopsin ganglion cell outer retinal dendrites in the mouse retina

Authors: J. R. ONYAK, S. W. ISLAM, *J. M. RENNA;
Biol., Univ. of Akron, Akron, OH

Abstract: There are 6 different subtypes of melanopsin ganglion cells that express the photopigment melanopsin and function as autonomous photoreceptors. These melanopsin ganglion cells are photosensitive prior to birth and are critical for a variety of non-image forming visual functions. Somas of M1 melanopsin ganglion cells are asymmetrically distribution in the retina, inverse to the asymmetrically distributed S-opsin expressing cones. We have previously found that a percentage of M1-type melanopsin ganglion cells extend dendrites into the outer retina. Here we examine the topographical distribution of these Outer Retinal Dendrites (ORDs) relative to S-opsin expressing cones at various stages of development.
Retinal whole-mounts of C57BL/6 mice at postnatal days 4, 8, 12, and 30 were double-labeled for S-opsin and melanopsin using immunohistochemistry. They were imaged via an epifluorescence microscope at 4x to capture the S-opsin gradient and to create a digital retinal map. Each region of the retina was then systematically examined at 40x magnification to identify and plot the topographical distribution of all ORDs. In house software (C#) was used to determine the area of highest S-opsin concentration. Retinal maps were aligned accordingly and divided into quadrants for quantitative analysis.
At all ages examined, S-opsin expression was confirmed to be most concentrated in the ventral half of the retina and ganglion cell ORDs were found to be more numerous in the dorsal half. Throughout development, ORDs show an asymmetric dorsal distribution. At P12 71% of ORDs were located in the dorsal retina and 29% were found in the ventral retina. In the mature retina (P30), 77% of ORDs were located in the dorsal retina and 23% were found in the ventral retina. While these data parallel previous reports of the asymmetric distribution of M1 ganglion cell somas, our data suggest that ORDs are even more asymmetrically distributed with a very strong preference for the dorsal retina. These data suggest a functional connection with cones in the dorsal retina, most likely M-opsin expressing cones.

Title: The diurnal control of visual sensitivity in the mouse retina and visually guided behavior

Authors: *S. KOSKELA[1], T. TURUNEN[2], P. ALA-LAURILA[1,2];
[1]Dept. of Biosci., Univ. of Helsinki, Helsinki, Finland; [2]Dept. of Neurosci. and Biomed. Engin., Aalto Univ., Espoo, Finland

Abstract: The retina is a rhythmic tissue, with its independent circadian clock and several circadian rhythms in its morphology and biochemistry. This has led to the hypothesis that visual functions are under circadian control. However, it has never been fully assessed whether visual sensitivity depends on the circadian clock. We determined if the sensitivity limit of light detection in mouse retinal ganglion cells (RGCs) and visually guided behavior depend on the diurnal rhythm. We used both melatonin proficient (CBA/CaJ) and melatonin deficient (C57BL/6J) mouse strains to compare the visual sensitivity of mice in their subjective night with those measured in their subjective day. We used flat-mounted retinas and cell-attached patch clamp technique to measure the sensitivity limit of alpha-like RGCs: On sustained RGCs (OnS) and Off sustained RGCs (OffS). We determined the visual threshold and detection strategies of mice in a water-maze test by using a novel fully-automated tracking system of mouse behavior. We show that the behaviorally measured visual performance near the detection threshold is better during the night than during the day, on both mouse strains. However, the sensitivity limit of RGCs does not show strong dependence on the diurnal rhythm. We have evidence that the difference in behavioral performance is, at least partly, due to diurnal differences downstream from retina, i.e. differences in cognitive functions.

Title: Gap junctional coupling between retinal ganglion and amacrine cells underlies reduced global object perception in connexin 36 knockout mice

Authors: *K. ROY, S. A. BLOOMFIELD;
Biol. and Vision Sci., SUNY, Col. of Optometry, New York, NY

Abstract: Widely separated retinal ganglion cells (RGCs) exhibit coherent spiking in response to global stimuli as opposed to local stimuli (Neuenschwander and Singer, 1996), which has been proposed to underlie global object perception. Since the large spatial separation between the RGCs eliminates common bipolar cell input, the mechanism responsible for this coherent activity remains unclear. Here we demonstrate that wide field amacrine cells (WFACs) and/or polyaxonal amacrine cells (PACs), electrically coupled to RGCs are responsible for correlated firing of RGCs in the mouse retina. Pharmacological blockade of gap junctions or genetic ablation of connexin 36 (Cx36) eradicates this coherent activity. Since, such coherence is proposed to underlie global object perception, we tested whether $Cx36^{-/-}$ mice will have poor global object perception compared to $Cx36^{+/+}$. $Cx36^{+/+}$ and $Cx36^{-/-}$ littermates were trained to perform a two-alternate forced choice task in a Y water maze. Each of the monitors adjacent to the arms of the Y maze pseudorandomly displayed two separate rectangles and a contiguous rectangle representing discreet vs. global objects, respectively. Mice were trained to swim towards the contiguous rectangle. The gap between the discreet rectangles was decreased in increments of 20, 10, 7, 5, 2, 1.5 and 1 degree of visual angle. Responses from both $Cx36^{+/+}$ and $Cx36^{-/-}$ mice were recorded and all the trials were concatenated together for both the genotypes individually. $Cx36^{+/+}$ and $Cx36^{-/-}$ mice were also tested for spatial acuity to determine whether any difference in global object perception might be due to attenuated spatial acuity. All the experiments were performed in photopic condition as $Cx36^{-/-}$ mice had been shown to have deficiencies in scotopic vision. The threshold was set at 75% accuracy. The percentage of correct responses of $Cx36^{+/+}$ mice indicated that they could distinguish rectangles separated by as close as 2 degree of visual angle. However, the $Cx36^{-/-}$ mice demonstrated a significantly inferior performance at 2 degree. The $Cx36^{-/-}$ mice could not distinguish rectangles separated by less than 7 degree of visual angle. Additionally, $Cx36^{+/+}$ and $Cx36^{-/-}$ did not show any significant difference in spatial acuity up to 0.5 cycles per degree, which is the threshold for mouse vision. Taken together the results indicate that concerted activity between distant RGCs is mediated via electrical coupling with the WFACs/PACs. Loss of this coherent spike activity results in an impairment of global object perception. Our findings suggest a novel role of retinal neuron gap junctions in stimulus encoding that plays a key role the perception of contiguous, global objects.

Title: Cell-attached recordings of light-induced postsynaptic potentials in mouse retinal ganglion cells.

Authors: S. KITORA, T. YAGI, *Y. HAYASHIDA;
Grad.Eng., Osaka Univ., Suita-Shi, Osaka, Japan

Abstract: Previous studies showed that the cell-attached mode of the patch-clamp techniques is useful for recording, not only single-channel currents on the patch membrane, but also supra-threshold action potential firings in retinal ganglion cells while preserving cytoplasmic integrity. However, little has been reported on the applicability of this method to record sub-threshold postsynaptic potentials. Thus, in the present, we made recordings of light-induced responses of the ganglion cells under the cell-attached (CA) as well as the ruptured-patch whole-cell (rpWC) configurations in mouse retinas. The isolated retinas were prepared as whole-mounts from juvenile C57/BL6 mice (3-8 week-old, n=18), and were kept under dark conditions (~0.5-1 nW/cm^2) while being perfused with oxygenated saline at ~30 ^oC. Na^+-based and K^+-based solutions were filled in the pipettes (1-2 μm and 3-7 MΩ at the tip) for CA and rpWC recordings, respectively. As similar to previous studies, relatively large amplitudes of the action-potential currents (60-600 pA in peak-to-peak) were recorded under voltage clamp at 0 mV in CA mode from the ganglion cells responding to light steps (~1 $x10^7$ Rh^* /rod/sec, ~525 nm). Not only that, light-induced graded changes of the holding currents (less than 10 pA in peak) were discernible when the current traces were averaged over 10-30 trials and low-pass filtered off-line (15 Hz cut-off, 3-order Bessel). These graded currents remained under blockade of the action-potential currents with 1-μM tetrodotoxin. Moreover, time courses of these currents were overlapped with those of the light-induced subthreshold potentials that were recorded from the same cells under current-clamp in rpWC mode within 6 minutes post-break-in; the peak coefficients of the cross-correlations between time courses of the graded currents and the subthreshold potentials were 0.82±0.07 and 0.87±0.04 (mean±SEM, *n*=5) in hyperpolarizing and depolarizing directions, respectively. These results suggested that the cell-attached voltage-clamp recording is usable for monitoring, not only the spike firings, but also the postsynaptic subthreshold activities in the retinal ganglion cells.

Title: Receptive field analysis using whole-cell spatiotemporal maps

Authors: *S. COOLER, G. W. SCHWARTZ;
Northwestern Univ., Chicago, IL

Abstract: Retinal neurons generate their particular response characteristics by nonlinearly combining spatially and temporally localized inputs. We measured the receptive field (RF) maps of several types of retinal ganglion cells (RGCs) and classified the patterns we observed, using whole-cell voltage-clamp recordings and flashed-spot visual stimuli. Using a closed-loop experimental system, we mapped the spatial extent of the contrast adaptation effect to identify nonlinear RF subunit locations.

RGCs varied in the spatial extent of their excitatory and inhibitory RFs. By fitting the RFs to a Gaussian approximation, we were able to quantify their sizes and positions. While the RFs generally had centers near the somas, a subset of RGCs had RFs centered some distance away, typically in alignment with the dendrites of the cell. A further subset of those RGCs had excitatory and inhibitory inputs spatially offset from each other. We were able to model the effects of these offsets, and predict qualities of the feature selectivity of the RGCs.

Using a novel contrast adaptation stimulus, we identified the spatial extent of input subunit adaptation. We studied how a high-contrast region shifted the light intensity response profile in the space around it. Using this protocol, we anticipate identifying the locations of individual subunits, and matching them to bipolar cell receptive field locations using immunohistochemistry and genetic labeling. Accurately mapping RF subunits online physiologically would be a major step in the field, allowing us to predict RGC responses to complex spatiotemporal patterns of light.

Title: The effects of D1 and D4 dopamine receptor knockouts on retinal ganglion cell receptive fields and contrast sensitivity

Authors: *D. SPRINZEN, H. DAI, A. KHANDHADIA, D. MCMAHON;
Vanderbilt, Nashville, TN

Abstract: Within the mammalian retina, it is believed dopamine acts as a circadian-regulated neuromodulator to reconfigure retinal processing during light adaption. Decreased retinal dopamine causes various deficits in light adapted visual responses including loss of visual acuity and decreased contrast sensitivity during optokinetic tracking. Furthermore, these deficits are independently mediated by dopamine receptors classes, with D1-like and D2-like receptors involved with visual acuity with contrast sensitivity, respectively. Here, we used multi-electrode array (MEA) recordings of D1 and D4 specific dopamine receptor knock out mouse models to elucidate the role of dopamine receptor activity on retinal function. Retinal Ganglion Cell (RGC) physiological responses are classified and compared based on spontaneous activity, on-off characteristics, response duration, directional selectivity, receptive field profile, center-surround antagonism, response latency, and contrast sensitivity. Analysis by K-means clustering found 5 broad RGC classes: ON-sustained, ON-transient, OFF, ON direction selective, and ON-OFF direction selective. Preliminary data for both D1 and D4 receptor knockouts showed an increase in the size of the receptive field center of ON-sustained and OFF cell classes of 30-50% as compared to control animals. Interestingly, contrast sensitivity profiles for D1 receptor knockout RGCs was similar to wildtype, however D4 receptor knockout RGCs exhibited a shift in spatial tuning such that ON-sustained cells preferred higher spatial frequencies and OFF cells preferred lower spatial frequencies compared to wildtype RGCs. To further study the control of dopamine receptors within the retinal circuit, we will record from retinas with targeted deletion of D1 receptors on horizontal cells.

Title: Light adaptation across diverse retinal ganglion cell types in the mouse retina

Authors: *K. RUDA, G. D. FIELD;
Neurobio., Duke Univ., Durham, NC

Abstract: Purpose: Adaptive coding is a fundamental feature of sensory systems. In vision, the retina must adapt to the 9 orders of light intensities between a starry night and a sunny day. How do retinal ganglion cells (RGCs), the sole output of the retina, encode this dynamic visual signal? A crucial framework for understanding this question is the organization of RGCs into distinct cell types, because light adaptation may impact RGC types differently. Here we determine how light adaptation changes the stimulus encoding of several types of RGCs in mouse.
Methods: We performed multi-electrode array recordings on isolated mouse retinas in response to visual stimuli. The multi-electrode array consisted of 512 electrodes. Spikes were identified and sorted by custom software, and 300-400 RGCs were identified in each recording. We measured differences in general spiking dynamics such as latency, interspike intervals distributions and spontaneous activity in several cell types. Next, we measured changes in spatiotemporal receptive fields (RFs) and gain. These quantities estimate the stimulus features that drive spiking and the relationship between these features and spike number; they correspond to the linear and nonlinear parts of a linear-nonlinear-poisson (LNP) model, respectively. We used measured RFs and gain in LNP models to determine which aspects of RGC encoding can account for the observed changes in spiking dynamics (RF changes, gain changes, or both).
Results: We observed changes in spiking activity in many RGC types across light levels, including background firing rates and interspike intervals. Similar to previous work, we found that response latency to stimulus features was shorter with increased light intensity across RGC types. We also observed that RF properties of different RGC types were altered in distinct ways, and that these changes contributed to differences in spiking dynamics across light levels.
Conclusions: These results suggest that RGC types have different input-output functions during light adaptation, and provide a starting point for elucidating how populations of specialized neurons can adaptively encode dynamic stimuli.

Title: Intra-retinal feedback connections composed of melanopsin expressing retinal ganglion cells and amacrine cells

Authors: *P.-T. YEH, S.-K. CHEN;
Dept. Life Sci., Natl. Taiwan Univ., Taipei City, Taiwan

Abstract: Retinal structure and functional circuit have been study for several decades. It is well known that the information flow of retinal circuit starts form light reception by rods and cones, to horizontal cells, amacrine cells and bipolar cells, and transduces to brain by retinal ganglion cells. However, our previous studies indicated that a group of melanopsin containing retinal ganglion cells, intrinsically photosensitive retinal ganglion cells (ipRGCs), connect to dopaminergic amacrine cells (DACs) by intra-retinal axon collaterals. By randomly genetic labeling of ipRGCs in mice and immunochemical methods, our study shows morphologically distinct groups of ipRGC intra-retinal axon collaterals, innervate varies layers in inner plexiform layer. At the same time, we also found those collaterals connect to different cells. The feedback connections via ipRGC intra-retinal collaterals may change our comprehension to visual and non-visual retinal circuitries.

Title: Adaptive and predictive coding by spatiotemporal dynamics in the retina

Authors: *K. S. CHEN[1,2], C.-K. CHAN[1], C.-T. YEN[2];
[1]Inst. of Physics, Academia Sinica, Nankang, Taipei 11529, Taiwan; [2]Dept. of Life Sci., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Adaptation to time-dependent stimulations in order to make predictions is a crucial task for sensory neural systems. It is known that the retina can detect periodic patterns and produce temporally precise omitted stimulus response (OSR) to violation of periodicity. When the simulation is consisted of multiple periods, it is not clear if a predictive phenomenon similar to OSR can still occur. In our experiments with bullfrog retina under simulations of multiple periods, an OSR-like response is found. In this second-order OSR phenomenon, the main output of the retina ganglion cells will follow the effective period of the stimulations. Even for spatial-uniform stimulations, heterogeneous spatiotemporal firing patterns can be observed during the adaptive process. Presumably, such adaptive heterogeneity enables the retina to make prediction to the upcoming stimuli. Distributing multiple temporal information spatially might be a general strategy for predictive coding in sensory systems under complex temporal stimulations.

Title: Congenital nystagmus gene FRMD7 is required to establish a neuronal circuit asymmetry for retinal direction selectivity

Authors: *A. DRINNENBERG[1], K. YONEHARA[2,3], M. FISCELLA[4], F. ESPOSTI[1], S. TRENHOLM[1], J. KROL[1], F. FRANKE[4,5], B. GROSS-SCHERF[1], A. KUSNYERIK[5], J. MUELLER[4], A. SZABO[5], J. Abstract: Neuronal circuit asymmetries underlie many circuit computations in the central nervous system. However, the molecular pathways controlling their establishment are poorly

understood. A principle feature of the retinal direction-selective circuit is asymmetric inhibitory input from starburst amacrine cells to direction-selective retinal ganglion cells (DS cells). Using a combination of molecular, genetic, physiological and behavioral strategies, we show that *FRMD7* - a gene that is defective in human congenital nystagmus - is required for proper functioning of the directionally selective retinal circuit. Remarkably, we find that the mutation of *FRMD7* in mice leads to the selective loss of the horizontal optokinetic reflex, as it does in humans. Microelectrode array recordings from *FRMD7* mutant mouse retina reveal that the loss of the horizontal optokinetic reflex can be ascribed to the selective loss of horizontal direction selectivity in retinal ganglion cells. Two-photon targeted patch-clamp recordings of cells with the genetic identity of wild-type horizontal DS cells show that the inhibitory input to horizontal DS cells switches from asymmetric to symmetric when *FRMD7* is mutated. To assess the differential impact of *FRMD7* mutation on ON vs ON-OFF DS cells we targeted these cell types using transgenic mouse lines (*Hoxd10-GFP* and *Drd4-GFP*). Indeed we found differential effects of *FRMD7* mutation on these different populations of DS cells. Finally, we pinpointed the source of the effect of the *FRMD7* mutation to starburst amacrine cells, which are the only cells in the mouse retina to express this gene. Interestingly, *FRMD7* is also expressed in ChAT expressing, starburst-like amacrine cells in the primate retina. We conclude that in the retina *FRMD7* is required to establish spatially asymmetric inhibitory inputs from starburst cells to DS cells along the horizontal axis, and is thus required for horizontal direction selectivity. This study indicates that FRMD7 is a key regulator for establishing a neuronal circuit asymmetry, and these results reveal the involvement of a specific inhibitory neuron type in the pathophysiology of a neurological disease.

Title: High resolution *In vivo* imaging tracks progressive retinal degeneration in aged marmosets

Authors: *T. NORO[1,2], K. NAMEKATA[1], A. KIMURA[1], T. NAKANO[2], H. TSUNEOKA[2], T. HARADA[1];
[1]Visual Res., Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan; [2]Ophthalmology, The Jikei Univ. Sch. of Med., Tokyo, Japan

Abstract: The population of elderly people is growing worldwide as life expectancy is drastically increased, and this creates new challenges as aging is a risk factor for many chronic conditions including neurodegenerative diseases such as glaucoma. Glaucoma is one of the major causes of blindness. It is a progressive optic neuropathy characterized by axonal injury at lamina cribrosa, retinal ganglion cell (RGC) loss, and visual field defects.
The common marmoset (*Callithrix jacchus*), a small New World monkey, is becoming increasingly attractive as an experimental animal model amenable to gene manipulation with transgenic technologies, particularly in neuroscience research.
The purpose of this study was to monitor age-associated changes in the common marmoset by evaluating retinal structure and function using non-invasive methods: spectral-domain optical coherence tomography (OCT) and multifocal electroretinogram (mfERG). We also examined the lateral geniculate nucleus (LGN) and visual cortex in young and aged marmosets.
Experiments were performed in 12 adult common marmosets. Aged 1 year 6 months - 2 years 6 months (n=6, 23.1±1.4 months, 357±9.7 g) for the young group, 7 years 11 months - 12 years (n=6, 117.8±5.4 months, 372±21.3 g) for the aged group.
The analyses from the scanned images using OCT showed that the thickness of the inner and outer retinal layers were significantly reduced in the aged marmoset compared with the young. Consistently, when we measured visual function *in vivo* using mfERG, the responses were significantly decreased in the aged marmoset compared with the young marmoset. Interestingly, we found one marmoset that presented with naturally occurring normal tension glaucoma (NTG) and observed disease progression after 1 year. As with glaucoma patients, reduction in the thickness of the lamina cribrosa and inner retinal layer was observed by using OCT in this NTG marmoset. Consistent with data from NTG patients, the glutathione level in the blood, brain-derived neurotrophic factor level in the cerebrospinal fluid (CSF), CSF pressure, the number of cells in the LGN and visual cortex were significantly decreased.
In summary, we demonstrate that the marmoset is a good model for studying aging and retinal degeneration such as glaucoma and that our *in vivo* imaging systems enable mapping and tracking of changes in retinal structure and function during aging or disease. This experimental system will provide useful information for development of novel treatment for retinal diseases.

Title: Circuit mechanisms underlying orientation selectivity in the zebrafish retina

Authors: *P. ANTINUCCI, R. HINDGES;
Ctr. for Developmental Neurobio., King's Col. London, London, United Kingdom

Abstract: In the vertebrate retina, visual stimuli are converted into electrochemical signals and the processed information is then sent to higher visual centres through parallel feature-specific neuronal pathways. How retinal circuits process and extract the orientation of elongated visual stimuli and how the underlying circuitry is established is, however, poorly understood. In this study, we dissect an orientation-selective circuit in the larval zebrafish retina and describe its underlying synaptic, cellular and molecular mechanisms. Using bacterial artificial chromosome transgenesis, we genetically identify a class of GABAergic amacrine cells (ACs) that express the cell-adhesion molecule Teneurin-3 (Tenm3) and possess elongated dendritic arbours. By performing two-photon calcium imaging in the intact retina we reveal that these cells show orientation-selective responses to drifting gratings. Notably, these orientation-tuned Tenm3^{+} ACs respond maximally when the orientation of elongated visual stimuli coincides with the orientation of their dendritic fields. Both selective optogenetic ablation of Tenm3^{+} ACs using KillerRed and pharmacological interference with their function through picrotoxin show that these cells generate orientation selectivity in retinal ganglion cells (RGCs) by being a source of tuned GABAergic inhibition. Furthermore, our morphological analyses suggest that Tenm3^{+} ACs connect to orientation-selective RGCs and that they require Tenm3 to correctly develop their dendritic morphology. Finally, we reveal that orientation tuning is present also among a fraction of bipolar cell presynaptic terminals. We propose a circuit model based on our findings whereby orientation-selective RGCs integrate orthogonal orientation-tuned inhibitory input from Tenm3^{+} ACs and preferred orientation-tuned excitatory input from bipolar cells to acquire their selectivity. In conclusion, our results outline how defined retinal cell types form a circuit capable of detecting elongated stimuli in visual scenes and provide orientation-specific information to the brain.

Title: Direction selective and intrinsically light sensitive retinal ganglion cells of the tree shrew

Authors: E. N. JOHNSON[1], R. SHAYESTEH[1], E. CHEN[1], J. SCHUMACHER[2], D. FITZPATRICK[2], *G. D. FIELD[1];
[1]Dept. of Neurobio., Duke Univ., Durham, NC; [2]Max Plank Florida Inst. for Neurosci., Jupiter, FL

Abstract: The tree shrew (Tupaia belangeri) is a diurnal, evolutionary intermediate between primates and rodents. Classified as a "living fossil," the tree shrew offers a potential view to the evolutionary origins of the primate visual system. While much is known about the functional and structural organization of the dorsal lateral geniculate nucleus (dLGN) and primary visual cortex (V1) in tree shrews, relatively little is known about the diversity of retinal ganglion cells (RGCs). The purpose of this study is to elucidate three structural elements of the tree shrew retina: (1) determine the organization and prevalence of direction selective RGCs and associated circuitry; (2) determine the density and diversity of melanopsin expressing, intrinsically light sensitive, RGCs, and (3) determine the density of RGCs across retinal eccentricity.
To determine the density of putative direction selective RGCs, we used CART antibodies. We show that CART positive cells are RGCs and not displaced amacrine cells. They are bistratified and approximately co-stratify with starburst (ChAT positive) amacrine cells. Thus, CART positive RGCs are likely direction selective, similar to mouse. Counter labeling with anti-RBPMS, revealed that CART positive RGCs are at least 20% of all RGCs. This prevalence is similar to that observed in mice and rabbits and distinct from that observed in primates. We further show that ChAT positive starburst amacrine cells express GABA, consistent with studies in other mammals, but contrary to a previous report in the tree shrew.
Similar to other mammals, anti-melanopsin revealed the presence of at least two distinct populations of intrinsically light-sensitive RGCs, one with cell bodies in the RGC layer and one with cell bodies in the inner nuclear layer. Each type formed an independent and complete mosaic of cells with dendrites that approximately tiled space. The pattern of melanopsin expression closely resembles previous reports of melanopsin expression in the marmoset retina, but differs from that observed in mouse. Finally, we show that RGCs are approximately half of all cells in the RGC layer.

These results point to elements of retinal organization that are similar to rodents, with other elements more similar to primates. An important direction for future studies is to determine the prevalence of a parvocellular-like pathway in the tree shrew retina.

Title: S100 alone or combined with HSP27 leads to specific retinal ganglion cell loss in a glaucoma model

Authors: *S. C. JOACHIM[1], S. REINEHR[2], C. CASOLA[2], S. KUEHN[2], H. B. DICK[2]; [1]Exptl. Eye Res. Insitute, Bochum, Germany; [2]Ruhr-University Bochum, Bochum, Germany

Abstract: Purpose: As previously shown, immunization with ocular antigens, like heat shock protein 27 (HSP27), leads to retinal ganglion cell (RGC) loss in an autoimmune glaucoma model. Aim of this study was to investigate how immunization with S100 alone and in combination with HSP27 affects neuronal and glial cells in the retina at late stages. **Methods:** Rats were immunized with S100 or S100 plus HSP27 (S100+HSP) and compared to controls (n=5/group). 4 weeks after immunization retinas were processed for immunehistology and Western blot analysis. Retinal ganglion cells (Brn-3a), amacrine cells (ChAT), and photoreceptors (rhodopsin, opsin) were quantified. Additionally, macroglia (GFAP, Vimentin) and microglia (Iba1, ED1) were analyzed. Groups were compared via ANOVA with Dunnett's post-hoc test. **Results:** No IOP alterations were noted in both immunized groups throughout the study ($p>0.05$). About a 30% RGC loss was observed in both immunized groups at 4 weeks (S100: $p=0.005$; S100+HSP: $p=0.004$). Cholinergic amacrine cells were also affected (S100: $p=0.02$; S100+HSP: $p=0.05$), while cone (S100: $p=0.5$; S100+HSP: $p=0.2$) and rod photoreceptors (S100: $p=0.9$; S100+HSP: $p=0.1$) remained intact in both immunized groups. An increase in $Iba1^+$ microglia cells was noted in both antigen groups at this late point in time ($p<0.001$), especially in the RGC layer. Also, the number of activated microglia was increased ($p<0.02$). A slight increase in astrocyte reactivity was noted in both immunized groups (S100: $p=0.05$; S100+HSP: $p=0.04$), while Müller glia remained unaltered ($p=0.9$). **Discussion:**

Immunization with ocular antigens rather damages RGCs and amacrine cells than photoreceptors. Also, an increase of activated microglia was seen. Surprisingly, combining S100 with HSP27 did not lead to additional retinal damage or more severe cell loss. Both antigens might interact, possibly having inhibitory effects on each other and thus preventing additional damage to the retina. This IOP-independent glaucoma model can serve as a tool to study specific neuroprotective agents in the future.

Title: Connectomics and color tuning of S-OFF midget ganglion cells

Authors: *L. E. WOOL[1], O. PACKER[2], Q. ZAIDI[1], D. M. DACEY[2];
[1]Grad. Ctr. for Vision Res., SUNY Col. of Optometry, New York, NY; [2]Dept. of Biol. Structure, Univ. of Washington, Seattle, WA

Abstract: The primate midget ganglion cell circuit has historically been considered selective for L- and M-cone inputs, but studies suggest S cones contribute to midget OFF cells. The anatomical and physiological origin of this input is unclear. In this study, we physiologically quantified the sign and magnitude of S cone input to midget OFF cells and identified the S-cone synaptic connection at the electron microscopic level. We also used a spatial receptive field model to predict the frequency and magnitude of S input across the visual field. Midget ganglion cells in macaque monkey retina were recorded extracellulary *in vitro* using a full-field stimulus whose chromaticity was modulated around a color circle in L-M versus S cone-opponent space (pure +L-M at 0°; pure +S at 90°; pure -L+M at 180°; pure -S at 270°). von Mises distributions were fitted to peristimulus time histograms; the cell's preferred color vector was the angle of

maximum response, from which signs and relative magnitudes of L, M, and S cone inputs were computed. The majority of midget ON and OFF cells had preferred vectors clustered along the 0-180° L-M axis and showed no appreciable S-cone input (*n*=93, mean +4.32±1.83%). A separate population of OFF midgets showed intermediate color vectors departing from the L-M axis toward the -S 270° pole, showing OFF S input (*n*=14, mean -30.89±7.28%). A previous study suggested that in macaque retina, S cones synapse with OFF but not ON midget bipolar cells (Klug et al., J. Neurosci. 2003 23:9881), but this result is controversial. Using serial block-face scanning electron microscopy of foveal retina, we identified S cones (*n*=17) by their exclusive input to S-cone ON bipolar cells. OFF bipolar cell reconstructions revealed that each S cone was linked to an OFF midget bipolar cell. We used a random-wiring receptive field model to predict S cone input to OFF midgets. We used cone mosaics randomly populated with realistic L:M cone ratios and 10% S cones. Cone density and midget receptive field size changed as a function of eccentricity. A difference-of-Gaussians kernel was applied to all cones in the receptive field, and relative L, M, and S inputs were evaluated for 5000 model cells. Our model predicts strong OFF S cone input to OFF midget cells in the perifovea, and weaker input to a larger number of OFF midgets in the periphery, where OFF midgets receive convergent inputs from L, M and S cones to the receptive field center. Our results confirm that S cones synapse with OFF midget bipolar cells and that this excitatory S OFF pathway contributes to the color tuning of a subpopulation of OFF midget ganglion cells. Our modeling results predict that these S OFF midget cells are present across the retina.

Title: Altered physiological function and dendritic morphology of retinal ganglion cells in optic neuropathy

Authors: *S. PASINI, M. L. RISNER, D. J. CALKINS;
Ophthalmology and Visual Sci., Vanderbilt Univ., Nashville, TN

Abstract: Developing effective therapeutic strategies for neurodegenerative diseases requires dissecting how different types of neurons are affected during early progression. The retina is a

well-characterized circuit that provides an accessible model to study how different neuronal compartments respond to stress in disease. Glaucoma is a neurodegenerative disease that selectively targets retinal ganglion cells (RGC) through sensitivity to intraocular pressure. Roughly 30 types of RGC have been identified. Studies indicate particular RGC types may be more vulnerable. Here we assessed how elevated ocular pressure affects the physiology and morphology of RGCs and if AMPA receptors are implicated.
To model glaucoma in C57 mice, we increased ocular pressure unilaterally by microbead occlusion of the anterior chamber; an equivalent saline injection of the opposing eye served as control. After 4 weeks of elevated pressure (+30%) we compared anterograde transport along RGC axons, current- and voltage-clamp responses of single RGCs to light and pharmacological agents, dendritic length, area, and complexity.
Microbead-induced elevation in ocular pressure led to a 55% deficit in the anterograde transport of cholera toxin b to the superior colliculus (saline n=5; microbead n=5, $p < 0.05$). Concurrently, we found that light-evoked AMPA-mediated currents were significantly reduced along with dendritic parameters in αOFF transient RGCs compared to control retinas (saline n=14; microbead n=8, $p < 0.05$). The αOFF sustained RGCs showed an increase in the OFF component of light-evoked AMPA-mediated currents along with a significant increase in dendritic parameters with elevated pressure (saline n=7; microbead n=5, $p < 0.05$). ON-OFF RGCs showed a significant reduction in both light onset and offset of AMPA-mediated light responses. Morphological analysis of ON-OFF RGC dendrites revealed a decrease in dendritic parameters in the ON sublamina of the inner plexiform layer, but no change in the morphology of dendrites that stratify in the OFF sublamina (saline n=17; microbead n=9, $p < 0.05$). Finally, we did not observe any differences in either physiology or dendritic morphology of αON sustained RGCs with elevated ocular pressure (saline n=11; microbead n=10).
Our study suggests that while ocular pressure has a profound effect on anterograde axonal transport to central brain structures, the effect on RGC physiology and morphology is highly specific. While the αOFF transient RGC is most dramatically influenced, αON sustained RGCs are the least vulnerable to elevated pressure. RGC-type specific modifications appear to arise at least in part by changes in AMPA receptor activation.

Title: Rapid processing of global motion images by locally coordinated retinal ganglion cells

Authors: *A. MATSUMOTO[1], M. TACHIBANA[1,2];
[1]Dept. of Psychology, Grad. Sch. of Humanities and Sociology, Tokyo, Japan; [2]Ctr. for Systems Vision Science, Organization of Sci. and Technology, Ritsumeikan Univ., Shiga, Japan

Abstract: Our eyes repeat fixation and rapid shift (saccade), and thus the retinal image is always in global motion induced by eye movements. Accumulating evidence indicates that the brain is equipped with specific mechanisms for processing global motion images. However, it is not yet known how the retina processes visual information during eye movements. Here we show that the global motion images evoke novel coordinated firing patterns among local groups of retinal ganglion cells (GCs), retinal output neurons to the brain. We simultaneously recorded the firing of GCs in the goldfish isolated retina using a multi-electrode array. GC subtypes were classified based on the temporal profile of classical receptive fields. Global jitter motion of background (simulated fixational eye movements) shortened the integration time of stimulus inputs and increased the spike sensitivity of specific GC subtypes. Subsequent global rapid motion (simulated saccades) evoked synchronous firings and temporally correlated firings to the moving target in local groups of specific GC subtypes. This response modulation was evoked under stimulus conditions comparable to those found for *in vivo* goldfish eye movements. The modulation was mediated by electrical and GABAergic synaptic transmission in the retina. These fast and temporally coordinated firings transmit afferent information during saccade to the brain and may contribute to visual computation.

Title: FLRT3 a new retinal ganglion cell marker and attempts towards a functional analysis

Authors: *T. RUFF, D. DEL TORO, R. KLEIN;
Molecules - Signaling - Develop., Max Planck Inst. For Neurobio., Martinsried, Germany

Abstract: In the vertebrate retina different subsets of retinal ganglion cells (RGC) code for distinct features of the visual scene, such as direction of motion or contrast. Dense retinal recordings of mouse RGCs suggest, that each feature is encoded by a defined subgroup of RGCs. However, so far only a few genetic markers are known to specifically label each RGC subpopulation.
Here we show the fibronectin leucine-rich transmembrane 3 (FLRT3) receptor as a genetic marker for a specific RGC subpopulation. Co-labeling of FLRT3-positive cells with the pan-RGC marker RBPMS revealed, that in adult mice the majority (90%) of FLRT3-positive cells in the ganglion cell layer are RGCs. FLRT3-positive RGCs distribute homogeneously across the whole retina and represent about 20% of all RGCs. Nearest neighbor distance analysis indicates that FLRT3-positive RGCs arrange in a non-random mosaic like pattern. These results raise the possibility that FLRT3-RGCs represent a specific subpopulation. To further characterize the function and circuit of FLRT3-RGCs, we generated a FLRT3-CreERT2 knock-in mouse. We will use virus-mediated approaches to map FLRT3-RGC projections, connectivity and investigate their morphology. We will also study their physiological responses to different visual stimuli by two-photon calcium imaging.
Using a FLRT3-LacZ reporter knock-in mouse, we also show that FLRT3 retinal expression starts postnatally and persists during adulthood. Hence, FLRT3 is expressed during a developmental timeframe when processes such as inner nuclear layer stratification, regular RGC distribution and dendritic arbor formation take place. Thus, we generated a RGC specific FLRT3 knock-out mouse to further investigate the role of FLRT3 in retina development. With these experiments we hope to reveal the role of a new genetically defined RGC subpopulation that contributes to our understanding of visual signal processing in distinct retinal circuits.

Title: Lycium barbarum polysaccharides delay the functional decay of retinal ganglion cells during photoreceptors degeneration

Authors: *F. LIU, J. ZHANG, Z. XIANG, D. XU, Y. XU;
GHM Inst. of CNS Regeneration, Jinan Univ., Guangzhou City, China

Abstract: Aims: To investigate whether lycium barbarum polysaccharides (LBPs) rescue the morphology and function of retina in rd1 mouse, a fast photoreceptor degenerated animal model, and how LBP affect the function of retinal ganglion cells (RGCs) during photoreceptors degeneration. **Methods:**LBP or PBS was i.p. injected in rd1 mouse everyday from P4 to P14, P20, P24 or P28 when photoreceptors totally degenerate. DAPI staining, electroretinogram, visual behavior and multi-electrode-array (MEA) recording were applied to check the structure and function of retina after treatment. **Results:** Our study showed that LBP treatment preserved the photoreceptors, enhanced the electroretinogram responses and improved the visual behavior significantly in rd1 mice compared to the non-treated group. For the function of RGCs, LBP treatment significantly enhanced the percentage of light-responsive RGCs and increased both the average and the peak responses during photoreceptors degeneration till P24. The spontaneous spiking, which usually increases during retinal degeneration, was overall inhibited by LBP; while the changes of the light-evoked responses and spontaneous spiking of various types RGCs in treated rd1 mice varied at different stages. Intensity profile tested with a series of increasing flash intensities also showed improved light sensitivity in most RGCs after LBP treatment. **Conclusion:** LBP recue the retinal morphology and function in rd1 mice, which is consistent with the reported results on rd10 mice, a slow photoreceptor degenerated animal model. Furthermore, LBP delay the functional decay of retinal ganglion cells during photoreceptor degeneration, which therefore, may help to elongate the effective time window for treatment of retinal degenerative diseases such as retinitis pigmentosa. **Keyword:**Retinal degenerative diseases; Retinal Ganglion Cells; Multi-electrode arrays; Lycium barbarum polysaccharides

Title: Temporal facilitation of retinal ganglion cell responses to drifting gratings

Authors: *A. R. GOEL[1,2], D. KERSCHENSTEINER[2,3,4,5];
[1]Dept. of Biol., Washington Univ. In St. Louis, Saint Louis, MO; [2]Dept. of Ophthalmology and Visual Sci., [3]Dept. of Anat. and Neurobio., [4]Dept. of Biomed. Engin., [5]Hope Ctr. for Neurolog. Disorders, Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Visual perception in mammals is modulated by past visual experience. A recent study identified pattern-specific flash facilitation in neurons in the primary visual cortex (V1). In this temporal facilitation, prior experience of a visual stimulus enhances subsequent responses, particularly to stimuli that share key features. This interaction appears to be conserved from rodents to human both physiologically and behaviorally. While the feedforward pathway of visual information to the V1 is responsible for hierarchical processing of features of the visual world, such as motion detection, many of these features are encoded by neurons as upstream as retinal ganglion cells (RGCs). The exact point along the visual processing pathway at which this facilitation phenomenon arises is unclear. In the present experiment, we test to see if the mechanism behind the observed priming effect based on stimulus features originates in the retina. We presented visual stimuli to an *ex vivo* retina and analyzed how RGCs respond to different combinations of stimuli to determine whether or not they use recent previous visual inputs to enhance their response to a new input. We created a stimulus set in which we displayed brief flashes of a solitary grating with no subsequent stimulus, drifting gratings with no subsequent stimulus, and a pair of a solitary grating followed by a drifting grating stimulus in either the same or a different orientation. Using multi-electrode array (MEA) technology, we recorded simultaneously from individual ganglion cells to see if the population response kinetics implicate early processing giving rise to this facilitation effect in the specific case of grating orientation. In addition, we characterized RGCs by typical response characteristics such as response polarity and direction selectivity to determine how the presence and strength of the temporal facilitation varied among these subpopulations of RGCs. While we know the retinal circuitry is capable of isolating salient features of visual stimuli, our experiment seeks to determine whether or not it compares the respective features to those of a preceding stimulus.

Title: The effect of retinal GABA depletion on mouse retinal ganglion cell receptive fields

Authors: *E. SERNAGOR[1], R. B. M. AMIN[2], S. SOFTLEY[2], G. HILGEN[2];
[1]Newcastle Univ., Newcastle Upon Tyne, United Kingdom; [2]Inst. of Neurosci., Newcastle University, Fac. of Med. Sci., Newcastle upon Tyne, United Kingdom

Abstract: GABA (γ-aminobutyric acid) is the main inhibitory neurotransmitter in the vertebrate retina. It is metabolized by glutamic acid decarboxylase (GAD) which exists in two isoforms in the mature CNS, GAD65 and GAD67. Allylglycine, a glycine derivative, is the precursor to 2-keto-4-pentanoic acid, a non-specific inhibitor of both GAD isoforms. Exposure to allylglycine therefore results in GABA synthesis inhibition, leading to the depletion of endogenous GABA over time (Orlowski *et al*, 1977; Chabrol et al., 2012). Here we applied Allylglycine *in vitro* over several hours to gradually deplete GABA in the adult mouse retina. We used immunohistochemistry to monitor the depletion of endogenous retinal GABA. A high-density large-scale MEA (Biocam, 3Brain) featuring 4096 electrodes (42 μm spacing) with an active area of 7.12 mm^2 was used to study light-evoked responses from hundreds to thousands of individual retinal ganglion cells (RGCs) simultaneously at pan- retinal level. We used a set of stimuli that allowed us to compare RGC receptive field organization, contrast sensitivity and direction selectivity. We compared the effects of GABA depletion on RGC receptive fields with those obtained by simultaneously blocking all GABAergic receptors (type A, B and C). Immunohistochemistry revealed that GABA was depleted from the retina after 6-8 hours of incubation in allylglycine, except for residual expression in inner retinal neurons, most likely reflecting starburst amacrine cells. Longer incubation times with allylglycine did not have any further effect on GABA expression. MEA recordings revealed that although allylglycine had several similar effects on RGC receptive fields as $GABA_{A+B+c}$ receptors blockade, there were nevertheless also some striking differences. Indeed, the overall RGC firing rate, loss of direction selectivity and the non-homogeneity of receptive fields is much more pronounced in GABA-

depleted retinas than during $GABA_{A+B+C}$ receptor blockade. In summary, pharmacological depletion of endogenous retinal GABA reveals profound changes in receptive field properties and suggest that in addition to activating its three classical types of receptors, GABA may have some other trophic roles that influence how RGCs respond to light.

Title: Genetic disruption of amacrine cell spacing alters the tuning of direction selective retinal ganglion cells

Authors: *S. ROY, J. CAFARO, J. N. KAY, G. D. FIELD;
Dept. of Neurobio., Duke Univ., Durham, NC

Abstract: Genes play major roles in establishing the locations and connectivity of neurons throughout the brain. Determining the consequences of altering these genetic programs is critical to understanding their role in shaping brain function. To gain insight into this problem, we leverage the recent discovery that a single gene, Megf10, is necessary for the regular spacing of starburst amacrine cells (SACs). Constitutive deletion of Megf10 causes SACs to be randomly spaced, introducing gaps and gluts in dendritic coverage across the retina. The purpose of this study is to determine the functional consequences of altering the spatial arrangement of SACs. SACs largely determine the tuning of direction selective retinal ganglion cells (DS-RGCs) by providing GABAergic inhibition to stimuli moving in the null direction. We tested for altered function among DS-RGCs by recording from the retinas of wild-type (WT) and Megf10 knockout (KO) mice using a multielectrode array (MEA). The MEA consisted of 512 electrodes with 30 μm pitch, allowing for simultaneous recording from 300-500 RGCs. Spikes were identified and sorted with custom software. Drifting gratings were used to identify ds-RGCs. Moving bars of different contrasts (10 to 100%) were used to measure the prefered direction, tuning width, and response sensitivity of ON and ON-OFF DS-RGCs. DS-RGCs were observed in Megf10 KO animals with a frequency similar to WT, indicating that the randomization of SAC locations did not eliminate direction selectivity. However, DS-RGCs from Megf10 KOs exhibited broader tuning to low contrast moving bars than those from WT animals. Furthermore,

while the preferred direction of the ON and OFF responses were closely aligned in WTs, they exhibited greater scatter in KOs. This is consistent with the observation that the spacing of ON and OFF SACs are randomized independently in Megf10 KO retinas. These results demonstrate that the mosaic arrangement of SACs produces sensitive and highly tuned responses among ds-RGCs. Furthermore, the function of a single gene can tightly regulate neural development to tune a complex computation. Finally, these results suggest that regular spacing of neurons in the retina reduces noise in computations in addition to generating uniform sensitivity across space.

Title: Chromophore acts on the retina to restore the intrinsic pupillary light reflex to isolated rd12 mouse eyes

Authors: *A. A. VUGLER, A. LYNCH;
Inst. of Ophthalmology, London, United Kingdom

Abstract: Introduction: The intrinsic pupillary light reflex (iPLR) allows the constriction of the pupil independently of the brain in nocturnal rodents. In mice, this response sustains pupil constriction under daylight conditions and requires the photopigment melanopsin, which is expressed in the iris sphincter muscle (Xue et al 2011). Functional and anatomical data also suggests a direct contribution to the iPLR from the ciliary body / neural retina retina (Semo et al., 2014). Here we examine the iPLR in rd12 mice, which lack retinal function due to a mutation in the RPE65 gene.
Methods: The iPLR was examined in dark-adapted rd12 mice in the presence or absence of systemic chromophore supplementation with 9 cis retinal (1mg/mouse i.p.). After cervical dislocation and eye removal, a bright white light was used to elicit the iPLR in isolated eyes *in vitro*, with recordings lasting for 3 minutes (30S baseline, 60S light stimulus, 90S recovery). In some rd12 mice the anterior chamber of the eyes was removed by either cutting along the limbus to disrupt the ciliary marginal zone (CMZ) or 1 mm below the limbus to include the CMZ and neural retina.
Results: The iPLR response was severely compromised in rd12 mice but could be restored by

systemic administration of 9-cis-retinal, which increased the iPLR 5-fold, pushing the constriction to surpass that of wild types. Chromophore administration also reliably restored the iPLR in rd12 mice when the preparation included retina (cuts made below the limbus). Here there was significant constriction from 6 seconds post-illumination with no clear recovery phase. However, no restoration of iPLR was seen in 9-cis-retinal-treated rd12 mouse anterior chamber preparations that had received cuts along the limbus which disrupt CMZ.
Conclusion: Here we show that RPE65 is necessary for the development of the iPLR in mice and provide functional evidence that systemic chromophore supplementation acts within the retina to restore the iPLR, presumably via a retino-iridial pathway.

Title: Electrical coupling between ganglion cell photoreceptors regulates light sensitivity of the developing retina

Authors: *F. HOLME, M. FELLER;
Helen Wills Neurosci. Inst., UC Berkeley, Berkeley, CA

Abstract: Prior to the maturation of rod and cone photoreceptors, intrinsically photosensitive retinal ganglion cells (ipRGCs) in the mouse retina exhibit robust light responses. Using two-photon calcium imaging of ganglion cells, we found that the number of light responsive cells decreased in the presence of gap junction antagonists. This indicates that in the developing retina, electrical coupling between ipRGCs regulates the extent and amplitude of light responses. Additionally, disrupting type-1 dopamine receptor signaling increases the number of light responsive cells. We report on recent progress to determine whether this modulation of gap junction coupling alters photo-aversion, an early ipRGC driven behavior described in mouse pups (Johnson et al. 2010). Taken together, our results suggest that electrical coupling between ipRGCs regulates light sensitivity of the developing retina.

Title: A portable steady-state visual evoked potential-based method for assessment of visual impairment in glaucoma

Authors: *M. NAKANISHI[1], T.-P. JUNG[1], Y.-T. WANG[1], Y.-Y. CHIEN[1], J. K. ZAO[2], A. DINIZ-FILHO[1], Z. WU[1], F. A. MEDEIROS[1];
[1]UCSD, San Diego, CA; [2]Cerebra Technologies (CerebraTek) Co. Ltd., Hsinchu, Taiwan

Abstract: Glaucoma is the leading cause of irreversible visual impairment. Functional losses in the disease have traditionally been evaluated by visual field testing with standard automated perimetry (SAP). However, SAP testing is limited by the subjectivity and large variability of patient responses, which hamper diagnosis and detection of progressive visual field losses. In addition, SAP testing is costly and lacks portability, making it unsuitable for at-home testing or for disease screening in remote locations. In recent studies, we have demonstrated the feasibility of using steady-state visual evoked potentials (SSVEPs) for objective assessment of glaucomatous visual deficits. We subsequently developed a portable head-mount AR/VR display (HMD) with noninvasive, wireless, dry electroencephalogram (EEG) sensors, which made it possible to measure SSVEP signals in response to different visual stimuli. This study shows the feasibility of the this portable device to evaluate visual field losses in glaucoma in comparison to SAP (10-2).
The study included 14 eyes of 8 glaucoma patients and 20 eyes of 10 age-matched control healthy subjects (mean age: 66.7±9.3 and 64.9±10.1, respectively; P=0.790). The visual stimuli consisted of a flashing light flickering at 9.2 Hz presented on a smartphone-based HMD display. In the experiment, the visual stimuli were presented for 1-minute in total as the subjects maintained fixation on a central red dot. 10 5-s long data epochs comprising 6-channels SSVEPs

were extracted from the recorded EEG data after band-pass filtering from 5 Hz to 50 Hz. Spatial filtering based on a canonical correlation analysis (CCA) was applied to the data epochs and discrete Fourier transform (DFT) was applied to the data to obtain the signal-to-noise ratio (SNR) of SSVEPs. All subjects were also tested with SAP and had measurements of retinal nerve fiber layer thickness acquired with spectral-domain optical coherence tomography (SDOCT).
The average SNR of SSVEP signals obtained by the portable device was significantly lower in glaucoma than in control eyes (9.92±4.63 vs. 22.95±13.10; P=0.001). SSVEP SNR values were significantly associated with the SAP mean deviation (r=0.462, P=0.006) and with SDOCT average RNFL thickness (r=0.539, P=0.001). The results showed that SSVEP signals acquired by a portable device were significantly related to structural and functional damage in glaucoma and hold promise as a method for diagnosing and detecting disease progression.

Title: Motion prediction in V1 is facilitated by cortico-cortical feedback.

Authors: *T. S. HARTMANN[1], S. G. LOMBER[2], R. T. BORN[1];
[1]Neurobio., Harvard Med. Sch., Boston, MA; [2]Brain and Mind Institute, Dept. of Physiol. and Pharmacology, Dept. of Psychology, Univ. of Western Ontario, London, ON, Canada

Abstract: Our brains routinely predict the trajectories of moving objects in order to, for example, catch a thrown ball. While it is clear that the motor commands sent to the muscles compensate for neural delays and anticipate the future location of an object, it is not known where along the neural pathways from vision to action that these functions begin.
We asked whether V1 responses to drifting bars have a predictive component. To do this, we recorded neuronal activity with a multi-electrode array in V1 of fixating monkeys and compared

responses under two conditions: 1) a white bar (75% contrast) drifted smoothly across the receptive fields (drifting-bar condition) or 2) an identical bar flashed at random locations along the same motion trajectory (space-time receptive field, or STRF). By convolving the STRF with the representation of the drifting bar stimulus we produced a feedforward model prediction of each unit's response profile. If V1 neurons respond linearly (i.e. without a predictive component), the feedforward model prediction should be identical to the drifting-bar response; however, we found that it significantly *lagged* the drifting-bar response (median difference 14 ms, $p<<0.001$, Wilcoxon signed-rank test). A second model, which included a negative feedback component, did a much better job of predicting the drifting-bar response profiles than the feedforward model (median improvement 11 ms, $p<<0.001$, Wilcoxon signed-rank test).
To gain insight into the underlying neural mechanism, we inactivated feedback by cooling areas V2 and V3, and repeated the drifting-bar experiment before, during inactivation, and after recovery. The average drifting bar response in V1 when V2/V3 feedback was inactivated significantly *lagged* the drifting bar response during the control periods ($p<<0.001$, Wilcoxon signed-rank test). The V1 response in the absence of feedback more closely resembled the response predicted by the purely feedforward model. Taken together these findings highlight an important role of feedback in shaping the temporal response profiles of V1 neurons.

Title: Primate V1 population responses to local properties of natural backgrounds predict behavioral target detection thresholds

Authors: *S. C.-Y. CHEN, Y. BAI, S. SEBASTIAN, Y. CHEN, W. S. GEISLER, III, E. SEIDEMANN;
Univ. of Texas At Austin, Austin, TX

Abstract: A central goal of systems neuroscience is to understand the neural mechanisms that mediate behavioral performance in natural, day-to-day, perceptual tasks. A fundamental natural

task is detection of targets in natural backgrounds. The goals of the current study are to examine how local properties of natural visual scenes affect neural representations in the primate primary visual cortex (V1), and to determine the possible contributions of these neural effects to behavioral detection sensitivity. To study the neural and behavioral masking effects of local background features, we cataloged and binned a variety of natural scene patches by their level of luminance (L), contrast (C) and similarity (S) to the detection target. We find that the masking effects of these scene properties in natural backgrounds on the neural responses in V1 are highly correlated with their behavioral masking effects. A rhesus monkey was trained to detect a 0.84 deg, 4 cpd additive Gabor target on a 3 deg natural scene patch at 2.5-3 deg eccentricity. While the monkey performed the task, voltage-sensitive-dye (VSD) optical imaging captured the neural population response from the corresponding location in V1. Thirty seven VSD detection experiments were conducted in 7 selected LCS bins (each repeated at least 7 times). The matched templates for the Gabor target at the retinotopic and orientation column scales were obtained in the same experiments. From these, we constructed neural response decoders in order to estimate the retinotopic- and columnar-scale neural response thresholds. Behavioral and neural target detection thresholds measured on natural scene backgrounds were significantly higher than those obtained on uniform backgrounds (background contrast = 0). The monkey's behavioral thresholds increased with background luminance, background contrast and target-background similarity. These trends are consistent with previously reported human psychophysical thresholds assessed with the same LCS natural scene binning paradigm (Sebastian et al., JoV 15:761, 2015). The monkey's neural thresholds on natural scene backgrounds were higher than the behavioral thresholds. Nonetheless, the behavioral and neural threshold values were highly correlated across the LCS bins, at both the retinotopic and columnar scales. The strong correlation between neural and behavior thresholds suggests that behavioral detectability of a visual target is largely determined by neural masking at, or prior to, V1.

Title: Mean luminance responsive cells in Primary Visual Cortex of Rhesus macaque

Authors: *S. CHANDRA, R. FALCONE, B. J. RICHMOND;
NIH, Bethesda, MD

Abstract: The cells in Primary Visual Cortex (V1) are known to be responsive to contrast. In their classic work, Hubel and Wiesel investigated V1 cells with bars, and Movshon et al used gratings as stimuli. The responses are thought to be dependent on changes in contrast across space, such in edges of bars or gratings. There are some studies of transient response to abrupt changes in mean luminance.
While recording from parafoveal V1 using an array of chronic electrodes (Utah array), we have found cells whose firing rate depends on the mean luminance even after adaptation. We present gratings at 4 orientations, and two phases, at a single mean luminance for several hundred trials, followed by another set of similar gratings but with different mean luminance for next several hundred trials, and so on. One of the stimuli is blank, that is, no stimulus comes on. We do all of these stimuli at four different mean luminances (1,3,10 and 50 cd/m^2) and then repeat the first mean luminance again at the end. In examining the activity for the blank stimulus, we find neurons with firing rate dependent on the mean luminance even after the excluding the transients. About half of the observed neurons show a significant variation in firing rate with change in mean-luminance. Out of these mean-luminance responsive neurons, approximately 60 per cent show an increase in firing rate with increasing luminance, another third show a decrease while for the remaining neurons the effect is idiosyncratic. There seem to be two populations of neurons, those with high background (17 Hz or greater) and those with low background (below 8 Hz). The high background neurons might be from layer 4.

Title: Altered functional circuitry in the primary visual cortex of amblyopic macaque monkeys

Authors: ***K. CLEMENS**[1,2], L. KIORPES[3], J. A. MOVSHON[3], M. A. SMITH[2,4,5];
[1]Univ. of Pittsburgh, Ctr. For Neurosci., Pittsburgh, PA; [2]Ctr. for the Neural Basis of Cognition, Carnegie Mellon Univ., Pittsburgh, PA; [3]Ctr. for Neural Sci., New York Univ., New York, NY; [4]Dept. of Ophthalmology, [5]Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Amblyopia is a developmental disorder of spatial vision. In amblyopia, early, imbalanced binocular inputs during the critical period for visual plasticity result in weakened inputs to neurons driven by one eye, and reduce their spatial resolution and contrast sensitivity. Single-unit studies in amblyopic monkeys have documented altered responses in primary visual cortex (V1) and extrastriate visual cortex, but these effects do not completely account for the behavioral deficits observed in the same animals. Given that cortical circuits in V1 are the first to integrate information from the two eyes, abnormalities in the functional circuitry of amblyopic cortex may help explain deficits in spatial vision in amblyopia. Here, we examined the correlation structure between pairs of neurons in V1 of amblyopic monkeys in order to investigate amblyopia's effect on the functional structure of cortex. We recorded from V1 of three anesthetized, paralyzed adult *Macaca nemestrina* using 100-electrode arrays. The animals had surgically-induced strabismus in infancy, which resulted in deep amblyopia. We collected control data from visually-normal animals. The arrays were implanted 0.6 mm into a region of V1 representing the parafovea, yielding superficial layer recordings. We presented identical sinusoidal grating stimuli of fixed, moderate spatial and temporal frequency separately to each eye; on different presentations the gratings drifted in one of twelve directions with one of three contrast levels (1, 0.5, 0.12). From each electrode, we recorded all responses that exceeded a threshold and sorted these waveforms offline. We analyzed data only from well-isolated single neurons from a total of seven array implants in the amblyopic monkeys. High contrast stimuli presented to the amblyopic eye evoked lower firing rates and higher correlated trial-to-trial variability (spike count correlation) compared to the fellow eye. Lowering stimulus contrast in the fellow eye resulted in a gradual increase in correlation, consistent with our previous results. In the amblyopic eye, however, lowering stimulus contrast produced only a small increase in correlation. In other words, the differential correlation between the amblyopic and fellow eye grew with increasing contrast. These results suggest that a stimulus presented to the amblyopic eye is processed as if of low contrast, irrespective of its actual contrast. We found no evidence for such an asymmetry between the eyes in normal controls. These findings suggest that the abnormalities in amblyopic vision may in part be explained by changes in V1 functional circuitry.

Title: Synaptic organization of ON and OFF inputs within the dendritic field of individual layer 2/3 neurons in tree shrew primary visual cortex

Authors: *K.-S. LEE[1,2], D. E. WILSON[1,2], D. FITZPATRICK[1];
[1]Max Planck Florida Inst., Jupiter, FL; [2]Florida Atlantic Univ., Boca Raton, FL

Abstract: Each pyramidal neuron in visual cortex receives excitatory synaptic inputs from thousands of presynaptic neurons. Establishing the functional properties and the organization of these inputs at the level of single neurons is essential for understanding cortical circuits. Recent published work from our lab shows that simple cells in tree shrew visual cortex orderly integrate the ON and OFF inputs from separate regions in the visual space to construct a smooth representation of orientation and spatial phase. However, the spatial arrangement of ON and OFF inputs in the dendritic field of individual neurons that is responsible for simple cell receptive field (RF) properties remains unknown. In this study, we sparsely labeled neurons in visual cortex with GCaMP6s calcium indicator, and applied *in vivo* two-photon imaging to measure the receptive fields, and the ON and OFF visuotopic organization of individual dendritic spines from single pyramidal neurons. Consistent with previous studies, the aggregate RF structure of the synaptic inputs reliably predicted the somatic RF structure for individual neurons. An ON & OFF overlap index, defined by the proportion of spine RFs overlapping with the somatic RF (same – opposite polarity), was computed to quantify the functional specificity of the synaptic inputs. We found high agreement between the ON and OFF organization of the synaptic inputs and the somatic response (mean overlap index 0.36). Surprisingly, when we calculated a spatial phase-based overlap index (comparing synaptic input to the optimal spatial phase of the somatic RF), the relationship of synaptic inputs to the somatic response was even stronger (mean overlap index 0.51), indicating that synaptic inputs display high specificity in spatial phase. We noted considerable diversity in the spatial properties of the ON and OFF response fields of nearby spines. However, by comparing the ON and OFF inputs potentially contributing to somatic RF (ON & OFF overlap index > 0.5), the distribution of OFF inputs was biased to the proximal dendritic field while the distribution of ON inputs was broader and centered at more distal locations in the dendritic field. This observation supports the recent finding that OFF inputs in the primary visual cortex anchor the fine map of visual space and ON inputs exhibit orientation specific visuotopic displacement consistent with the map of orientation preference.

Title: An optogenetic study of feedback circuitry in macaque visual cortex

Authors: *S. S. SOLOMON, A. ASCHNER, A. KOHN;
Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Feedback pathways, which project from higher to lower cortex, make up roughly half the inter-areal connections in the cerebral cortex. Feedback has been proposed to mediate critical functions that include providing information about perceptual and cognitive context, relaying learned information and implementing attention. Although implicated in such diverse and important functions, the physiological properties of feedback circuits remain poorly understood. Prior studies in macaque visual cortex have shown that disrupting feedback modulates how spatial context affects single neuron responses. While important, this work has two important limitations. First, feedback was silenced with coarse manipulations, such as lesions and cooling. Second, the effects of disrupting feedback were only evaluated in single neurons, whereas feedback could function to alter network coordination. To address these limitations, we used an optogenetic approach to evaluate how feedback arising in area V2 influences neuronal populations recorded in primary visual cortex (V1) of an anesthetized macaque monkey. We injected AAV1 viral vectors (hSyn promoter) encoding channelrhodopsin and eYFP in V2, near its border with V1. After 11 weeks, we targeted a small fiber optic into V2 and were able to modulate V2 neuronal responses with laser light. Histology confirmed robust and widespread expression in V2 and V1, particularly in the deep layers. We measured the effect of V2 stimulation on V1 spontaneous activity and responses evoked by drifting gratings of different orientations, sizes, and contrasts. V2 stimulation modulated the firing rates of about half the neurons in V1; most of these neurons showed increased firing rates, but some were inhibited. The effect of V2 stimulation was evident nearly immediately after laser onset, but V1 responses grew slowly over time and persisted ~0.25 s after laser offset. Firing rates of V1 neurons were least modulated by V2 stimulation when driven by gratings of optimal size. While firing rates were only modulated in a subset of V1 neurons, nearly all V1 neurons showed a decrease in response variability during V2 stimulation. Finally, V2 stimulation caused a substantial and widespread decrease in V1 pairwise ‘noise correlations’. Decorrelation was evident even in V1

pairs whose firing rates were not modulated by V2 stimulation. We conclude that local recruitment of feedback signals can induce robust changes in firing of lower cortex, including substantial changes in network coordination.

Title: Stimulus dependent laminar microcircuit interactions in primate V1

Authors: *M. A. GIESELMANN, A. THIELE;
Newcastle Univ., Newcastle upon Tyne, United Kingdom

Abstract: Changing stimulus sizes has profound effects on neuronal firing rates and oscillatory activity in primary visual cortex. Stimuli that extend beyond the classical receptive field generally result in suppression of neuronal firing rates and increased gamma oscillatory power. RF center responses are assumed to be generated predominantly by feedforward inputs from the thalamus into the thalamorecipient layers, which is then further processed in the superficial layers (2/3), while suppression from the far surround in V1 is believed to be mediated by feedback from higher visual areas, which predominantly terminates in layer 1 and layer 5. We used 16-channel laminar electrodes, inserted perpendicular into V1, to analyse the flow of information across V1 cortical layers when different sized square wave grating stimuli were presented in the neuronal receptive fields. 24 recordings were obtained (17 in monkey, 7 in monkey 2). Recording channels were aligned in depth to the channel showing an early (40-50 ms) sink in the current-source density analysis (CSD) of the visual potential evoked by the stimulus onset, likely representing the thalamic input into layer 4c. Analysis was done based on locally bipolar LFP referenced signals. Activity in the gamma frequency power showed the most profound changes with stimulus size across cortical layers, even if differences existed in terms of its size dependent modulation across layers (Gieselmann et al., SFN 2014). To determine functional connectivity between cortical laminae we computed the non-conditional and conditional granger-causality-indices (GCI) between the bipolar LFP signals recorded from all pairs of electrode contacts for the gamma frequency band (30-55 Hz) interactions. Two connections showed high causality indices while being positively modulated by the stimulus size at the same time. The upper infra-granular (IG) channels granger caused gamma in lower IG channels (non-cond. GCI small: 0.06 large: 0.38), which in turn granger caused gamma in lower

supra-granular (SG) channels (non-cond. GCI small: 0.07 large: 0.33). These results were confirmed by gamma phase-triggered averaging analysis of individual channels/layers. The gamma oscillations in the lower IG layers lagged the upper IG layers by 4.5 ms and preceded the lower SG layers by 6.1 ms at 44.4 Hz. These results suggest that gamma oscillations induced by surround suppression are transmitted to upper IG layers by feedback connections (or at least are generated by upper IG layers), and the flow of gamma entrainment then entails lower IG, followed by SG layers.

Title: Structural evolution of high-acuity circuitry in the primate primary visual cortex

Authors: *D. J. MILLER, J. H. KAAS;
Psychology, Vanderbilt Univ., Nashville, TN

Abstract: Discovering the cellular composition of neurobiological tissues informs our understanding of brain evolution, and is a first step towards generating the computational models necessary to probe sensory system function. In the mammalian visual system, information from the retina is routed through the thalamus and on to the cerebral cortex. In particular, previous work has shown that the neurons in the lateral geniculate nucleus (LGN) of the thalamus that support high-acuity vision predominantly project to neurons in layer four (Layer 4A, 4B of Hassler, 1967; or Brodmann's 4C alpha, beta) of the primary visual cortical field (V1) (Casagrande & Kaas, 1994). Comparative anatomical studies of the primate visual system suggest differences between diurnal and nocturnal species, although clear evolutionary trends are difficult to establish. In this project, we investigated the evolution of visual acuity circuitry in primates by measuring the volume and counting the number of cells in layer 4 relative to the rest of the cortical mantle in V1. Our sample includes humans, chimpanzees, baboons, macaques, squirrel monkeys, owl monkeys, tamarins, marmosets, tarsiers and galagos. Our preliminary data show that V1 in diurnal catarrhine primates contains fewer cells per unit volume than in diurnal platyrrhines. In addition, V1 in nocturnal species exhibits fewer cells per unit volume than in closely related diurnal taxa. Our volumetric comparisons indicate an expansion of layer 4 in

haplorrhine relative to non-haplorrhine taxa. However, these data also show an expansion of layer 4 in the nocturnal owl monkey relative to diurnal platyrrhines and nocturnal prosimians. Together, these observations provide evidence of major evolutionary shifts in the structure of the primate visual system that are correlated with changes in behavioral foraging ecology. Furthermore, our analysis suggests that specific functional pathways, such as circuits serving high-acuity vision, may drive structural changes in the opposite direction of larger phylogenetic trends.

Title: Spatiotemporal profile of dichoptic cross-orientation suppression across the layers of primate V1

Authors: ***M. A. COX**, K. DOUGHERTY, A. MAIER;
Vanderbilt Univ., Nashville, TN

Abstract: Dichoptic cross-orientation suppression (dCOS)—a core mechanism in models of binocular rivalry and amblyopia—is defined as the reduction in a neuron's response to an optimally oriented stimulus in the neuron's preferred eye when an orthogonally oriented stimulus appears in the other eye. Determining when and where dCOS is instantiated in the primate visual stream is critical for a comprehensive understanding of binocular vision, yet these questions remain unresolved. Anatomically, V1's main input layer (L4) is the primary cortical site where signals from the two eyes converge onto single neurons. Consistent with this structural layout, virtually all V1 neurons are sensitive to both eyes, even though stimulation of one eye often evokes stronger responses compared to stimulation of the other eye. Neurons downstream of V1 are largely invariant to ocularity, and the vast majority of LGN neurons upstream of V1 are

sensitive to only one eye and indifferent to orientation. Taken together, these functional and anatomical findings render V1's L4 a prime candidate for the instantiation of dCOS. This study aimed to test this hypothesis. Using intracranial linear microelectrode arrays, we recorded spiking responses across the layers of V1 in two macaque monkeys. L4 was defined functionally using current-source density (CSD) analysis of visually evoked potentials. Stimulus conditions included monocular gratings, matching binocular gratings (dioptic), and orthogonally oriented dichoptic gratings intended to evoke dCOS. In order to quantify the stimulus drive required for dCOS, we parametrically varied stimulus contrast and stimulus onset asynchrony for all stimulus conditions. We found that most V1 neurons respond less to binocular stimulation than to preferred eye stimulation alone. In order to localize dCOS within V1's layers, CSD for dichoptic stimuli was compared to dioptic stimuli. We found that dioptic non-preferred stimuli elicited greater net depolarization than dichoptic stimuli within L4, suggesting that dCOS cannot be explained by a decrease in excitatory drive. Taken together, these findings support the hypothesis that orientation-specific interocular suppression first emerges within V1's retinogeniculate input layer.

Title: The origins of spatial frequency tuning in macaque visual cortex

Authors: *P. LEVY, C. ZIEMBA, J. MOVSHON, E. SIMONCELLI, R. GORIS;
Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Neurons in primary visual cortex (V1) are selective for the spatial frequency of image features. This selectivity first arises in the retina, is modified by the LGN, and is further sculpted by cortical mechanisms. To identify the contributions of these elements, we measured responses of V1 neurons in anesthetized macaques to mixtures of sinusoidal gratings dispersed in spatial frequency. For a fixed total contrast, we varied the frequency dispersion and studied selectivity for the modal frequency of the mixtures. Many neurons exhibited contrast-dependent frequency tuning: At low contrast, neurons had narrower octave bandwidths and preferred lower spatial frequencies. These contrast dependencies were more pronounced for responses to more dispersed

stimuli.
To explain these results, we developed a cascaded model of cortical computation. In the first stage of the model, visual stimuli are processed in parallel by two linear-nonlinear channels, each containing the half-wave rectified responses of center-surround filters whose properties are based on those of parvocellular and magnocellular LGN cells that project to cortex. In the second stage, these channel responses are combined linearly, scaled by a contrast gain control, and passed through a nonlinearity to obtain a firing rate. The model simulates cortical responses to mixture stimuli well, and suggests that contrast-dependent spatial frequency tuning might emerge from combinations of inputs with different contrast sensitivity and spatial frequency selectivity.

Title: Contextual effects of spatial receptive fields in macaque monkey V1

Authors: *H.-Y. WU[1], C.-P. LIN[2], C.-I. YEH[2,3,4];
[1]Inst. of Neuroscience, Natl. Yang-Ming Univ., Taipei, Taiwan; [2]Dept. of Psychology, [3]Neurobio. and Cognitive Sci. Ctr., Natl. Taiwan Univ., Taipei, Taiwan; [4]Grad. Inst. of Brain and Mind Sci., Natl. Taiwan Univ. Col. of Med., Taipei, Taiwan

Abstract: Using natural stimuli to study receptive field properties has become an important branch of visual research. In contrast with artificial stimuli that have simple and well characterized properties, natural stimuli have very complex dynamics. Some studies use both natural and artificial stimuli to study V1 properties (Ringach et al 2002; Sharpee et al 2006), but a systematic investigation of the contextual effect of receptive fields with both stimulus types has not been accomplished. It therefore remains unclear whether receptive fields measured with

natural and artificial stimuli are comparable. To address this question, we measured receptive fields with both the natural stimulus (a movie recorded with a camera mounted on the head of a cat walking in the wood, Einhäuser et al 2002) and the artificial stimulus (a binary white noise generated by m-sequence, Reid et al 1997). In addition, we investigated the context effect by changing the parameters of the natural movie: the orientation (a 90-degree rotation) and the spatiotemporal correlation (a randomized frame sequence). Natural-scene receptive fields were calculated by regularized pseudoinverse reverse correlation to deconvolve with the natural scene (Smyth et al 2003), and white-noise maps were calculated by reverse correlation. A multi-electrode matrix (8x8 array, 200 um spacing, Neuronexus) was used to simultaneously record from multiple neurons in different layers of macaque V1. Here we report some of the main findings. First, the average receptive field sizes measured with natural and artificial stimuli are comparable. Second, a stimulus-dependent change in the preferred orientation is found in some V1 neurons -- the preferred orientations can be very different (more than 45 degree) between the natural-scene map and the white-noise map. Third, the signal-to-noise ratio of the natural-scene map tends to be higher than that of the white-noise map and the random-natural-scene map (no significant difference in the average firing rate under these conditions). Overall, these results indicate that the primary visual cortex is highly adaptive and dynamic: V1 neuron's receptive field may change accordingly with the statistics of the visual scene.

Title: Response properties in cytochrome oxidase modules of capuchin monkey visual area V2.

Authors: *R. PERES, J. GM SOARES, B. LIMA, M. FIORANI, M. CHIORRI, M. FLORENTINO, R. GATTASS;
UFRJ, Rio DE Janeiro, Brazil

Abstract: Cortical columns are considered a basic building block of cortical organization. Within these structures, nearby neurons encode similar stimulus features, such as selectivity for orientation, direction or color contrast. The second visual area (V2) of primates exhibits a compartmental organization based on stripes that run along its surface. These compartments can be revealed using histochemical staining for the mitochondrial enzyme cytochrome-c oxidase (CO), and are comprised of CO-rich (thin and thick stripes) and CO-poor (inter-stripe) bands. Notably, it has been hypothesized that these bands have different neuronal properties, and participate in functionally distinct streams of visual information processing. However, there is still controversy whether the different V2 compartments indeed correlate with specialized neuronal response properties.
In this study, we use multiple-electrode arrays (16-32 tungsten microelectrodes per array, ~ 250 μm inter-electrode spacing) to record spiking activity along the dorsal-ventral extent of area V2 in the anesthetized and paralyzed capuchin monkey (Sapajus apella formerly Cebus apella). As visual stimulus, we presented moving bars and gratings with different contrasts, orientations, directions of motion, spatial frequency, velocity and color contrast. Receptive field position was mapped for each recording site. The individual V2 stripes were identified by means of CO histochemistry.
We recorded from 1080 V2 sites in 6 hemispheres of 3 monkeys. Overall, our preliminary results show that neurons recorded from nearby electrodes share similar functional response properties. Specifically, we found a correlation between orientation selectivity, as measured by circular variance, and electrode position relative to the distinct V2 stripes. Sites with stronger orientation selectivity were more frequently located on thick and inter-stripe bands in V2, as compared to those on thin stripes. We also observed that the responses for neurons on thick stripes showed a significantly shorter latency compared to neurons located on the thin stripes. We are currently studying the neuronal responses to the other stimulus features and correlating them to V2 modular organization.

Title: Tracking orientation map and neural response dynamics during discrimination and perceptual learning in tree shrew V1 with chronic calcium imaging

Authors: *J. W. SCHUMACHER, T. WALKER, V. K. HOKE, S. FRELING, R. J. CORLEW, D. FITZPATRICK;
Functional Architecture and Develop. of Cerebral Cortex, Max Planck Florida Inst., Jupiter, FL

Abstract: Neurons in primary sensory regions of neocortex encode stimulus features that are important for representing the external world. In some sensory circuits, neuronal feature preference is mapped in a highly organized fashion. Orientation preference is mapped across the surface of primary visual cortex (V1) of highly visual mammals, but whether these structured orientation maps contribute to fine orientation discriminations in visually guided behavior is unclear. To assess how orientation maps are engaged during active behavior, we first trained adult tree shrews (*Tupaia belangeri*) to perform a simple go/no go discrimination task. Licking in response to a grating stimulus at a target orientation yielded liquid rewards, while licking for a distractor orientation caused a timeout. We found that tree shrews typically learn the easiest form of their task within two to three weeks. Psychometric analysis shows that unrestrained tree shrews easily discriminate targets from distractors at an offset of 25 degrees, and can have discrimination thresholds as low as 10 degrees. Shrews that expertly learned an easy form of the task were imaged using 2 photon microscopy with the genetically encoded calcium indicator GCaMP6s in V1 layer 2/3. Neurons in layer 2/3 of tree shrew V1 represent the earliest stage of cortical processing to encode orientation. To assess if this stage of visual processing was sensitive to behavioral context we tracked the activity of relatively large populations of neurons during visually guided behavior across several days. Following each behavioral imaging session, we presented the shrews with oriented gratings for passive viewing to assess how well the neural population could discriminate orientations in the absence task-related attention. In some cases, neurons exhibited task-related response modulation, with somatic fluorescence magnitudes differing for the active discrimination and passive viewing contexts. When headfixed animals achieved a criterion level of discrimination performance ($d' > 1.5$), we increased the difficulty of the task by replacing the no go grating with a more similar orientation to the target. Increased task difficulty was accompanied by a decrease in behavioral performance and increased response latencies. To determine whether the layer 2/3 orientation map is the target of learning-related plasticity, we tracked the neural population during the subsequent perceptual learning of the more difficult task. This allowed us to ask whether the learning of fine orientation discriminations improves neural discrimination performance, and where in the orientation map the corresponding changes in neural responses occurred.

Title: Emergence of structured neuronal correlations during the learning of a perceptual discrimination task

Authors: *C. GOMEZ-LABERGE[1], R. M. HAEFNER[2], R. T. BORN[1];
[1]Neurobio., Harvard Med. Sch., Boston, MA; [2]Univ. of Rochester, Rochester, NY

Abstract: The senses are our gateway to the world, yet the information they provide is insufficient to unequivocally determine what is "out there." How then are competing interpretations of sensory input resolved to form a stable percept? This problem of inferring the state of the world from limited sensory information is mathematically ill-posed and could be resolved by combining incoming sensory input with prior information about the possible states. We hypothesize that structured correlated activity in the cerebral cortex is a manifestation of this prior information, encoded by top-down inputs that prime neuronal populations whose stimulus preferences are most compatible with one of the expected states. Studies have demonstrated decision-related activity in the visual cortex of animal subjects trained to discriminate noisy visual stimuli, which is consistent with an underlying correlation structure that could be encoding the task-related alternatives. To test this hypothesis, we implanted a chronic multi-electrode array to record from single cells and multi-unit clusters in the primary visual cortex of a rhesus monkey, while it was trained to perform a coarse orientation discrimination of bandpass-filtered noise images. We monitored behavioral performance and neuronal activity over daily sessions, spanning approximately one month, during which the subject first performed the task at a chance level and gradually approached psychophysical threshold. We found that the average spike-count correlation coefficient was small (daily mean 0.03, s.d. 0.08) and was comparable in magnitude throughout the study. As predicted by theory, correlation structure reflecting task contingencies emerged over the course of training. In later sessions when the monkey was performing at a stable threshold, the mean correlation between pairs of units with preferred orientations corresponding to the *same* contingency were larger than in pairs with preferences corresponding to *opposite* contingencies. And this correlation structure was absent in early sessions when the animal was performing at or near chance. Prior information about expected perceptual states may be reflected in the correlation structure of populations of sensory cortical neurons. Because

perceptual expectations can change rapidly with context, this structure may be under the control of top-down input such as feedback from higher sensory cortical areas.

Title: Comparing the time course of adaptation in V1 neurons with perception.

Authors: *P. L. APARICIO, B. G. CUMMING;
Lab. of Sensorimotor Res., Natl. Eye Inst., Bethesda, MD

Abstract: Adaptation, or changes in response due to stimulus history, have been observed in both the responses of neurons and perceptual behavior. In the visual cortex, adaptation occurs on several time scales, which complicates direct quantitative comparisons between the neural and psychophysical effects of adaptation. Here we examine the temporal structure of adaptation recorded from neurons in the striate cortex of two monkeys with the timecourse of psychophysical adaptation using identical adaptation protocols in both a human and monkey subject. Subjects were presented with 3s trials, consisting of a constant disparity (the adaptor) followed by a sequence of correlated random dot stereograms (RDS). Psychophysical subjects reported whether the sequence of RDS appeared far or near. To ensure that the psychophysical effects could not be caused by subjects' awareness of the adapting stimulus, we used an anticorrelated random dot stereogram (aRDS) to induce adaptation because aRDS of opposite disparity are indistinguishable, yet produce adaptation in V1 neurons that depends upon the sign of the adapting disparity. Our protocol produced changes in the reported depth of RDS in a direction that matched the changes in rate observed in adapted V1 neurons. To quantify the timecourse of adaptation, we pooled data across blocks according to the trial position within a block. This generated a neuronal tuning curve for the first trial after a switch in adapting disparity, and separate curves for each subsequent trial position. Each of these was compared with the mean response for all data using a type II regression. We used the regression slope to quantify adaptation magnitude. Adaptation was clearly evident in the first trial of a block, but strengthened over 2-3 trials. The data were well described by an exponential function with a timecourse of 0.54 trials (mean of data from 16 neurons). Psychophysical data was similarly grouped and fit with cumulative Gaussian functions to the response data for each trial within a block. We characterized psychophysical adaptation as the difference in the fitted mean between

trials adapted with near and far aRDS. The extent of adaptation at each trial in a block was fit with an exponential function. The fitted time-constant (0.7 trials) was not significantly different from that observed for the neuronal data, suggesting that the perceptual effects of adaptation in our disparity task can be explained by the effects of the adaptor on neurons at the one of the earliest stages of the visual representation.

Title: Cortical areas with low dopamine content represent prospective regions for voltammetric detection of norepinephrine *In vivo*

Authors: *N. J. WARD, A. A. DISNEY;
Psychology Dept., Vanderbilt Univ., Nashville, TN

Abstract: Selectivity is an important consideration when detecting catecholamines in neural tissue. Structural similarities between dopamine and norepinephrine result in electrochemical signatures that are challenging to distinguish from one another. One solution is to accept a catecholamine signal that represents contributions of both dopamine and norepinephrine, but this does not allow for differentiation of the individual signals. Another solution is to conduct studies in brain regions with privileged innervation or content, such that signal measured can be attributed to one catecholamine rather than another. Prior studies involving subsecond detection of catecholamines in awake, behaving non-human primates have involved measurement of dopamine in the striatum. In the present study, we sought to identify candidate brain regions in non-human primate where norepinephrine can be detected using subsecond voltammetric recordings. We used high performance liquid chromatography with electrochemical detection on unfixed, frozen tissue samples from macaques to identify prospective neocortical regions for norepinephrine voltammetry. These results indicate that primary visual cortex (V1) and potentially primary somatosensory cortex exhibit low enough levels of dopamine that would allow for voltammetric detection of norepinephrine. Our V1 results support previous studies that have indicated low contribution of dopaminergic axons to the catecholaminergic innervation of

V1. Altogether, these results indicate promising cortical regions for subsecond detection of norepinephrine in awake, behaving macaques.

Title: Interactions between feedback and lateral connections in the primary visual cortex

Authors: H. LIANG[1], X. GONG[1], M. CHEN[2], Y. YAN[2], C. D. GILBERT[3], *W. LI[2]; [1]Sch. of Biomed. Engin., Drexel Univ., Philadelphia, PA; [2]State Key Lab. of Cognitive Neurosci. and Learning, Beijing Normal Univ., Beijing, China; [3]The Rockefeller Univ., New York, NY

Abstract: Grouping of visual contours to form coherent percept has been thought to be mediated in part by long-range horizontal connectivity intrinsic to the primary visual cortex (V1), with a contribution by top-down feedback projections. In a recent study (Chen et al., Neuron 82:682-694, 2014), by simultaneous recording with microelectrode arrays implanted in monkey V1 and V4, we have shown that information about global contours within a complex background emerges initially in V4 and then rapidly builds up in both cortical areas. Bidirectional inter-areal interactions not only facilitate V1 neurons encoding the contour elements but also suppress those responding to the background. Since the onset of contour-related signals in V1 is much delayed relative to that in V4, an unsolved important question is whether the contour signals in V1 are derived from feedback inputs alone, or whether they are mediated by an intimate interaction between feedback and horizontal connections. In the current study we applied conditional Granger causality analysis of spike-train data to dissect the contributions of intra- and inter-areal connections. Our results showed that discounting the influences from V4 markedly reduced V1 lateral interactions, indicating dependence on feedback signals of the effective connectivity within V1. On the other hand, the feedback influences were reciprocally dependent on V1 lateral interactions, as the modulation strengths from V4 to V1 were greatly reduced after discounting the influences from other V1 neurons. By separating the data from trials in which the monkeys

made correct or erroneous choices in the contour detection task, we found that both the strengths of V4 to V1 feedback modulation and V1 intrinsic lateral interactions correlated with behavioral performance. Our findings suggest that feedback and lateral connections closely interact to mediate image grouping and segmentation.

Title: Coordinated neuronal activity reflects correct perceptual reports

Authors: *N. SHAHIDI[1], M. HU[2], A. R. ANDREI[3], V. DRAGOI[3];
[1]Univ. of Texas, Med. Sch. At Houston, Houston, TX; [2]MIT, Cambridge, MA; [3]Univ. of Texas, Med. Sch. at Houston, Houston, TX

Abstract: Visual perception is an active process of extracting relevant information for decision making. The degree to which spiking activity reflects perceptual choices vary widely across visual areas. We recorded simultaneously from small populations of neurons in V1 and V4 areas of monkeys while animals were engaged in a delayed match-to-sample orientation discrimination task. To our surprise, firing rates of single neurons and pairwise spike-time correlations were independent of behavioral choices. However, in area V4, but not V1, we found that coordination across three or more neurons was able to predict whether the monkey correctly detected the change in stimulus orientation (Figure 1). These results demonstrate that neuronal ensembles in visual cortex carry behaviorally relevant information that individual neurons or pairs do not. We also examined the spike time coordination between V1 and V4 by analyzing multiple neurons simultaneously in both areas. Interestingly, we found a significant inter-areal coordination when V4 lags V1 by 30 ms only when the animal was able to detect the orientation change correctly. This indicates that effective feed-forward connectivity plays a crucial role for perceptual discrimination.

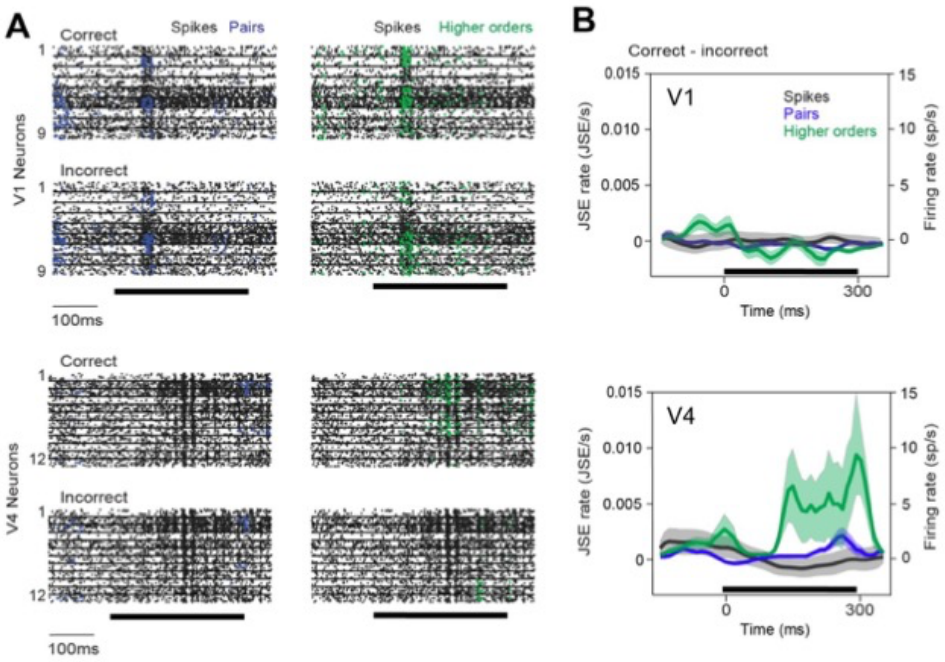

Figure 1| In V4, coordinated spikes occur more often in correct trials. (A) Raster plots of 9 cells in V1 and 12 cells in V4 for correct and incorrect trials overlapped with combinations of 2 (blue) or more (green) coordinated spikes (time bin of 5 ms). For better representation, the same number of random trials were selected from correct and incorrect set and only patterns for which the frequency of occurrences are significantly different between correct and incorrect sets (Wilcoxon rank sum, $p<0.01$) are shown. The horizontal lines show the presentation time of the test stimulus. **(B)** The frequencies of occurrences of coordinated spikes (JSE rates) were calculated for a 300ms window sliding with steps of 10ms (blue and green). Firing rates of all neurons were also calculated in the same time window and the difference between correct and incorrect firing rates were averaged across all neurons (gray).

Title: The effects of adaptation on normalization signals within the receptive field

Authors: *A. ASCHNER[1], S. G. SOLOMON[2], M. S. LANDY[3], D. J. HEEGER[3], A. KOHN[1]; [1]Dominick P Purpura Dept. of Neurosci., Albert Einstein Col. of Med., Bronx, NY; [2]Dept. of Exptl. Psychology, Inst. for Behavioral Neurosci., London, United Kingdom; [3]Dept. of Psychology & Ctr. for Neural Sci., New York Univ., New York, NY

Abstract: Adaptation alters the responsivity of most sensory neurons. Although we have a rich description of adaptation effects in single neurons, we lack a conceptual framework that integrates this phenomenology and can predict how a neuron will adapt to different stimuli. We and others have proposed that explaining adaptation effects through altered normalization signals may provide such a framework. Normalization is a 'canonical' computation whereby a neuron's responses are suppressed by the pooled activity of other neurons (normalization pool). Previous work has shown that adaptation can weaken normalization from the receptive field (RF) surround, which can explain some facilitory effects of adaptation. Here we ask how adaptation alters normalization within the RF.

We performed extracellular recordings in primary visual cortex (V1) of anesthetized monkeys. We measured responses to plaid stimuli composed of two orthogonal, sinusoidal gratings of varying contrast, before and after adaptation with two high contrast gratings presented asynchronously ('component' adaptation). The strength of normalization was estimated by (1) fitting a standard descriptive model to the full set of plaid responses; and (2) comparing the area under the contrast-response function for the preferred grating alone and when paired with a mask. Both metrics revealed that normalization was strongly weakened after component adaptation.

We next tested whether adaptation can strengthen normalization, needed in this framework to explain the suppressive effects of adaptation. Recent theoretical work proposes that normalization is strengthened when a neuron and its normalization pool are consistently co-activated. Thus, we adapted neurons with two gratings presented synchronously ('contingent' adaptation). Using the same test stimuli and metrics, we found normalization was only slightly weakened by contingent adaptation. Further, when we controlled for changes in response magnitude, we found that signal summation was more sublinear after adaptation than before, consistent with a stronger interaction between a neuron and its normalization pool.

Our results indicate that normalization within the RF is shaped by adaptation. As a result, the diverse effects of adaptation may be explained in part by the manner in which a particular adapter and test stimulus recruit and alter those normalization signals.

Title: Neurogranin gates experience dependent synaptic pruning and maturation in visual cortex

Authors: *K. HAN, S. COOKE, M. F. BEAR, W. XU;
MIT, Cambridge, MA

Abstract: Modification of synaptic connections by sensory experience during post-natal development is essential for functional maturation of cortical circuits. Here we show that neurogranin (Ng), a postsynaptic calmodulin (CaM)-binding protein in cortical principal neurons, regulates experience-dependent synapse maturation and synapse pruning in the primary visual cortex. In Ng KO mice, primary visual cortex exhibits a dramatically impaired response to visual stimuli and experience-dependent synaptic potentiation within primary visual cortex, known as stimulus-selective response potentiation (SRP), is also deficient. Additionally, loss of Ng in primary visual cortex impairs visually guided behavior, consistent with a profound impairment in cortical circuitry. At the synaptic level, Ng is required for experience-dependent maturation of AMPAR-silent synapses, stabilization of AMPAR-transmitting synapses, and regulation of spine loss. Knockdown of Ng in primary visual cortex during the commonly defined postnatal critical period leads to a significant decrease in spine density, AMPARergic synapse numbers and an abnormal retention of AMPAR-silent synapses. These functional deficits can be prevented by dark exposure during the molecular manipulation, suggesting that Ng levels gate experience-dependent modification of glutamatergic synaptic transmission in visual cortex. Decrease of Ng levels lowered threshold for LTD expression, providing a potential cellular substrate for experience-dependent damping of AMPAR-transmitting synapses. Taken together, our studies show that neurogranin levels control experience-dependent synapse

stabilization and synapse pruning for functional optimization of the cortical circuit during critical in primary visual cortex.

Title: Network coding strategies underlying perceptual learning in primary visual cortex

Authors: ***N. D. OLIVAS**, L. O. JIMENEZ, D. L. RINGACH, J. T. TRACHTENBERG; Neurobio., UCLA, Los Angeles, CA

Abstract: We imaged large ensembles of pyramidal (PYR) neurons in L2/3 primary visual cortex (V1) of alert mice using resonant scanning 2-photon excitation of neurons expressing GCaMP6. Responses were recorded over 30 minute epochs as mice viewed continuous natural scenes taken from various BBC Nature episodes followed by 50 identical repeats of a 6-second long natural scene. Locomotion and pupil diameter were measured throughout the experiments. We find that cortical processing of naturalistic scenes is represented by sparse network level coding. Network sparseness is achieved as a consequence of the selectivity of V1 neurons for specific scenes. Sparse coding is modulated by the behavioral state where network sparseness is diminished during periods of locomotive activity. Whether network spareness is computationally advantageous for perception is under active investigation.

Title: Visual perceptual learning and visual cortical plasticity in monkeys caused by VTA microstimulation in the absence of attention.

Authors: *J. T. ARSENAULT[1,2], W. VANDUFFEL[1,2,3];
[1]K.U. Leuven, Leuven, Belgium; [2]Mass. Gen. Hosp., Athinoula A. Martinos Ctr. for Biomed. Imaging, Charlestown, MA; [3]Dept. of Radiology, Harvard Med. Sch., Boston, MA

Abstract: Visual perceptual learning (VPL) is influenced by the interaction of attention and reinforcement. Interestingly, VPL can occur in absence of stimulus-directed attention (Seitz et al., 2009). Such task-irrelevant perceptual learning (TIPL) has been hypothesized to result from the temporal coincidence of a stimulus and neuromodulatory signals triggered by reinforcement. Consequently, TIPL offers an opportunity to isolate the role of neuromodulatory signals in the regulation of VPL and plasticity while excluding the role of attention. Although several neuromodulatory centers may be involved in VPL, the ventral tegmental area (VTA) is a good candidate because its neurons are activated by reinforcement, have widespread connections and release dopamine that facilitates plasticity. Therefore, we microstimulated monkey VTA (VTA-EM) to determine its causal role in VPL and cortical plasticity.
In Exp 1 we looked for plasticity. To do this we performed fMRI mapping (pre-association) to determine the response to 4 different grating stimuli [(L/R visual field) x (45°/135°)]. During all phases, the animals performed a difficult, orthogonal color discrimination task (80% correct performance) during grating presentation to avoid grating-directed attention. Next came a cue-VTA-EM association phase in which all gratings were shown but one was temporally associated with VTA-EM (20 sessions). Again, the color task was used to control attention. Finally, post-association fMRI mapping was identical to phase 1. The analysis demonstrated representation-specific enhancements (post vs. pre) in fMRI activity for the stimulated grating orientation within the ‘trained’ visual field, especially pronounced in PIT. These changes were not found for gratings displayed in the ‘untrained’ visual field.

In Exp 2 we looked for VPL effects. Exp 2 also consisted of pre- and post-association phases bookending a cue-VTA-EM association phase (6 - 20 sessions). Within the pre- and post-association phases the animals discriminated between upward and downward random dot motion stimuli presented in the left or right visual field at 6 motion coherences (0 - 50%). The cue-VTA-EM association phase consisted of bilateral presentations of 0 and 2% motion stimuli with only one 2% coherence stimulus being associated with VTA-EM. The color task was again used to avoid directed attention to the motion stimuli. Enhanced performance for lower motion coherences (2 - 12%) were consistently observed in the test phase for the 'trained' visual field. These results provide causal evidence for the role of primate VTA in VPL and stimulus-specific plasticity in the absence of stimulus-oriented attention.

Title: Modulation of visual processing by projection from the orbitofrontal cortex to the primary visual cortex

Authors: *L. DECHEN, J. DENG, Y.-G. SUN, H. YAO;
Inst. of Neuroscience,CAS, Shanghai, China

Abstract: Information processing in the primary visual cortex (V1) can be modulated by long-range corticocortical projections (Zhang et al, Science, 2014). A recent study showed that the orbitofrontal cortex (OFC) is reciprocally connected with V1 in mice (Zingg et al, Cell, 2014). Although many studies have shown that the OFC plays an important role in learning, the functional role of the OFC projection to V1 remains unclear. Here, we examined how this projection modulates visual processing in V1 and impacts learning of visual discrimination in mice. Using *in vivo* extracellular recordings from V1, we found that optogenetic activation of the OFC fibers in V1 decreased the response amplitude of V1 neurons without changing the orientation selectivity. In acute brain slices, optogenetic activation of the OFC fibers in V1 produced EPSPs and monosynaptic EPSCs in a large fraction of somatostatin (SOM)-expressing neurons but rarely elicited responses in parvalbumin (PV)- or vasoactive intestinal peptide (VIP)-expressing neurons in V1. Our behavioral experiments showed that neurotoxic lesion or

optogenetic inactivation of the ventral OFC could improve the learning rate of visual discrimination in mice. We are currently investigating how the OFC-V1 projection modulates responses of V1 neurons in different layers and how inactivation of the OFC-V1 projection influences the learning of visual discrimination behavior. Since the OFC receives dopaminergic projections from the ventral tegmental area (VTA) (Berger et al, TINS, 1991), we are also examining the effect of activating the VTA fibers in OFC on V1 responses and visual behavior.

Title: Gamma-band synchronization in primate visual cortex can increase or decrease with stimulus repetition

Authors: *A. PETER[1], J. DOWDALL[1], L. KLEIN[2], J. KLON-LIPOK[2], K. KOUROUPAKI[1], M. SCHOELVINCK[1], J. SCHMIEDT[1], K. SHAPCOTT[1], M. SCHMID[1], W. SINGER[2], P. FRIES[1];
[1]Ernst Struengmann Inst. For Neurosci. In Cooperation With Max Planck Soci, Frankfurt Am Main, Germany; [2]Max Planck Inst. for Brain Res., Frankfurt, Germany

Abstract: Repeated encounters with visual stimuli often lead to reduced firing rate responses throughout the visual system. This phenomenon is known as adaptation or, especially in higher-order cortical areas, as ‘repetition suppression’. However, behavioral performance typically remains stable or improves with repeated encounters despite reduced visual responses. To explain this apparent discrepancy, it has recently been proposed that stimulus repetition results in a more efficient stimulus representation by means of increased neuronal synchronization (Gotts et al., 2012).
Brunet et al. (2014) indeed showed that over the course of several hundred repetitions of grating stimuli, there was an increase in V1 and V4 LFP gamma-band power and V1-V4 gamma-band coherence. In V4, MUA and putative interneurons showed firing rate decreases, yet increases in gamma synchronization. Putative pyramidal cells showed no firing rate change, yet changes in synchronization that were positively correlated with stimulus drive. These results suggest that repetition leads to a sharpening of the stimulus representation.
However, the study repeated a small fixed set of gratings many times, and it therefore remained unclear whether changes were specific to the repeated stimuli, or whether a new set of stimuli

would be affected by those changes. Moreover, the exclusive use of grating stimuli precluded generalization to more naturalistic stimuli. Here, we investigate the stimulus specificity of repetition effects by presenting pseudo-randomly repeating natural images. Monkeys were engaged in a change detection task on the presented objects (20 repetitions per image, ~2s presentation duration, with maximally 4 intervening stimuli between repetitions). Neural data were recorded from V1 and V4 in several rhesus monkeys. Visually induced MUA in both V1 and V4 showed repetition-related decreases. All natural stimuli induced gamma-band activity, ranging from few ten to few thousand percent power increases. Repetition could induce either decreases, increases or an initial decrease followed by an increase, depending on the particular stimulus, yet reliable across recording sessions. The interleaved and independent dynamics per stimulus demonstrate that repetition-related changes of gamma-band synchronization are specific to the respective stimulus. We provide preliminary evidence that repetition-related changes in V1 gamma are stimulus-location specific and therefore likely a local phenomenon. Ongoing recordings investigate the effects of massed repetitions. Collectively, these analyses demonstrate changes in stimulus representation on the timescale of seconds.

Title: Effect of training on stimulus representation in V1 and V2 neuronal ensemble.

Authors: ***T. LEE**, G. HUANG, Y. ZHANG;
Carnegie Mellon Univ., Pittsburgh, PA

Abstract: We studied how familiarity due to repeated exposure to a class of patterns or object images could modify neural representation of V1 and V2 neurons at the population level. In this study, we exposed awake behaving monkeys to specific classes of patterns or specific classes of

objects seen in different views, and monitored the evolution of the representation of V1 and V2 neuronal population responses during this process. To monitor neuronal activities, we used semi-chronically implanted SC32 multi-electrode arrays with independently movable electrodes from Gray Matter Research which can track the same neurons over weeks. We found that (1), intense exposure to specific stimuli or specific class stimuli over days leads to a sharpening of the tuning curves of individual neurons, as well as an increase in the sparsity of the population responses to the trained stimuli; and (2) exposure training leads to a change the stimulus representation of the neuronal population for this class of stimuli, resulting in better stimulus discrimination. We compared these results with simulation results of a variety of neural models. Preliminary results suggest hierarchical models with predictive coding and sparse coding constraints can account for these observations.

Title: Contextual modulation is responsible for image familiarity effect in V1 and V2 neurons

Authors: ***G. HUANG**, S. RAMACHANDRAN, J. SAMONDS, T. LEE, C. R. OLSON;
Ctr. for the Neural Basis of Cognition, Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Neurons in monkey inferotemporal cortex (IT) show truncated responses to images of complex objects that the monkey is highly familiar with ('familiar images'), compared to images the monkey encounters for the first time ('novel images') (Mruczek and Sheinberg (2007)). Ramachandran, Lee and Olson (2014) have demonstrated that similar effects can be observed in neurons with much smaller receptive fields in earlier visual areas (V2 and V4) in the ventral stream. Do these neurons become familiar with the global images or the local receptive field features? This familiarity truncation effect could arise from feedback from the object recognition area (IT), or from recurrent horizontal connections within each early visual area, or arise from the modification of bottom-up feed-forward connections responsible for receptive field tuning

properties. To dissociate these causal factors, we familiarized the monkeys with a set of 25 images for up to 21 days, using a semi-chronic SC32 multi-electrode array (Gray Matter Research) to monitor V1 and V2 neurons' responses in awake behaving monkeys during this familiarization process. First, we found that the familiarity truncation of neural responses observed in V2 and V4 can also be observed in V1. More importantly, we found that the familiarity truncation effects observed in V2 neurons were greatly attenuated or eliminated when the familiar images were presented in a 3° aperture, which still covered all the receptive fields but eliminated much of the global context of the image. This second observation suggests that the familiarity truncation effects observed in V2 were likely not due to modification in the feed-forward circuits for processing receptive field stimuli, but due to changes in recurrent circuits for mediating contextual modulation. Given the latency of the truncation was earlier in V2 and V4 neurons compared to the latency of the effect in IT neurons, our observations suggest that the familiarity truncation effect might be mediated by the horizontal connections within each visual area.

Title: Single trial familiarity judgments are reflected in the IT population response

Authors: *T. MEYER, N. C. RUST;
Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Extensive exposure of images is known to markedly alter responses in macaque inferotemporal (IT) cortex. Typically, these changes are manifest as firing rate response reductions for familiar as compared to novel images. Given that familiarity memories are stored after single exposures, we wondered whether IT neurons reflect visual familiarity memories after just a single image viewing. Previous investigations were limited in two ways: (1) traditional (largely single-neuron) analyses relied on averaging responses across many trials, however a "novel" image cannot be repeated multiple times; and (2) prior experimental designs utilized passive viewing and thus could not explore the relationship between putative familiarity signals

and behavior. To address these issues, we applied single-trial population-based approaches to analyze neural responses in IT collected from monkeys performing a visual familiarity task. Monkeys were able to report whether individual images were “novel” (never seen before) or “familiar” (seen only once). For each recording session, we computed the cross-validated performance of a linear population read-out optimized to classify images presented as “novel” versus “familiar”. We found that on average, novel and familiar conditions were correctly classified on trials in which the monkey reported the correct answer, whereas novel and familiar conditions were significantly misclassified on trials when the monkey made errors. These results establish that behaviorally-relevant familiarity signals are reflected in IT following single image exposures.

Title: A neural mechanism of retaining category information in prefrontal cortex

Authors: *Y. KASHIMORI;
Univ. Electro-Communications, Tokyo, Japan

Abstract: The ability to categorize objects is a fundamental function of visual recognition. In daily life, we can rapidly and effortlessly categorize huge objects. Much effort has been devoted to the studies of how category information is processed in the brain circuits. Freedman et al. trained monkeys to categorize the computer-generated images of dogs and cats and demonstrated the involvement of the interaction between inferior temporal (IT) cortex and prefrontal cortex (PFC) in the categorization task. Moreover, they showed that neurons in the IT were more sensitive to object features, whereas neurons in the PFC exhibited a larger sensitivity to object categories. However, it still remains unclear how working memory of category information is formed in the PFC and what a role the top-down from the PFC to IT plays in the categorization task. To address these issues, we develop a model of visual system which consists of a PFC and an IT network. Each network has two-dimensional array of neurons, and single neuron was modeled with the leaky-integrator model. According to the categorization task conducted by Freedman et al., three dog images and three cat ones were memorized in the IT network, and the category information of dog and cat was represented by the PFC network. Each object or category information was represented as a dynamical attractor in the respective networks. Using

the model, we show that PFC neurons with lower firing thresholds are dominantly responsible for the formation and retention of working memory whereas those with higher firing thresholds have high sensitivity to category information of dogs/cats images. The lower-threshold neurons stabilize the attractors of category information and are capable of retaining recent history of neuronal activity even after stimulus is turned off. We also show that top-down from PFC to IT enables PFC neurons to improve the categorization ability of the dogs/cats images that are hard to discriminate between dog and cat categories. The improvement arises from the mechanism by which top-down signal elevates membrane potential of IT neuron in subthreshold region and allows IT neurons to be sensitive to forthcoming stimulus. These results suggest that the difference in sensitivity of PFC neurons and the top-down from PFC to IT may be involved in efficient performance of categorization task.

Title: Neuronal population changes underlying visual perceptual learning and attention

Authors: *A. M. NI, D. A. RUFF, J. J. ALBERTS, J. SYMMONDS, M. R. COHEN; Dept. of Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Both visual attention and perceptual learning improve performance on visually guided tasks: attention allows observers to focus on particular parts of a crowded scene, and perceptual

learning improves perception of specific stimuli. But while these two processes can both improve perception, their effects differ in timescale: attention can fluctuate on the scale of hundreds of milliseconds, while perceptual learning improves performance over weeks to months of repeated practice. Attention is known to affect the extent to which trial-to-trial variability is shared between pairs of neurons in visual cortex (noise correlations), which may affect the amount of visual information that can be decoded from the population of neurons. However, the effects of learning on neuronal populations have not been as well studied, and the neuronal underpinnings of attention and learning have never been directly compared. To test the hypothesis that all processes that improve perception share a common neural mechanism, we simultaneously measured effects of attention and learning on behavior and populations of neurons in visual cortex. We implanted two rhesus monkeys with multi-electrode arrays in area V4. We then recorded neuronal activity while the monkeys learned to perform a change detection task that required that they switch spatial attention between two visual stimuli. We found that both attention and learning improved behavioral sensitivity and decreased noise correlations. We observed attention-related changes in performance and noise correlations within individual experimental sessions. The animals' behavioral sensitivity for both the attended and unattended stimulus increased slowly over many training sessions, and noise correlations in responses to both attended and unattended stimuli decreased at the same rate. These changes were location-specific: sensitivity worsened and correlations increased when we switched stimulus locations and then gradually changed during learning. The changes in noise correlation were also task-specific: noise correlations remained stable during a passive fixation task across the course of training. Additionally, these multi-neuron data sets allow us to differentiate whether these attention- and learning-related perceptual improvements reflect improved information encoding by the neuronal population or the animals' improved ability to optimally decode the available information. Similarities between the neural signatures of attention and learning support the hypothesis that all processes that improve perception have similar neural mechanisms.

Title: Central versus peripheral vision in scene recognition: a modeling exploration

Authors: *P. WANG[1], G. COTTRELL, 92093[2];
[1]Electrical and Computer Engin., UCSD, LA Jolla, CA; [2]Computer Sci. and Engin., UCSD, La Jolla, CA

Abstract: What are the roles of central vision and peripheral vision in human scene recognition? While brain imaging studies show that the scene recognition region (Parahippocampal Place Area; PPA) is associated with peripheral vision, a careful examination of the relative contribution for central versus peripheral vision is needed. In a behavioral study done by Larson and Loschky (2009), scenes were presented using the "Window" and "Scotoma" paradigm, in which only central or peripheral information is shown inside or outside a circular region. They showed that peripheral vision contributes more than central vision in obtaining the maximum scene recognition accuracy. However, central vision is more efficient for scene recognition than peripheral based on the amount of visual area needed for accurate recognition. In our study, we modeled and explained the results of Larson and Loschky (2009) by using a neurocomputational modeling approach.
We have four main findings. First, we showed for the first time that the advantage of peripheral vision in scene recognition can be replicated nicely using state-of-the-art deep neural network models. We trained different models (namely AlexNet, VGG, and GoogLeNet) on the ten scene categories used in the behavioral study, and all models demonstrated the peripheral advantage in scene recognition. All networks also modeled the efficiency of central vision. Second, we proposed and provided support for the hypothesis that the peripheral advantage comes from the inherent usefulness of peripheral information, which is consistent with the result of Thibaut et al. (2014), who showed that patients with central vision loss can still categorize natural scenes efficiently. Third, by using a deep mixture-of-experts model ("The Deep Model", or TDM) that receives central and peripheral visual information on separate channels simultaneously, we showed that the peripheral advantage emerges naturally in the learning process: The model “attends” to the peripheral pathway more than the central pathway. As we have seen in our previous modeling work, learning creates a transform that spreads different scene categories into different regions in representation space. Finally, we visualized the features for the two pathways, and found that the central and peripheral pathways complement each other rather than competing: different preferences for scene categories emerge for the two pathways during the training process.

Title: Long-term high-capacity memories of object values in the primate brain - fMRI study on macaque monkeys

Authors: *A. GHAZIZADEH[1], W. GRIGGS[1], D. A. LEOPOLD[2], O. HIKOSAKA[1,3];
[1]LSR NIH, Bethesda, MD; [2]NIMH NIH, Bethesda, MD; [3]NIDA NIH, Baltimore, MD

Abstract: During our lifetime we are bombarded by a large number of visual stimuli that need to be memorized and discriminated based on their ecological relevance such as their reward value. The basal ganglia, especially their posterior part, play an important role in such visual discrimination (Hikosaka et al 2014). Beyond this basal ganglia circuitry, the neural mechanism involved in such discrimination is not well-known. We addressed this issue by doing whole brain functional magnetic resonance imaging (fMRI) in two rhesus monkeys. Before the scans, the monkeys repeatedly viewed many computer-generated fractals (n>80) which were consistently associated with a large reward (Good objects) or a small reward (Bad objects) for >10 days. During block design scans (>1 day after training), these objects were passively viewed in the periphery (left or right, 6deg) while the monkey kept central fixation with no contingent reward. Thus the differential coding of objects in passive viewing would represent acquired stable object values rather than immediate reward expectations. Scan results showed widespread object Goodness coding (Good > Bad) along the ventral bank of superior temporal sulcus (STS) particularly in areas V4, TEO, TEa as well as in orbitofrontal cortex (OFC) and lateral prefrontal cortex (LPFC). Weaker effects were also observed in early visual areas (V1-3) and lateral intraparietal area (LIP). Various subcortical areas such as basolateral amygdala, ventral claustrum also showed significant Goodness coding (cluster corrected, alpha<0.01). Concomitant with neuronal discrimination, we found strong behavioral discrimination outside the scanner measured as strong gaze bias toward Good objects during free viewing sessions. To test whether neural and behavioral discrimination is maintained in long-term memory, we retested the same objects after 8-12 months with no visual exposure (memory period). Importantly many of the same visual areas along the ventral bank of STS fully retained their Good object discrimination despite long memory interval. There was significant discrimination in areas such as LPFC but with reduced magnitude. Notably free viewing of objects following the memory period revealed persistent gaze bias toward Good objects despite absence of any encounter for many months. Our

results reveal a robust and large capacity neural mechanism for discriminating and orienting toward valuable objects. It is not known how such diverse brain areas acquire and maintain Goodness coding. One possibility is that Goodness coding arises in basal ganglia first which in turn train cortical areas. This hypothesis remains to be tested.

Title: Representing features and summary statistics

Authors: *S. HOCHSTEIN;
Hebrew Univ. Jerusalem, Jerusalem, Israel

Abstract: Intensive research has uncovered diverse dimensions of summary statistic perception, including simple and complex dimensions (from circle size and Gabor orientation to face emotion and attractiveness), the type of statistics acquired (mean, variance, range), and our ability to summarize elements presented simultaneously or sequentially and to divide displays into separate groups, detecting statistics of each. But how does the brain compute scene summary statistics without first attaining knowledge of each scene element? One possible solution is that the brain uses implicit individual element information to compute summary statistics, which become consciously accessible first. This added step is superfluous. On the contrary, direct acquisition of summary statistics is not surprising and no novel computational principle is required for summary perception. A simple population code representation, as found for single element parameters, may be scaled up to compute mean values for element groups. The range of active neurons is broader, but the computation is the same for sets of elements as for a single element. Using a population code adds tremendous power, as it allows direct determination of which elements to include in the set, which elements are outliers - to be excluded and trigger pop out attention - and how to divide between simultaneously presented sets. Population coding provides a direct and efficient representation of set summary statistics. As suggested by Reverse Hierarchy Theory, conscious perception may begin with summary statistics, seeing many similar elements as a group, and only later focus attention to individual elements. Interestingly, a similar

population code representation may underlie categorization, including both category prototype and its boundaries.

Title: Cooperative encoding of visuo-spatial categories in human posterior parietal cortex and primary visual cortex

Authors: *L. WANG[1], Y. LI[1], X. HU[2], K. ZHAO[1], Y. YU[2];
[1]Inst. of Psychology, Chinese Acad. of Sci., Beijing, China; [2]First Affiliated Hosp. of Anhui Med. Univ., Hefei, China

Abstract: Categorization is a fundamental cognitive process by which the brain assigns meaning to incoming sensory stimuli in our environment. Human and/or non-human primate studies have found categorical representations of stimuli in higher-order lateral prefrontal, posterior parietal and lateral occipital cortex. Because higher-order areas lack visual specificity of early sensory areas, it has remained unclear how human can process fine-scale features that aid in refining categorization. One proposal is that coarse categories processing occurs first in a higher-order cortical area, whereas fine categories processing occurs later in early visual areas. Here, using multi-voxel pattern analysis (MVPA), we show that higher-order posterior parietal cortex (PPC) reflected coarse categories information; whereas primary visual cortex (V1) was involved in processing categories information at a finer resolution when humans perform visuo-spatial categories task. By analyzing time series in the two areas, we obtained evidence that categorical signal was selectively in a top-down direction from PPC to V1, and stronger influence from PPC to V1 was associated with better categorical performance. Moreover, the selectivity of PPC and V1 responses shifted markedly with retraining to group the same stimuli into two new categories. These findings suggest that both PPC and sensory cortex, which processes diagnostic features for each category, abstract experience-dependent categorical representations cooperatively.

Title: MVPA investigation of working memory maintenance period: Decoding memory content and retrieval success from EEG

Authors: ***S. ALIZADEH**[1,2], M. SCHÖNAUER[1], H. JAMALABADI[1,2], S. GAIS[1];
[1]Med. Psychology and Behavioral Neurobio., Univ. of Tuebingen, Tuebingen, Germany;
[2]IMPRS for Cognitive and Systems Neurosci., Tübingen, Germany

Abstract: Recent advances in multivariate pattern analysis (MVPA) methods have further improved our understanding of memory processes by decoding what kind of information is stored in memory representations. In particular, combining these methods with measures of brain oscillations that feature high temporal resolution (e.g. electroencephalogram (EEG) or magnetoencephalography (MEG)) can provide new insights about the underlying mechanisms of human memory function. Here, we employed an MVPA based decoding approach see if electrical brain activity during working memory maintenance period contains information about the content and subsequent performance of the working memory. To do this, 19 healthy subjects underwent high-density EEG recording in two sessions. Each subject performed two Sternberg tasks in each session, once pictures of faces and houses and once picture of digits and letters were presented. During each trial of the first task, a random sequence of 8 pictures of either faces or houses was presented to the subjects with the instruction to remember all pictures of the sequence. After a 4-s retention phase, one picture of either a face or house was presented and the subjects had to decide if the probe item was part of the previously viewed sequence. The same procedure was repeated in the second task with digits and letters stimuli.
We then used MVPA to test whether we can predict solely based on EEG during maintenance period (1) if a trial is subsequently remembered or not, and (2) what kind of stimulus is maintained during the delay period. We used a two-step channel-specific frequency-domain classifier based on an ensemble of linear support vector machines. This procedure aims at reducing dimensionality of data while simultaneously increasing signal-to-noise ratio which improves the classification performance. Our results show that the subsequent working memory performance can be reliably predicted across subjects for both kinds of weak (digits/letters) and

strong (faces/houses) stimuli. In addition, we can successfully decode the working memory content for the face/house stimuli. Classification accuracy was positively correlated with the subsequent memory performance of subjects, i.e. the more confident the classifier was in decoding the memory content, the higher the retrieval success rate of subjects. Finally, we adopted a searchlight approach to localize the spatiotemporal sites of information. Our data suggest that activity in frontal and parietal areas within the gamma, beta, and alpha frequency bands predicts the subsequent retrieval success while temporal alpha and beta contain information about the content of working memory.

Title: Behavioral and neuronal outcome of generalization following visual aversive learning

Authors: L. SHALEV[1], R. PAZ[2], *G. AVIDAN[1];
[1]Dept. of Psychology, Ben-Gurion Univ. of the Negev, Beer Sheva, Israel; [2]Dept. of Neurobiology, Weizmann Inst. of Sci., Rehovot, Israel

Abstract: The ability to generalize across similar stimuli and respond appropriately is a basic survival skill. Studies have shown that aversive learning (pairing of a neutral conditioned stimulus to an aversive stimulus) increases discrimination thresholds of the neutral stimuli (generalization). This finding was demonstrated under a number of aversive conditions such as pain, negative odors or sounds and monetary loss. A number of brain regions, including the amygdala, the insula, the anterior cingulate cortex (ACC), and the relevant sensory cortices, were suggested to underlie this effect. Our work is focused on extending this line of studies to the visual modality. We first tested participants in a behavioral setting, while they viewed images from the International Affective Picture System (IAPS) database with either aversive or neutral valance and were asked to learn to associate auditory or visual neutral stimuli with the appearance or absence of those images. Generalization for the conditioned stimuli was tested immediately prior to, and following learning. We found wider generalization curves for the neutral stimuli that predicted aversive visual outcomes. This effect was demonstrated with auditory (tone discrimination) as well as visual (contrast discrimination and discrimination of oriented stripes) neutral stimuli. Next, we set out to examine the neural basis underlying these behavioral changes. We conducted similar experiments to those described above using fMRI

during learning and found that activity in the amygdala, insula, the ACC, and the primary visual cortex (V1) was associated with aversive learning. These findings further strengthen the notion that generalization resulting from aversive learning is not modality specific, and suggest a global neuronal mechanism, which is utilized during the exposure to dangerous and emotionally arousing situations.

Title: Perceptual learning with minimized early cortical plasticity and neuron-specific response reweighting

Authors: ***C. YU**, X.-Y. XIE;
Peking Univ., Beijing, China

Abstract: Two types of mainstream theories explain visual perceptual learning (VPL): Early cortical neural plasticity (e.g., Karni & Sagi, 1991; Stoups et al., 2001) and neuron-specific response reweighting (e.g., Dosher & Lu, 1987; Law & Gold, 2008), as motivated by observed learning specificities. However, our double training studies (e.g., Xiao et al., 2008; Zhang et al., 2010; Wang et al., 2016) demonstrate that VPL often shows complete transfer to untrained locations, orientations/directions, and physical properties, indicating that VPL is primarily a rule-based high-level process operating at a conceptual level. Here we test a hypothesis that VPL requires neither early cortical neural plasticity nor neuron-specific response reweighting.
In a peripheral orientation-discrimination learning task, training took place with the Gabor stimulus either rotated in 12 locations (anti-clockwise) and 4 orientations 90 deg apart (clockwise), or in a random order. Each location/orientation combination received 2 trials per block of trials, 12 trials per 2-hr session, for a total of 60 trials over 5 daily sessions, which minimizes the possibility of training-induced early neural plasticity and neuron-specific response reweighting. A single staircase controlled the base vs. target orientation difference for all location/orientation conditions. The pre/post condition was never practiced. Training with rotating and random stimuli both produced significant orientation learning, indicating that the observers can learn orientation discrimination with multiple stimulus conditions that minimize

early neural plasticity and neuron-specific response reweighting. Learning transferred to the untrained pre/post condition, so that the improvement was comparable to that in a control group that only practiced the pre/post condition for an equal number of trials. Therefore, orientation learning with multiple stimuli is genuine and unspecific to the more difficult multiple stimulus task. Similar results were obtained in a motion-direction learning task with 6 rotating locations and 8 rotating directions 45-deg apart, which also showed no direction and location specificity. These results indicate that early cortical plasticity and neuron-specific input reweighting are unnecessary for VPL. Instead sensory inputs can be reweighted at a later stage in a neuron unspecific manner.

Title: Investigating neural plasticity in the amblyopic brain with perceptual learning in a global motion discrimination task.

Authors: *Y. GAO, A. BALDWIN, R. HESS;
Ophthalmology, McGill Univ., Montreal, QC, Canada

Abstract: Neural plasticity after the critical period holds implications for the treatment of brain damages, amblyopia and learning difficulties. It is also involved in improving cognitive functions through physical exercises. Amblyopia is a neural developmental disorder caused by deprived visual input from one eye during the critical period of the visual system's development. It was widely believed that the effects of this deprivation are permanent unless corrected during the critical period. Recent work however has demonstrated plasticity in the brains of adult amblyopes, and raised the possibility of repairing visual functions.
Perceptual learning of simple tasks such as orientation and motion direction discrimination is a common method to study neural plasticity. Former studies found that perceptual learning can induce significant improvements in the impaired visual acuity, contrast sensitivity, stereo-acuity and binocular combination in amblyopic observers. Amblyopes show a deficit for the processing of global motion which, unlike those mentioned previously, also affects monocular perception in the eye that was not deprived during development (the "fellow" eye). Although learning for

global motion has been demonstrated for normals it has not been shown in human amblyopes. The current study investigates i) whether perceptual learning can improve global motion processing in amblyopic observers, and ii) whether the learning effects are specific to the trained eye.
Amblyopic observers and normal controls were trained on a motion direction discrimination two-interval forced choice task for 5 days. The stimuli were a field of isotropic log-Gabors (spatially band-pass "dots") with peak spatial frequencies of 3.8 c/deg and contrasts of 10 times or higher of the detection thresholds of each observer. The difficulty of the task was varied by modifying the offset angle. Amblyopes were split into two groups and trained either with their amblyopic or fellow eye.
Even though there was considerable individual variability, we found a learning effect in the trained eye and no transfer to the untrained eye in both amblyopic and normal observers. Specifically, we found that for the amblyopic observer who was trained with the fellow eye and for all the normal observers, training improves the performance of the trained eye in global motion processing while the performance in the untrained eye hardly changed. Yet for the amblyopic observers who were trained with the amblyopic eye, training induces much smaller improvement in the trained amblyopic eye and the untrained fellow eye was even worse-off. We conclude that amblyopes show less perceptual learning on this task.

Title: The feature-weighted receptive field: an interpretable encoding model for complex feature spaces

Authors: *T. NASELARIS[1], G. ST-YVES[2], N. DESISTO[3];
[1]Neurosciences, [2]Med. Univ. of South Carolina, Charleston, SC; [3]Physics, Col. of Charleston, Charleston, SC

Abstract: Voxel-wise encoding models used in studies of the visual system can vary widely with respect to their interpretability and expressiveness. For example, the population receptive field (pRF) is a highly interpretable model because it has a small number of parameters that explicitly reveal the size and spatial location voxel-wise receptive fields. The pRF is a very effective tool for delineating area- and state-dependent variations in receptive field size; however, it's expressiveness is limited because it does not characterize variation in feature tuning. More expressive models include the Gabor wavelet model and encoding models based on deep convolutional neural networks. Such models are expressive because they can reveal variations in feature tuning even when the feature spaces are extremely complex; however, they typically contain thousands of parameters and so can be difficult to interpret.
We introduce the feature-weighted receptive field (fwRF), an encoding model designed to balance interpretability and expressiveness. The fwRF is organized around the notion of a feature map—an arbitrary transformation of visual stimuli into visual features that preserves the topology of visual space (but not necessarily the native resolution of the stimulus). According to the model, activity in each voxel encodes stimulus variation in a spatially localized region across multiple feature maps. This region is fixed for all feature maps; however, the contribution of each feature map to voxel activity is weighted. Thus, the model has two separable sets of parameters: "where" parameters that characterize the size and position of the receptive field, and "what" parameters that characterize tuning to visual features. This space/feature separability makes it possible to estimate explicit receptive field parameters without compromising model expressiveness. It also drastically reduces the number of adjustable parameters relative to models with non-separable space-feature terms (e.g., the Gabor wavelet model).
We describe an optimization algorithm for fitting the fwRF parameters, as well as a fast GPU-based implementation in Theano. We then demo the model in three use cases: population receptive field mapping; Gabor wavelet modeling; and modeling with a feature space supplied by a deep convolutional neural network. We show that the fwRF models recover consistent receptive field size and locations, as well as complex feature tuning. Our results suggest that the feature-weighted receptive field model will be particularly useful as a method for regressing the activities of deep neural networks onto measured brain activity.

Title: Imagery receptive fields

Authors: ***J. BREEDLOVE**[1], G. ST-YVES[1], T. NASELARIS[1], C. OLMAN[2];
[1]Med. Univ. of South Carolina, Charleston, SC; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: Mental imagery is difficult to study due to the inevitable loss of signal that results from the absence of a visual stimulus. Most previous fMRI studies of mental imagery have taken a bootstrapping approach to the problem by applying a model derived from a perceptual experiment to activity measured during imagery. In the current study, we modelled imagery directly. We measured whole-brain BOLD activity as participants viewed and then imagined previously memorized objects at 8 distinct locations in the visual field. We then estimated for each voxel a perceptual receptive field model (pRF) and an imagery receptive field model (iRF) using the activity generated during perception and mental imagery, respectively. The fitting procedure assigned a receptive field size and center to each voxel, as well as a spatial frequency and orientation tuning profile.

We found that it is possible to accurately predict imagery activity using the iRF; it is also possible to decode the location and extent of imagined objects. These findings demonstrate the feasibility and potential power of the iRF for quantitatively characterizing mental imagery. Furthermore, our analysis revealed that the predictive accuracy of the iRF increased with ascent of the visual hierarchy: predictions were worst in early visual cortex, but by V3A on the dorsal side and LOC on the ventral side prediction accuracy of the iRF was on par with accuracy of the pRF.

Consistent with previous findings, pRFs cross-predicted activity during mental imagery, strengthening support for a conservation of spatial and feature tuning between mental imagery and perception. However, differences were also apparent. Because of the weak signal during imagery, the centers, sizes, and locations of iRF's were scattered relative to the pRFs. More interestingly, underneath this scatter we uncovered what appear to be some systematic differences in tuning: in many visual areas, iRFs appear to be larger in size, and show a shift toward smaller preferred spatial frequencies than the pRFs.

Our results suggest that during mental imagery, activity is propagated toward early visual areas from higher-level areas that have relatively large receptive fields and low spatial resolution, and in which patterns of activity during imagery are largely equivalent to patterns of activity during perception.

Title: A deep predictive coding model of mental imagery

Authors: *G. ST-YVES[1], T. NASELARIS[2];
[2]Neurosciences, [1]Med. Univ. of South Carolina, Charleston, SC

Abstract: There is solid empirical evidence that mental imagery (i.e. the conjuring of a visual percept in absence of external visual stimuli) uses the same cortical machinery as visual perception. The process of generating mental images is thus apparently very closely related to the perception of retinal ones. We present a predictive coding account of the relationship between mental imagery and perception in the form of a deep predictive coding network. Mental images are equated with predictive signals in the network that reconcile the multiple representations of a retinal image that arise at distinct stages of visual processing. Mental imagery is experienced most strongly when the retinal image is removed (e.g., when eyes are closed) and the strength of the predictive signal is increased relative to its strength during perception. A mental image of a specific visual scene is realized when activity at one stage of visual processing is clamped to the pattern induced during retinal perception of the same scene. We show that in our network, activity induced during mental imagery is invariably weaker than its corresponding activity during perception. Mental images are also inherently imprecise and unstable. The precision of mental imagery is constrained by the pooling structure of the network, while the stability is limited by the competition of the predictive feedback and the feed-forward propagation of information. These aspects of the model are consistent with known empirical results, and vindicate the commonly shared experience of imagery as a weak form of perception. However, we show that the strength of activity at any stage of in the network depends strongly upon the stage that is clamped during imagery, and that this dependence is largely asymmetric with respect to the clamped stage. Importantly, we show that a significant increase in the strength of predictive signaling during mental imagery can alter the receptive field properties of the network in an intuitive way that reflects the pooling structure of the network and the presence of feedback. Our model provides a normative theory of mental imagery by showing how it might arise as a natural consequence of predictive coding, and accounts for known empirical findings and intuitions about mental imagery while making new and directly testable predictions.

Title: Oscillatory activity in motor cortical regions is modulated by expected visual reafferent feedback

Authors: ***P.-M. BERNIER**[1], B. DUFOUR[2], F. THÉNAULT[2], K. WHITTINGSTALL[2]; [1]Dept. de Kinanthropologie, Univ. De Sherbrooke, Sherbrooke, QC, Canada; [2]Univ. de Sherbrooke, Sherbrooke, QC, Canada

Abstract: The planning of voluntary movement involves predicting its associated sensory consequences. While the primary motor cortex plays a critical role in the specification of motor commands, recent fMRI work suggests it is also modulated by the expected visual consequences of an action (Eisenberg et al., 2011). Here electroencephalography was used to investigate oscillatory activity over motor and parietal regions during a visual-motor dissociation task. Participants planned and executed reaching movements toward a single visual target positioned straight-ahead of midline, with visual feedback of the hand provided via a cursor. Before every trial, they were precued as to the direction of the visual feedback, which could be either spatially congruent with the actual hand position, rotated leftward or rightward by 20º, or not provided at all. Results revealed that subjects produced similar movement kinematics across conditions, suggesting similar motor commands. EEG activity during planning revealed strong alpha-band (8-15 Hz) desynchronization at parietal electrodes contralateral to the expected visual feedback. In contrast, neither alpha- nor beta-band (15-30 Hz) activity at motor electrodes was modulated by the direction of the expected visual feedback. Interestingly, theta-band (3-7 Hz) activity at motor electrodes showed greater desynchronization in anticipation of visual feedback, irrespective of its direction, as compared to no visual feedback. These results demonstrate that while oscillatory activity in motor regions is sensitive to the upcoming presence or absence of visual feedback (i.e. theta-band), it is not modulated by its direction.

Title: Establishing normative eye movement patterns during upper-limb functional tasks

Authors: *E. B. LAVOIE[1], E. A. CROCKETT[1], O. KOVIC[1], A. M. VALEVICIUS[2], Q. A. BOSER[2], P. M. PILARSKI[3], A. H. VETTE[2], J. S. HEBERT[3], C. S. CHAPMAN[1];
[1]Fac. of Physical Educ. and Recreation, [2]Dept. of Biomed. Engin., [3]Div. of Physical Med. and Rehabil., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Recent advances in eye-tracking technology have allowed researchers to move from testing stationary and seated individuals to testing fully mobile participants engaging with real objects. However, even with these advances, the majority of studies still use restrictive lab-based tasks that are not representative of the demands on the eye-movement system in the real world. Akin to the Cognitive Ethology research approach (Kingstone et al., Brit J Psychol, 2008), it is necessary to connect lab-based tasks to real-world tasks in order to gain an understanding of natural human behaviour. Thus, we recorded eye movements in two tasks mimicking real-world demands, establishing a normative model for functional eye gaze.
The first task emulates moving a box of pasta from a counter-top into a cupboard (PB) and the second task emulates moving cups across a table (C). The tasks were designed to mimic everyday activities and each had unique requirements: the PB task required the individual to turn their head and body and interact with different heights while the C task has smaller objects filled with beads requiring more precision and putting a consequence (spilling) on errors. We used a Dikablis Professional 2.0 eye-tracker to track the eye movements of 20 healthy participants while they performed 20 trials of each of the PB and C tasks.
Data analysis identified specific areas of interest (AOIs): the participant's hand, the targets (pasta box & cups) and the placement locations. Measuring the timing of eye fixation on each AOI allowed derivation of measures such as fixation duration and the offset between when the eyes reach a target and when the hand reaches the same target. In line with previous work (Mennie et al., Exp Brain Res, 2007), we found that the eyes lead the hand, and that these "anticipatory

saccades" are modulated by task demands such that tasks requiring greater precision and having error consequences (e.g. the C task) show reduced anticipatory looking. As well, there is very little, if any, eye fixation on a participant's own hand. Likely other sensory systems, predominantly proprioception, mediate the lack of requirement for continual eye fixation on the hand and object of interest.
An important extension of this work will be to test individuals who have compromised proprioception – most notably, upper limb prosthetic users. The strong prediction is that these participants will need to fixate on their moving prosthetic limb as it interacts with objects because they do not have proprioceptive feedback from the device. This project has made these comparisons possible by establishing a normative data set for eye movement patterns during functional tasks.

Title: Reach-related sensory prediction errors produce event-related potentials similar to feedback-related negativity during visuomotor rotation.

Authors: *F.-A. SAVOIE[1], K. WHITTINGSTALL[2], P.-M. BERNIER[3];
[1]Dept. de Médecine Nucléaire et Radiobiologie, [2]Dept. de Radiologie diagnostique, [3]Kinanthropologie, Univ. De Sherbrooke, Sherbrooke, QC, Canada

Abstract: INTRODUCTION: Feedback-related negativity (FRN), a negative event-related potential (ERP) with a mid-frontal topography, has typically been involved in the monitoring of reward prediction errors (i.e. a mismatch between the actual and expected behavioral outcomes) (Walsh & Anderson, 2012). However, it is unclear whether the FRN is sensitive to other types of mispredictions, such as sensory prediction errors (i.e. a mismatch between the actual and expected sensory consequences of motor commands), which results in sensorimotor learning. In this light, the purpose of this study was to investigate whether sensory prediction errors produce an FRN-like ERP in absence of reward prediction errors. METHODS: Electroencephalography

(EEG) was recorded while participants (n =17) completed a center-out reaching task to one of two visual targets positioned 22.5° left and right of a central fixation point. Visual feedback of a cursor corresponding to the position of the hand was provided during movement. In a strategy condition (STR, 96 trials), reaches were made under 45° visuomotor rotation, though participants were explicitly given the strategy to counter the rotation. To prevent visuomotor remapping from occurring in STR trials, these were interspersed with ≥ 2 non-rotated trials. Once all STR trials were completed, participants were exposed to a constant 45° rotation (196 trials) to induce visuomotor remapping. The last 96 of these served as control (CTRL) trials. Because CTRL and STR were matched for end-point errors, sensory inputs and motor outputs, the sole difference between these conditions was that visuomotor remapping had occurred in CTRL. Hence, EEG signal differences obtained by contrasting CTRL and STR after movement onset would reflect neural activity solely attributable to the processing of sensory prediction errors. RESULTS: To prevent potential reward prediction errors from confounding results, trials in which participants failed to displace the cursor through the correct target were removed. No significant differences were detected between STR and CTRL for reaction times (STR: 350 ± 36 ms, CTRL: 359 ± 49 ms, $p = 0.11$) or movement times (STR: 300 ± 35 ms, CTRL: 289 ± 40 ms, $p = 0.19$). However, a mid-frontal ERP, akin to the FRN, was observed after movement onset in STR but not CTRL. Specifically, this ERP consisted of a negative deflection, which peaked at electrode C2 (~ 225 ms), followed by a positive deflection, which peaked at electrode Cz (~ 285 ms). CONCLUSION: These findings suggest that the neural processing of sensory prediction errors, which lead to the updating of internal models, may share neural substrates with reward prediction error processing.

Title: Decoding perceptual consequences of swiping movements

Authors: ***S. FABBRI**, K. SUTTER, I. TONI, P. MEDENDORP;
Radboud Univ., Nijmegen, Netherlands

Abstract: Interacting with objects is a fundamental characteristic of human behavior. With the advent of touchscreen technologies, the interaction with 3D virtual objects on touch screens evokes new computational challenges compared to manipulation of real objects. Swiping movements on touch screen, even though the swipes themselves are constrained to a 2D plane. Due to noncommutativity of rotations ($a \times b \neq b \times a$), a horizontal swipe followed by a vertical swipe evokes a different final orientation of the virtual object than a vertical swipe followed by a horizontal swipe, even though the swiping movements themselves commute (i.e. order makes no difference for the final position of the finger on the touch screen). In this experiment, we measured brain activity while participants performed swiping movements to rotate a 3D virtual object on an MR-compatible touch screen. By manipulating the order of the swipes and the initial orientation of the object, we could disentangle between commutative processes (when different orders of swipes led to the same position of the finger on the screen) and noncommutative processes (when different orders of swipes led to different orientations of the object). The univariate contrasts on functional magnetic resonance imaging (fMRI) data identified distinct networks of regions involved during non-commutative compared to commutative processes. We currently use Representational Similarity Analysis (RSA) to further characterize the neural representation of these processes. We conclude that the brain makes use of commutative and noncommutative computations to implement the mapping between 2D motor actions and the 3D perceptual consequences.

Title: Subtle preparatory movements reveal future actions

Authors: *M. VAZIRI PASHKAM[1], R. GONZALEZ[2], S. CORMIEA[1], K. NAKAYAMA[1];
[1]Vision Scinces Laboratory, Dept. of Psychology, Harvard Univ., Cambridge, MA;
[2]Massacheusetts Inst. of technology, Cambrdige, MA

Abstract: To act quickly and appropriately in the social environment, we need to predict others' goals and infer their intentions. To study this predictive ability in the lab, we designed a two-person competitive reaching task in a naturalistic setting. Two otherwise naïve subjects faced

each other separated by a plexiglass screen. One (Attacker) was instructed to tap one of two targets on the screen and the other (Blocker) was told to tap the same target as quickly as possible. Blocker reaction times were surprisingly fast, almost 100 milliseconds faster than reaction times to a dot projected on the screen moving in the same manner. Using video recordings of an Attacker and through systematic manipulation of the videos, we showed that Blockers use subtle preparatory movements of Attackers to predict their goal. We occluded various body parts of the Attacker and showed that reaction times slowed down only when most of the Attacker's body was occluded. This indicates that preparatory cues are widely distributed over the body of the Attacker. There was no learning during the session indicating that the blockers already have this built in capacity prior to the experiment. To determine the exact spatiotemporal profile of the preparatory cues, we used a machine vision approach to predict Attacker's movements from the videos. Attacker videos were analyzed using an optic flow algorithm and the optic flow frames were used to measure the performance of a linear support vector machine (SVM) classifier in discriminating leftward from rightward movements at various points in time and space. The accuracy of the classifier's started at chance level in the earlier frames of the video and gradually increased to reach 100% accuracy in the later frames. The shape of the classifier's psychometric function closely matched that of the human performance in predicting the movement goal. We then used the weights of the SVM to determine the spatiotemporal profile of the informative cues. In the beginning high weights were located on the head and neck region. They later moved to the torso, shoulder and arms and finally concentrated on the hand and arm region. These results demonstrate that humans possess a remarkable action prediction ability and are able to use any and all predictive cues from the body for accurate and speeded responses.

Title: The effects of varying cognitive and motor demand on an attention-mediated reaching task

Authors: *C. FUEGER, L. PETROVSKA, W. E. HUDDLESTON;
Kinesiology: Integrative Hlth. Care & Performance, Univ. of Wisconsin - Milwaukee, Milwaukee, WI

Abstract: Every day, vision guides one's actions to facilitate successful navigation through a complex environment. Yet, one's available neural resources needed to successfully perform visually-guided movements do have limits. The purpose of this study is to examine the effects of both cognitive and motor demand on an attention-mediated reaching task. Ten females (20-29 y.o.) quickly and accurately performed a delayed reach to a previously cued location. Participants sat in front of a vertical screen with 8 peripheral targets, while visually focusing on the center of the screen. The trial sequence was as follows: a brief location cue in 1 of the 8 peripheral targets, a delay, and a central go cue. Participants performed each of two trial types. The first was a simple reach (SIMPLE) to the previously cued location. The second involved touching a target 3 locations clockwise from the initial cue (SPatial REmapping; SPRE). Participants performed the 2 types of delayed reaches under 4 task conditions. The two BASELINE conditions included either only SIMPLE trials or SPRE trials. The choice condition (CHOICE) included both trial types. The final condition was the same as CHOICE; however, during the delay participants touched 4 cued targets (i.e., a motor mask; MOTOR). Dependent measures included reaction time and variability, reach endpoint accuracy and variability, and normalized path length and variability. In the MOTOR condition, the SPRE trials compared to the SIMPLE trials had increased reaction times ($p < .001$), longer normalized path lengths ($p = .007$) and greater path length variability ($p = .008$), but no difference in reaction time variability ($p = .082$). Participants had increased reaction times ($p = .008$) on the SPRE MOTOR trials versus SPRE CHOICE trials, with no differences in reaction time variability ($p = .192$), normalized path length ($p = .080$) and variability ($p = .041$). Therefore, the addition of a motor task during the delay lengthened participants' reaction times when the task required spatial remapping. Alternately, path length increased only with a combination of an intervening motor task and spatial remapping, but not with spatial remapping only. Spatial remapping (a presumably cognitive task component) was either interrupted or slowed during the motor mask-related reaching. Thus, the completion of the motor and cognitive components of the reaching task were limited, possibly due to the task exceeding the limits of available neural resources. The next step is to replicate this experiment with a patient population, such as individuals whom have sustained a mTBI, to explore the effects of this injury on attentional resource limits.

Title: Hd-tDCS modulated EEG correlations during reaching

Authors: *J. JEYACHANDRA[1,2,3], S. XU[1,2,3], J. P. GALLIVAN[1], G. BLOHM[1,2,3];
[1]Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada; [2]Canadian Action and Perception Network (CAPnet), Toronto, ON, Canada; [3]Assn. for Canadian Neuroinformatics and Computat. Neurosci. (CNCN), Kingston, ON, Canada

Abstract: EEG signatures can indicate upcoming reaching movements in the dorsal premotor cortex (PMd) and medial intraparietal sulcus (mIPS) (Hoshi and Tanji, 2004; Grefkes and Fink, 2005). However, the exact contributions of PMd and mIPS to reaching behavior is unclear. To address this, we used EEG to investigate if PMd and mIPS activity was related to reaching metrics. Furthermore we modulated PMd and mIPS activity with HD-tDCS and investigated whether changes in EEG were predictive of changes in behavioral performance.
Both left mIPS and PMd were localized for each participant using a combination of functional magnetic resonance imaging and neuronavigation software. Participants performed memory-guided reaches from one of two initial hand positions (IHP) to one of four randomly chosen targets. HD-tDCS electrodes were placed in a 4x1 placement and either cathodal or anodal stimulation was administered (20min duration, 2mA). EEG recordings were taken prior to stimulation and after stimulation using the same electrode placement. Each participant completed 250 trials for pre-stimulation, stimulation and post-stimulation conditions. Time-frequency response (TFR) analysis was performed on the EEG data using Morlet wavelets and baseline was selected as the period stretching 500ms prior to target onset in order to compute z-scores during the time after target onset.
We examined whether the TFR derived from EEG was correlated to behavioural performance across all possible movement directions. Prior to stimulation, vertical endpoint error was strongly correlated with the beta band frequencies for both mIPS and PMd. This suggests a role of both mIPS and PMd in determining movement amplitude. Next we examined how relative changes in performance from baseline between anodal and cathodal stimulation polarities corresponded to changes in the TFR. Vertical endpoint errors were strongly correlated with changes in the beta band for both areas (mIPS $r = -0.680$, $p < 0.05$; PMd $r = -0.717$, $p < 0.05$) suggesting that behavioural differences due to HD-tDCS are reflected in changes of EEG activity. Finally we examined whether the difference in anodal and cathodal post-stimulation EEG was related to baseline activity. We found a strong correlation between pre-stimulation and post-stimulation EEG signals between stimulation polarities for both areas (mIPS $r = 0.906$, $p < 0.01$; PMd $r = -0.719$, $p < 0.05$). This suggests that HD-tDCS effects may be predicted by EEG activity prior to stimulation.
We conclude that measuring EEG activity before and after applying hd-tDCS might provide

useful complementary information regarding the actual effect of tDCS on the brain (as compared to the intended effect).

Title: Reaching across midline is increased by cognitive load

Authors: *J. LIANG[1,2], K. M. WILKINSON[2], C. REGIEC[4], R. L. SAINBURG[3];
[1]The Pennsylvania State Univ., University Park, PA; [2]Communication Sci. and Disorders, [3]Kinesiology and Neurology; Dept. of Penn State Col. of Med., The Pennsylvania State Unversity, University Park, PA; [4]Communication Sci. and Disorders, Western Carolina Univ., Cullowhee, NC

Abstract: Previous studies have suggested that hand selection for reaching is modulated by task difficulty (Mamolo, Roy, Bryden, & Rohr, 2004, 2005), although exactly which features of a task contribute to this 'difficulty' have not been systematically determined. We have previously shown that biomechanical and kinematic factors such as smoothness and energy can predict patterns of selection across the workspace, emphasizing the role of predictive cost-analysis in selection. We hypothesize that the decision of which hand to use when reaching to various locations in space requires implicit cognitive processes, and thus predict that increasing the cognitive load of the task will alter the hand selection patterns. We designed a memory and search task with 3 levels of difficulty: In the control condition, a stimulus was presented in the middle of the workspace for 2 seconds, then replaced by the same stimulus presented as a target in one of 16 positions across the workspace. Participants were given a go signal and asked to reach to it with either hand. In our cognitive load conditions, the stimulus was replaced by an array of 16 pictures with one matching the cued stimulus. They were required to find and reach to the previously cued stimulus. In our lower-load condition, the 16 stimuli were clustered into one of 4 color groups to assist in the search process. In the higher-load condition the stimuli were distributed throughout the workspace, regardless of color.
Our findings indicate a strong influence of cognitive load on arm selection, such that the dominant arm was selected progressively more often under higher load conditions. Surprisingly,

however, the increased load led to an increase in cross-midline reaches by both arms. Because crossing midline is more costly in terms of kinematic and kinetic factors, our findings suggest that cognitive processes are required to avoid crossing midline. We suggest that kinetic and kinematic costs are inadequately assessed under higher cognitive load conditions and hand selection becomes biased by which hand was used on the previous trial, regardless of efficiency. We conclude that the choice to NOT cross midline requires cognitive resources.

Title: Human neuroimaging suggests overlapping but distinct representations for planning vs. imagining hand actions

Authors: *S. MONACO[1], G. MALFATTI[1], J. C. CULHAM[2,1], L. TURELLA[1], L. CATTANEO[3,1];
[1]Univ. of Trento, Ctr. for Mind/Brain Sci., Trento, Italy; [2]Brain and Mind Inst., Univ. of Western Ontario, London, ON, Canada; [3]Dept. of Neurological, Neuropsychological, Morphological, and Movement Sci., Univ. of Verona, Verona, Italy

Abstract: The role of motor imagery is relevant in patients with motor deficits as well as in neurologically intact individuals. In patients with motor impairments, the successful use of brain-computer interfaces follows extensive training that consists of having the patients imagining what they want the effector to do (Green & Kalaska 2001; Alonso-Valerdi et al. 2015). In neurologically intact individuals, motor imagery improves the performance of acquired skills and acquisition of new ones (Annett 1995). Previous studies have compared the neural activity elicited during imagery tasks and action performance (Oosterhof et al. 2012). However, real actions require more efforts than imagined ones and involve somato-motor components that are absent in imagery tasks. The behavioral impact of motor imagery on real actions might be related to the fact that action representations generalize between planning real actions and imagining them. We explored: i) whether areas traditionally implicated in hand actions, such as the anterior intraparietal sulcus (aIPS), have a shared representation for planning and imagining specific hand movements, and ii) the role of early visual cortex (EVC) in planned and imagined actions.

We used a slow event-related functional magnetic resonance imaging (fMRI) paradigm in which participants (N=16) performed or imagined performing actions with the right dominant hand towards a centrally located object composed of a small shape attached on a large shape. The actions consisted of grasping the large shape, grasping the small shape, or reaching to touch the center of the object while fixating a point above the object.
At the beginning of each trial an auditory cue instructed participants about the task (Imagery, Movement) and the action (Grasp large, Grasp small, Reach-to-touch) to be performed at the end of the trial. A delay of ten seconds was followed by a go cue to perform or imagine performing the action (go phase). Importantly, for both Imagery and Movement only the object, but not the hand, was visible to the participants.
Using multi-voxel pattern analysis, we decoded action type in the planning phase of Movement tasks as well as in the go phase of Imagery tasks in bilateral anterior intraparietal sulcus (aIPS) and in early visual cortex (EVC), but only in the right hemisphere. Moreover, we found cross-decoding between planning and imagery in aIPS, but not in EVC. Our results suggest a shared representation for planning and imagining specific hand movements in aIPS but not in low-level visual areas, such as the EVC. Taken together, these results suggest that planning and imagining actions have overlapping but not identical neural substrates.

Title: Differential effects of hd-tDCS on mIPS and PMd in reach planning

Authors: *S. XU[1,2,3], J. JEYACHANDRA[1,2,3], J. GALLIVAN[1], G. BLOHM[1,2,3];
[1]Queen's Univ., Kingston, ON, Canada; [2]Canadian Action and Perception Network (CAPnet), Toronto, ON, Canada; [3]Assn. for Canadian Neuroinformatics and Computat. Neurosci. (CNCN), Kingston, ON, Canada

Abstract: Making a reaching movement to a target requires a movement plan, i.e., a difference vector of the target position with respect to the starting hand position. While it is known that activity in the PMd and mIPS reflects aspects of a kinematic plan for a reaching movement, it is unclear how the two regions may differ.

We investigated the functional roles of the left mIPS and PMd in the planning of reaching movements using high definition transcranial direct current stimulation (hd-tDCS) and examined changes in reaching performance when participants were subjected to anodal and cathodal stimulation at each site. The left mIPS and PMd were functionally localized with fMRI using an interleaved center-out pointing and saccade task and mapped onto the scalp using Brainsight. We adopted a randomized, single-blind design and applied anodal and cathodal stimulation (2mA for 20 min; 3cm radius 4x1 electrode placement) during separate visits scheduled at least a week apart. Each participant performed 250 baseline, stimulation, and post-stimulation memory-guided reaches starting from one of two initial hand positions (IHPs) to one of 4 briefly flashed targets (20 cm distant, 5 cm apart horizontally) while fixating on a straight-ahead cross located at the target line.

In separate 2-way ANOVAs of horizontal endpoint error difference, we found a significant IHP by target interaction effect when cathodal stimulation was applied at the mIPS, but only significant IHP and target main effects when applied at the PMd. Cathodal stimulation at the mIPS produced a IHP-dependent contraction, such that reaches from the left IHP undershot and reaches from the right IHP overshot targets. Contrastingly, the movement vector was modulated independently of IHP when cathodal stimulation was applied at the PMd. These results suggest that the movement vector is not yet formed at the input level of mIPS, but is encoded in the input of PMd.

Furthermore, there were differences in the extent to which anodal and cathodal stimulation had on behavior across sites of stimulation. We quantified the effect of stimulation on movement amplitude using the difference of amplitude error during and post-stimulation from baseline performance. At the mIPS, cathodal stimulation reduced amplitude error compared to anodal stimulation. Contrastingly, the effects are reversed at the PMd, such that anodal stimulation reduces amplitude error compared to cathodal stimulation. This difference might be due to competitive vs non-competitive dynamics in PMd and mIPS respectively.

In summary, we conclude that tDCS is a viable, useful method in investigating movement planning through temporary perturbations of the system.

Abstract: Cross-modal signaling interactions between different sensory systems, specifically the centrifugal signals in modulation of the visual system, in vertebrate animals have been reported. While much progress has been achieved in understanding the anatomy, our knowledge of the underlying regulatory mechanism and physiological roles of centrifugal input to the retina is still in its nascent stage. Understanding the impact of centrifugal signals for retinal sensitivity will have far reaching consequences not only in our quest for understanding brain functions across species, but also in the development of computer algorithms that can integrate information from heterogeneous sources.

We use zebrafish as model organisms for *in vivo* and *in vitro* studies of brain centrifugal feedback in visual system functions. Zebrafish possesses a prominent olfacto-retinal centrifugal (ORC) pathway, which originates from the terminalis neurons (TNs) in the olfactory bulb and terminates in the retina. The TNs synthesize GnRH as a major neurotransmitter. In the retina, the TN fibers synapse with dopaminergic interplexiform cells (DA-IPCs) and retinal ganglion cells (RGCs), and possibly other retinal cell types. The function of the ORC pathway is regulated by the olfactory input. It may also be affected by the presence of endocrine hormones, such as melatonin.

Based on the results from wet-bench research examining the above circuit-level phenomena, we created computational neural models that leverage the principles of the statistical extreme value theory (EVT) to simulate and predict the consequence of sensory integration in retinal function. The overall objective of this work is to uncover facets of the mathematical and algorithmic underpinnings of sensory integration in the brain, with the dual goal of advancing understanding in biology and building more robust and powerful artificial information processing systems.

Title: Claustrum neurons projecting to anterior cingulate cortex are topologically organized and exhibit sexual dimorphism

Authors: *Z. CHIA[1,2], G. J. AUGUSTINE[1,3];
[1]Lee Kong Chian Sch. of Med., [2]Sch. of Biol. Sci., Nanyang Technological Univ., Singapore, Singapore; [3]Inst. of Mol. and Cell Biol., A*STAR, Singapore, Singapore

Abstract: Among the reciprocal anatomical connections the claustrum shares with cortical regions, the connection with the Anterior Cingulate Cortex (ACC) appears the densest and most widespread. However, the function of this connection is unknown. To address this question, we have characterized the neurons projecting from the claustrum to the ACC. Claustrum cells that project to the ACC were identified by injecting into the ACC fluorescent beads that were retrogradely transported to the sites of ACC input. To identify the claustrum in live slices, we used a transgenic mouse line that expresses YFP-tagged *Volvox* channelrhodopsin-1 at high levels within the claustrum (Front. Neural Circ. 7:160). Many bead-labelled neurons were found in the claustrum, while few were found in the insular cortex; this indicates a preferential and monosynaptic connection between claustrum and ACC. The majority of ACC-projecting claustrum neurons were found ipsilateral to the bead injection site, with a greater density of labelled cells observed in the claustrum lateral to the preoptic area. Whole-cell patch clamp recordings from bead-labelled claustrum neurons were used to characterize the intrinsic properties of these neurons. These properties varied in different regions of the claustrum: labelled projection cells were predominantly (44%) type 4 Strongly Adapting cells (SA4) in the most anterior part of the claustrum, while type 2 Mildly Adapting cells (MA2) were predominant (77%) in claustrum lateral to the preoptic area, and SA4 cells were the majority (63%) of neurons found in the posterior part of the claustrum. When sorted by sex, the male claustrum showed a significant bias toward SA3 type cells (53%) within the anterior claustrum and no SA4 type cells were found, while in female mice there was a bias for SA4 cells in the anterior claustrum (76%) and no SA3 cells. Our results show that there is ipsilateral dominance for ACC-projecting claustrum neurons, with topological selectivity varying along the anterior-posterior axis. We have also found, for the first time, sexual dimorphism in ACC-projecting claustrum cells. These results demonstrate a direct pathway from claustrum to ACC, consistent with the

hypothesis that the claustrum serves as a link for information flow between the insular cortex and the ACC, a circuit that may play an important role in the salience network.

Title: Expression patterns of NF200, $Na_v1.6$, Ankyrin G and related proteins in a multimodal cell type of the avian optic tectum

Authors: K. LISCHKA[1], S. LADEL[1], H. LUKSCH[1], *S. WEIGEL[2];

Abstract: The vertebrate midbrain is an important subcortical area involved in different functions such as integrating different sensory modalities, movement initiation and bottom-up attention. Our group is particularly interested in cellular computation of multisensory integration. We focus on the visual part of the avian midbrain, the optic tectum (TeO, homologous to the mammalian superior colliculus). In non-mammalian vertebrates, this area has a complex layered structure with the great advantage of distinct in- and output regions. In chicken, the TeO is organized in 15 layers where visual input targets the superficial layer while auditory input terminates in deeper layers.
One specific cell type, called Shepherd's crook neuron (SCN), has dendrites in both input regions. The characteristic feature of these neurons is the axon that originates up to 120 µm from the soma at the apical dendrite. The molecular identity of this characteristic area and thus, the site of action potential generation are of particular importance to understand signal flow and cellular computation. Based on the morphology of the SCN, action potentials at the axon could be evoked either by summation of auditory input at the basal and visual input at the apical dendrite, or maybe just by a strong visual input to the apical dendrites that bypasses the soma. This axopetal information flow was already proposed by Ramon y Cajal. However, despite the involvement of SCN in bottom-up attention little is known about the detailed neuroanatomy and cellular computation.
Here we present immunohistochemical data of the structural proteins NF200 and Ankyrin G, ion

channels $Na_v1.6$ and $K_v1.2$ and myelin. The structural protein NF200 is strongly expressed in the entire axon from its origin on. In contrast, the distribution of $Na_v1.6$ channels on the axon is primarily located at a specific region on the axon. The voltage-gated potassium channel subtype 1.2 is restricted to the cell soma. The structural protein Ankyrin G is mainly expressed from the axon origin and ends at the position where $Na_v1.6$ expression begins. Combining these expression patterns we can locate the initial segment of the axon. Interestingly, we find variations in the expression patterns which suggest diverse SCN subtypes. The molecular identification of the axon and ion channel distribution in SCN allows delineating the information flow and particularly the integration of sensory modalities in the TeO of the avian midbrain.

Title: *In vivo* investigation of the morphogenesis of sensory spinal neurons in zebrafish

Authors: *L. DESBAN[1], A. E. PRENDERGAST[2], C. WYART[2], P.-L. BARDET[2];
[1]Wyartlab, Inst. For Brain and Spinal Cord, Paris, France; [2]ICM, Paris, France

Abstract: During development, neurons undergo various differentiation processes to acquire a highly specialized morphology intimately connected with their function. Little is known about the actual regulation of the morphological changes during their differentiation. This project aims to understand the cellular mechanisms underlying neuromorphogenesis. We take advantage of the transparency of the zebrafish embryo to investigate *in vivo* the differentiation of sensory spinal neurons, the cerebrospinal fluid-contacting neurons (CSF-cNs). Spinal Spinal CSF-cNs display a very characteristicdistinctivecharacteristic morphology with the projection into the central canal of an unusual apical extension, reminiscent of sensory organelles, in contact with the CSF.
Using LifeAct, a marker of F-actin, we undertook a descriptive approach of time-lapse imaging to characterize the main steps of CSF-cN morphogenesis. This allowed the identification of the early stages leading to the elaboration of the apical extension. First, F-actin seems to beis recruited at the level of a transient ring of actin. From this structure starts the initiation, and followed by thethen the elongation, of microvilli, structures usually supported by bundles of

actin filaments. Our timelapse approach also enabled us to characterize various shapesforms of the apical extension developed bygenerateddeveloped by distinct subpopulations of spinal CSF-cNs.
We To understand the molecular mechanisms underlying the formation of the apical extension, we investigated an actin-bundling factor of interest named Espin. W we showeded that Espin is highly expressedpresentexpressed in CSF-cN apical extension from the beginning of its formation. We generated *espin* mutants using the CRISPR/Cas9 system to test the contribution of this factor in the formation/maintenance of the apical extension. Characterization of these mutants is underway. Altogether, this work enables us to dissect *in vivo* mechanisms underlying the acquisition of an apical extension by sensory neurons of their functional mature morphology.

Title: An implicit approximate normalization model for multisensory integration across reference frames

Authors: ***P. ABEDI KHOOZANI**[1], D. STANDAGE[1], G. BLOHM[1,2,3];
[1]Queen's Univ., Kingston, ON, Canada; [2]Canadaian Action and Perception Network, Toronto, ON, Canada; [3]Assn. for Canadian Neuroinformatics and Computat. Neurosci., Toronto, ON, Canada

Abstract: Many brain processes - such as primary sensory processing, attentional modulation, multisensory integration, reference frame transformations, decision making, etc. - can be performed by probabilistic inference. It has been suggested that inference can be implemented in the brain by marginalization across variables through explicit divisive normalization, requiring intractable sums/integrals. Here, we propose an alternative, more physiologically feasible mechanism to perform marginalization. This alternative mechanism (implicit approximate normalization: IAN) is based on well-established parallel computing and machine learning principles and is functionally equivalent to divisive normalization without requiring divisive

operations. Specifically, we implemented a multi-layer feed-forward neural network using different neural coding schemes within the same network (i.e. probabilistic spatial codes and probabilistic joint codes) and trained it to perform multisensory integration across different reference frames in one step using a standard pseudo-Newton method with preconditioned conjugate gradient descent. The performance of this network was comparable to a probabilistic population code network, but without requiring non-linear or divisive operations. IAN produces a wide range of behaviors similar to recorded activity in the brain. These behaviors include inverse effectiveness, the spatial correspondence principle, gain-like modulations, super-additivity, and multi-sensory suppression. In addition to key empirical principles of multisensory integration, IAN accounts for quantitative features of cue combination: we observed modulation of neural activity in our network by varying the cue reliability, similar to area MSTd. The strength of IAN is that it performs well with a fraction of the neurons required by explicit methods (i.e. in a network with two cues to be combined in 3-D and 100 units in each dimension, divisive normalization requires 10^{12} while IAN requires 10^3 units). Furthermore, IAN doesn't require a neat preconfigured connectivity structure between neurons or explicitly matching population codes for individual neurons, in contrast to explicit divisive normalization. In conclusion, the results of this study demonstrate that marginalizing operations can be done in simple feed-forward networks of purely additive units without the requirement of explicit divisive normalization.

Title: Neural circuit basis for decision-making in *C. elegans* chemotaxis

Authors: T. MURAYAMA[1], *I. MARUYAMA[2];
[2]Senior Investigator, [1]Okinawa Inst. of Sci. & Technol. Grad. Univ., Okinawa, Japan

Abstract: Monitoring of environmental and tissue pH is crucial for the survival of animals. The nematode *C. elegans* is an excellent model organism for the analysis of neural circuits that regulate behavioral responses to environmental changes, because of its simple nervous system. We are interested in neural circuits responsible for *C. elegans* chemotactic behavior to environmental alkalinity. The animal is attracted to mildly alkaline pH, and avoids strongly alkaline pH higher than pH 10. Previous genetic dissection and Ca^{2+} imaging demonstrated that

ASEL and ASH are major sensory neurons responsible for attraction to mildly alkaline pH and repulsion from strongly alkaline pH, respectively. ASEL was activated by alkaline pH ranging from pH8 to pH 11. ASH was activated by alkaline pH higher than 10. Moreover, ASEL was transiently activated by pH up-step, whereas ASH showed long-lasting activation during stimulation. These results suggest that ASH and ASEL activities compete each other and ASH activity overrides that of ASEL upon stimulation with strongly alkaline pH. The long-lasting ASH activity may override the transient activation of ASEL. Since there is no chemical or electric connection between ASEL and ASH, signals from these 2 alkaline pH sensors must be integrated by downstream circuits. We have now analyzed interneurons responsible for the behavioral switch, and will discuss how the decision-making occurs.

Title: Adaptive shifts in owls reared with single pane prisms

Authors: *W. M. DEBELLO, D. SANCULI, D. TOTTEN;
UC Davis, Davis, CA

Abstract: Prism adaptation in barn owls is a valuable model for understanding the neural mechanisms of plasticity and learning. Previous work has employed dual pane (DP) prism lenses, which can be knocked out of alignment during aviary life. We investigated the utility of a single pane (SP) prism lens that ensures binocular registration. Auditory and visual receptive fields were measured in normal owls (n=13), owls adapted to dual pane prisms (n=6) and owls adapted to single pane prisms (n=7). Visual spatial receptive fields of multi-units within the optic tectum (OT), measured using static or moving dots displayed via a digital light projector, were displaced horizontally as expected but otherwise similar with slight changes reflecting optical distortion artifacts. Auditory spatial receptive fields measured using a free-field speaker array were indistinguishable before and immediately after mounting a prototype design, indicating that SP prisms do not alter the binaural cues on which localization is based. The chronic effects were studied by rearing juvenile barn owls with surgically attached prisms (19^{o} optical displacement) for up to two years. Adaptive shifts in tuning for interaural time difference (ITD) measured using

dichotic stimuli were robust and significantly larger in the SP group (mean = 42 μs) than in the DP group (mean = 33 μs). Site-to-site variability in auditory-visual alignment was reduced with SP prisms, and auditory responses in the deep layers of optic tectum were slightly faster. Yet, site-to-site variability with SP prisms was still larger than in normal owls. Across all groups no significant changes were observed in visual receptive field structure or latency of visual responses. In total, these results demonstrate that SP prisms promote modest improvement in the degree and reliability of adaptive shifts. The fact that prism-adapted owls come to close but not quite equal to normal owls in neuronal performance metrics indicates that the prism-adapted circuit is altered in ways that could impact population code read-out.

Title: Sensory cross-modulation in thalamo-reticular interactions

Authors: *K. PAUL, D. A. LLANO;
Beckman Inst., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: The thalamic reticular nucleus (TRN) consists of GABAergic neurons that have been hypothesized to modulate the flow of sensory or motor information through first- and higher-order thalamic nuclei. The TRN has closed loop reciprocal connectivity with the thalamus which are well established, however, there is a growing evidence of non-reciprocal or open loop connectivity between them. While the majority of information transmission to and from the cortex occur via separate thalamic nuclei corresponding to the sensory modalities, there has also been evidence of crosstalk in the thalamus between the modalities which occur through an inhibitory disynaptic pathway involving the TRN. Previous literature (Crabtree et. al., 1998; 2000) used pressure ejection of glutamate to show disynaptic connectivity between first order and higher order thalamic nuclei. In our investigations, we have used laser scanning photostimulation with glutamate uncaging to systematically identify the pattern of functional intrathalamic connectivity via TRN. Whole-cell patch-clamp recordings were done in cells in discrete thalamic nuclei which were obtained in the horizontal and thalamocortical slice orientation from mice (P12-28). MNI-caged glutamate (Tocris) was added to recirculating ACSF

and stimulated using a pulsed UV laser (355 nm, DPSS). A grid of points (20 by 20 array) was created encompassing several thalamic nuclei and focal photolysis was accomplished by non-neighbor stimulation of points within the grid. Current responses were obtained in the voltage clamp configuration with the outward current amplitude representing strength of the disynaptic connection. We found strong disynaptic connectivity between neurons in the thalamus and TRN which were topographically organized. We also found disynaptic connectivity between nuclei in the thalamus which suggest the presence of open loop connections. By employing laser scanning photostimulation with glutamate uncaging we have performed a comprehensive investigation of the functional intralathalmic connectivity pattern to add to the previous work in the realm of sensory cross-modulation within the thalamus.

Title: Multiple spatial and temporal orders of cortical mesoscale spontaneous activity are present in in GCaMP6 mice

Authors: ***M. P. VANNI**, G. SILASI, Y. SEKINO, M. BALBI, A. CHAN, J. LEDUE, D. XIAO, F. BOLANOS, T. H. MURPHY;
Dept. of Psychiatry, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: While behavior is expected to be strongly locked with neuronal activity, the link between spatiotemporal cortical dynamics and perception/action still needs to be better described experimentally and is still one of the major challenges of systems neuroscience. At the mesoscopic scale, which explores the function of large groups of neurons, cortical activity can reveal the topography of connections between areas, as well as the boundaries of systems in multiple temporal domains from slow global oscillations to fast waves. The use of transgenic mice expressing calcium indicators offers the possibility to explore mesoscale dynamics on large regions of cortex that include multiple imbricated spatial levels of organization. However, the temporal dynamics of calcium activity was never investigated in behaving mice and was

explored here for different frequency components. Transgenic mice expressing GCaMP6s or GCaMP6f (Allen Institute: Ai94 and Ai93, n=40) were implanted with a bilateral chronic window covering most the dorsal cortex. Cortical fluorescence was collected in quiet and behaving mice and temporally filtered. Brain activity as well as connectivity was analyzed using seed pixel correlation and clustering approaches such as K-means. Mouse behavior was measured by collecting videos of body movements with a webcam. Beyond 10Hz, few specific patterns of brain parcellation was observed. Around 4Hz (delta and theta rhythms), a territory of strong activity was observed in visual and retrosplenial regions in contrast to somatosensorimotor areas more associated with lower frequency components. Thus, a clear clustering was observed, delimitating two mediolateral domains that may correspond with previously defined borders of the default mode and lateral networks in mice. At lower frequency, below 1Hz, 3 functional modules were generally observed within activity regularly alternating between them. Thus, multiple cortical patterns of activity co-exist in different temporal scales and could be associated with fine balance of neuronal processing during perception, decision making, and action. Beyond the impact of monitoring cortical organization in disease models, this study could open new orientations in developing more advanced brain machine interface technologies.

Title: Toric spines in the owl inferior colliculus

Authors: *D. SANCULI[1], K. PANNONI[1], M. SUNG[1], V. POPAT[1], C. ZAHER[1], W. DEBELLO[1,2], M. ELLISMAN[2], E. BUSHONG[2];
[1]Univ. of California Davis, Davis, CA; [2]Univ. of California San Diego, San Diego, CA

Abstract: Space-specific neurons (SSNs) in the barn owl inferior colliculus compute a map of auditory space. Their function is well-characterized but their ultrastructure is not. We used serial

block electron microscopy (SBEM) and stimulated emission depletion (STED) microscopy to analyze SSNs labeled in vivo by injections of the tracer micro-ruby. Injections were targeted to the deep layers of OT at map locations representing frontal space. Retrogradely labeled cells were consistently observed in the external nucleus of the inferior colliculus (ICX) and more rarely in the lateral shell of the IC. The SBEM volume (45 x 45 x 75 μms) contained one labeled neuron whose soma and proximal dendrites were studded with unusual dendritic spines evocative of thorny excrescences (TE) found in mammalian hippocampus and amygdala. In contrast to mammalian TEs: (1) Many SSN spines had holes ("toric spines"). Some holes manifested as cytoplasmic continuities while others were formed by adhesions between filopodia. (2) They largely lacked spine head protrusions, tending towards narrow cylindrical structure, (3) They appeared more evenly distributed across the soma and dendrites, as opposed to the clustered organization of TEs, and (4) Nearly all toric spines integrated synaptic inputs arising from multiple axons. STED imaging of >40 retrogradely labeled cells revealed at least two morphological classes: one exhibiting high density of toric spines distributed widely throughout the dendritic field (a minority of cells), and one devoid of toric spines but studded with typical spines (a majority). To our knowledge, this is the first report of a toric postsynaptic structure in any species or brain region. We propose that toric spines represent an independent computational subunit of SSNs.

Title: Air-Track: A real-world environment for active sensing in head-fixed mice

Authors: ***M. N. ABDELHAMID**[1,2], H. ORABY[1], S. DOMINIAK[1], R. SACHDEV[1], Y. WINTER[1], M. E. LARKUM[1];

[1]Biol. Dept., Neurocure Cluster of Excellence, Humboldt Universi, Berlin, Germany; [2]Berlin Sch. of Mind and Brain, Berlin, Germany

Abstract: Natural behavior occurs in multiple sensory and motor modalities and in particular is dependent on sensory feedback that is constantly adjusts behavior. To investigate the underlying neuronal correlates of natural behavior, it is useful to have access to state-of-the-art recording equipment (e.g. 2-photon imaging, patch recordings, etc.) that frequently requires head-fixation. This limitation has been addressed with various approaches such as virtual reality/air ball or treadmill systems. However, achieving multimodal, realistic behavior in these systems can be challenging. These systems are often also complex and expensive to implement. Here we present "Air-Track", an easy to build, head-fixed behavioral environment that requires only minimal computational processing. The Air-Track is a lightweight, physical maze floating on an air table that has all the properties of the "real, physical" world, including multiple sensory modalities tightly coupled to motor actions. To test this system, we trained mice in Go/No-Go and two-alternative forced choice tasks in a plus maze. Mice chose lanes, and discriminate apertures or textures by moving the Air-Track back and forth, and rotating it around themselves. A custom-controlled Arduino/Pixy system is used to monitor animal location, and generated an interactive environment to control stimulus presentation and reward delivery. We are currently developing the ability to use the Air-Track system to elicit and track natural behavior in concert with the ability to monitor or manipulate brain activity.

Title: Basal forebrain circuits implicated in cortical modulation

Authors: *I. CHAVES-COIRA[1], A. NUNEZ[2], M. L. RODRIGO-ANGULO[2];
[2]Anatomia, Histologia, Neurociencia, [1]Univ. Autonoma Madrid, Madrid, Spain

Abstract: Previous studies indicate that there is specificity in the projection pathways linking the different basal forebrain (BF) nuclei with the cerebral cortex. The aim of present study is to

provide evidences of different circuits between BF and motor, sensory and prefrontal cortices implicated in sensory-motor integration. Sprage-Dawley rats have been used in the experiments. The Ethical Committee of the Autonomous University of Madrid approved all animal procedures. Animals received injections of the retrograde tracers: Fluoro-Gold in the Horizontal Diagonal Band (HDB) and Fast Blue in Basal Magnocelular Nucleus (B). Fluorescent and confocal microscopy was used to locate the retrograde labeled neurons. Our results show the existence of two different reciprocal circuits: 1) Projections arising the prefrontal and sensory cortices, implicated in processing and integration of sensory information, aim the HDB. 2) Projections arising the motor and sensory cortices drive forward B neurons. Since it is known that the BF cholinergic neurons degenerate at the first stage of Alzheimer disease, these circuits could be implicated in different ways in the progression of the disease.

Title: Thalamic inputs to cortical areas involved in skilled forelimb movements and tool use

Authors: ***A. MAYER**[1], G. LEWENFUS[1], R. E. BITTENCOURT-NAVARRETE[2], J. G. FRANCA[1];
[1]Federal Univ. of Rio De Janeiro, Rio De Janeiro, Brazil; [2]Federal Univ. of Juiz de Fora, Juiz de Fora, Brazil

Abstract: The posterior parietal cortex (PPC) of primates plays a crucial role in manual behaviors such as object manipulation and tool use. Corticocortical connectivity of different sectors of areas 5 and 7 in cebus and macaque monkeys suggest that segregated cortical circuits promote the somatosensory-motor and visuomotor integration necessary for implementation of such behaviors. However, the part played by thalamic nuclei projecting to those cortical circuits is not yet known. In this study we investigated the thalamic projections to areas 5v (or PEip), anterior intraparietal area (AIP), PFG, and PF in the cebus monkey.
After a brief electrophysiological mapping of the parietal cortex, five adult cebus monkeys were

injected with different retrograde tracers at different sectors of the PPC. Three injections were made in the hand/forearm representation of area 5v, five in the expected location of AIP and/or PFG, and two in area PF. After a survival of 11-14 days, animals were perfused and the diencephalon was cut coronally. Distribution of labeled thalamic neurons was represented in schematic drawings of coronal sections. Identification of thalamic nuclei was performed on cytochrome oxidase and Nissl-stained sections.
Most labeled cells were found in the lateral posterior nucleus (LP) and pulvinar complex. The main sources of thalamocortical projections to area 5v were the anterior pulvinar nucleus (PuA, 50%), the lateral posterior nucleus (LP, 18%), and the ventral posterior superior nucleus (VPs, 15%). In contrast, injections in area AIP/PFG revealed retrograde labeling mainly in LP (55%) and medial pulvinar nucleus (PuM, 37%). Despite some variability between cases, thalamocortical projection to area PF was similar to both that to area 5v and to AIP/PFG. More specifically, area PF received projections mainly from LP (57% and 20%, respectively in the two injection cases) and PuM (11% and 62%), followed by PuA (15% and 12%) and VPs (16% and 2.5%).
When projections to areas 5v and AIP/PFG were compared, different patterns of thalamocortical connectivity indicated that circuits dedicated for integration of somatosensory and visual information with motor processing were also segregated at subcortical levels. PuA seems to be the main source of higher-order inputs to somatosensory-motor circuits, whereas PuM contributes relatively more with the visuomotor processing. Additonally, thalamic inputs common to areas 5v, AIP/PFG and PF, especially from LP, suggest that the thalamus could also perform functional integration between these segregated cortical circuits involved in implementation of skilled forelimb behaviors.

Title: Early sensory experience sculpts the development of multisensory connections of primary sensory cortices

Authors: J. U. HENSCHKE[1], A. M. OELSCHLEGEL[2], F. ANGENSTEIN[4], F. W. OHL[1], J. GOLDSCHMIDT[1], P. O. KANOLD[5], *E. BUDINGER[3];

Abstract: Multisensory integration does not only recruit higher-level association cortex, but also primary sensory cortices like A1 (auditory), S1 (somatosensory), and V1 (visual). The underlying anatomical pathways include direct cross-modal thalamocortical and intracortical connections. Sensory loss from birth in humans results in functional recruitment of the deprived cortical territory by the spared senses. We investigated if the multisensory recruitment could be due to changes in the early development of thalamocortical and intracortical projections. Neuronal tracer injections into A1, S1, and V1 within the first postnatal month of normally developing Mongolian gerbils revealed that multisensory thalamocortical connections emerge before intracortical connections but mostly disappear during development. However, early auditory, somatosensory, or visual deprivation leads to an increase of these connections encompassing lemniscal, non-lemniscal, and multisensory pathways. The specific changes in the connectivity patterns are not due to a neurogenesis or apoptosis of projection neurons but rather to axonal remodeling. Consistent with our anatomical findings, functional single-photon emission computed tomography (SPECT) revealed altered stimulus-induced activity and higher functional connectivity specifically between primary areas in deprived animals. Together, we show that early sensory experience has a dramatic effect not only on the development of sensory thalamocortical and intracortical pathways underlying the deprived sense but also on pathways serving the non-deprived senses enabling a functional recruitment of deprived cortical areas by the spared senses.

Title: Auditory input and receptive fields in the optic tectum of the chicken, an auditory generalist avian species.

Authors: *H. LUKSCH, H. A. SCHNYDER, B. NIEDERLEITNER, Q. KRABICHLER, C. GUTIERREZ-IBANEZ, U. FIRZLAFF;
Tech. Univ. of Munich, Freising, Germany

Abstract: The auditory system of birds has been intensely studied over several decades. For example, the processing of monaural and binaural cues in the brainstem has been investigated in various species, most notably the chicken and the barn owl. In contrast, the integration of auditory input to the midbrain multimodal map in the optic tectum has almost exclusively been studied in the barn owl. The latter can be considered an auditory specialist as, contrary to most other birds, it can locate auditory cues in space with great precision. As the comparison between specialist and non-specialist circuit layout allows for an assessment of essential elements, here we analyzed, for the first time, the auditory midbrain, its projection upon the optic tectum, and the auditory receptive fields of tectal neurons in the chicken, an auditory generalist. In barn owls an auditory spatial map is formed in the external nucleus of the inferior colliculus (ICX) and then conveyed to the TeO by a direct projection. In the chicken, we found this projection to be quite weak, but discovered a second projection from the ICx that reaches a lateral part of the Formatio reticularis (FRLx), which then projects broadly upon the TeO. Intracellular labeling demonstrated that individual neurons cover up to 40 degrees of visual space in the lateral aspects of the TeO. Extracellular recordings of units in IC, TeO, and FRLx stimulated with virtual acoustic stimuli revealed spatially defined auditory receptive fields that were typically broad, centered at lateral directions from the animal. Some tectal neurons had very large, conspicuous circular center-surround receptive fields (donut-shaped), which had a coarse topography in the TeO. Thus, while the chicken is a generalist without specialized auditory capabilities, spatial auditory information is integrated into the multimodal map of space in the TeO. Future comparative analysis will show whether the newly described projection via the FRLx is a plesiomorphic feature and the enlarged direct projection from the ICx to the TeO in the owl a consequence of being an auditory specialist.

Title: Controlling plasticity in sensory cortical regions using multisensory neuromodulation

Authors: *C. GLOECKNER, J. NOCON, H. LIM;
Biomed. Engin., Univ. of Minnesota, Minneapolis, MN

Abstract: Sensory systems are vastly connected through multisensory integration. The ability to induce plasticity in cortical areas using noninvasive, controlled sensory stimulation that takes advantage of existing multimodal pathways may treat various neural sensory disorders characterized by abnormal neural firing. We investigated changes in sensory cortical activity induced by paired stimulation of two different sensory systems with specific temporal delays. We recorded sensory receptor-driven spike activity in the right olfactory piriform cortex (**OC**), gustatory cortex (**GC**), primary somatosensory cortex (**S1**), primary auditory cortex (**A1**), and primary visual cortex (**V1**) of ketamine-anesthetized guinea pigs using 32-site electrode arrays. Spontaneous and receptor-driven activity before and after paired stimulation were compared to assess plasticity effects. Subcutaneous needles electrically stimulated the skin of various body regions for somatosensory stimulation. Surface electrodes stimulated the tongue and nasal cavity for gustatory and olfactory stimulation. Broadband noise was used for auditory stimulation, and an LED light board was used for visual stimulation. Several animals also received chronic recording implants to confirm cortical plasticity effects in an awake state. All cortices were located using stereotactic coordinates and functional responses to receptor activation. Significant changes in cortical firing ($p<0.01$, ranked-order t-test, $n=13394$ total) were induced with paired sensory stimulation compared to control condition (no stimulation) that depended on sensory input and recording location. Pairing somatosensory and auditory stimulation suppressed or facilitated firing in A1 depending on inter-stimulus delay, and induced differential effects in S1 depending on body stimulation location. Paired gustatory and somatosensory stimulation suppressed or facilitated GC depending on left/right body stimulation location. OC was facilitated by paired olfactory and somatosensory stimulation, but was suppressed with paired olfactory and acoustic stimulation. V1 was facilitated by paired visual and right shoulder or acoustic stimulation, but was suppressed by paired visual and left shoulder stimulation.
We can induce differential effects in neural firing in sensory cortices through multisensory stimulation. By optimizing stimulation parameters, such as location and inter-stimulus delay, we can control the type, location, and amount of cortical plasticity, which may potentially treat neural sensory disorders (e.g. tinnitus or chronic pain) noninvasively by altering abnormal spike patterns with specificity.

Title: Integration of auditory and visual inputs depends on differential properties of Mauthner-cell dendrites.

Authors: V. MEDAN[1], T. MÄKI-MARTTUNEN[2], J. SZTARKER[1], *T. PREUSS[3];
[1]Dept. Physiology, Cell. and Mol. Biol., Univ. of Buenos Aires, Buenos Aires, Argentina; [2]Inst. of Clin. Med., Univ. of Oslo, Oslo, Norway; [3]Psychology, City Univ. of New York, Hunter Col., New York, NY

Abstract: Most animals take advantage of multiple information sources to form a coherent percept of the world for adaptive behavioral decisions, however, the underlying mechanisms of such interactions are still far from clear. Here we address two essential questions (i) how do neurons process multimodal sensory inputs with different temporal characteristics, and (ii) what role do intrinsic properties of dendrites play in selective sensory filtering? For that we took advantage of the startle escape network in goldfish, which is centered on a pair of indefinable decision-making neurons, the Mauthner-cells (M-cells). These cells receive auditory and visual inputs via separate dendrites, both accessible for morphological characterization, *in vivo* recordings, and computational modeling.
Reconstructions of labeled cells (N=3) revealed that the visual dendrite (VD) is on average 30% longer and 25%, thinner than the auditory dendrite (LD), resulting in a 28 ± 8 % higher surface/volume ratio of the VD when compared to the LD (t-test; $p = 0.036$). Accordingly, our electrophysiological results showed differences in cable properties in the two dendrites. Namely, a lower transfer resistance in the VD (29.1 ± 20.2 kΩ) than in the LD (77.9 ± 33.4 kΩ; $t=3.55$, $df=13$, $p=0.004$), and a longer time constant in the VD (0.57 ± 0.23 ms) compared to the LD

(0.25 ± 0.07 ms; t=2.66, df=5, p=0.04). Similarly, the dendritic space constant of visually evoked PSPs in the VD ($\lambda_{ortho,VD}$=145 μm) is about half of that for auditory PSP in the LD ($\lambda_{ortho,LD}$=361μm).
Modeling experiments showed that these passive cable properties fully account for the observed differences in PSP decay in the two dendrites.
Interestingly, our electrophysiological experiments showed that auditory evoked PSPs originating in the LD also invade the VD, as well as the opposite, visual PSPs invading the LD. The effects of the antidromically propagating PSPs are asymmetrical between the dendrites however, with auditory PSPs being more prominent in the VD than visual PSPs in the LD. Modeling experiments imply that this asymmetry might be due to active conductances expressed in the proximal segments of the VD.
Taken together, our results suggest modality-dependent membrane specialization in the two M-cell dendrites that are suited for processing stimuli of different time domains (e.g. visual looms and auditory clicks), which might be critical for vital startle-escape decisions.

Title: Input-specific functional heterogeneity of the thalamostriatal circuitry

Authors: *B. C. JONGBLOETS, B. J. HUNNICUTT, W. T. BIRDSONG, K. GERTZ, H. ZHONG, T. MAO;
Vollum Inst., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: The basal ganglia play an essential role in movement control and learning. Their primary input station - the striatum - is responsible for sorting contextual and motor information from the thalamus into specific downstream pathways. Knowledge of the precise circuits and organizational principles between the thalamus and striatum is essential for the mechanistic dissection of how these structures orchestrate movement control and learning. We systematically

analyzed excitatory thalamic inputs to the mouse striatum based on our viral-mediated anterograde fluorescent tracing dataset (Hunnicutt et al., *Nat Neurosci*, 2014). Whole brain image datasets were obtained and analyzed using custom algorisms to generate a map of individual thalamic subregions differentially projecting to the striatum. Guided by these projection maps, optogenetic experiments were carried out to assess functional properties of thalamostriatal projections originating from specific thalamic subregions. We found that converging inputs from different thalamic subregions onto the same medium spiny neurons (MSNs) may exhibit distinct synaptic properties. The present functional data provides a framework for investigating the convergence of multimodal information onto individual MSNs. Our comprehensive thalamostriatal projectome may guide functional studies aimed at understanding the diverse functions of the striatum.

Title: Identification of multiple classes of GABAergic sensory neurons contacting the cerebrospinal fluid in the vertebrate spinal cord

Authors: *A. PRENDERGAST, L. DJENOUNE, L. DESBAN, J. GOMEZ, J. STERNBERG, P.-L. BARDET, C. WYART;
Inst. du Cerveau et de la Moelle Épinère, Paris, France

Abstract: Multiple lines of evidence indicate that molecular and mechanical cues from the cerebrospinal fluid (CSF) can affect the development and function of the central nervous system (CNS). However, the mechanisms by which these cues are detected and relayed to the CNS remain elusive. Cerebrospinal fluid-contacting neurons (CSF-cNs), being situated at the interface between the CSF and the CNS, are in an ideal location to convey this information to local networks. These neurons extend an apical microvilliary extension into the CSF, express the transient receptor channel PKD2L1, and project an axon rostrally onto local targets. In zebrafish larva, we recently showed that CSF-cNs constitute a mechanosensory loop detecting bending of the spinal cord that tunes the frequency of locomotion. Evidence from zebrafish and mouse

indicates that CSF-cNs originate from two distinct progenitor domains. Here, we ask whether these two groups of CSF-cNs have different morphological and molecular characteristics. We first show that the morphology of the apical extension and the axonal projection differ between the two CSF-cN groups. We further identify a repertoire of peptides and neuromodulators that distinguish more subtypes within each group. Our study reveals more CSF-cNs are more heterogeneous than previously believed, suggesting that multiple neuromodulatory functions are likely carried out by distinct CSF-cNs within this sensorimotor feedback loop.

Title: Pkd2l1 underlies spontaneous activity in intraspinal sensory neurons

Authors: *J. R. STERNBERG[1], L. DJENOUNE[1,2], A. PRENDERGAST[1], J. MCDEARMID[3], H. PASCAL MOUSSELLARD[1], C. WYART[1];
[1]Inst. Du Cerveau Et De La Moelle Épinière, Paris, France; [2]Muséum Natl. d'Histoire Naturelle, CNRS UMR 7221, Paris, France; [3]Univ. of Leicester, Leicester, United Kingdom

Abstract: In the spinal cord, cerebrospinal fluid-contacting neurons (CSF-cNs) are sensory neurons responsible for relaying mechanical and chemical sensory information locally to motor circuits. CSF-cNs in diverse species express GABA and the transient receptor potential channel TRPP3 or PKD2L1, involved in sour taste. Here we use genetic targeting, calcium imaging, pharmacology and electrophysiology in the zebrafish to investigate the role of PKD channels in spontaneous activity in these neurons. We show that Pkd2l1 forms a complex with Pkd1l2 in CSF-cNs in zebrafish. Calcium imaging showed large long-lasting calcium transients in a subpopulation of CSF-cNs at early developmental stages that reflect high frequency firing, which were abolished in a *pkd2l1* mutant. We used whole-cell patch clamp recordings to investigate whether differences in frequency of spontaneous firing between the two subpopulations were due to differences in subcellular localization of Pkd2l1 or intrinsic properties. We found that Pkd2l1 opens spontaneously and that current from a single channel opening is sufficient to generate an action potential in all CSF-cNs. Current investigation is focused on understanding the intrinsic

and extrinsic properties that alter the probability of channel opening in these two subpopulations. These data demonstrate that a single channel opening can generate an intrinsic source of spontaneous activity in sensory CSF-cNs. Additionally, our results suggest that differences in channel activity reflect functional differences in subpopulations of CSF-cNs.

Team, RIKEN Ctr. for Advanced Photonics, Wako, Japan

Abstract: Although multimodal integration is an essential brain function for sensory processing, the underlying mechanism of cortical interactions in sub-populations of different cell types remains challenging. Cortex-wide imaging is a powerful technique for visualizing intercortical activity. We established a transgenic mouse line expressing a calcium indicator, Yellow Cameleon 2.60, under the control of the Cre/loxP system and performed wide-field transcranial calcium imaging in excitatory and inhibitory networks of the cerebral hemisphere. We revealed that spontaneous slow waves represented functional connectivity between primary sensory areas and associative areas, and the wave flows formed a hub-like structure at the associative regions. Area-wide amplitude responses to combinations of somatosensory, auditory, and visual stimuli simply consisted of superposition over unimodal responses, not being cell-type specific.

Contrarily, phase responses to the combined inputs in the excitatory networks, not in the inhibitory networks, indicated phase-locked ongoing slow-oscillation for several seconds. Medial and parietal areas were locations where the phase-locking was markedly induced, and coincided with the hub areas identified from spontaneous activity. These findings suggest that association cortices serve as a hub and converged multisensory information is integrated by phase-locking.

Title: Characterization and functional analysis of claustral VIP interneurons

Authors: *M. GRAF[1], G. J. AUGUSTINE[2];
[1]A*STAR/ Inst. of Mol. and Cell Biol., Singapore, Singapore; [2]Lee Kong Chian Sch. of Med., Singapore, Singapore

Abstract: The claustrum is a little-understood structure that is embedded within the deep layers of the insular cortex. As in all other brain regions, it is likely that interneurons play important roles in information processing within the claustrum. We have defined the morphology, intrinsic electrical properties and functional connectivity of one type of claustral interneuron, VIP expressing interneurons (VIP^+ INs). The electrical properties of these interneurons were determined via patch clamp recordings in acute brain slices. VIP^+ INs from transgenic mice expressing Channelrhodopsin-2 exclusively in VIP neurons could be identified by photostimulation when exposed to blue light. VIP^+ INs differed from other claustral INs in their somatic shape, which were either multipolar or elongated/ bipolar. Their neurites projected mainly to the shell or edge of the claustrum core, which contrasts from the enrichment of processes from PV INs within the core. VIP^+ IN had the highest input resistance, broadest AP half-width, the shallowest AHP, and lowest maximum firing rate of any claustral INs. High-speed optogenetic circuit mapping (PNAS 104: 8143) revealed that VIP^+ INs are connected to projection neurons as well as to other IN populations. Remarkably, this inhibitory input was much stronger and more efficient for INs than for projection neurons. Thus, it appears that claustral VIP^+ INs specifically target other local IN populations and might relieve projection

neurons from local inhibition imposed by PV^+ and SST^+ interneurons. In general, VIP^+ INs are strategically situated to increase signaling of claustral projection neurons via disinhibition, well-positioning these INs to regulate information flow through the claustrum during attention allocation (TINS 38: 486), consciousness (Philos Trans R Soc Lond B Biol Sci. 360: 1271), or other functions proposed for this highly interconnected brain region.

Title: Cellular and behavioral correlates of the principle of inverse effectiveness in multisensory integration in the developing optic tectum

Authors: *T. L. S. TRUSZKOWSKI, O. A. CARRILLO, J. L. BLEIER, C. M. RAMIREZ-VIZCARRONDO, C. D. AIZENMAN;
Neurosci., Brown Univ., Providence, RI

Abstract: Sensory information representing different modalities is combined in the brain to provide information necessary for an organism to interact with the world. This process, termed multisensory integration, is known to occur in single cells in the optic tectum, or its mammalian homologue, the superior colliculus. However, little is known about intracellular and network level processes giving rise to multisensory integration. In this study, we use the *Xenopus laevis* tadpole optic tectum to build a multi-dimensional model of multisensory integration. The optic tectum receives sensory information from the ears, eyes and lateral line and integrates it to generate behavioral output. Using both behavioral and cellular techniques to assess multisensory

integration, we provide a robust, integrative approach to understanding multisensory integration. One important manifestation of multisensory integration, known as the principle of inverse effectiveness, states that when weak sensory stimuli are combined, the result is a supralinear enhancement of the combined response that increases its saliency, whereas combination of strong sensory stimuli that are already salient does not result in additional benefit. Behaviorally, we show that this principle is conserved across species: when tadpoles are presented with a low saliency visual stimulus, adding a subthreshold acoustic stimulus increases behavioral response likelihood, while the subthreshold acoustic stimulus provides no added benefit when paired with a high saliency visual stimulus. To assess inverse effectiveness at the cellular level, we used intracellular whole-cell current clamp recordings and found that combining large suprathreshold stimuli does not result in an increased response magnitude. However, when two subthreshold stimuli are combined, the resulting response is amplified in a supralinear manner, showing that the principle of inverse effectiveness holds at the intracellular level. We further showed that this response depends on NMDA receptor activation. To build on these results, we studied network activity in the tectum in response to visual and mechanosensory stimuli using *in vivo* Ca++ imaging. Preliminary results show that integrating cells are distributed throughout the tectum, often adjacent to cells that only respond to a single modality and have varying levels of integration. In conclusion, our data provide evidence for the conservation of multisensory processing across vertebrates and lay the groundwork for investigation of many unanswered questions.

Abstract: We recently reported the discovery of toric spines, novel dendritic structures found on a subset of space-specific neurons (SSNs) in the barn owl inferior colliculus. To determine convergence patterns we located all synaptic inputs to one SSN that had been imaged at 10nm resolution using serial block electron microscopy. Active zones made onto the 76 toric spines were identified, as well as those onto the cell body, six proximal dendrites and one thin dendrite. The total number of active zones made onto toric spines was 512, while the soma received 131 and the dendrites 386. Thus, toric spines represent a major input-output hub of SSNs. Toric spines varied in volume (>10-fold), number of holes (0-7) and number active zones received (1-49), and these features were significantly correlated. The axonal inputs to eight representative toric spines were reconstructed to the point at which they exited the local neighborhood (~20 microns). All but one toric spine received synapses originating from multiple axons with distinct incoming trajectories (range 1-11). These likely represent distinct input sources. This is in stark contrast to hippocampal thorny excrescences, which receive dominant input from a single mossy fiber termed the “detonator” synapse. The large majority of axons coursing through each local neighborhood did not synapse onto the toric spine. Thus, the filling fraction was low and on par with that observed in mammalian cortex. In addition, the large majority of local axons were unmyelinated, though hundreds of myelinated axons were embedded in the larger volume. We propose that toric spines are a subcellular locus of adaptive plasticity. Identification of the source of the diverse inputs is a current goal.

Title: Auditory dominance over visual perception in the mouse integrating visual-auditory conflict

Authors: *Y.-H. SONG, J.-H. KIM, H.-W. JEONG, I. CHOI, D. JEONG, K. KIM, S.-H. LEE; Biol. Sci., KAIST, Daejeon, Korea, Republic of

Abstract: We often experience the conflicts between the sensory modalities, and our brain resolves these conflicts through the fast and accurate integration and elicits coherent perceptual behavior. During the integration of visual-auditory conflict, one modality often dominates the other. However, we still do not understand the neural mechanism of perceptual dominance during the integration of the conflict between sensory modalities. Here, we devised the visual-auditory discrimination tasks both under the actual and artificial conditions. Mice learned to discriminate visual and auditory information, and they showed auditory-dominant perceptual behaviors during the integration of the conflict. We found that the direct inputs from V1 and A1 to the posterior parietal cortex (PTLp) are critical for inducing auditory dominance over visual perception. Inactivation of the PTLp switched the auditory dominance to visual dominance without affecting visual or auditory perception. Furthermore, only V1-selective neurons in PTLp showed significant reduction in their responses to simultaneous V1 and A1 stimulation. Our results demonstrate that the converging inputs from V1 and A1 to PTLp mediate the auditory-dominant perception during the integration of visual-auditory conflict.

Title: Visual modulation of activity in mouse auditory cortex

Authors: *R. J. MORRILL[1,2,3], A. R. HASENSTAUB[1,2,3];
[1]Univ. of California, San Francisco, San Francisco, CA; [2]Kavli Inst. for Fundamental Neurosci., San Francisco, CA; [3]Coleman Mem. Lab. for Auditory Neurosci., San Francisco, CA

Abstract: To construct an actionable percept of the world, the brain integrates information streams from multiple sensory modalities. In the cortex, this process is traditionally held to occur in higher-order association areas; however, work over the past decade suggests that even primary sensory cortex may receive and integrate information from other modalities (Wallace et al., 2004; Ghazanfar & Schroeder, 2006). In a variety of organisms, auditory cortex responds to stimuli from other modalities, both in conjunction with and independent of acoustic stimulation (Kayser et al., 2008; Bizley et al., 2007). Despite the importance of the mouse as a systems neuroscience model for circuit dissection, it remains unknown to what degree visual stimuli modulate or drive responses in mouse auditory cortex. Here we describe the temporal and laminar organization of visual influences on neural firing in the auditory cortex of the awake mouse, using multisite probes to sample across multiple cortical layers. We demonstrate that these recording sites are located in auditory cortex based on highly characteristic neural responses to sounds such as click trains and pure tones of varied frequencies and sound levels. We then determine whether depths of the electrode penetration are within cortex through electrode track tracing using fluorescent dye. We find that spiking responses to visual stimulation are biased to deeper layers, while field potential modulation is present throughout the cortical column. We speculate as to the role of these responses in modulating auditory cortex during sound processing.

Title: Lack of intrinsic GABAergic connections in the thalamic reticular nucleus of the mouse

Authors: G. HOU, A. G. SMITH, *Z.-W. ZHANG;
The Jackson Lab., Bar Harbor, ME

Abstract: The thalamic reticular nucleus (TRN) provides the major GABAergic input to the thalamus and is critically implicated sensory detection, selective attention, and arousal. Dysfunction of the TRN is associated with epilepsy and schizophrenia. It is generally thought that TRN neurons form GABAergic synapses with other TRN neurons and that these interconnections are important for the function of the TRN. However, the existence of such intrinsic connections is controversial. We combined two complementary approaches to examine intrinsic GABAergic connections in the TRN of the mouse. First, we expressed channelrhodopsin in nearly all TRN neurons. We found that optogenetic activation of TRN neurons and their axons evoked GABAergic postsynaptic currents (IPSCs) in TRN neurons in mice younger than 2 weeks of age but failed to do so after that age. Second, we genetically blocked synaptic release from TRN neurons through conditional deletion of vesicular GABA transporter. This had no effect on spontaneous IPSCs recorded in TRN neurons while dramatically reducing spontaneous IPSCs in thalamic relay neurons. Our results demonstrate that except for a short period after birth, the TRN of the mouse lacks intrinsic GABAergic connections.

Title: The role of ionotropic glutamate receptors in non-synaptic cross-depolarization in the mammalian dorsal root ganglia

Authors: G. CARVALHO[1], Y. MULPURI[2], A. DAMASIO[1], *I. SPIGELMAN[2];
[1]Brain and Creativity Inst., USC, Los Angeles, CA; [2]Div. of Oral Biol. & Medicine, Sch. of Dent., Univ. of California Los Angeles, Los Angeles, CA

Abstract: Afferent pathways are thought to act largely as isolated channels relaying information from the periphery to central synapses connecting to secondary neurons. However, several

instances of orthogonal, non-synaptic communication have been described between parallel pathways that challenge this simplistic view of neuronal communication. Here we sought to investigate the physiological mechanisms of cross-depolarization (CD) in mammalian dorsal root ganglia (DRG), a phenomenon where action potentials evoked in afferent axons and propagated to the neuronal somata in DRG induce sub-threshold depolarizations in neighboring neurons. Mammalian DRG neurons are anatomically isolated from one another and are not synaptically interconnected. Yet, CD is observable in a majority of these cells, encompassing both A- and C-type fibers. CD has been proposed to be mediated by a chemical neurotransmitter(s) released from the somata of DRG neurons (Amir & Devor, J. Neurosci., 1996), however, the identity of the neurotransmitter(s) remains elusive. We used electrophysiological recording techniques in L5 DRG preparations isolated from naïve rats to begin exploring the identity of neurotransmitter(s) that may mediate CD. During intracellular recordings with 3M potassium acetate filled sharp microelectrodes, CD could be evoked by stimulation of the spinal nerve at 85% intensity necessary to elicit an action potential in the recorded neuron. CD magnitude was proportional to the frequency (10-500 Hz) of spinal nerve stimulation (n = 20 cells). Since glutamate is considered as the primary neurotransmitter at the central terminals of sensory afferents, we hypothesized that glutamate and its cognate receptors may mediate CD in DRG neurons. To test this hypothesis, we recorded CD before and after combined application of selective ionotropic glutamate receptor blockers, D(-)-2-amino-5-phosphonopentanoate (40 μM) and 6-cyano-7-nitroquinoxaline-2,3-dione (10 μM), in the recording chamber. Glutamate receptor blockade had no significant effect on the magnitude of CD (average magnitude was 85.1% ± 25.2 of the controls, n=7 cells), suggesting that ionotropic glutamate receptors do not play a central role in non-synaptic cross-depolarization in mammalian sensory ganglia.

Title: Cell-type-specific plasticity at corticostriatal synapses prevents suppression of habitual control of behavior

Authors: *A. CAVACCINI[1], V. PAGET-BLANC[1], M. TRUSEL[1], A. ROCCHI[2], M. PENNUTO[3], A. CONTESTABILE[1], B. GRECO[1], R. TONINI[1];

Abstract: The ability to adapt behavior and effectively cope with an ever-changing environment requires flexible, goal-directed control of behavior, which strictly depends on the causal relationship between the action and the outcome (A-O). With repetition, behavior becomes more automatic and habitual, and actions are no longer sensitive to changes in A-O associations. In learning processes triggered by repeated training trials, priming stimulation of intracellular signaling pathways relevant for synaptic plasticity can affect the extent to which subsequent learning occurs, a process conceptualized as metaplasticity. This might also apply to the impossibility of updating changes in A-O contingencies that characterize inflexible habitual control of behavior. Nonetheless, whether instrumental learning triggers metaplastic processes at corticostriatal synapses on striatal projections neurons (SPNs) of the direct- (dSPN) and indirect (iSPN) pathway remains unexplored.
To test these hypotheses we subjected mice to different training regimes of instrumental conditioning of nose poke for food reward, which promote either goal-directed (short training) or habitual behavior (over training). Training was followed by an omission procedure in which mice have to learn a new causal A-O relation. We found that the inability of reverting A-O association was directly associated with reduced activation of signaling cascades downstream of striatal metabotropic glutamate receptors 1/5 (mGluR1/5), resulting in opposite changes in spike-timing dependent plasticity in dSPNs and iSPNs of the dorsolateral striatum (DLS). Consistent with a metaplastic process, these synaptic and biochemical effects occurred selectively in over trained habitual mice when tested upon omission. Preventing the activation of DLS mGluR5 in-vivo during training restored behavioral sensitivity to omission contingency, and averted biochemical and synaptic changes. Together, our findings point to cell-type-specific mechanisms of metaplasticity at corticostriatal synapses as habit forms, and establish mGluR5-mediated signaling as key molecular substrate for cognitive inflexibility in habitual behavior.

Title: Excitatory serotonergic signaling regulates synaptic plasticity at striatal glutamatergic inputs

Authors: *M. GRITTI[1], M. TRUSEL[1], A. GIORGI[2], A. CAVACCINI[1], S. MIGLIARINI[2], A. GOZZI[3], M. PASQUALETTI[2], R. TONINI[1];

[3]Fondazione Inst. Italiano di Tecnologia, Rovereto, Italy

Abstract: The dorsal striatum receives glutamatergic cortical and thalamic afferents, which are extensively modulated by monoaminergic inputs, such as dopamine and serotonin (5-HT). Various models have been proposed regarding the interactions between reward and punishment, with serotonin closely associated with learning of negative events, and countervailing dopamine regulation of corticostriatal circuits and reward. Recent evidence has challenged this view, suggesting that 5-HT signaling can synergize with dopamine signaling to shape reward-guided behavior. However, the molecular and synaptic correlates of this behavioral role of 5-HT at striatal circuits remain to be established.
In the dorsolateral striatum, we found that the chemogenetic inhibition of 5-HT release resulted in a spike-timing-dependent form of long-term depression (t-LTD) at glutamatergic synapses on striatal projection neurons of the direct pathway (dSPNs). These synaptic effects of chemogenetic inhibition of 5-HT release were recapitulated by the pharmacological inhibition of the Gs-coupled 5-HT4 receptor subtype (5-HT4R). t-LTD is independent from endocannabinoid signaling, shows a postsynaptic locus of expression, and it is associated with an increased dendritic Ca^{2+} signal. Additionally, optogenetic interrogation of glutamatergic inputs to dSPNs indicated that this form of t-LTD is expressed at thalamostriatal synapses. Inhibiting *in-vivo* 5-HT4R during instrumental conditioning of nose-poke for food reward affected goal-directed control of behavior, thus supporting the role of striatal 5-HT signaling in mediating aspects of reward-guided behavior.

Title: Chemogenetic control of striatal cholinergic interneurons in haloperidol treated mice

Authors: *A. ZUCCA, S. ZUCCA, J. WICKENS;
Neurobio. Res. Unit, Okinawa Inst. of Sci. and Technol., Okinawa, Japan

Abstract: Dopamine antagonists used in treatment of schizophrenia often induces side effects, including a syndrome of muscle rigidity and frozen posture known as catalepsy. Anti-cholinergic drugs are commonly used to relieve the symptoms of catalepsy but their cellular mechanism of action is not fully understood. The striatum is a brain region rich in acetylcholine which is provided mostly by local cholinergic interneurons (CINs). We investigated the hypothesis that lowering activity in the striatal CINs would ameliorate catalepsy, and that increasing CIN activity would worsen the symptoms. We induced catalepsy in transgenic rodents by administering haloperidol, and used ChAT-cre lines and specific expression of designer receptors exclusively activated by designer drugs (DREADDs), to experimentally test the effect of manipulation of CINs on measures of catalepsy. Haloperidol induced catalepsy and impaired locomotion measured with the bar-test and open field test. DREADD-induced increase in CIN firing in haloperidol treated animals did not cause increase of bar time score nor decreased locomotion. In addition, decreasing activity in CINs did not reverse haloperidol-induced catalepsy or increase locomotor activity. These negative results may indicate that anti-cholinergic drugs work by effects on other cholinergic systems that are extrinsic to the striatum, or alternatively, that the DREADD-induced manipulations of CINs were localized to regions that do not mediate cataleptic effects. Further work is needed to characterize the role of CINs in catalepsy.

Title: A dual purpose optical system for fluorescence imaging and spectrally resolved fiber array photometry in freely moving animals

Authors: *C. MENG[1], G. CUI[2];
[1]Lab. of Neurobiology/ In Vivo neurobiology group, NIH/NIEHS, Research Triangle Park, NC;
[2]NIEHS/NIH, Research Triangle Park, NC

Abstract: Monitoring the cellular and molecular events in specific types of cells in behaving animals using genetically encoded fluorescent sensors is a powerful approach to decode neural correlates of specific behaviors, and to uncover the mechanisms underlying the psychiatric and neurological disorders. Two types of optical methods are currently available for collecting fluorescence signals from deep brain structures in freely moving animals: the fiber photometry technique and the GRIN lens imaging method. Fiber photometry is a minimally invasive method that collects signals through an optical fiber probe placed above the targeted brain structure. The small size of the probe (125 micrometer OD) and long detection depth (up to 250 -500 micrometer from the tip) can minimize the disturbance of the measured structure. However, fiber photometry method cannot resolve individual cells. The signals collected by a fiber photometry system can only be interpreted as the population activity within the detection cone. When more detailed information on the activity pattern of individual neurons is desired, the GRIN lens-based imaging technique is currently the best option. The major concerns associated with GRIN lens imaging are the relative large tissue damage due to the size (typically 1 mm OD) of the GRIN lens and the low successful rate of the surgeries. Thus, fiber photometry and GRIN lens imaging are two complementary techniques that both have their own strengths and weaknesses, and should be chosen by the need of specific experiments. The current fiber photometry systems and GRIN lens imaging systems are based on completely different platforms; therefore, two separate systems are required to perform photometry and imaging experiments. To integrate the functionality of a fiber photometry system and a GRIN lens imaging system into a single system, we have built a dual purpose microscope that can be easily converted between the GRIN lens-based imaging mode and the spectrally resolved fiber array photometry mode to measure the fluorescence signals in freely moving animals. We were able to resolve individual neurons in the striatum in the imaging mode in mice expressing fluorescent sensors in specific striatal pathways, and simultaneously monitor the neural activity in 8 discrete locations in the dorsal and ventral striatum using the fiber photometry mode.

Title: Simultaneous multi-component measurements in the striatum using spectrally resolved *In vivo* fiber photometry

Authors: *J. ZHOU, C. MENG, G. CUI;
NIEHS/NIH, Research Triangle Park, NC

Abstract: The striatum is the central hub of the basal ganglia that integrates glutamatergic inputs from the cortex and the thalamus and dopaminergic input from the substantia nigra pars compacta (SNc). We have recently reported that the two principal types of striatal projection neurons (SPNs), the D1 dopamine receptor-expressing direct-pathway SPNs and the D2 dopamine receptor-expressing indirect-pathway SPNs, are both activated during action initiation. To further investigate how dopamine modulates these two pathways and facilitates voluntary movements in vivo, we have developed a novel spectrally resolved fiber photometry system that allows for simultaneous monitoring of multiple cellular events from molecularly defined groups of neurons in the local brain circuit using different color fluorescent sensors. Using this system, we are able to simultaneously record glutamatergic inputs and postsynaptic responses in individual striatal pathways using the green glutamate sensor iGluSnFR and the red calcium sensor jR-GECO1a. We are also able to simultaneously record the presynaptic dopaminergic axon terminal activity and the corresponding postsynaptic responses in each pathway using the green calcium sensor GCaMP6f and jR-GECO1a.

Title: Exploration - exploitation at the cellular level

Authors: R. LINDROOS[1], *J. HELLGREN KOTALESKI[2];
[1]Dept. Neurosci., Karolinska Institutet, Stockholm, Sweden; [2]Kungliga Tekniska Hogskolan, S-10044 Stockholm, Sweden

Abstract: The dorsolateral striatum is involved in motor learning and habit formation. During learning the principal cells of striatum, the medium spiny neurons (MSN), attain a stereotypical firing pattern — as the variability of the output is reduced the performance is increased. Dopamine has been proposed to play an active role in regulating this type of learning. However, little is known about how this regulation could take place at the single cell level. We here use computational modeling to investigate the dopaminergic modulation of signal integration in the MSN, specifically comparing signals that are spatially clustered with randomly dispersed input. The assumption is that structurally similar inputs form clusters that are strengthened through learning to generate a deterministic output, while noise or randomly dispersed inputs provide variability to the output. Our simulations predict that clustered inputs give the largest somatic response if triggered in the middle of the dendritic tree, where the axial resistance and the input resistance are balanced. At this point the input can trigger an NMDA spike that is not attenuated too much as it propagates to the soma. When comparing the somatic response resulting from either spatially clustered or randomly dispersed input we see the same type of pattern. The clustered input is more efficient than dispersed in the middle of the dendritic tree while the opposite is true for the more distal parts. In the proximal dendrites no significant difference between the two types of inputs is seen. Finally when repeating the same type of stimulation with concurrent dopamine modulation we see that the relative optimal distance is changed. Under the previously mentioned assumptions our simulations support the idea that dopamine is responsible for regulating the exploration/exploitation balance and provides a plausible mechanism for how this can be regulated at the single cell level.

Title: Nociceptin/orphanin FQ and dopamine receptors co-localization in the mouse basal ganglia

Authors: *D. MERCATELLI[1], A. RIMESSI[2], P. BOLOGNESI[3], A. CIPPITELLI[4], B. L. KIEFFER[5], L. TOLL[4], M. MORARI[3];
[1]Dept. of Med. Sciences, Section of Pharmacol., [2]Dept. of Morphology Surgery and Exptl. Med., [3]Dept. of Med. Sci., Univ. of Ferrara, Ferrara, Italy; [4]Torrey Pines Inst. for Mol. Studies, Port St Lucie, FL; [5]McGill University, Douglas Res. Ctr. and Inst. de Génétique et de Biologie Moléculaire et Cellulaire, Univ. de Strasbourg, Montreal and Illkirch, QC, Canada

Abstract: Nociceptin /Orphanin FQ (N/OFQ) and dopamine (DA) interact to regulate motor function through the basal ganglia in vivo. A functional interaction between signaling downstream of the N/OFQ opioid peptide (NOP) receptor and the DA receptors has also been detected in striatal slices. To investigate whether these interactions reflect co-localization of NOP and DA receptors in the basal ganglia, we performed immunohistochemistry (IHC) in striatum, substantia nigra pars compacta (SNc) and reticulata (SNr), and globus pallidus (GP). Due to the lack of validated antibodies for the NOP receptor, we used mice expressing the NOP receptor tagged with eGFP (NOP-eGFP mice; Ozawa et al, *J Neurosci* 35:11682-93, 2014). This study was performed under either basal or NOP activation conditions, to investigate whether NOP receptor activation affects D1 or D2 subcellular localization.
NOP-eGFP mice showed a moderate but consistent (~20%) NOP-D1 membrane co-localization in different portions (dorsal, central and ventral) of the striatum. Conversely, a clear segregation of NOP and D1 receptors was found in SNc (lack of D1 staining) and SNr (lack of NOP staining). Also in GP no NOP receptor signal was observed. In mice treated with the NOP agonist SR-16835, the extent of NOP-D1 receptor co-localization was unaffected in dorsal and central striatum while it was abolished in ventral striatum. To circumvent the failure of directly staining D2 receptors with different commercial IHC antibodies, we attempted to indirectly localize striatal D2 receptors using adenosine A_{2A} receptor antibodies, since A_{2A} receptors selectively localize on the membranes of striato-pallidal medium-sized spiny neurons (MSNs) where they dimerize with D2 receptors. NOP receptors did not localize with striatal A_{2A}-positive neurons in any striatal regions analyzed.
These data indicate that a significant proportion of striatal D1 and NOP receptors co-localize on the membranes of MSNs. This provides a morphological basis to the functionally negative interaction between NOP and D1 receptors observed in striatal MSNs, which might subserve the antidyskinetic action of NOP receptor agonists in a rat model of levodopa-induced dyskinesia (Marti et al, *J Neurosci* 36:16106-19, 2012). NOP-eGFP mice might thus represent a valuable tool to investigate NOP-DA receptors interaction and help shed light on the mechanisms through which N/OFQ regulates motor function in physio-pathological conditions.

Title: Striosome-dendron bouquet formations: a unique striatonigral circuit connection engaging dopamine-containing neurons and their ventrally extending dendrites

Authors: *J. R. CRITTENDEN[1], M. H. RIAD[2], P. W. TILLBERG[2], Y. SHIMA[3], D. E. HOUSMAN[2], S. B. NELSON[3], E. S. BOYDEN[2], A. M. GRAYBIEL[2];
[1]McGovern Inst. for Brain Research, Brain & Cognitive Sci., [2]MIT, Cambridge, MA; [3]Brandeis Univ., Waltham, MA

Abstract: Neurons of striosomes are considered to be the main source of dorsal striatal input to the dopamine-containing neurons of the substantia nigra pars compacta (SNc), both via direct projections to dopamine-containing nigral neurons, and via indirect projections through a pallido-lateral habenula circuit. This striatonigral system is known to target the ventral SNc, and evidence suggests that such ventral dopamine-containing neurons are among SNc neurons projecting back to striosomes. Thus the classic nigro-striato-nigral loop is at least in part based on the striosomal system. This possibility is of great interest, because striosomes are in a position to modulate and transmit signals to the SNc from limbic regions of the neocortex known to be dysregulated in mood disorders in humans. Here, we describe the discovery of an unusual form of synaptic connectivity between striosomal axons and bundled ventrally extending dopamine-containing SNc dendrites entwined and collected together in bouquet-like formations within the substantia nigra. Identifying these striosome-dendron formations was enabled by exploiting new tool-sets. First, we capitalized on our prior discovery of two members of the Ras/Rap signaling cascade that have complementary preferential expression in striosomes (CalDAG-GEFII) and matrix (CalDAG-GEFI) to detect striatonigral inputs in BAC transgenic mice with green fluorescent protein reporters for these genes (Kawasaki et al., 1998, *PNAS*; Gong et al., 2003, *Nature*; Crittenden et al., 2009, *PNAS*). Second, we used an additional, highly specific striosome-reporter mouse line (PiggyBac line P172-mCitrine; Shima et al., 2016, *Elife*) to confirm

striosome targeting of the dendron bouquet formations. Third, we used optimized expansion microscopy (proExM; Tillberg et al., 2016, submitted) to resolve striosomal terminal axons and their dopamine-containing targets with a resolution of 100 nm, along with synaptic markers related to specific types of neurotransmission. With ProExM imaging, we examined inhibitory, excitatory and neuromodulatory synaptic connections within the striosome-dendron plexus formations. We suggest that these dendron bouquet formations are integrative units relating striosomal signals to signaling by glutamate, GABA and acetylcholine for potential control of specific subclusters of nigral dopamine-containing neurons. These results could be critical to understanding nigro-striato-nigral loop function and the human disorders to which dysfunctions of the dopamine system have been related.

Title: Striatal cholinergic interneurons: their depletion and its progression

Authors: *N. ABUDUKEYOUMU[1], M. GARCIA-MUNOZ[1], O. P. JAIDAR[1,2], G. ARBUTHNOTT[1];
[1]Brain Mechanism for Behaviour Unit, Okinawa Inst. of Sci. and Technol., Okinawa, Japan;
[2]Dept. of Neurosurg., Stanford Univ., Palo Alto, CA

Abstract: Even before the discovery that Parkinson's was produced by the loss of dopaminergic neurons, this neurological disease was treated with anticholinergic drugs. A balance between cholinergic and dopaminergic activity in striatum is not only important in PD but for the normal function of the nucleus (i.e., behavior, reward, memory and cognitive functions). An important source of striatal acetylcholine (Ach) comes from giant and sparsely distributed cholinergic interneurons (ChI). However, their study has been hampered by a concentration of only 1-3 % of the whole striatal cell population. We performed a stereological systematic random sampling of striatal tissue from 21 days old C57BL/6J male mice. To selectively deplete ChI we performed a stereotaxic injection of saporin ribosome inactivating immunotoxin that targets choline acetyltransferase (0.3µl). Following survival periods of 2, 4 or 6 weeks, animals were sacrificed

and brain sections immunostained against ChAT to identify ChI, or against vesicular acetylcholine transporter (vAChT) to identify synaptic boutons. For each of the three survival periods, we counted and compared the number of ChIs between the intact and the lesioned hemispheres and the change in the number of vesicular acetylcholine transporters (vAChT). Compared to striatal sections from naïve controls and sham injections, we observed a decrease in ChIs according to each survival period of 24.4% (week 2, n=9), 33.74% (week 4, n= 11) and 19.89% (week 6, n=10). In contrast, we observed a percent increase in vAChT positive boutons of 42.3, 21.6 and 28.3% for each of the respective survival periods (n=9, n=11 and n=10). We are investigating whether the increase in vAChT positive terminals is due to an indirect upregulation produced by compensatory axonal sprouting from surviving ChI, or from afferent axonal terminal fields of cholinergic mesopontine neurons.

Title: Striatal cholinergic interneuron firing evokes spontaneous synaptic activation of muscarinic receptors

Authors: *A. MAMALIGAS[1,2], C. P. FORD[3];
[2]Neurosci., [3]Physiol. and Biophysics, [1]Case Western Reserve Univ., Cleveland, OH

Abstract: Temporally patterned cholinergic interneuron (ChI) activity is critical for striatal movement and motivated behaviors. The pacemaker activity and broad axonal arborizations of ChIs have been thought to create a background tone of acetylcholine that tonically activates muscarinic receptors on medium spiny neurons (MSNs), the main output neuron of the striatum. Despite the importance of acetylcholine at these synapses, it remains unclear how postsynaptic cholinergic receptors on MSNs directly encode the firing patterns of ChIs in the striatum. To examine this, we used viral overexpression of G-protein activated inwardly rectifying potassium (GIRK2) channels, which efficiently couple to endogenous $G_{i/o}$ coupled receptors, to readout muscarinic receptor activation on MSNs in response to ChI firing. Using a combination of optogenetics and paired recordings between ChIs and MSNs, we found that muscarinic receptors

could encode spontaneous monosynaptic acetylcholine release from the firing of individual ChIs. The resulting inhibitory post-synaptic currents (IPSCs) in GIRK2 expressing MSNs were transient and phasic in nature due to the efficient enzymatic activity of striatal acetylcholinesterase. We found that, despite the synaptic convergence of multiple ChIs on a given MSN, the efficient degradation of acetylcholine allowed for distinct phasic activation of postsynaptic receptors. Our results also show that in native systems not overexpressing GIRK channels, ChI firing was able to decrease collateral GABA release between pairs of direct pathway MSNs as a result of transient muscarinic receptor signaling within 500 ms. The high probability of release and large number of release sites at the ChI-MSN synapse allowed muscarinic receptors to entrain the physiological firing patterns of individual ChIs without failure. Our results show that muscarinic receptors on striatal output neurons respond to ChI firing such that they consistently encode the activity patterns of ChIs.

Title: Effect of striatal membrane cholesterol removal and replenishment on the dopamine transporter

Authors: *T. P. DIPAOLO[1,2], N. MORIN[1], M. MORISSETTE[1];
[1]Ctr. de Recherche de CHUQ-CHUL, Quebec, QC, Canada; [2]Laval University, Fac. of Pharm., Quebec City, QC, Canada

Abstract: The dopamine transporter (DAT) is abundant in the striatum where it reaccumulates dopamine (DA) molecules into presynaptic nerve terminals. It is the target of drugs of abuse such as cocaine and amphetamine that inhibit the reuptake of DA. It is also the target of antidepressants. There is a loss of DAT associated with the loss of DA neurons in Parkinson disease. The lack of DAT leads to less controlled release of L-DOPA replacement therapy that is implicated in L-Dopa-induced dyskinesias. Membrane cholesterol was previously shown to modulate the outward facing conformation of the DAT and a cholesterol binding site was observed in the crystal structure of the *drosophila* DAT. The present study investigated the effect of cholesterol removal and replenishment *in vitro* in rat total striatal homogenates. DAT protein

levels measures by Western blot showed no change with *in vitro* incubation in all experiments where cholesterol was removed from the membranes with methyl-beta-cyclodextrin (MbetaCD) incubations (1 hour) as well as in *in vitro* incubations (1 hour) to increase membrane cholesterol content. By contrast, significant changes of specific binding to the DAT in the striatum were measured with the radioligand 3-(4-[^{125}I] iodophenyl) tropane-2-carboxylic acid isopropyl ester ([^{125}I]-RTI-121). Non-specific binding was evaluated with binding in the presence of 100 nM of mazindol. A dose-response decrease of striatal [^{125}I]-RTI-121 specific binding was measured with increasing concentrations of MbetaCD (a decrease of 35-50% with 5mM MbetaCD) while the opposite was measured with cholesterol loading (increase of 43% with 1mM cholesterol). Moreover, [^{125}I]-RTI-121 specific binding of striatal membranes depleted of cholesterol with MbetaCD could be restored to their initial DAT content with addition of cholesterol showing the rapid and reversible effect of cholesterol manipulation on DAT binding. Moderate doses of MbetaCD to modulate DAT specific binding maintained the affinity of dopamine for the DAT as measured with dopamine competition for [^{125}I]-RTI-121 specific binding (Ki=5.4 microM in control homogenate). By contrast other striatal dopamine binding sites such as the dopamine receptors 1 and 2 as well as the monoamine vesicular transporter 1 showed no or limited changes by cholesterol manipulations. These results suggest that cholesterol has an important effect on the DAT and this could be taken into consideration for optimization of drug therapies.

Title: Novel glycinergic circuitry in the basal ganglia

Authors: *R. A. PEREZ, R. ORTEGA, Y. P. HUIZAR, E. CASTANEDA, M. MIRANDA; Bio-Science, Univ. of Texas At El Paso, El Paso, TX

Abstract: The basal ganglia controls somatosensory perception, motor movement, emotions, and certain types of memory. Dopaminergic projections stemming from the substantia nigra pars compacta and reticulate (SNc and SNr, respectively) innervate the striatum to modulate GABAergic neuronal activity through activation of dopamine receptors. This study seeks to dissect out the cell type and precise location of glycine transporter 1 (GlyT-1) immunoreactivity in the basal ganglia. The presence of the GlyT-1 transporter has been documented in glial cells; however, recent immune-histochemical studies suggest the presence of this transporter in neuronal cells. Our initial findings using a retrograde tracer (Fluoro-Gold) injected into the Globus pallidus (GP) suggests the existence of several glycinergic nuclei in subcortical regions of the basal ganglia, including the midbrain. Confocal microscopy analysis of GlyT1 immunoreactivity suggests co-localization with several neuronal markers, including NeuN and Map2, in flouro-gold positive cells, consistent with the idea that GlyT-1 is present in neurons. To support our hypothesis, adeno-viral particles delivered into the midbrain, expressing mCherry under control of a neuronal promoter demonstrate reporter expression in GlyT-1 positive cells. Altogether this data confirms the presence of GlyT-1 in neurons in the midbrain that project to the GP, probably contributing to the regulation of activation of neurons in the striatum.

Title: Local action of 17beta-estradiol increases phasic dopamine release in the dorsal striatum.

Authors: *W. SHAMS, M.-P. COSSETTE, P. SHIZGAL, W. G. BRAKE;
Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Studies using *in vivo* microdialysis provide evidence that 17β-estradiol (E2) increases dopamine (DA) transmission in the dorsal striatum (Becker, 1990; Xiao & Becker, 1994; Becker & Rudick, 1999). For example, both systemic administration of E2 and local infusion into the dorsal striatum rapidly enhance amphetamine-induced DA release (Becker, 1990; Castner, Xiao

& Becker, 1993; Becker & Rudick, 1999). However, it is not known to what degree these effects reflect tonic and/or phasic DA release. In urethane-anaesthetized (1.5mL/kg) female rats, we used fast-scan cyclic voltammetry (FSCV) to study the effects of E2 on phasic, electrically-evoked release of DA in the dorsal striatum. Rats were ovariectomized and implanted with a silastic tube containing 5% E2 in cholesterol, previously shown to mimic low physiological serum concentrations of 18-32 pg/ml. Dopamine release was evoked every 1 min by delivering electrical stimulation to the substantia nigra (500ms trains of biphasic, 2ms pulses, 200 – 400 μA, 60Hz). Local infusions of E2 (244.8 pg/µl) in the vicinity of the dorsal striatal FSCV probe increased the amplitude of the electrically evoked DA transients, thus demonstrating that E2 action in the dorsal striatum specifically enhanced phasic DA release *in vivo*.

Title: Effect of reduction in GABA function using a modified diphtheria toxin on behavior in mice

Authors: S. CALDWELL[1,2], D. KNOWLAND[1], J. DESLAURIERS[1,2], *S. B. POWELL[1,2], X. ZHOU[1,2];
[1]Univ. of California San Diego, La Jolla, CA; [2]San Diego VA Healthcare Syst., La Jolla, CA

Abstract: Decreased GABA function is a characteristic of schizophrenia and other neuropsychiatric disorders. Thus, being able to target GABA neurons specifically, producing a chronic state of decreased GABA function, will be critical to our understanding of the consequences of this reduced function. Diphtheria toxin which inhibits protein translation and causes apoptosis of cells can be used in an attenuated form to target GABA neurons. The current studies used a modified DTA-YFP fusion protein mutated for reduced toxicity, which inhibits protein translation but is not sufficiently toxic to kill cells, and examined changes in behavior. Specifically, we used an attenuated form of diphtheria toxin A (DTA), DTA tox-176. We generated a YFP-DTA tox-176 fusion protein to further decrease the DTA toxicity. We then

inserted the fusion gene, floxed by double lox-p sites, into an AAV vector which gets expressed in the presence of cre-recombinase and confirmed expression of the control AAV-YFP in striatum of Dlx6a-Cre mice (Cre expression in GABAergic neurons). GAD67 and dopamine D2 receptor expression were measured in striatum via immunohistochemistry to confirm the effects of the modified DTA. In behavioral experiments, AAV-DTA-YFP or AAV-YFP control were infused bilaterally into the dorsal striatum of Dlx6a-cre mice. After 6-8 weeks, mice were tested in locomotor activity, prepulse inhibition of startle, and spontaneous alternation in a t-maze. To probe function of the glutamate system in these mice, locomotor activity was also measured in open field after injection of 50 mg/kg ketamine hydrochloride. Mice infused with DTA tox-176-YFP in the striatum exhibited locomotor hyperactivity in an open field, increased prepulse inhibition of startle, and decreased spatial working memory. Ketamine increased distance traveled in both the control AAV5 Floxed EYFP and in the DTA tox-176-YFP infused mice. Disrupting GABA function by targeting GABA interneurons with DTA in striatum directly affected behavior of mice. Ketamine, which acutely blocks the NMDA receptor and facilitates glutamate release did not have an effect on the distance traveled of mice infused with DTA tox-176-YFP.

Title: Critical role of striatal d2r signaling in the psychomotor effects of cocaine

Authors: *D. RADL, G. KHARKWAL, R. LEWIS, E. BORRELLI, 92617;
Microbiology and Mol. Genet., Univ. of California Irvine, Irvine, CA

Abstract: The intake of drugs of abuse generates a strong elevation of dopamine (DA) levels (Di Chiara and Imperato, 1988) in brain areas that belong to the limbic system (Di Chiara et al., 2004, Hyman et al., 2006) . DA signaling is thus believed to play a central role in the mechanisms underlying the behavioral effects of drugs of abuse in the central nervous system

(Vallone et al., 2000). The psychomotor effects of cocaine strongly depend on the activation of the major striatal output neurons, the medium spiny neurons (MSNs). In particular MSNs expressing DA D1 receptors (D1R) appear responsible for these effects. Indeed, mice lacking D1Rs fail to respond to cocaine (Xu et al., 1994). Nevertheless, the constitutive ablation of the DA D2 receptor (D2R) in mice also prevents the motor stimulating effects induced by cocaine (Welter et al., 2007). Since D2Rs have a wide and abundant distribution in the brain, it is yet unclear what are the mechanisms responsible for this phenotype. The recent generation of cell-specific D2R mutants allowed addressing the question. For this, we analyzed and compared the behavioral response to cocaine of wild type (WT) versus constitutive D2RKO, MSN-D2RKO and DA-D2RKO mice. MSN-D2RKO and DA-D2RKO are lines in which the specific ablation of D2R has been achieved in MSN, and in mesencephalic DA neurons, respectively. The effect of increasing concentration of cocaine was tested in acute in animals of all genotypes habituated to a novel home cage for 2 h. We hypothesized that since MSN neurons are the only output neurons of the striatum, D2R in these cells is important for the locomotor response to cocaine and other drugs of abuse. Indeed, we observed that MSN-D2RKO mice do not respond to cocaine at any of the dose tested. On the contrary, DA-D2RKO mice respond with an increase of motor activity as WT littermates. We conclude that the absence of D2R specifically in MSNs is responsible for the blunted response to cocaine observed previously in D2RKO mice. Further analyses will be aimed at exploring the molecular mechanisms underlying the phenotype of MSN-D2RKO mice.

Title: GABAergic input to the globus pallidus externus (Gpe) is depressed by activation of dopamine D4 receptors.

Authors: I. CONDE-ROJAS[1], R. CABALLERO-FLORAN[1], J. ACEVES[1], D. ERLIJ[2], *G. B. FLORAN[1];
[1]CINVESTAV IPN, Mexico DF, Mexico; [2]State Univ. of New York, New York, NY

Abstract: Two major GABAergic afferents modulate the activity of the GPe. One group are the projections from medium spiny striatal neurons the other are the recurrent pallido-pallidal fibers that are collaterals of pallido-striatal fibers. In whole cell patch studies we have confirmed that the evoked inhibitory currents (eIPSCs) produced by release of GABA elicited by electrically stimulating striato-pallidal projections is inhibited by activation of D2Rs. In addition we found that quinpirole depresses the rate of discharge, but not the amplitude, of TTX sensitive GABAergic spontaneous currents (sIPSCs) in GPe neurons. This spontaneous activity has been generally identified as caused by transmitter release by recurrent collateral fibers of pallido-striatal neurons. The quinpirole effect is blocked by L 745,870 a selective D4R antagonist indicating that the response is mediated by D4Rs. In current clamp experiments we found that quinpirole reduces the frequency of spontaneous spiking rate of GPe neurons. This effect is blocked by D4R antagonist L 745,870. Determinations of quinpirole inhibition of [^{3}H] GABA release in K^{+}-depolarized slices show two components; one that is blocked by L 745,870 the other that is not affected by this antagonist. Our findings indicate that sIPSC rate of firing is depressed by activation of D4Rs.

Title: Evidence for cross-hemispheric preconditioning in experimental Parkinson's disease

Authors: *R. K. LEAK, J. N. WEILNAU, N. NOURAEI, D. F. HUTCHISON, K. M. MINER, M. A. CARCELLA;
Pharmacol., Duquesne Univ., Pittsburgh, PA

Abstract: Parkinson’s disease often emerges unilaterally, with motor deficits eventually appearing on the contralateral side only after a considerable delay. It is well established that exposure to mild, subtoxic stress can prepare cells or organisms to survive subsequent toxic

challenges, a phenomenon known as preconditioning, tolerance, or stress adaptation. For example, preconditioning the hindlimbs with a mild ischemic episode has been shown to protect the heart and brain against a second ischemic hit. This type of ischemic stress tolerance acquired at a distant site is termed remote preconditioning, but has not been examined in Parkinson's disease. Given the asymmetrical nature of Parkinson's deficits, we hypothesized that unilateral striatal infusions of the oxidative toxicant 6-hydroxydopamine (6-OHDA) would remotely precondition the contralateral nigrostriatal pathway against the toxicity of a second 6-OHDA infusion in the opposite hemisphere. Consistent with the principles of remote preconditioning, 6-OHDA infusions in one mouse striatum completely abolished loss of the dopaminergic terminal marker tyrosine hydroxylase (TH) in response to a second 6-OHDA infusion in the contralateral striatum. TH^+ cell bodies in the contralateral substantia nigra were also robustly protected against the second 6-OHDA hit, demonstrating complete preconditioning of the entire nigrostriatal pathway in the opposite hemisphere. The results of the cylinder test for forelimb asymmetry were consistent with these histological observations. 6-OHDA infusions increased activation of the phosphokinase ERK2 and expression levels of the antioxidant enzyme CuZn superoxide dismutase (SOD1) in the striata of both hemispheres. In contrast, the phosphokinase ERK1 was only activated on the side ipsilateral to the first 6-OHDA hit. 6-OHDA failed to impact the striatal expression of Mn superoxide dismutase (SOD2), the protein DJ1, the phosphokinase Akt, the growth-associated protein GAP43 (axonal outgrowth marker), or the D1 and D2 dopamine receptors. These findings support the existence of cross-hemispheric preconditioning in experimental Parkinson's disease. Unlike in most preconditioning studies, the preconditioning stimulus was not mild or subtoxic, suggesting that even severely toxic stress can enhance endogenous defenses in the remaining cells. If these results generalize to humans, Parkinson's pathology may progress more slowly on the side opposite to the initial deficits because the contralateral hemisphere is better prepared to combat injury after exposure to the disease-precipitating stressor

Title: Influence of aversive stimulation on haloperidol-induced catalepsy in rats

Authors: *A. R. OLIVEIRA[1,2], N. C. B. BARROCA[2,3], M. D. GUARDA[1], N. T. SILVA[1], A. COLOMBO[2,4], A. E. REIMER[2,3,5], M. L. BRANDÃO[2,3];
[1]Dept. de Psicologia, Univ. Federal do Rio de Janeiro, Rio de Janeiro, Brazil; [5]Dept. of Psychiatry, Harvard Med. Sch., Boston, MA

Abstract: Catalepsy is characterized by varying degrees of muscle rigidity resulting in an immobile state in which the subject is not able to change externally imposed postures. This condition can be observed in patients treated with haloperidol, a dopamine D2 antagonist widely used in schizophrenia. The pattern of the rigidity of haloperidol-induced catalepsy in rats is very similar to that observed in Parkinson's disease (PD); so this condition makes the haloperidol-induced catalepsy a potential animal model to PD motor impairments. PD seems to have many of its symptoms dependent on emotional state, for example, some immobile patients are able to make quick movements after hearing the cry "fire". On the other hand, anxiety disorders are common in PD. Therefore, it is possible that central mechanisms that regulate emotional and cataleptic states interplay. In this direction, a study suggested that interference in the neural substrates of the inferior colliculus - a midbrain structure involved in auditory and aversive processing and linked to structures of the motor system - can influence haloperidol-induced catalepsy. In addition, in a previous study, we showed that haloperidol reduced alarm calls emission and enhanced freezing response of rats re-exposed to a conditioned aversive context. Now, the current work aims to evaluate the influence of aversive events on the duration of haloperidol-induced catalepsy. For this, male Wistar rats were subjected to tests of catalepsy 15, 30, 45, 60, and 75 min after intraperitoneal administration of haloperidol or saline. To test the influence of aversive states on catalepsy, 30 min after treatment, distinct groups were exposed to open field (OF), elevated plus maze (EPM), confinement in an open arm of EPM, inescapable footshocks, contextual conditioned fear, or remained in the home-cage. Haloperidol-induced catalepsy was verified in all drug-treated animals, regardless their exposure to the aversive situations. Exposure to OF and EPM did not change haloperidol-induced catalepsy, compared to home-cage groups. Confinement to open arm of the EPM, footshocks and conditioned fear increased haloperidol-induced catalepsy 45, 60 and 75 min after drug administration in relation to the same group at 30 min time point. An interesting finding was that exposure to fear conditioning experiment increased haloperidol-induced catalepsy after 75 min compared to the group not exposed at the same time point. Our findings suggest that different threats, that presumably recruit partially distinct defensive circuitry, can influence differently the cataleptic state caused by haloperidol.

Title: Regulation of striatal circuit function by fast-spiking interneurons.

Authors: *S. F. OWEN[1], J. D. BERKE[2], A. C. KREITZER[1];
[1]Gladstone Inst. of Neurolog. Dis., San Francisco, CA; [2]Univ. of Michigan, Ann Arbor, MI

Abstract: The striatum is the primary input nucleus of the basal ganglia, a set of sub-cortical nuclei that are essential for motor planning and action selection. Parvalbumin-expressing fast-spiking interneurons (FSIs) in the dorsal striatum have been linked to decision making during goal-directed behavior, while defects in striatal FSIs have been associated with movement disorders including tics and dyskinesias. Acute slice recordings have demonstrated that FSIs form powerful inhibitory synapses onto Spiny Projection Neurons (SPNs), the principal neurons in the striatum, but cross-correlograms computed from chronic recordings have failed to uncover any clear evidence for this inhibition in vivo. This apparent contradiction raises questions regarding exactly how FSIs influence the striatal network in vivo. Using a combination of acute slice physiology, in vivo physiology, behavioral assays and imaging approaches we are investigating the role of FSIs in striatal physiology and behavior. Surprisingly, in contrast to previous studies using less specific pharmacological interventions, our genetically targeted manipulations of striatal FSIs caused no observable deficit in gross motor behavior. Interfering with striatal FSI function does, however, impair performance on more cognitively demanding basal ganglia-dependent tasks.

Abstract: The striatum contributes to many cognitive processes and disorders, but its cell types are incompletely characterized. We show that microfluidic or FACS-based single-cell RNA sequencing of mouse striatum provides a well-resolved classification of striatal cell type diversity. Transcriptome analysis revealed 10 differentiated distinct cell types, including neurons, astrocytes, oligodendrocytes, ependymal, immune, and vascular cells, and enabled the discovery of numerous novel marker genes. Furthermore, we identified novel medium spiny neuron (MSN) subtypes with specific markers, many of which are linked to cognitive disorders and addiction. We also describe continuous cellular identities, which increase heterogeneity within discrete cell types. Finally, we identified cell type specific transcription and splicing factors that shape cellular identities by regulating splicing and expression patterns. Our findings suggest that functional diversity within a complex tissue arises from a small number of discrete cell types, which exist in a continuous spectrum of functional states.

Title: Modeling mechanisms underlying K-ATP mediated bursting in medial SNc dopaminergic neurons.

Authors: *C. J. KNOWLTON[1], J. ROEPER[2], C. C. CANAVIER[1];
[1]Cell Biol. and Anat., LSUHSC, New Orleans, LA; [2]Inst. of Neurophysiol., Goethe Univ. Frankfurt, Frankfurt, Germany

Abstract: We use a computational model of a dopamine neuron to explain how agonists of ATP-sensitive potassium (K-ATP) channels gate bursting selectively in medial substantial nigra (mSN) dopamine neuron and what factors may contribute to the sustained generation of rhythmic bursts as opposed to phasic bursts. Phasic bursts in midbrain dopamine neurons were previously thought to provide homogeneously reward-related signals. Recently, bursts in different subpopulations have been suggested to encode distinct signals. Specifically, bursts mediated by K-ATP channels in medial, but not lateral, substantia nigra (SN) dopamine neurons are thought to signal novelty (Schiemann et al 2012). The same study showed that only calbindin positive (CB+) neurons exhibit a sustained, rhythmic form of burst firing *in vivo*. Dopamine neurons *in vitro* fire in a regular, single spike firing, pacemaking pattern. Our computational model seeks to account for an *in vitro* model of K-ATP mediated bursting in which bath application of an NN414 K-ATP selective channel opener decreases the firing rate, and that of NMDA increases the firing rate, but the co-application of these drugs induced a bursty firing pattern with an even faster average firing rate. Our previous model assumed that the K-ATP channel was activated by the ADP/ATP ratio, which depended upon the cytosolic Ca^{2+} concentration with a delay (introduced by a first order differential equation). NN414 was assumed to increase the sensitivity of the K-ATP channel to the point that the faster spiking evoked by NMDA was periodically silenced, resulting in rhythmic bursting. We have extended these results to show that decreasing the Ca^{2+} buffering, as might be expected in CB- neurons, decreased the burst regularity. Moreover, we developed a new model that includes an explicit dependence on [ADP]. Pump activity converts ATP to ADP driving [ADP] accumulation, which decays exponentially due to ADP uptake. The rate of ADP uptake in the model controls the propensity to burst, providing a possible explanation for why this type of bursting occurs only in the medial and not the lateral SN despite similar levels of K-ATP conductance in both populations.

Title: Striatal neurons show aberrant firing in levodopa-induced dyskinesia.

Authors: *M. RYAN[1], A. B. NELSON[2];
[2]Neurol., [1]UC San Francisco, San Francisco, CA

Abstract: As the target of both dopaminergic projections and sensorimotor cortical inputs, the striatum is hypothesized to be a major site of normal motor control and a primary site of pathological activity in Parkinson's Disease. Long-term dopamine replacement therapy is often complicated by the development of abnormal involuntary movements, known as levodopa-induced dyskinesia (LID). The cellular mechanisms underlying LID are unknown, but dopamine-driven aberrant striatal firing is a prevailing hypothesis. The standard model of basal ganglia function posits that the two main cell types in the striatum, the direct and indirect pathway neurons, have opposing responses to dopamine, and this leads to opposing changes in activity in parkinsonism. Reciprocal changes would be predicted in LID, as well. However, these hypotheses have not been tested directly in an animal model of parkinsonism, as labeling these cell types in vivo has proven challenging. In this study we recorded optically identified striatal direct and indirect pathway units before and after levodopa administration in awake, behaving hemi-parkinsonian mice. We found that baseline firing rates in the parkinsonian condition were lower in direct pathway compared to indirect pathway neurons, in line with the standard model of basal ganglia function. In addition, direct pathway neurons increased firing while indirect pathway neurons decreased firing following administration of levodopa, also supporting the standard model. Unit responses to levodopa in both direct and indirect pathway neurons could be sub-classified into those tracking therapeutic (prokinetic) and those tracking pathological (dyskinetic) behaviors. While changes in rate in both pathways correlate with dyskinesia, we hypothesized that increased direct pathway activity was responsible for dyskinesia. To test this hypothesis, we optogenetically stimulated direct pathway neurons in the dorsolateral striatum in vivo. In both normal and parkinsonian animals such stimulation was sufficient to trigger dyskinesia in the absence of levodopa. These results support many tenets of the standard model, and also provide evidence for the hypothesized role of aberrant striatal firing in dyskinesia.

Furthermore, they may point to an opportunity to manipulate the sub-populations of neurons which track dyskinetic behavior to improve treatment for LID and other hyperkinetic disorders.

Abstract: The basal ganglia are a group of interconnected subcortical nuclei that participate in the control of movement, mood, cognition, and reward processing, and whose dysfunction is linked to movement disorders like Parkinson's Disease. A common side effect of chronic dopamine replacement therapy in Parkinson's Disease is the development of levodopa-induced dyskinesia (LID), in which levodopa triggers abnormal involuntary movements at therapeutic doses**.** While extensive clinical research has characterized LID, the cellular and circuit mechanisms underlying this condition are still unknown. In rodent models of LID, increased expression of immediate early genes, like c-Fos, has been observed in several brain areas, suggesting these regions may develop aberrant activity in the context of dyskinesia. One hypothesis is that aberrant activity generated within the striatum, the primary input nucleus of the basal ganglia, causes LID. This abnormal neuronal signaling may start in the striatum, propagate through the basal ganglia circuit, ultimately leading to involuntary movements. We have sought to test the hypothesis that aberrant striatal activity, as opposed to activity in other brain regions, causes LID. To test our hypothesis, we utilized a novel transgenic mouse tool, Targeted Recombination in Activated Populations (TRAP), which uses activation of c-Fos to gain permanent genetic access to previously activated populations in vivo. In hemiparkinsonian mice, we combined TRAP with optogenetics, behavior, and in vivo and in vitro electrophysiological

recordings to test our hypothesis that aberrant striatal activity causes dyskinesia. Our data demonstrate that c-Fos expression increases in several key regions brain-wide during dyskinesia, including the somatosensory cortex and striatum, and activated neurons can be captured using TRAP. We found that dyskinesia-associated striatal neurons are more likely to be direct pathway neurons. In addition, optogenetic reactivation of TRAPed neurons in the striatum, and not in somatosensory cortex, is sufficient to produce dyskinesia in the absence of levodopa. Optogenetic inhibition of striatal TRAPed neurons reduces levodopa-induced dyskinesia during a dyskinetic attack. Together, these findings support the hypothesis that aberrant activity in the striatum causes levodopa-induced dyskinesia.

Title: Striatal microcircuit mechanisms for the expression of habit

Authors: *J. O'HARE[1,2], K. ADE[2,1], E. GAIDIS[3], H. LI[3], N. KIM[3], H. YIN[3], N. CALAKOS[2,1]; [1]Neurobio., [2]Neurol., Duke Univ. Med. Ctr., Durham, NC; [3]Psychology & Neurosci., Duke Univ., Durham, NC

Abstract: Habits are automated motor programs that can be initiated by environmental cues. This stimulus-response style of behavior is adaptive because it liberates attentional and

computational resources that would otherwise be needed to evaluate an action-outcome relationship. Good habits can make healthy behaviors feel routine. On the other hand, maladaptive compulsions such as drug abuse are hypothesized to share mechanistic features with habit. Therefore, a mechanistic understanding of habit formation is doubly important for its role in health and disease. The dorsolateral striatum (DLS) is required for habit formation and this brain region changes significantly with habit formation. Previously, we reported that habitual lever pressing in mice corresponds with strengthened striatal output to both the direct and indirect pathways as well as a timing bias shift where direct pathway striatal projection neurons (SPNs) fire before indirect pathway SPNs in DLS. Here we examine local microcircuit mechanisms for these effects. We employ two-photon calcium imaging of SPN populations and cellular electrophysiological recordings in naïve and operantly trained mice. Using pharmacological, optogenetic, and chemogenetic approaches, we find that the activity of one class of interneuron in DLS, the parvalbumin-positive fast-spiking interneuron, is sufficient to reproduce striatal circuit features of habit and is necessary for the expression of habitual behavior. These findings reveal a microcircuit mechanism for habit and suggest new strategies for targeting the striatal circuitry to modulate habitual and compulsive behaviors.

Title: Spike time predictability and noise sensitivity in repetitively firing striatal spiny neurons

Authors: *C. J. WILSON;
Univ. Texas San Antonio, San Antonio, TX

Abstract: An adequate model for any neuron should predict its firing times in response to any input pattern. We previously found that the interspike intervals of a repetitively firing subthalamic nucleus neuron stimulated using current noise could be predicted with high accuracy using a phase model. The phase model was created from a phase resetting curve measured for the same neuron. We have applied a similar approach to prediction of the spike timing of repetitively firing spiny striatal neurons, but this time during stimulation by sine wave currents. Repetitive

firing was maintained in spiny neurons by passage of suprathreshold (250-400 pA) constant currents. Small (20-80 pA peak-to-peak sinusoidal intracellular currents with frequencies from 0.5-40 Hz were superimposed on the constant depolarization. A phase model based on the phase resetting curves measured from the same neuron was integrated to predict the phase of spiking relative to the stimulation current at steady state.The predictability of spike timing was limited by the cell's intrinsic current noise. The influence of the noise in turn depended on the frequency of the sinusoidal stimulus relative to the cell's unperturbed firing rate. For stimulus frequencies close to the neuron's firing rate, firing was phase-locked to the stimulus. In this case the model accurately predicted the phase of firing on each cycle of the stimulus and the changes in phase as stimulus frequency was varied. In this range, the variance of interspike intervals decreased to well below that during unperturbed firing, indicating a reduced sensitivity to the cell's intrinsic noise. Firing was also highly predictable at other frequencies near those commensurate with the cell's unperturbed firing rate. Interspersed with the ranges of predictable firing there were frequencies at which the model predicted a reliable sequence of firing phases, but the cell showed increased spike time variability, indicating a stimulus-induced enhancement of sensitivity to intrinsic noise.The frequencies at which these changes in noise sensitivity occurred were predicted by analysis of the iterative map of the phase of firing predicted by the model. An analysis of the map can explain the changes in spike time predictability and noise sensitivity of spike timing on a cell-by-cell basis. Funded by NIH/NINDS.

Title: Calcium-activated chloride currents regulate spiking in striatal LTS interneurons by generating medium AHPs

Authors: *S. C. SONG[1], J. A. BEATTY[2], C. J. WILSON[1];
[1]Biol., Univ. of Texas At San Antonio, San Antonio, TX; [2]Physiol., Michigan State Univ., East Lancing, MI

Abstract: Striatal interneurons exhibit unique electrophysiological characteristics. Two neurons, the cholinergic interneuron and the low-threshold spike (LTS) interneuron are autonomously

active in slice. We have previously found that LTS interneurons possess a membrane oscillation and membrane resonance that is generated by the combination of L-, N-type calcium channels and calcium-activated chloride channels (CaCCs). These phenomenon were observed under tetrodotoxin to remove action potentials. We wanted to investigate the contribution of CaCCs to the firing properties of LTS interneurons. In our experiments, we used perforated-patch recordings in mice that expressed GFP under the control of the NPY promoter. This allowed for identified recording of LTS interneurons in striatal slices. Both current clamp and voltage clamp recordings were used to measure effects of blocking specific voltage-gated calcium channels and CaCCs. In voltage clamp, we found that the LTS interneuron expressed a mAHP following a spike that was blocked by niflumic acid, a blocker for CaCCs. This mAHP was not blocked by apamin to prevent SK currents, a classic source of mAHPs in various other neurons. The tail current was also unaffected by application of TRAM34, a specific blocker of IK currents. The mAHP was blocked by specific N-type calcium channel blocker ω-contoxin GVIA, showing calcium dependence, but not isradipine. We have previously shown that L- and N-type calcium channels could drive CaCC-dependent membrane oscillations in LTS interneurons. For the mAHP, the depolarization caused by the action potential could be sufficient for enough calcium to enter through the N-type calcium channel, which has a higher voltage range for activation than L-type calcium channels. Finally the mAHP reversed between -60 and -70 mV, indicative of a chloride current and not potassium. The reversal potential as not affected by changes in the external potassium concentration. In current clamp, blockade of the mAHP increased the CV of the interspike interval, which reflects previous findings which showed that mAHPs make spike timing more regular. Blockade of specific calcium channels narrowed the individual spikes while blockade of CaCCs broaden individual spikes. We also investigated whether the membrane resonance mechanism caused the spiking resonance in LTS interneurons. We found that specific calcium channel blockers had no effect on the spiking resonance while blockade of CaCCs increased the strength and frequency selectivity of the spiking resonance in LTS interneurons.

Title: Unexpected diversity of striatal Drd2-expressing neurons revealed by cell-type specific mRNA profiling

Authors: *E. PUIGHERMANAL[1], M. MARTIN[1], J. VITRE[1], A. ESTEVE[2], M. GUT[2], E. VALJENT[1];
[1]Inst. of Functional Genomics (CNRS-INSERM-UM), Montpellier Cedex 5, France; [2]CNAG-CRG, Ctr. for Genomic Regulation (CRG), Barcelona Inst. of Sci. and Technol. (BIST), Univ. Pompeu Fabra (UPF), Barcelona, Spain

Abstract: The striatum, the primary input structure of the basal ganglia, is broadly implicated in motor action and reward-based behaviors, as well as in neurological and psychiatric disorders. Compelling evidence indicate a functional dichotomy between the dorsal striatum and the nucleus accumbens since they receive different afferents and project to distinct brain structures. However, the diversity of molecular markers between these two subregions remains largely unknown. By crossing Ribotag with Drd2-Cre mice, we isolated the mRNAs bound to tagged-ribosomes selectively from striatopallidal cells and cholinergic interneurons in both dorsal striatum and nucleus accumbens. Remarkably, high-throughput RNA sequencing of Drd2-containing neurons revealed almost 6000 genes differentially regulated between these two brain subregions. *In situ hybridization* and immunofluorescence analyses confirmed the vast majority of the differentially expressed genes and showed a diverse topographic distribution within the striatum, suggesting an unsuspected diversity of striatopallidal neurons. The sensitivity of this approach also allowed the identification of novel markers for cholinergic interneurons. Interestingly, Gene Ontology analysis unraveled distinct biological processes, cellular components, and molecular functions of Drd2-expressing neurons depending on their regional pattern. In-depth analysis and classification of differentially expressed genes also revealed a high degree of segregation. Altogether, the present findings indicate that there is a vast diversity of Drd2-containing neuronal subpopulations depending on the striatal subregion where they are located. Future studies will be necessary to determine whether some of the genes differentially regulated define new striatopallidal neuronal ensembles associated with projection-specificity and/or functional properties.

Title: Evidence of synchronous and asynchronous activity between left and right striatum in both direct and indirect paths during goal oriented behaviors in mice

Authors: *R. M. MIKOFSKY[1], J. M. LAWSON[2], H. MACOMBER[2], S. CLARK[2], D. SULZER[2];
[1]Suzler Lab. At Columbia Univ., New York, NY; [2]Neurosci., Columbia Univ., New York, NY

Abstract: Striatal spiny projection neurons (SPNs) regulate movement through two major circuits. The direct pathway SPNs expressing D1 receptors (dSPNs) directly project to the substantia nigra pars reticulata (SNr) and globus pallidus externa (GPe). The indirect pathway SPNs expressing D2 receptors (iSPNs) trigger a multisynaptic circuit, synapsing to the globus pallidus interna (GPi), which then projects to the SNr /GPe. Activation of the direct and indirect paths correlates with enhanced locomotion in mice and dysfunction in both is implicated in the pathology of Parkinson's disease. To our knowledge, previous studies have not delineated the extent of synchronous activity between left and right striatum in the direct or indirect pathways during locomotion. We used time correlated single photon counting (TCSPC) (χ2- 202 ChiSquare Bioimaging), an optical recording method, to record neuronal activity in the direct and indirect paths in both the left and right dorsal lateral striatum. D1-Cre (direct path) and A2A-Cre (indirect path) mice were injected with AAV9 Flex GCaMP6f virus. Imaging fibers were implanted in both the right and left dorsal lateral striatum. Mice were recorded with a high speed video camera framelocked to the sampling rate of the TCSPC machine. This enables simultaneous recording from both the left and right dorsal lateral striatum at millisecond precision, allowing us to correlate locomotor behavior with GCaMP6f changes in fluorescence. Interestingly, in preliminary results we find evidence of both synchronous and asynchronous activity in amplitude and frequency of firing in dorsal lateral striata during goal oriented behaviors in mice.

Title: Mapping spatial connectivity between the subthalamic nucleus and substantia nigra in brain slices using optogenetic 'functional mapping'

Authors: *P. S. FREESTONE[1,2,3], K. L. TODD[1,2,3], J. LIPSKI[1,2,3];
[1]Univ. of Auckland, Auckland, New Zealand; [2]Ctr. for Brain Res., Auckland, New Zealand; [3]Brain Res. New Zealand, Auckland, New Zealand

Abstract: The basal ganglia is a sub-cortical network receiving a wide range of inputs from the entire brain. As such, this network is involved in motor control, learning, memory and reward-driven behaviour. The subthalamic nucleus (STN), a major glutamatergic nucleus of the basal ganglia projecting to the substantia nigra pars reticulata (SNr) and pars compacta (SNc) nuclei, plays a crucial role in the *indirect* and *hyperdirect* pathways. We have previously shown this nucleus to be important for modulating SNc dopaminergic activity via an endocannabinoid-mediated attenuation of inhibitory input from the SNr. In the present study, we studied the spatial relationship of the STN and SNr/SNc and the connections between them to better understand the interplay of these three nuclei in regulating basal ganglia function. CD-1 mice expressed channelrhodopsin (H134R) under the CaMKIIα promotor after injection of the viral (AAV5) construct into the STN. Neuronal activity was monitored using whole-cell patch-clamp electrophysiological recordings from horizontal ventral midbrain slices (250 μm) containing the STN, SNr and SNc after 4-8 weeks expression. 'Functional mapping' was conducted using a digital mirror device (*Polygon400*, MightEx) to sequentially illuminate squares (20-80 μm^2) of a grid (800 x 600 μm) in a pseudorandom fashion, while recording post-synaptic currents from a single neuron. Using this approach, we have shown that focal photo-stimulation (6 mW/mm^2, 5 ms) of individual neurons within the STN can evoke excitatory post-synaptic currents in downstream connected SNr neurons. These connections extended over 900 μm between the site of photo-stimulation and the recorded cell body, and the synaptic responses were completely blocked by bath application of ionotropic glutamate receptor blockers (5 μM CNQX and 10 μM MK-801). Focal photo-stimulation within the SNr revealed in some cases several discontinuous 'hot-spots' where excitatory synaptic transmission could be evoked. These hot-spots were located at the cell body and at locations >300 μm distal to the soma. These results confirm the

feasibility of mapping functional connections in ventral midbrain brain slices using optogenetic techniques, and reveal unique patterns of innervation from the STN to neurons in the SNr.

Title: Coordinated corticostriatal input produces supralinear calcium in dendritic spines in a spiny projection neuron model

Authors: *D. B. DORMAN, J. JEDRZEJEWSKA-SZMEK, K. T. BLACKWELL;
Krasnow Inst. for Advanced Study, George Mason Univ., Fairfax, VA

Abstract: Spiny projection neurons (SPNs) of the striatum, by integrating cortical, thalamic, and dopaminergic input, underlie goal-directed learning and habit formation. These neurons exhibit state transitions *in vivo* between a hyperpolarized down-state and a subthreshold depolarized up-state that is driven by spontaneous, asynchronous synaptic activity. This activity produces elevations in calcium that control synaptic plasticity when synaptic activity is coupled with back-propagating action potentials (bAP) for proximal synapses, but not distal synapses due to bAP decay. One experimental study (Plotkin et al., 2011) has shown that temporally aligned synaptic stimulation of ~11 adjacent spines on a distal (but not proximal) tertiary dendrite produces a regenerative up-state like plateau potential at the soma, which is dependent on NMDA and voltage-gated calcium channels. This suggests a potential mechanism for associative synaptic plasticity at distally located synapses. To investigate how various patterns of spatially and temporally distributed synaptic input interact and the degree of spine-specific calcium transients, we developed a biophysical, multi-compartment SPN model with a branching dendritic structure and explicitly modeled dendritic spines. Our model uniquely incorporates complex calcium dynamics including buffers, pumps, and diffusion. We tuned the model with experimental data including electrical response to injected current, calcium imaging of action potentials and synaptic inputs, and the generation of plateau potentials by closely aligned synaptic stimulation of distal dendritic spines. Simulation experiments reveal a supralinear calcium elevation in

spines active during a plateau potential when stimulating distal spines on a single tertiary dendritic branch, whereas non-stimulated, neighboring spines exhibit a significantly lower calcium elevation. When stimulating clusters of distal spines on neighboring branches, we find a reduction in the number of spines per branch required to evoke a plateau potential, indicating a small interaction between neighboring branches. When neighboring branches are stimulated with a delay, the spine calcium elevation of the second branch is greater than that of the first branch. Overall our results show that spine calcium exhibits spine specificity and the spine calcium response is sensitive to the temporal order of branch stimulation. As calcium is critical to downstream signaling pathways required for plasticity, these results suggest a mechanism for calcium mediated associative plasticity between either coordinated or sequential synaptic inputs to SPNs of the striatum.

Title: Calcium based plasticity rule can predict plasticity direction for a variety of stimulation paradigms.

Authors: *J. JEDRZEJEWSKA-SZMEK[1], D. B. DORMAN[1], K. T. BLACKWELL[2];
[1]The Krasnow Inst. For Advanced Study, [2]The Krasnow Inst. for Advanced Study, George Mason Univ., Fairfax, VA

Abstract: The striatum is a major site of learning and memory formation for both sequence learning and habit formation. One of the mechanisms used by the brain for memory storage is synaptic plasticity -- the long-lasting, activity dependent change in synaptic strength. All forms of synaptic plasticity require an elevation in intracellular calcium, though which characteristics of calcium dynamics actually control plasticity are still not completely understood. Our previous research demonstrated that both the amplitude and duration of the calcium transients are required to determine the direction of synaptic plasticity for spike timing dependent plasticity. In this research we extend our previous model spiny projection neuron, with sophisticated calcium

dynamics including calcium diffusion, buffering, and pump extrusion, to include AMPAR desensitization in order to evaluate frequency dependent plasticity paradigms. To further test our two amplitude and duration rule for synaptic plasticity, we use a moderate frequency stimulation of 20 Hz, which has been shown experimentally to elicit LTD, and a theta burst stimulation paradigm (4 pulses at 50 Hz repeated at a theta frequency of 10.5 Hz), which has been shown experimentally to elicit LTP. Our simulations show that, despite the different calcium patterns elicited by frequency dependent stimulation patterns, the same calcium-based weight change rule (plasticity rule) that correctly predicts spike timing dependent plasticity also can explain the change in synaptic weights for these frequency dependent plasticity paradigms. We further show that LTP elicited by the theta burst stimulation paradigm is NMDA receptor dependent and LTD elicited by 20 Hz is independent of L-type calcium channels activation, which is consistent with experimental data. We also investigate the role of dopamine by evaluating synaptic plasticity of direct and indirect pathway spiny projection neurons, both in control conditions and dopamine depleted conditions. Illuminating the role of calcium and dopamine, and their interactions in synaptic plasticity, will allow for better understanding mechanisms of memory storage in health and disease.

Title: Neuronal diversity in substantia nigra pars reticulata delineates specialized basal ganglia output pathways

Authors: *L. E. MCELVAIN[1,2,3], B. LIM[2], D. KLEINFELD[1], R. COSTA[3];
[1]Physics, [2]Neurobio., UCSD, La Jolla, CA; [3]Champalimaud Neurosci. Programme, Lisbon, Portugal

Abstract: The basal ganglia play a central role in motor control, but the circuit mechanisms that mediate their effect on the broader motor system remain poorly understood. We interrogated the largest basal ganglia output, the substantia nigra pars reticulata (SNr), to delineate the organization of basal ganglia efferent signaling. Viral tracing methods were combined with electrophysiological recordings to define the unique projection populations in SNr and their downstream targets in the brainstem and thalamus. Anterograde AAV tracing in mice from GABAergic and parvalbumin-positive SNr neurons revealed major projections to the superior colliculus; the inferior colliculus; the midbrain, pontine, and medullary reticular formations; the pedunculopontine nucleus; the dorsal raphe; and the VM, VA, MD, and Pf thalamic nuclei. To determine whether these regions receive inputs from segregated or overlapping SNr populations, we retrogradely labeled SNr neurons projecting to each structure and assayed their intrinsic electrophysiological properties in vitro. All SNr projection neurons shared several intrinsic features, i.e., spontaneous firing, sustained fast-firing (> 50 Hz) capabilities, and linear firing rate responses to depolarizing currents. However, SNr subpopulations that projected to brainstem regions exhibited specialized intrinsic characteristics and differed significantly from each other in properties that included hyperpolarization-gated currents, firing rate ranges, and passive membrane properties. Brainstem-projecting SNr neurons were topographically organized and, in some cases, morphologically distinct. In contrast, thalamus-projecting SNr neurons exhibited heterogeneous electrophysiological and morphological properties and were distributed throughout the nucleus. In a final set of experiments, intersectional virus strategies mapped the axonal collateralizations from SNr neurons to determine whether their projections to thalamus arose from brainstem-projecting SNr neurons. Our experiments delineate specialized populations of SNr projection neurons and demonstrate their specific and extensive collateralization projection patterns. Further, our experiments establish a framework for future investigations to link individual SNr subpopulations to their motor functions.

Abstract: Parkinson's disease (PD) is characterized by progressive loss of the dopaminergic neurons of the substantia nigra pars compacta. In primates rendered parkinsonian by treatment with the neurotoxin MPTP, parkinsonism is associated with abnormally increased and patterned inhibitory outflow from sensorimotor portion of the internal segment of the globus pallidus (GPi) to the thalamus, targeting preferentially the centromedian nucleus (CM) and the parvocellular part of the ventral anterior nucleus (VApc). While these nuclei receive axon collaterals from the same GPi neurons (Parent and De Bellefeuille, 1983, Brain Res. 278:11), our previous ultrastructural study showed surprising differences in the morphology and pattern of synaptic connectivity of GPi terminals in these nuclei (Sidibe et al.,1997, JCN 382:323). The goal of this study is to compare the ultrastructural features of GPi terminals in VApc and CM of normal and MPTP-treated parkinsonian monkeys, using high resolution electron microscopy (EM) and 3D reconstructed models of individual anterogradely labeled pallidothalamic terminals. Preliminary EM data from an MPTP-treated monkey that received an injection of an adeno-associated viral (AAV5) vector which expressed green florescent protein (GFP) in the GPi show that ~50% GPi terminals in VApc contact mostly medium-sized (0.5-1.0 μm in diameter) dendrites, while ~30% target large (> 1.0 μm diameter) dendrites. In the CM, ~65% of the labeled GPi terminals contacted large dendrites. Ultrastructural observations from single ultrathin sections are consistent with results of our previous study (Sidibe et al., 197, JCN 382:323) such that GPi terminals in VApc are larger in size, have a different morphology, and form more symmetric synapses than those in CM. Additional AAV5 injections in the GPi of normal rhesus monkeys will be performed to complete this analysis. Three dimensional reconstructions of single GPi terminals are in process to further quantify these morphometric characteristics across nuclei and animal groups. Based on data from pallidal terminals in the subthalamic nucleus (Fan et al., 2012, JNS 32:13718) and from multisynaptic GABAergic terminals (ie GPi-like) from the anterior pretectal nucleus in the thalamus (Wanaverbecq et al., 2008, JNS 28:11848), we hypothesize that potential morphological differences and plastic changes of the ultrastructural features of GPi terminals in VApc and CM are linked to their physiological properties.

Title: Morphological study of calbindin-positive and calbindin-negative dopamine neurons located in the substantia nigra pars compacta

Authors: *M. ZHU, R. EVANS, Z. KHALIQ;
NINDS, NIH, Bethesda, MD

Abstract: Dopamine neurons of the substantia nigra pars compacta (SNc) can be divided into cell groups that either express or lack expression of calbindin. In Parkinson's disease, calbindin-negative dopamine neurons of the SNc are vulnerable to degeneration while calbindin-positive dopamine neurons tend to be spared. Therefore, examining the morphological characteristics may help explain why these two subpopulations are differentially vulnerable to degeneration. We analyzed the morphology of 33 calbindin-positive and 47 calbindin-negative SNc dopamine neurons. Dopamine neurons were filled with a red morphological dye, Alexa-594, and high-resolution Z-stack images were taken with a two-photon microscope. Cells were then reconstructed using a semi-automated software and the morphological characteristics were extracted. Relative to calbindin-positive dopamine neurons, we found that calbindin-negative dopamine neurons had larger somas (Calb-neg vs Calb-pos, 26.5 ± 0.64 μm vs 23.1 ± 0.92 μm) and more total dendritic bifurcations (5.08 ± 0.55 vs 2.85 ± 0.4). Using sholl analysis, we examine the amount of dendritic length in relation to the distance from the soma. While the distal (>100um from soma) dendritic lengths were not significantly different between the two subpopulations, calbindin-negative neurons had significantly more proximal (10-100um from soma) dendritic length (527 ± 36.6 μm vs 389 ± 30 μm) due to a larger number of proximal bifurcations. In conclusion, calbindin-positive and calbindin-negative dopamine neurons of the SNc are morphologically unique and these differences may contribute to differences in electrophysiological properties and integration of synaptic inputs between the two subpopulations.

Title: AMP kinase regulates ligand-gated K-ATP channels in substantia nigra compacta dopamine neurons

Authors: *S. W. JOHNSON[1,2], Y. WU[2], A. C. MUNHALL[1], K.-Z. SHEN[2];
[1]Dept Neurol, Portland VA Med. Ctr., Portland, OR; [2]Neurol., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: AMPK is a master enzyme that regulates expression of K-ATP channels in pancreatic beta-cells and cardiac myocytes. K-ATP channels are also expressed in the SNC where they strongly inhibit neuronal activity. However, an AMPK K-ATP interaction in the SNC is unknown. Patch-clamp recordings were used to investigate effects of AMPK on K-ATP currents evoked by diazoxide in SNC dopamine neurons in slices of rat midbrain. In the presence of the AMPK activator A769662, diazoxide current increased 372% when measured 60 min after starting whole-cell recording. But unexpectedly, we found that diazoxide currents also increased over time when pipettes did not contain A769662; although currents increased 200% over control, this was significantly less than the increase observed when A769662 was present ($P < 0.001$). Moreover, superfusing the slice with the AMPK blocking agent dorsomorphin (Compound C) significantly reduced diazoxide current to 38% of control, whether or not A769662 was present. Current-voltage plots showed that the increase in diazoxide current was associated with an increase in whole-cell conductance with a reversal potential near that expected for K+. Control experiments showed that outward currents evoked by the K-ATP channel opener NN-414 also increased over time, but not currents evoked by the GABA-B agonist baclofen. Delaying the application of diazoxide after starting whole-cell recording correlated with augmentation of current, suggesting that the increase in diazoxide current was associated with dialysis of intracellular contents. Diazoxide produced small but significant slowing of spontaneous firing rate using loose-patch recordings. However, superfusion with A769662 significantly augmented the inhibitory effect of diazoxide on firing rate, suggesting that AMPK activation mimics the potentiation of ligand-gated K-ATP current that is seen with whole-cell recording. We conclude that K-ATP channel function is augmented by AMPK, which

is activated during the process of making whole-cell recordings. By potentiating the inhibitory effect of K-ATP channels in SNC neurons, AMPK could significantly alter many dopamine-dependent behaviors and conditions.

Title: Comparison of high-frequency firing mechanisms in mesocortical,mesoaccumbal and mesostriatal dopamine neurons

Authors: *R. A. TARFA[1,2], Z. KHALIQ[3];
[1]NIH, Bethesda, MD; [2]Neurosci., Brown Univ., Providence, RI; [3]NIH/NINDS, Bethesda, MD

Abstract: Midbrain dopamine neurons function in brain circuits mediating reward signaling, motivation, aversion and movement. Because dopamine-dependent circuits vary widely in their function, it is possible that dopamine neurons also display functional heterogeneity. Consistent with this idea, prefrontal cortex projecting dopamine neurons display high firing frequency rates compared to the nucleus accumbens and striatum projecting dopamine neurons (Lammel et al., 2008). However, the mechanism that mediate the differences in firing rates between the subpopulations remain to be elucidated.
We examined spontaneous and high-frequency firing in retrogradely-labeled mesocortical, mesoaccumbal and mesostriatal dopaminergic neurons. As compared to mesostriatal neurons, mesocortical dopamine neurons fired at slightly higher spontaneous rates (MC vs MS: 3.7 ± 0.6 Hz vs 2.4 ± 0.1 Hz, p= 0.003), had significantly narrower action potential widths, shorter spike peaks and more hyperpolarized threshold voltages. Moreover, mesocortical neurons fired at substantially higher maximal firing rates (MC vs MS: 26.8 ± 3.2 Hz vs 11.5 ± 0.6 Hz, p= 0.02). One possible contribution to the difference in high frequency firing among the subpopulations is the difference in the impulse-regulating dopamine (D2) autoreceptors, which is present in mesostriatal dopamine neurons and may slow their firing, but absent in mesocortical dopamine neurons. However, in the presence of sulpiride and Ba^{2+}, to block D2-receptors and G-protein coupled inward rectifying potassium currents (GIRKs), we found that the difference in maximal firing frequencies of both subpopulations was preserved.
Past work has shown that the large-conductance calcium-activated (BK) and delayed rectifier (K_v2) potassium currents are major contributors to spike repolarization in substantia nigra

compacta (SNc) dopamine neurons, however the currents that shape repolarization in mesocortical dopamine neurons remain unknown. Following the block of BK and K_v2 currents, our preliminary experiments demonstrate the presence of a remaining TEA sensitive current in both SNc (4.0 ± 1.1 nA) and VTA (2.3 ± 0.7 nA) dopamine neurons. In response to 1mM TEA, 35.2% of the remaining outward current was blocked in VTA dopamine neurons, and 34.78% in SNc dopamine neurons. We hypothesize that the faster repolarization rates in mesocortical neurons may be as a result of a higher density of fast, high threshold (K_v3) potassium currents, that facilitate their high-frequency firing. We plan to test the contribution of all three potassium currents to action potential repolarization in the mesocortical and mesostriatal subpopulations.

Title: Time-course of cortical motor preparation during self-paced reaches

Authors: *A. J. ZIMNIK[1], A. H. LARA[1], G. F. ELSAYED[1], J. P. CUNNINGHAM[2,5], M. M. CHURCHLAND[1,2,3,4];
[1]Dept. of Neurosci., [2]Grossman Ctr. for the Statistics of Mind, [3]David Mahoney Ctr. for Brain and Behavior Res., [4]Kavli Inst. for Brain Sci., Columbia Univ. Med. Ctr., New York City, NY; [5]Dept. of Statistics, Columbia Univ., New York City, NY

Abstract: Voluntary movements are believed to be prepared prior to execution. While reaction times (RTs) for visually-guided reaches are typically 300-350 ms, RTs could in principle be ~150 ms given physiological delays. The 'extra' 150-200 ms has been attributed to sluggish preparatory processes (e.g., Riehle and Requin 1993; Churchland et al., 2006). Yet other behavioral experiments argue that preparation can be rapid, completing within 50 ms (Haith et al., 2016). Our recent physiological experiments support this assertion: when reaching under extreme time pressure, preparatory activity leads movement-related activity by only ~30 ms. Conversely, both delayed-reach and decision paradigms reveal that preparation can span 1000 ms or more. This range in preparatory activity durations raises the question: what is the typical time course of preparatory activity before a 'normal', self-paced movement? Is preparation a naturally brief process, becoming extended only when artificially required by laboratory tasks? Or does preparation naturally consume ~150-200 ms as initially proposed? We analyzed the activity of 222 neurons recorded from motor and premotor cortex of monkeys performing a delayed-reach task. We focused on the self-paced return movements made after each trial was complete. These movements returned the hand to the center of the screen, were not time-locked to any particular cue, and involved little time pressure. We leveraged a recent method that separates the population response into preparatory and movement-related components by exploiting their occupancy in orthogonal subspaces (Elsayed et al., submitted). We confirmed that preparatory and movement subspaces (inferred from the outgoing-reach neural data) continued to capture preparatory and movement-related activity for return reaches. We then tracked the time course of preparatory activity. Preparatory activity disappeared by the onset of the outgoing reach, but reappeared before return reaches. The patterns of preparatory activity preceding return and outward reaches made in a common direction were similar (Monkey B: $rho = 0.75$, Monkey A: $rho = 0.79$, $p < 0.01$, *both*). The reappearance of preparatory activity occurred well after the hand became stationary on the target, and began 150-200 ms prior to the onset of the movement-related activity. This time course is briefer than observed with an imposed delay but much longer than observed under time pressure. Thus, while the minimum time needed to prepare may be 30 ms, the 'natural' time course of neural motor preparation is 150-200 ms, matching prior estimates from behavioral data.

Title: Changes in motor cortex population structure between movement types

Authors: *A. A. RUSSO, B. LONDON, S. PERKINS, M. CHURCHLAND;
Columbia Univ., New York, NY

Abstract: Even a single limb can perform many movement types: throwing a ball, brushing one's teeth, executing a push-up. To investigate the neural basis of switching between movement types, we employed a novel task where monkeys navigate a virtual environment using a hand pedal to cycle for a variety of prescribed distances. Visual cues instruct the monkey to pedal 'forward' (moving away from the body at the top) or 'backward' (the reverse). We reasoned that the motor system must use very different dynamics (internal and feedback) during forward versus backward pedaling. Yet the two directions exhibit mirrored kinematic patterns. Given this, different hypotheses regarding motor cortex function make different predictions. If activity codes kinematics (e.g., velocity), the population response during forward and backward pedaling should be similar but reversed. If activity codes muscle commands, responses should change in parallel with muscle activity. Finally, if motor cortex participates in dynamics that generate muscle activity, the population response should additionally reflect network-level strategies necessary to switch dynamics. To explore these hypotheses we recorded activity from motor and premotor cortex of two monkeys (112 and 108 neurons) and EMG from the major arm muscles (36 and 22 recordings).
Single neurons exhibited striking differences between forward and backward pedaling. Many such differences paralleled those seen in the muscles: profound changes in the 'preferred direction', the depth of modulation, and the temporal response pattern. Indeed, EMG could be successfully decoded from neural activity, with reasonable generalization across directions (generalization R^2= 0.42 and 0.52). In contrast, fits to hand velocity failed to generalize (generalization R^2 was negative). These results support the hypothesis that responses relate to muscle commands, with incidental relationships to kinematics. Yet the neural population response differed from the muscle population response in at least two ways. First, forward and backward responses were separated in neural state space by distances larger than expected from the muscle state space. Second, forward and backward responses occurred in neural subspaces that overlapped less than the corresponding muscle subspaces. Both findings are consistent with a strategy where different dynamics for forward versus backward are achieved by employing

different regions of neural state space. Consistent with this interpretation, the evolution of the neural population was well fit by a single linear dynamical system (R^2 = 0.80 and 0.75) while the evolution of the muscle population was not (R^2 = 0.40 and 0.21).

Title: Comparison of the modulation of primary motor cortex by dorsal and ventral premotor areas in Cebus apella

Authors: *S. COTE[1], A. HAMADJIDA[1], M. DEA[1], S. QUESSY[1], N. DANCAUSE[1,2]; [1]Neurosciences Department, Univ. of Montreal, Montreal, QC, Canada; [2]Groupe de Recherche sur le Système Nerveux Central, Montreal, QC, Canada

Abstract: The primary motor cortex (M1) plays a crucial role in the control of forelimb movements in primates. The premotor areas of both hemispheres are highly interconnected with M1 and thereby contribute to its corticospinal outputs. Whereas some studies have examined the intrahemispheric influence of premotor areas on M1 outputs, little is known about the influence of premotor areas of the opposite hemisphere. In *Cebus apella*, we investigated the modulatory effects of contralateral dorsal and ventral premotor cortex (cPMd, cPMv) on M1 outputs using paired pulse protocols and compared them to those of ipsilateral PMd and PMv (iPMd, iPMv). After a bilateral craniotomy and durectomy, a conditioning electrode was placed in cPMd, cPMv, iPMd or iPMv to deliver a sub-threshold conditioning stimulus (C). A second electrode was placed in M1 to deliver a supra-threshold stimulus (T). The C and T stimuli were separated by 6 inter-stimulus intervals (ISIs; range: 0-20ms). To quantify the conditioning effects, motor evoked potentials (MEPs) were recorded in 8 forelimb muscles from 4 monkeys (cPMd-M1: n=41, cPMv-M1: n=44, iPMd-M1: n=41, iPMv-M1: n=42). Following cPMd conditioning, facilitation (62%) was more common than inhibition (38%). Facilitatory effects were similarly prevalent across tested ISIs while inhibitory effects were most prevalent with intermediate ISIs (5-10ms). Conversely, cPMv conditioning generated more interhemispheric inhibition (83%) than

facilitation (17%). Inhibitory effects were most prevalent with longer ISIs (15-20ms) and facilitatory effects with intermediate ISIs (5-10ms). In comparison, iPMd-M1 interactions were most often inhibitory (55%) while iPMv-M1 interactions were most often facilitatory (60%). The contrast between the modulatory effects produced by PMd and PMv suggest the existence of a complex premotor-motor dialogue that could reflect the different functions of premotor areas in the production of forelimb movements.

Title: Preparatory responses in primary motor and premotor cortex are conserved across self-initiated, quasi-automatic and cue-initiated movements

Authors: *A. H. LARA[1], G. F. ELSAYED[1], J. P. CUNNINGHAM[2], M. M. CHURCHLAND[1]; [1]Neurosci., [2]Statistics, Columbia Univ., New York, NY

Abstract: Neurons in primary and pre-motor cortex exhibit preparatory responses during delayed-reach tasks. Most real-world movements, however, are not preceded by a delay period. Movements may be initiated internally (e.g. when reaching for a cup of tea) or quasi-automatically in response to a sudden event (e.g. when catching a falling object). Whether preparatory processing exits in such real-world contexts remains unknown. We trained two

monkeys to make the same set of reaches in three initiation contexts: cue-initiated, self-initiated and quasi-automatic. In the cue-initiated context, a target was presented and a subsequent visual go cue indicated when to initiate the reach (as in the standard delayed-reach task). In the self-initiated context, the decision to move is made internally: waiting longer yielded larger rewards, creating a tradeoff between a small immediate reward and a larger deferred reward. In the quasi-automatic context, reaches had to intercept a rapidly moving target with no time for hesitation. Reach trajectories and patterns of muscle activity were nearly identical across contexts. We used a novel dimensionality reduction approach to isolate preparatory and movement-related processing at the level of the neural population. Leveraging the cue-initiated context, we identified a preparatory subspace and an orthogonal movement subspace of neural activity. We projected the population response for all contexts onto those subspaces. Responses in the movement subspace were nearly identical across contexts consistent with a unified cortical mechanism for producing movement regardless of why it was initiated. All three contexts also had activity in the preparatory subspace, supporting the hypothesis that preparation is an obligatory stage. However, there were marked differences in the timing of preparatory events. In the cue-initiated context, preparation was sustained throughout the delay. In the self-initiated context, preparation was deferred until shortly before movement onset. In the quasi-automatic context, preparation lasted only a few tens of milliseconds before movement-related activity began. Despite these differences, in all three contexts the same neural state was achieved in the preparatory subspace around 70 ms before movement onset (correlation of 0.91 and 0.99 for monkey A and B). We conclude that preparation always precedes the onset of neural dynamics that generate movement. However, the time course of preparation varies according to task demands, and can be remarkably rapid.

Title: Emergence of neural representations in premotor (M2) and primary motor (M1) cortices during early motor learning

Authors: *T. VEUTHEY[1], K. GANGULY[2,3];
[1]Ganguly Lab, UCSF, San Francisco, CA; [2]Dept. of Neurol., UCSF, San Francisco, CA; [3]Neurol. and Rehabil. Service, Veterans Affairs Med. Ctr., San Francisco, CA

Abstract: Introduction: Motor learning is a vital capacity impaired in a wide range of psychiatric and neurologic disorders. However, we still do not have a detailed neurophysiological and computational understanding of the neural circuits that enable motor learning. In rodents, recent work indicates that both primary motor and premotor cortex are necessary for learning skilled movements, and that patterns of activity stabilize in each region during skill learning. However, fundamental questions regarding the mechanisms of motor learning remain. Are new movements encoded at single neuron or population levels? Are representations of new movements selected from available movement variations, or do novel representations develop over time and practice? Do primary motor and premotor cortices contribute differentially to new movement learning?
Methods: We studied motor learning in rats learning a single-pellet reach-to-grasp task. We used in vivo electrophysiology methods to chronically record single-neuron spiking activity and aggregate local field potential (LFP) activity simultaneously from both primary motor (M1) and premotor (M2) cortices. We recorded neural signals from the very beginning of motor learning (< 30% reach success) through plateau performance (stable performance above 60% reach success).
Results: During the very earliest phase of motor learning when there was rapid behavioral improvement, single neurons in both M1 and M2 developed strong task-dependent modulation. Interestingly, the emergent patterns appeared to build upon existing patterns, albeit with weak modulation depths. Moreover, modulation of M1 neurons was more temporally precise than that of M2 neurons, potentially reflecting differential encoding of specific movements in M1 versus "planning" of the entire movement sequence in M2.
Conclusion: Our results suggest that single-neuron coding for new movements develops very early during learning and is further strengthened and refined with practice.

Title: Action planning and action observation in rodent parietal cortex

Authors: *T. TOMBAZ, B. A. DUNN, K. HOVDE, J. R. WHITLOCK;
Kavli Inst. for Systems Neurosci., NTNU, Trondheim, Norway

Abstract: Our brains continuously plan and execute goal-directed actions, and without any effort we are readily aware of the behavior and actions of others around us. There is a broad consensus that action planning takes place in the brain between parietal and frontal motor cortices, and that these same regions facilitate action understanding via "mirror" neurons, which are activated whether an action is performed or merely observed. The topic of mirror neurons has drawn both considerable excitement and debate over the last two decades and many fundamental questions remain unresolved, such as the biological basis of the mirror mechanism, the utility of mirror neurons, or the existence of mirror neurons in mammals other than primates. These issues stand to be resolved using lower model organisms, such as rodents, for which powerful tools exist to perform anatomical and functional dissections at the circuit level. To determine if mirror neurons exist outside of primates, we are currently conducting *in vivo* calcium imaging in parietal cortex of freely-behaving mice while they perform and observe various goal-directed motor behaviors. A major advantage of this approach is that typical datasets consist of 100-150 neurons imaged simultaneously, which allows us to compare the population coding of actions either when they are executed or observed. I will discuss preliminary results from single-cell and population-level analyses on imaging data collected during performance and observation of a pellet-reaching task.

Title: Endogenous motor errors in parietal area 5 but exogenous target errors in area 7 drive adaptation in reaching

Authors: *M. INOUE[1], S. KITAZAWA[1,2,3];
[1]Ctr. for Information and Neural Networks (CiNet), Natl. Inst. of Information and Communicatio, Suita-Shi, Japan; [2]Dynamic Brain Network Laboratory, Grad. Sch. of Frontier Biosci., [3]Dept. of Brain Physiology, Grad. Sch. of Med., Osaka Univ., Suita-Shi, Japan

Abstract: We have recently shown that motor cortical circuits (primary motor cortex and premotor cortex) encode information on end-point errors in reaching, and post-movement microstimulation to these regions caused trial-by-trial increases in errors. The study suggested

that motor cortical circuits provide error signals that drive trial-by-trial adaptation in reaching movement (Inoue et al., *Neuron*, 2016). On the other hand, human imaging studies to date have reported that reaching errors are encoded in parietal association areas as well. We thus aimed at testing whether the error signals in parietal regions are causally related to adaptation in reaching. To this end, we examined neuronal activities of parietal area 5 and 7 while two monkeys made rapid reaching movements toward a visual target that appeared at a random location on a tangent screen. We examined the relationship between neuronal discharges and 1) target position, and 2) visual errors by using information theory. About half of area 5 (59% for target positions and 43%for visual errors) and area 7 (72% for target positions and 49% for visual errors) neurons started to encode information on target positions and/or visual errors with a latency of 100 ms. We then delivered electrical microstimulation after the touch by using the same electrode (area 5: n = 24, area 7: n = 23). Repetitive pairing of reaching movements with microstimulation produced a gradual and significant increase of the endpoint error over 20-30 trials (area 5: 15/24, area 7: 10/23). After stimulation to the area 5, the error increased opposite to the preferred direction of visual errors. After stimulation to the area 7, by contrast, the error increased toward the preferred direction of target position. These results suggest that neurons in the area 5 provide error signals for adaptation to endogenous motor errors whereas those in the area 7 provide error signals for adapting to exogenous target errors.

Abstract: More than a century of research on the cortical motor system has led to the view that planning and executing even simple motor behaviors occurs across several regions of cortex, and

it is now appreciated that early stages of movement planning occur in posterior parietal cortex (PPC). Non-human primates have historically served as the premiere system for studying cortical motor physiology, and indeed the vast majority of our current understanding of PPC derives from head-fixed monkeys performing isolated saccadic movements and reaches. However, recent advances in recording techniques for rodents, such as *in vivo* calcium imaging using miniaturized microscopes, have made it possible to sample large-scale ensemble activity in cortex during unrestrained, natural behavior. Here, we imaged activity in 100-150 neurons at a time in superficial PPC while mice performed a variety of spontaneous behaviors, such as foraging for food, eating in place, running on a running wheel, and drinking from a waterspout, in an open arena. To capture the subtleties and recurring patterns in the animals' movements we employed a 9-camera high-speed tracking system to track the major joints, head and limbs of the animals. We are currently building unsupervised deep architectures for time series data to classify dynamic 3D pose and posture, as well as to capture transitions between movement states. Once the behavior is mapped we will test for single neuron and population correlates of ongoing and upcoming movements. By observing multiple spontaneous behaviors, each containing unique and overlapping 3D movements, we aim to shed light on how PPC activity generalizes to the complex and diverse activities of an average day "at home" for a mouse.

Title: Ensemble coding of self-motion in parieto-frontal circuits in rats

Authors: *B. MIMICA, B. A. DUNN, J. R. WHITLOCK;
Kavli Inst. for Systems Neurosci., NTNU, Trondheim, Norway

Abstract: Efficient traversals of environments are enabled by a synergy of interconnected brain structures, integrating information about the animals' past and desired future positions. The hippocampus and parahippocampal cortices code space in world-based coordinates, while posterior-parietal cortex (PPC) and premotor cortex (M2) code movement sequences in egocentric coordinate frames; the different frames of reference are combined such that

behavioural sequences can be synthesized to reach spatial goals. Recent work in freely behaving rodents has shown that PPC and M2 both exhibit robust prospective tuning properties in accordance with orienting movements up to and greater than 1 second in advance.. The aim of our current experiments is to characterize the respective contributions of PPC and M2 during the on-line synthesis of movements plans while rats forage for food crumbs in the open field arena. To do so we are conducting simultaneous single-unit recordings in PPC and M2 using silicone probes while tracking the animals' head and spine positions with a 6-camera, infrared 3D tracking system. Our ongoing recordings suggest that cells in both regions show similar types self-motion representation, and we are investigating the relative extent of prospective coding across areas (i.e. whether one area codes movements further ahead in time). In addition, to test whether the properties of prospective coding generalize across tasks, we are recording the same cells in a task where animals repeatedly switch between exploratory and goal-oriented modes of navigational behaviour. The goal of these experiments is to determine whether the temporal properties of action planning are hard-wired or change flexibly according to cognitive demand, and, if possible, to measure how quickly complex movement plans emerge once a goal is established.

Title: Predicting neural activity in behaviorally-irrelevant dimensions

Fndn., Stanford, CA; [11]Dept. of Electrical Engin., Stanford Univ., Stanford, CA

Abstract: The activity of millions of neurons in the motor cortex drives the contraction of hundreds of muscles. Because there are so many more neurons than muscles, a vast number of different population activity patterns would likely generate the same movement. The activity patterns that all lead to the same movement thus define a behaviorally-irrelevant space. How does the brain choose from among these behaviorally equivalent options?
We know that not all neural activity can be generated by the subject due to physiological constraints, such as limitations on minimum and maximum firing, and constraints due to connectivity among neurons. We consider three hypotheses of behaviorally-irrelevant activity, given these constraints. First, the activity may be "uncontrolled," and vary over the allowable range of network states. Second, the motor system may prefer activity patterns that minimize energy usage, in analogy to previous studies of muscle activity. Finally, rather than minimizing energy expenditure, activity in this space may still reflect task demands, despite being behaviorally-irrelevant.
To compare these hypotheses, we analyze data from a brain-computer interface (BCI) center-out task. In this task, Rhesus macaques controlled a computer cursor using their neural activity, recorded in the primary motor cortex using a Utah array. In contrast to traditional approaches (e.g., monitoring neural activity while a monkey performs arm reaches), in a BCI the mapping from neural activity to cursor movement is defined by the experimenter. This allows one to define precisely the set of neural activities that will result in the same cursor movement, i.e., the behaviorally-irrelevant space. Our aim is to assess how well the above hypotheses predict the monkey's selection of neural activity from this behaviorally-irrelevant space.
We find that predictions made by the uncontrolled and energy-minimizing hypotheses fail to match the observed data. Instead, behaviorally-irrelevant activity varies with both task demands and behavioral output. Assessing this activity in the context of two different mappings between neural activity and behavior provides an explanation for this observation: When a monkey learns a new mapping, he chooses from among the same patterns of neural activity that he generated under similar conditions in the previous mapping. Neural activity in the behaviorally-irrelevant space is thus a result of the monkey intervening minimally on the behavior he used in the previous mapping. This finding suggests that the way redundancy is resolved at the level of neural population activity may be different than the way it is resolved at the level of the muscles.

Title: Neuronal activity in the posterior parietal cortex encodes arm direction, not saccade direction, during bimanual reaching

Authors: *E. F. MOOSHAGIAN, L. H. SNYDER;
Neurosci., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: We often orient our gaze to the target of our reaches. Eye-hand coordination may depend in part on circuits in the posterior parietal cortex (PPC). Within the PPC, the spatial locations of saccade and reach goals are preferentially represented by the neurons in the lateral intraparietal area (LIP) and the parietal reach region (PRR), respectively. The stereotyped nature of unimanual coordinated eye-arm movements makes it difficult to dissect the role of these circuits in coordination. Primates, including humans, frequently coordinate two or more limbs at once. For example, we may pick up a pitcher with one hand and a glass with the other. Limb movements can occur more or less simultaneously, but our eyes are yoked together and can move to only one target at a time. As a result, we can move our limbs in parallel but we make eye movements in series, first to one target and then to another. This facilitates a novel means of investigating eye-hand coordination. We recorded neuronal activity in LIP and PRR while monkeys planned a simultaneous reach to two targets, with no constraints on eye movement. PRR neurons coded the direction of the contralateral arm movement irrespective of the direction of the saccade; there was no effect of the direction of the first saccade on PRR activity. Surprisingly, LIP neurons showed a very similar response. That is, LIP neurons did not code the direction of the saccade during the planning period, but instead coded the direction of the contralateral arm movement during bimanual reaches. Only as the saccade was actually executed was a small saccade-specific response seen in LIP. These results challenge a role for LIP in eye-hand coordination.

Title: Populations of mirror neurons capture similar sequences of hidden Markov states during execution and observation of a reach, grasp, and manipulate task

Authors: *K. A. MAZUREK, M. H. SCHIEBER;
Dept. of Neurol., Univ. of Rochester, Rochester, NY

Abstract: Mirror neurons (MNs) discharge during both the execution and observation of a movement. We applied Hidden Markov Models (HMM) to detect hidden states in populations, asking whether MNs represent behavioral states in addition to the movement.
Two Rhesus monkeys performed a task in which a visual cue instructed the monkey to reach to, grasp, and manipulate one of four target objects: a button, a sphere, a coaxial cylinder, or a perpendicular cylinder. After first performing multiple trials itself, the monkey observed an experimenter performing trials of the same task. Single- and multi-unit activity was recorded from microelectrode arrays implanted in primary motor cortex (M1) and ventral premotor cortex (PMv) during action execution (AE) and action observation (AO) trials.
A recorded unit was considered task related if its firing rate was significantly different after the visual cue as compared to a baseline period 0.5s before the cue. A unit was classified as a MN if it modulated significantly during both AE and AO. For the two monkeys, 16 and 9 MNs were identified, respectively. HMMs were trained using these MN populations to identify between 2 and 5 hidden states. The number of hidden states was selected based on the average HMM state probabilities and their consistency across trials. Although information about the timing of behavioral events—cue presentation, onset of movement, and final hold—was not provided to HMMs during training, the resulting hidden states showed transitions occurring near these behavioral events.
Across all trained HMMs, the baseline state probability fell near the cue presentation. A movement state increased in probability at times that correlated with the onset of movement. A final state transitioned from low to high probability during the final hold. These states were observed in both AE and AO trials, with the state transitions occurring similarly relative to the behavioral events in each trial. Neural activity from AE and AO trials was compared across objects during each type of hidden state to examine how the activity of each MN varied. The HMM state sequences trained on AO trials were similar to those trained on AE trials.

Our results indicate that MNs do not simply respond to the observation of actions. Rather, populations of MNs encode entire sequences of observed behavioral events.

Title: Neural correlates of motor skill learning in dorsal premotor cortex (PMd) reflect mainly predictive feedforward compensation rather than online error correction.

Authors: N. BHUTANI[1], *J. F. KALASKA[1], R. SHADMEHR[2], A. M. GREEN[1];
[1]Univ. De Montréal, Montréal, QC, Canada; [2]BME, Johns Hopkins Univ., Baltimore, MD

Abstract: As we practice a new motor skill, we learn by making errors. Error feedback signals help correct the movements in real time, and also guide incremental changes in the motor system to permit predictive improvements in performance in subsequent movements (Kawato & Gomi 1992; Thoroughman & Shadmehr 2000; Li et al. 2001; Padoa-Schioppa et al. 2004). However, the neural processes that lead to this transformation remain poorly understood. We recorded neural activity in the dorsal premotor cortex (PMd) of a Rhesus monkey (*Macaca mulatta*) during reaching movements made while holding onto a torquable robotic manipulandum. PMd neurons are implicated in the early preparatory activity for the movement (Crammond and Kalaska 1996, 2000; Padoa-Schioppa et al. 2004). Each neuron's preferred reach direction (PD) was identified while the monkey made unperturbed reaches in 8 directions in a visually-guided instructed-delay reach task. Each neuron was then studied while the monkey made movements in unpredictable clockwise (CW) and counterclockwise (CCW) velocity-dependent "curl" force fields that pushed on the monkey's arm perpendicular to the direction of movement. Most PMd neurons showed weak feedback-error responses to these unpredictable perturbations. To examine the contribution of PMd to predictive compensatory changes, the monkey was then re-trained each day in one curl field (CW or CCW) while reaching in a direction perpendicular to the neuron's PD. As the monkey learned to compensate for the force field, PMd neurons showed gradual response changes primarily during the delay period before movement onset, but showed

much less modification of their movement-related activity. This contrasted with many primary motor cortex (M1) neurons, which responded strongly at 100-250ms latencies to the unpredictable perturbations and whose predictive compensatory changes in activity during reaches in the predictable curl field were seen mainly during the peri-movement period after the end of the delay period. These findings suggest that PMd contributes mainly to predictive feedforward compensation for task dynamics and less to feedback-mediated error correction, whereas M1 is implicated in both real-time error feedback-mediated corrections for unpredicted perturbations and to feedforward compensation for predictable perturbations.

Title: More active neural dynamics during movement control in monkey dorsal premotor cortex compared to parietal reach region

Authors: *H. GUO[1], S. KUANG[1,2], A. GAIL[1,3,4];
[1]German Primate Ctr., Goettingen, Germany; [2]Inst. of Psychology, Chinese Acad. of Sci., Beijing, China; [3]Bernstein Ctr. for Computat. Neurosci., Goettingen, Germany; [4]Georg-August-Universität Göttingen, Goettingen, Germany

Abstract: The dorsal premotor cortex (PMd) and the parietal reach region (PRR) both belong to the frontoparietal reach network in monkeys and are involved in the planning and control of visually guided reach movements. A recent study showed that sustained motor goal encoding in PRR during movement planning predominantly reflects the physical rather than the visual goal of impending reaches conducted under reversed vision (1). Also, preliminary statistics on the numbers of motor-goal encoding neurons in area PMd compared to PRR suggested high similarity in both areas during the planning period of a movement. Yet, pre-selecting and grouping subsets of neurons based on their selectivity as function of spatial task parameters can mask single-neuron heterogeneity since neural response patterns might be partially driven by

internal network dynamics rather than external drive. Here we test if, despite the similarity of PMd and PRR during steady-state motor planning, both areas exhibit similar or different spatial encoding properties and neural dynamics during movement execution. Monkeys conducted memory-guided delayed center-out reaches under normal or reversed vision. First, we assessed the predominance of either physical or visual motor goal encoding in the population dynamics by computing a 'vector of selectivity' (VOS) in the high-dimensional state space of all neurons activity as a function of time. The VOS was defined as vector connecting the state space trajectories of right- and left-side cued trials separately in each viewing context (normal vs. reversed). Opposing VOS between the two viewing contexts, for example, indicate preferential encoding of physical rather than visual goals. During movement planning, PMd exhibited predominant physical goal encoding, but less predominantly than PRR. Second, in both areas physical goal encoding strongly predominated during the movement period. Finally, the neural dynamics during transition from reach planning to reach execution revealed larger dynamical changes in PMd compared to PRR. These state space dynamics suggest more compound encoding in PMd compared to PRR during motor planning, followed by richer intrinsic dynamics in the transition from planning to movement in PMd. We conclude that PMd during motor planning seems to exhibit more diversity in spatial encoding, i.e. less predominance of a single frame of reference, which then leads to larger dynamical changes from planning to movement, because physical goal representation dominate during reach execution in both areas. Title: Deactivation of PMd and A5 in non-human primates impairs feedback responses to mechanical disturbances of the limb.

Authors: *T. TAKEI[1], S. G. LOMBER[2], D. J. COOK[1], S. H. SCOTT[1];
[1]Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada; [2]Dept. of Psychology, Western Univ., London, ON, Canada

Abstract: Recent studies highlight that neural responses to mechanical disturbances of the limb are quickly transmitted throughout sensory and motor cortices in non-human primates. However, the causal relationship between the neural activities of these areas and the generation of the feedback response to the mechanical perturbations remain unclear. Here we investigated the contribution of dorsal premotor cortex (PMd) and parietal area 5 (A5) to feedback control of the upper limb by deactivating these areas with a reversible cortical cooling technique. We trained a male rhesus monkey to perform a unilateral arm postural control task. While the monkey maintained the finger tip in a circular target (0.8 cm radius), a mechanical step-torque perturbation was applied on his elbow and shoulder joints and the monkey was required to return to the target within 500 ms. During the task, we cooled PMd, A5 or both with chronically implanted probes (cryoloops). We quantified the speed ('return time') and accuracy ('endpoint error') of the corrective response before, during and after cooling. Results showed that the PMd cooling increased both of the return time and the endpoint error relative to the control condition (sham cooling). On the other hand, the A5 cooling increased the endpoint error, but did not change the return time. In addition, when we cooled the areas simultaneously, the cooling impaired both of the return time and the endpoint error and the effects were predictable by a linear summation of the individual cooling. These results indicated that these areas have unique contributions to the feedback control of voluntary limb movements.

Title: Local circuits in reshaping of motor cortex projection neurons during motor training

Authors: *D. C. CHAN[1], H. KO[3], Y. KE[2], W. YUNG[2];
[1]The Chinese Univ. of Hong Kong, Hong Kong, China; [2]Sch. of Biomed. Sci., The Chinese Univ. of Hong Kong, Hong Kong, Hong Kong; [3]Dept. of Med. and Therapeut., Li Ka Shing Inst. of Hlth. Sci., Hong Kong, Hong Kong

Abstract: The recruitment of primary motor cortical neurons in the formation of motor memory is not well understood. While extensive work has been done in literature regarding the intrinsic encoding of motor primitives such as limb kinematics as well as changes to ensemble dynamics in the learning of a novel motor task, the circuit mechanisms that mediate the conversion of individual primitive-encoding neurons to task-encoding neurons remain unclear. Previous work in our laboratory using in vivo microelectrode array recordings in rats learning a forelimb reaching task observed the formation of a subset of temporally-coupled neurons from a wider neuron pool, with differential long-term potentiation profiles between different dendritic layers of layer 5B projection neurons. We therefore hypothesize that the local circuits in specific cortical layers mediate the reshaping of the roles of individual neurons.We approach this problem using chronic in vivo two-photon imaging while head-fixated mice are trained to perform a stereotyped forelimb motion on a manipulandum not normally found in the animal's motor repertoire. Functional calcium recordings were taken from both layer 2/3 and layer 5 of the contralateral caudal forelimb region of the primary motor cortex, and local connectivity was inferred via histological reconstruction. We then explore the causal role of local inputs in the final task-relevance outcome of the projection neurons.

Title: Strong neuron-to-body coupling implies weak neuron-to-neuron coupling in motor cortex.

Authors: *P. KELLS[1], S. GAUTAM[2], W. L. SHEW[2];
[1]Physics, [2]Univ. of Arkansas, Fayetteville, AR

Abstract: Cortical neurons can be strongly coupled to the network in which they are embedded, firing in sync with the majority, or they can fire more independently. Both these scenarios - strong and weak population coupling - have potential computational advantages when considering the information output from a cortical network. In motor cortex, for instance, if the information output to the body is conveyed by a strongly coupled population of neurons, one might expect that the information would be more robustly conveyed, benefiting from strength in numbers. On the other hand, a motor code with greater information capacity could be

implemented by neurons that fire more independently. To determine which of these scenarios is employed, here we directly measured information transmission from motor cortex neurons to bodily movement in awake, freely moving rats, as well as the population coupling for these neurons. First, we found that neurons in motor cortex exhibit a wide range of different population coupling, which was tunable by manipulating inhibitory signaling in the motor system. All neurons with high population coupling had low information transmission from cortex to body movement. Conversely, low population coupling was a necessary condition for high information transmission from motor cortex to body movement. Inhibitory tuning of population coupling did not change these functional roles. Our results suggest that the population of neurons in motor cortex is divided into an 'internal processing' group with high population coupling and an 'external output' group devoted to high capacity information output to the body.

Title: Dynamic representation of reach speed in the motor cortex

Authors: *S. B. SUWAY[1], J. ORELLANA[2], A. B. SCHWARTZ[1];
[1]Univ. of Pittsburgh, Pittsburgh, PA; [2]Carnegie Mellon Univ., Pittsburgh, PA

Abstract: In primate motor cortex (M1), single neurons are broadly tuned to reach direction, with each cell discharging maximally for a particular direction. The speed of the reach also affects neural activity, contributing both a multiplicative and additive influence on firing rates. Early studies reported a "representation" of reach speed in single units and in population

analyses. However, such studies commonly restricted analysis to the trial period in which the arm was moving. It was subsequently suggested that representation of speed is less robust in the firing rate fluctuations that continue after movement ceases. Recently, our group identified distinct epochs in the activity of M1 neurons spanning the reaction time through the target-hold period of a reaching trial. Directional tuning of single neurons is robust and stable within an epoch, but preferred direction may change from one epoch to the next. We wondered if speed encoding might also vary between epochs. We recorded spiking of M1 neurons from three monkeys during a center-out reaching task. Firing rates of each neuron were analyzed using two models: a direction-only tuning model, and a velocity-speed tuning model. Both models were fitted during each epoch, and the goodness-of-fit of each model was assessed. We found clear evidence of dynamic coding, with the velocity-speed model fitting rates of many neurons markedly better during the early epochs. Using the population vector algorithm (PVA), we reconstructed reach trajectories using firing rates from only the speed-related epochs. We found the decoded trajectories were highly accurate, and the time course of their magnitude was strikingly similar to the recorded reach speeds. Given that velocity can be extracted from the population with high fidelity by selectively utilizing segments of firing, we wondered if a simpler computation, using all the data, could yield similar results. This would be useful for example in neural prosthetics because it would allow us to estimate arm velocity despite the ongoing changes in single unit tuning during a reach. We developed a simple regression method to find a linear combination of single unit firing rates that closely matches the measured arm velocity. The method identifies an axis in the n-dimensional population firing rate space. When the population activity is projected onto this axis, we find robust and accurate velocity tuning while the hand is moving. When the arm comes to a stop, and despite continued fluctuations in firing of most neurons, activation along this axis drops nearly to zero. This method may be advantageous in neural prosthetics, which often fail to afford subjects control of output speed.

Title: Neural dynamics of reach-to-grasp: sequential location-potent and then object-potent projections of state-space trajectories.

Authors: A. G. ROUSE, *M. H. SCHIEBER;
Neurol. and Neurosci., Univ. of Rochester, Rochester, NY

Abstract: In reach-to-grasp movements, reaching with the arm and grasping with the hand typically are thought to proceed concurrently. Recent evidence suggests, however, that neural activity in motor and premotor cortex may control location early and grasp shape later in the same movement. We therefore examined the neural state-space trajectories of primary motor cortex (M1) neuron populations to determine whether location-potent projections were distinct from object-potent projections, and if so, whether the state-space trajectories projected simultaneously or sequentially onto location-potent and object-potent planes.
We analyzed data recorded from two Rhesus monkeys, each of which performed a reach-grasp-manipulate task that dissociated the location to which the hand reached from the object the hand grasped. Populations of M1 neurons were recorded in multiple sessions from microelectrode arrays implanted in each monkey. For each session, we examined the state-space in which the firing rate of each neuron constitutes an orthogonal state-space dimension. In this space the simultaneous firing rate of all sampled neurons constitutes a state which moves in time, forming a trajectory. We identified two 2-dimensional planes: one on which the projection of firing-rate trajectories segregated best according to reach location, another on which the trajectories segregated best according to the object grasped. The location-potent plane and object-potent plane in a given session were distinct.
Next, we followed the time course of the trajectories. Prior to movement onset the trajectories moved in state-space directions that projected substantially onto the location-potent plane, but were relatively null in the object-potent plane. After the onset of movement, however, the direction of the neural trajectories changed, coming to project substantially onto the object-potent plane while being relatively null in the location-potent plane. Additional analyses showed that the location-potent motion and object-potent motion occurred in overlapping neural sub-spaces, i.e. the firing rates of many individual neurons modulated during both the location-potent phase and the object-potent phase of the same movement.
Our findings demonstrate how distinct latent output features may be represented in the joint activity of a neural population. In theory, multiple latent features could be represented simultaneously. But during the present reach-to-grasp movements the direction of neural trajectories changed such that first one feature and then the other could be controlled sequentially by the same population of neurons.

Title: Decoding kinetic information from PMd and M1 during reaching

Authors: *E. TRAUTMANN, S. STAVISKY, J. KAO, S. RYU, K. SHENOY;
Stanford Neurosciences, San Francisco, CA

Abstract: Several experiments have characterized the tuning properties of neurons PMd and M1 when loads are applied to the arm [Kalaska 1989, 2005], though less is understood about the relationship between population-level neural dynamics and reach kinetics. Here, we report how neural dynamics in PMd and gyral M1 adapt to external loads to control force, demonstrating that the arm's output force along the vertical axis can be decoded from neural activity before and during movement.

Two rhesus macaque monkeys, implanted with two 96 electrode arrays in PMd and M1, made delayed reaches in a vertical workspace to eight targets with three levels of added weight: 0g, 100g, or 200g. Weights were attached to the top of the wrist for randomly selected blocks of 250 trials. At the start of a trial, monkeys held their arm at the center, resisting gravity against the different weights.

For monkey J, 109 of 192 (monk R: 50/171) electrodes' multiunit activity displayed tuning to the applied weight, while 170/192 (80/171) displayed target tuning. While statistically significant, the applied weights modulated firing rates only modestly. Despite this, we asked whether it is possible to discriminate the level of weight attached from the neural activity before movement. Classification accuracy between the 0g and 200g weight levels was 75.3% (58.9%), using a multi-class SVM with 10-fold CV.

We used the SVM to define a neural Gravity Force Axis (GFA) that best discriminates applied weight before movement, and ask whether this axis contains information about the arm force generated in the vertical dimension during the reach. Targets at the top and bottom of the workspace require different force profiles to accelerate the arm with or against gravity. We modeled the required force profile for each target, and compared this to the trial-averaged force

decoded from the projection of the neural state along the GFA. The correlation coefficient between decoded force and modeled force was .67 (.26), suggesting that this axis can serve as a readout of behavioral kinetics along one dimension of physical space.
Curiously, the percentage of neural variance captured by the GFA was only 0.7% (0.59%). The top principal components of neural activity are dominated by the large changes in firing rate during the movement period, which are largely independent of the total force. Despite this, we show that kinetic information is available in the population activity in gyral PMd and M1, amenable to recordings using multielectrode arrays, and potentially important as an additional channel of information for controlling neural prosthetic devices.

Title: Neural activity in primary motor cortex correlates with previous trial performance during adaptation of reaching movements to a visuomotor rotation

Authors: *A. J. SUMINSKI, J. KOSER;
Electrical Engin. and Computer Sci., Milwaukee Sch. of Engin., Milwaukee, WI

Abstract: It is well understood that the adaptation of reaching movements to unpredictable environmental perturbations flows from the nervous systems ability to update motor commands based on performance information from only the most recent movement attempts. The neural mechanisms supporting reach adaptation remain unclear as previous studies non-human primates have demonstrated that neurons in primary motor cortex (M1) show learning related changes in response to constant perturbations over the course of many reaches. However, these studies have not addressed changes in neural activity that occurs on a much shorter timescale (i.e. from one trial to the next). Here we investigate whether M1 participates in this short term adaptive process. Two rhesus macaques were implanted with a 100 micro-electrode array (Blackrock Microsystems) that was used to record the spiking activity of neural ensembles in M1 while they reached from a central target to one of eight peripheral targets (6cm) using a two degree of freedom, planar robotic manipulandum. Experiments contained three phases. During the pre and

post adaptation phases, the monkeys made at least 5 unperturbed movements to each of the peripheral targets, which were pseudo-randomly selected prior to each trial. During the adaptation phase, all movements were directed to the 90 degree target and were perturbed by a counter-clockwise rotation of the cursor position about the central target that varied in magnitude pseudo-randomly from trial-to-trial. Movement error was calculated as the peak deviation orthogonal to the line connecting the center and peripheral target. Consistent with the results of previous human subject experiments, we observed a linear relationship between movement error and rotation magnitude and that current trial movement errors were best predicted by an autoregressive model incorporating error and rotation information from the most recent movement attempts. We found a significant correlation between the time series of binned firing rates (on a trial-by-trial basis) of a subset of M1 neurons and the measured reaching errors and rotation magnitudes from previous movement attempts. Furthermore, we found that the binned firing rates of a separate subset of neurons were also significantly correlated with the expected rotation on the upcoming trial predicted by the autoregressive model. These results suggest that M1 incorporates information from previous movement attempts into the planning and execution of subsequent movements when there is environmental uncertainty.

Title: Cortico-cerebellar integration in the motor thalamus.

Authors: *C. B. SCHAEFER, S. V. GORNATI, F. HOEBEEK;
Dept. of Neurosci., Erasmusmc, Rotterdam, Netherlands

Abstract: Relating sensory information about the surroundings with the current posture of the body and the upcoming motor plans is essential for executing coordinated movements. Sensorimotor integration has been studied separately in the cerebellum and in the cerebrum, but how these two networks converge remains to be elucidated. Within the motor system the most suitable candidate nucleus for cortico-cerebellar convergence is the thalamic ventro-lateral nucleus, as it receives direct synaptic input from cerebellar nuclei neurons but also feedback from primary motor cortex, in particular from layer VI neurons. Cerebellar input in the thalamus

has been shown to exhibit driver properties, in that microstimulation in the superior cerebellar peduncle can evoke postsynaptic action potential firing, whereas the synaptic properties of the input from layer VI of the primary motor cortex remains to be defined. We hypothesize that synapses from layer six of the motor cortex converge with cerebellar synapses upon single thalamic relay neurons and modulate the thalamic response to cerebellar input. Therefore, we established an optogenetic dual-channel photostimulation approach by expressing channelrhodopsin2 (ChR2) in cerebellar nuclei and a flexed version of red-shifted ChR2-construct in layer VI of the motor cortex of Ntsr1-Cre mice. Using isolated photostimultion of both axonal populations synapsing in the thalamus we found that information from both cerebellar nuclei and motor cortex layer VI converges on individual neurons in the ventral-lateral nucleus. Furthermore, our electrophysiological recordings revealed that motor signals from cortical layer VI show paired-pulse fascilitation, which together with the presence of a metabotropic receptor mediated current indicates that these inputs show modulatory properties. In contrast, higher frequency stimulation of cerebellar synapses resulted in paired-pulse depression indicative of driver properties. These results support a role of relay neurons in ventro-lateral thalamic nucleus in integrating cortical and cerebellar information. The properties of input coming from layer VI of motor cortex are suggestive of a modulatory role that might shift the thalamic membrane potential from a hyperpolarized to a more depolarized state. We speculate that this gating signal induces a switch in the thalamic responses to cerebellar input from burst firing in absence of layer VI input to tonic thalamic firing in presence of layer VI input. These findings may shed light on how thalamic relay cells respond to high-frequency excitatory cerebellar nuclei input that converges with modulatory excitatory cortico-thalamic inputs.

Title: Electrical microstimulation in primate premotor cortex hijacks local neural activity

Authors: *D. J. O'SHEA[1], K. V. SHENOY[2];
[1]Stanford Univ., Stanford, CA; [2]Electrical Engineering, Bioengineering, Neurobiology, HHMI, Stanford Univ., Stanford University, CA

Abstract: Intracortical electrical microstimulation (ICMS) is a powerful tool for probing neural circuit function and organization. Evidence from behavioral studies and intrinsic, functional MR, and calcium imaging suggest that the activity evoked by high frequency ICMS is spatially and temporally complex. However, the responses of local neural populations to ICMS are typically challenging to record directly due to the large electrical artifact. Consequently, it is unclear how ICMS engages local neural populations and how these activation patterns interact with the dynamics of normal task-related activity. Here, we developed an artifact removal method to directly record the local effects of high frequency ICMS delivered to dorsal premotor cortex (PMd) in a rhesus macaque engaged in a reaching task. We find that neural activity near the stimulation site no longer reflects pre-existing task-related activity.

We stimulated in PMd (60 ms, 333 Hz biphasic pulses) and verified that twitches of the arm and shoulder were evoked above threshold. Within 1 mm of the stimulating electrode, we acutely recorded neural activity using a linear multielectrode array (Plexon V-probe). During the task, we stimulated on a subset of interleaved trials (3 distinct timepoints, 5 reach directions). For currents below 40 uA, the recorded artifacts did not saturate the amplifier. We developed a method to remove the artifact by exploiting the common structure of the artifact over electrodes, pulses, and trials, enabling us to detect spiking activity during and after the stimulation. 59 / 77 neurons' firing rates were altered by stimulation ($p < 0.05$).

For each of 61 neurons exhibiting significant modulation during the reaching task ($p < 0.05$, ANOVA), we summarized the contribution of the underlying task-related neural activity to during-stimulation activity using an index ranging from 0 (no task contribution) to 1 (purely additive interaction). The median index across the population was 0.25 (0.15-0.47, 95% CI), indicating that ICMS-evoked activity mostly replaced, rather than superimposed with, task activity. Immediately after stimulation, many neurons were suppressed for > 150 ms; the index recovered to pre-stimulation level only 180 ms following stimulation. These results provide direct neural evidence for the hypothesis that ICMS can "hijack" local neural circuitry (Griffin et al., 2011), and contrasts with earlier reports that optogenetic stimulation interacts additively with task-activity (O'Shea et. al, SFN 2013) in PMd. The results highlight that combining stimulation with recording and artifact rejection methods can provide precise, causal insight into neural computation.

Title: Multi-scale electrophysiology in macaque motor cortex during reaching

Authors: *A. L. ORSBORN[1], C. WANG[2], K. CHIANG[2], N. C. BOLES[1], J. VIVENTI[2], B. PESARAN[1];

Abstract: Neural computations governing behavior span many spatial scales, from individual neurons to large-scale networks within and across brain areas. Similarly, electrophysiology can monitor neural activity from microns, to millimeters, and up. Relationships between these different measures are poorly understood. Moreover, how each scale of neural computation relates to behavior is unclear. Connecting neural computations across spatial scales will require simultaneous multi-scale measurements during behavior. We therefore developed a flexible platform to combine multiple measurement scales and used it to study motor cortex during reaching. The platform can integrate subdural micro-electrocorticography (μECoG) and a microdrive of independently movable electrodes to measure action potentials, local field potentials (LFP), and surface potentials (μECoG) within the same volume of tissue. We embed a μECoG array within a silicone artificial dura (AD), providing chronic subdural access and precise alignment between the μECoG array and penetrating microdrive. We implanted this multi-scale system in one macaque (Macaca Nemestrina, male). A custom-shaped chamber (2.6cm inner diameter) was implanted over the primary motor cortex, using MRI-based targeting (BrainSight software, Rogue Research). A 244-contact μECoG array (50 μm LCP with 0.3 μm thick gold traces; 200 μm diameter contacts with a 0.15 μm platinum coating; 0.75 mm contact spacing) was implanted, followed by a 32-electrode microdrive (Gray Matter Research; glass-coated tungsten electrodes, 125 μm diameter; 1.5 mm spacing). Spiking, LFP, and μECoG activity were recorded during rest, full-field light-flash visual stimulation, and a reach-to-grasp task. Visual stimulation-triggered responses were used to assess day-to-day variability in signal

recordings. Reaching behavior was monitored with motion tracking (Motion Analysis Inc.) of the arm and hand in 3-dimensions. The subject performed a naturalistic reach and grasp task in which he grasped a small square with a power grip presented in random locations in the workspace. We present analysis of spike, LFP, and μECoG signals' relationships to behavior (decoding analyses) and relationships between measurement scales. By using an artificial dura, our system provides chronic, flexible brain access for multi-scale, multi-modal measurements. Future work will extend our approach to incorporate transparent μECoG for optical imaging and stimulation access. Such multi-scale recording and interrogation of neural circuits will be critical for dissecting neural circuits and their relationships to behavior.

Title: Error-related motor cortical activity transforms from output-null to output-potent dimensions

Authors: *S. D. STAVISKY[1], J. C. KAO[2], S. I. RYU[2,6], K. V. SHENOY[2,3,4,7,5]; [1]Neurosciences Grad. Program, [2]Electrical Engin. Dept., [3]Neurobio. and Bioengineering Departments, [4]Bio-X Program, [5]Stanford Neurosciences Inst., Stanford Univ., Stanford, CA; [6]Palo Alto Med. Fndn., Palo Alto, CA; [7]Howard Hughes Med. Inst. at Stanford Univ., Stanford, CA

Abstract: The sensorimotor system must continuously monitor afferents so as to detect movement errors, compute a response, and then output this command to muscles. This constrains the system: error-related computation must be decoupled from causing movement until it has progressed enough to generate the appropriate correction. We investigated how this separation is achieved in the primary (M1) and dorsal premotor (PMd) cortex, areas in which activity can drive movement and strongly reflects sensory inputs signaling errors. We found that the 'output-null hypothesis' (Kaufman et al., 2014, Druckmann & Chklovskii 2012) is a mechanism by which error processing can occur in motor cortex without prematurely "leaking out" as output. This proposed mechanism takes advantage of the many-to-few mapping between motor cortex and its downstream movement-generating targets: because of this redundancy, there are many ways in which cortical neurons' activities can change while still "canceling out" as far as the downstream readout is concerned. For a simplified linear model of the network, this is equivalent to restricting motor cortical changes to the null space of the matrix mapping firing rates to movement.

To study neural dynamics following errors, we recorded from M1 and PMd of two rhesus macaques as they performed a 2D cursor task to which we added random mid-trial 'cursor jump' perturbations. In the first experiment, the monkeys controlled a computer cursor with their hand. We approximated the relationship between cortex and movement with a linear mapping, W, between firing rates and hand velocity. When we projected perturbation-evoked firing rate changes into the output-null and output-potent spaces of W, we observed that an output-null response preceded (putatively) output-potent changes by as much as 55 ms. While this result is consistent with our hypothesis, we recognize that W is only a rough estimate of the relationship between motor cortical activity and muscles.

To address this limitation, we performed a second experiment in which the monkeys controlled the cursor via a brain-machine interface (BMI). This paradigm removes all intermediaries between motor cortex and its effector: the cortical output command is solely determined by the recorded neural population via a mapping, M, that we have full knowledge of. We observed output-null changes as early as 66 ms after perturbation, followed by (definitively) output-potent changes after 103 ms. This result shows that motor cortex can indeed isolate early error-related activity through an internal output-null mechanism. It also suggests that sensory-evoked cortical activity need not interfere with ongoing BMI use.

Title: Dorsal premotor (PMd) neurons code reaching movements preferentially in a space of action choices, not the salient sensory-property space of instructional cues.

Authors: *C. MONTANEDE, J. F. KALASKA;
Neurosciences, Univ. of Montreal, Montreal, QC, Canada

Abstract: Coallier & Kalaska (2015) recorded PMd neural activity while monkeys did a Choose-and-Go (CG) task. Two colored (Blue, Yellow) spatial cues (SC) appeared at two potential reach target locations, followed after a delay by a checkerboard-like decision cue (DC) containing different numbers of B and Y squares. The color bias of DCs, the difference in numbers of B and Y squares, varied from net-100 to net-4 between trials. The monkeys had to decide on the DC's dominant color and reach to the color-matched SC as quickly as possible. One monkey's response times (RTs) increased as DC color bias decreased. The rate of growth of directional activity of many PMd neurons was modulated by each DC's color bias, but few responded differentially to its dominant color. However, any color-related activity while the monkeys assessed the DC and chose a target during the RT period before reach onset may have been masked by activity related to initiation of the chosen reach. This motivated two new tasks. 1) CG task with delay (CGD): the DC appeared for an imposed delay period before the Go signal. This could allow expression of color-related activity during the sensory decision and action selection without movement-related confounds. 2) Match-to-Sample (MS) task: temporally-inverted CG task; the DC appeared first for a delay period, followed by the SCs and Go (Wang et al SfN 16). This could allow the monkey to make a sensory decision about the DCs' dominant color before knowing the spatial locations of the colored SCs. The RTs of a new monkey trained in all 3 tasks were shorter for net-20 and net-4 DCs in the CGD and MS tasks than the CG task, indicating that it made a sensory decision during the DC delay periods. The rate of growth of PMd directional activity was modulated by DC color bias during the DC delay period of the CGD task, but color per se had little effect. In the MS task, many PMd neurons showed little response to the DCs during the initial DC delay period but responded strongly after the SCs appeared. Other neurons responded to the DC, but showed little differential response to either its color or color bias, even though the monkey was assessing its color content. Our results show that PMd neurons weakly encode a critical sensory property of the DCs, their color. Instead, they express the DCs' salient sensory properties in terms of their support for different specific known actions defined by the color-location conjunctions of the SCs. The monkey had this information before the start of the DC delay period of the CGD task, but not during the initial DC delay period of the MS task. PMd neurons could not map the DCs' sensory properties onto specific actions in the MS task until after the SCs appeared to end the DC delay period.

Title: Dorsal premotor cortex activity reflects a candidate decision variable during the action selection epoch of an abstract perceptual decision-making task

Authors: *M. WANG[1], C. CHANDRASEKARAN[2], D. PEIXOTO[3,5], W. T. NEWSOME[3,6], K. V. SHENOY[2,6,3,4];
[1]Neurosciences Program, [2]Electrical Engin., [3]Neurobio., [4]Bioengineering, Stanford Univ., Stanford, CA; [5]Champalimaud Neurosci. Inst., Lisbon, Portugal; [6]Stanford University/HHMI, Stanford, CA

Abstract: Neuroscientists have often studied decision-making using tasks in which decisions about a stimulus are made concomitantly with the action selection to report the outcome. These two processes, perceptual decision-making and action selection, may be independent or may occur together as one broader sensorimotor process. Here, we use psychophysics and electrophysiology to compare the role of dorsal premotor cortex (PMd) when these processes are concurrent or temporally dissociated. We trained rhesus monkey T to report the dominant color of a red-green checkerboard by reaching to a corresponding colored target (Wang et al., SfN 15; Montanède and Kalaska, SfN 16), under two task blocks, within session. The target locations are fixed, but the colors are assigned randomly. In the Target First (TF) task, targets are presented before checkerboard onset, so that decision-making (determining checkerboard color) and action selection (determining reach direction) are concurrent. In the Stimulus First (SF) task, this presentation order is reversed. The animal cannot plan a reach when the checkerboard alone is present, since the target colors are not yet available. In addition, a blank screen is introduced between the two events to further dissociate decision-making and action selection. In the SF task, psychophysical thresholds are higher and reaction times (RT) longer overall. RT are weakly negatively correlated with checkerboard strength. We used single electrodes and linear electrode arrays to record 159 units (54 single, 105 multi) in PMd. 1) Firing rates (FR) during the TF task

are consistent with previous reports: initially there is no response to the targets, and after checkerboard onset, FR increase in a manner that correlates with reach direction, checkerboard strength, and RT (Chandrasekaran et al., SfN 13, 14, 15). 2) In the SF task by contrast, FR do not change in response to checkerboard onset. 3) Rather, FR modulate only after the target onset in the SF task, in a manner that is correlated with reach direction, checkerboard strength, and RT. This is surprising because the putative decision epoch has already passed. These SF task data are consistent with two possible interpretations. One possibility is that the perceptual decision is made before target onset and is represented elsewhere but not in PMd; other cognitive elements involved in action selection are then reflected in neural activity after target onset. Alternatively, decision-making may be intentionally delayed until target onset, and the stimulus-dependent activity that follows target onset could reflect integration of the noisy stimulus representation retrieved from working memory.

Title: Conserved patterns of neural coordination across sleep, movement and brain-control training

Authors: *A. JACKSON, F. DE CARVALHO, J. TULIP, T. M. HALL;
Newcastle Univ., Newcastle-upon-Tyne, United Kingdom

Abstract: Understanding how skilled behaviour emerges from the coordinated activity of distributed neural populations is a central problem in modern neuroscience. Previous studies of synchronous or sequential activity in waking and sleeping states have typically examined whether such patterns encode information about *extrinsic* factors (e.g. sensory stimuli, spatial location or movement parameters) during or after a specific behaviour. However neural coordination may also arise from *intrinsic* constraints that limit network dynamics to a low-dimensional manifold within the neural state space, in which case these patterns should be preserved across diverse behavioural states and direct the learning of new skills towards neural solutions that lie within the manifold. Here we use long-term neural recordings from monkey

motor cortex to reveal conserved coordination patterns across awake behaviour and slow wave sleep. Neurons active sequentially during movements fired in the same sequence within the slow oscillation cycle in sleep, while neurons coactive at low frequencies during movements also fired synchronously with fast sleep spindles which were modulated by the slow oscillation phase. Moreover, taking both synchronous and sequential coordination patterns into account improved prediction of the neural strategies that emerged as animals learned abstract 'brain-control' tasks over several weeks. By contrast, the learning process did not cause task-specific changes to coordination patterns in sleep over the same period. We conclude that intrinsic network constraints shape low-frequency neural coordination patterns in behaviour, and these are manifested at higher frequencies in sleep due to cross-frequency coupling between sleep rhythms.

Title: spatial tuning for both manual and oculomotor movement in dorsal anterior cingulate cortex neurons

Authors: *S. YOO[1], S. PIANTADOSI[2], B. HAYDEN[2];
[1]Brain and Cognitive Sci., [2]Univ. of Rochester, Rochester, NY

Abstract: Several studies have revealed that the dorsal anterior cingulate cortex (dACC) is responsible for associating action with reward. Until recently, however, only a few studies have addressed the question of whether specific movement variables like direction selectivity are encoded in dACC. Even the studies that have explored whether the dACC encodes action information only addressed a specific type of movement: oculomotor movement. Here we show that firing rates of dACC neurons are sensitive to direction of movement by the physiological data from the dynamic-interactive-reward pursuit (DIRP) task. The task is conceptually similar to a simplified Pac-man game. Compared to more conventional laboratory tasks in which responses are constrained to one modality, our current task enabled the subject to continuously generate movement with a high degree of freedom in multiple possible directions for both oculomotor and manual modalities. We find that dACC neurons encode not only the direction of

oculomotor movement as previously reported but also the direction of manual movement. Furthermore, tuning direction in the two domains was often distinct.

Title: Development of a rootlet interface to localize cutaneous stimuli applied to specific regions of the rat hindlimb

Authors: *I. BLACK[1], J. ABBAS[2], A. THOTA[1], R. JUNG[1];
[1]Biomed. Engin., Florida Intl. Univ., Miami, FL; [2]Sch. of Biol. and Hlth. Syst. Engin., Arizona State Univ., Tempe, AZ

Abstract: Mapping of mammalian dermatomes has demonstrated a relationship between the rostral-caudal point of emergence of dorsal roots from the spinal cord and the specific cutaneous zones innervated by them, and studies have shown similar relationships to be preserved at the rootlet level. In rodent models, high signal-to-noise ratio recordings of bladder and cutaneous afferents have been obtained using dissected portions of lumbar roots implanted in microchannel electrode arrays. However, the somatotopic arrangement of rootlets has not been used to preferentially target and record neural signals arising from stimulation of specific cutaneous zones. This work reports the development of a rootlet interface (RI) implanted on teased lumbar dorsal rootlets to localize stimuli applied to different skin regions of the rat hindlimb.
Custom microchannel electrode arrays were developed by gluing together 8mm long silicone tubes having inside diameters of 310um. Tubes were slit longitudinally and opened along their entire length by pulling on flanges connected to both sides of the array to facilitate nerve insertion and reduce trauma. Pt/Ir and stainless steel recording electrodes were inserted into each channel. Silver wires at both ends of the array were used as a reference electrode for all channels. L4-L6 dorsal roots were exposed by removing the dorsal and lateral processes of T13-L3 vertebra in Sprague-Dawley rats and a portion of each root (i.e., “rootlet”) was dissected and implanted into the microchannel array. A variety of cutaneous stimuli were applied using an

instrumented von Frey device. The leg joints were also moved independently and simultaneously. Raw signals were amplified (10,000x), band-pass filtered (0.3-10kHz) and sampled at 50kHz. An audioscope was used to monitor real-time activity in each channel. Preliminary results demonstrate that activity in specific channels corresponded to stimuli applied to specific skin regions. As expected, the more rostral the emergence of the recorded "rootlet", the more proximal the skin zone that activated it. Leg movement produced activity in the majority of recordings in which responses to cutaneous stimuli were detected.
The RI concept appears to be a viable method to localize stimuli applied to different regions of the hindlimb. Methods to separate proprioceptive signals from those of cutaneous origin may be required. Ongoing work is focused on further characterization of the organization of afferents across the rootlets and on microfabrication of rootlet interfaces with greater channel counts and smaller channel cross sectional areas.

Title: Detection of sensory information in whole nerve recordings using a multi-contact cuff

Authors: *E. K. BRUNTON[1], C. BLAU[2], K. NAZARPOUR[1];
[1]Electrical and Electronic Engin., Newcastle Univ., Newcastle Upon Tyne, United Kingdom;
[2]Fac. of Med. Sci., Newcastle Univ., Newcastle, United Kingdom

Abstract: The performance of neuroprostheses that stimulate muscles to generate controlled and functional movement of paralysed limbs has been shown to be significantly enhanced when sensory feedback is provided. For sensory feedback to be provided, robust detection of the type and strength of sensory signals is required. Previously it has been shown that different types of sensory information can be decoded using a single channel cuff electrode. Here we report on the use of a multi-contact cuff electrode for recording and decoding sensory information from peripheral nerves.
All animal care and procedures were performed under appropriate licenses issued by the UK Home Office under the Animals (Scientific Procedures) Act (1986) and were approved by the Animal Welfare and Ethical Review Board of Newcastle University. Commercially available

nerve cuffs with 16 electrodes, comprising of 4 rings of 4 electrodes were implanted around the sciatic nerve of Sprague Dawley rats under terminal general anaesthesia, the electroneurogram signal (ENG) was recorded in response to sensory stimulation applied to the ipsilateral foot. Five different sensory stimuli were used: ankle flexion, ankle extension, outer toe pinch, thumb pinch, and stroking the dorsum of the foot. Each stimulus was repeated at least five times, and the beginning and culmination of the stimulus were indicated on the recording. The ENG signals were analogue filtered between 0.3 and 7.5 kHz and subsequently digitally filtered between 250 Hz and 5 kHz. During post-processing the mean absolute value (MAV) of the recorded signal was measured over 200 ms during the time that the stimulus was applied to the foot. This gave at least 5 measures for each stimulus type.
Clustering of data points showed that the ratio of MAV on pairs of electrodes located at different positions on the nerve cuff could be used to identify different sensory signals. Additionally, the results showed that the amplitude of the MAV recorded may be used to decode the strength of the stimulus applied.
The results of this study indicate that multi-contact nerve cuffs can be used to decode sensory signals recorded from whole nerves using features with low computation times that could be implemented in real time. Future research is still required to determine whether sensory information can still be obtained in awake and moving animals.

Title: Artificial sensations through cortical stimulation of human somatosensory cortex with subdural mini-ECoG grids

Authors: *M. ARMENTA SALAS[1], D. R. KRAMER[2], B. LEE[2], D. BROWN[1], T. DOBREVA[1], C. KLAES[1], C. Y. LIU[3], R. A. ANDERSEN[1];
[1]Biol. and Biol. Engin., Caltech, Pasadena, CA; [2]Neurosurg., [3]Neurosurgery, Neurology, Biomed. Engin., USC, Los Angeles, CA

Abstract: In recent years, we have seen an extraordinary advance in BMI systems control (Aflalo et al., 2015; Collinger et al., 2013; Hochberg et al., 2012), however there are still numerous open questions concerning the restoration of sensation, and the sensory feedback given to subjects controlling these BMI systems. We are interested in characterizing the somatic sensations elicited through cortical electrical stimulation, and the information these stimuli can deliver. We designed a proof of concept study, aimed at generating artificial sensation through cortical stimulation in humans. We recruited six epilepsy patients (4 female, 24-55 yrs.) undergoing Phase II electrocorticography (ECoG) monitoring, and implanted a 64-electrode mini-ECoG subdural grid (Adtech FG64C-MP03) over the somatosensory hand area on the ipsilateral side of the epilepsy mapping grid. The stimulation grid along with the standard subdural grid were connected to a clinical electroencephalography machine. We used the Grass Technologies S12X Cortical Stimulator to deliver the electrical stimuli. We mapped the somatotopy of the hand for all six patients and found self-reported sensations which ranged from electric "tingling" to "moving" of the fingers. Next, we tested the effect different stimulation parameters (frequency, current amplitude, pulse width, and waveform polarity) had in the perceived sensations. Finally, subjects used these artificial sensations to complete three behavioral tasks. Two were target acquisition tasks, where the patient was asked to move his/her hand over hidden targets and notify the experimenters when the target was found. The target locations were indicated through electrical stimulation on the mapped hand region. The last task was a discrimination one, where subjects had to differentiate between "natural" and "artificial" sensations. Our results show that, with standard parameters, we were able to stimulate distinct regions of the hand with the mini-subdural grid. The sensations described ranged from distinctly artificial sensations to more natural sensations of finger and hand movements. Each sensation also had variable intensities as we modified waveform parameters. On target localization trials, subjects had 100% accuracy and consistently reported the stimulation sensations. Furthermore, on discrimination trials, the subjects correctly detected the artificial sensation in all trials. This initial study is encouraging, given the consistency of the stimulation, reliability and speed of detection by subjects, and opens the possibility to combine touch timing and topographical localization to create finer and more complex movement control.

Title: Electrical stimulation of the cervical dorsal root ganglia for sensory restoration in upper-limb amputees

Authors: *S. CHANDRASEKARAN[1], A. NANIVADEKAR[2], E. HELM[3], M. BONINGER[3], J. COLLINGER[3], R. GAUNT[3], L. FISHER[3];

Abstract: Sensory feedback greatly enhances the embodiment, acceptance, and also the ease of use of a prosthetic device. Electrical stimulation of the peripheral and central nervous system is the focus of extensive research as a means to provide this sensory feedback. In our study, we attempted to target the dorsal root ganglion (DRG) as the site of electrical stimulation. The DRG is a uniquely advantageous site for introducing sensory feedback as it is the most peripheral site that provides clear separation between the sensory and motor pathways. There are also multiple minimally invasive techniques for surgical access to the DRG. Further, it has been shown that DRG stimulation could help alleviate phantom limb pain. In animal studies, we have previously shown that sensory afferents from nerves throughout the hind limb can be recruited selectively by stimulating at the DRG. Here, we present observations from human psychophysics experiments performed while stimulating the C5-C8 DRG in two upper-limb amputees using FDA-approved spinal cord stimulation (SCS) leads. Study participants were implanted with three 8-contact SCS leads (Boston Scientific) in the lateral epidural space near the cervical spinal cord. Multi-polar current-steering was used to improve the focality of sensory percepts. Feedback about the modality, location, and intensity of perceived sensations was provided by the subject through a structured reporting setup. Preliminary testing showed that sensory percepts, primarily in the form of paresthesia, could be evoked via selective stimulation through different SCS lead contacts. The sensations reported by the subjects include focal percepts localized to the amputated shoulder, arm, hand, wrist, palm, and fingers. In one subject, these sensations were stable for more than two weeks of testing. Continuous modulation of stimulus amplitude was perceived as intensity changes and did not affect the overall location of the percepts. DRG stimulation using current-steering approaches can generate focal sensory percepts in specific regions of the missing limb in long-term amputees.

Title: Fascicular organization affects tactile sensation evoked from peripheral nerve cuff stimulation

Authors: *E. L. GRACZYK[1], M. A. SCHIEFER[1], H. P. SAAL[2], B. P. DELHAYE[2], S. J. BENSMAIA[2], D. J. TYLER[1];

Abstract: Electrical nerve stimulation has restored sensation for amputees and can be a powerful tool to investigate the neural coding of touch. We performed psychophysical experiments on the perceived magnitude of sensations evoked from peripheral nerve stimulation and developed a computational model to describe the relationship between stimulation parameters and evoked sensations. We hypothesize that the underlying neuroanatomy can predict afferent recruitment from stimulation and that population activity estimated by computational modeling can predict tactile intensity. Two trans-radial amputees, chronically implanted with nerve cuff electrodes on their median, ulnar, and radial nerves, participated in the study. On multiple electrode contacts, the subjects performed intensity discriminations (n=7), perceived magnitude estimations (n=4), and mechanical indentation matching ratings (n=5) with stimulation that varied in pulse width (PW), pulse frequency, or both. A biophysical model of the human median nerve surrounded by a cuff electrode was constructed based on cadaveric cross sections. Populations of neurons were simulated within the fascicles and the activation of each neuron was determined using a linear approximation method. Fiber recruitment was plotted as a function of stimulation PW and approximated with a linear function. The thresholds and slopes were compared based on fascicle cross-sectional area and electrode-to-fascicle distance. From the experimental data, we found that perceived magnitude of sensation is predicted by the “activation charge rate” (ACR), which can be calculated from stimulation parameters. While the relationship between ACR and sensation magnitude was constant for each contact, it differed across contacts in a way that was

predicted by the computational model. The model showed that the threshold and slope of afferent recruitment differ between fascicles. Based on their distance from the stimulating contact, fascicles can be divided into two groups with different activation thresholds (two-sample t test, $p<0.001$). When the distance between the contact and fascicle is > 0.45 mm, the recruitment function is significantly shallower (two-sample t test, $p<0.001$) and does not depend on fascicle area. For shorter distances, slopes are steeper and increase linearly with fascicle area. Nerve anatomy helps explain the variability in perceived magnitude scaling. Future work in clinical subjects with known fascicular organization will be used to validate the model. Understanding the relationship between nerve anatomy, afferent recruitment, and subjective perception will enable us to improve stimulation paradigms.

Title: Psychophysical correspondence between vibrotactile stimulation of glabrous skin and intracortical microstimulation of the primary somatosensory cortex in the rat

Authors: *I. DEVECIOGLU[1,2], B. GÜÇLÜ[1];
[1]Inst. of Biomed. Engin., Bogazici Univ., Istanbul, Turkey; [2]Dept. of Biomed. Engin., Namık Kemal Univ., Tekirdağ, Turkey

Abstract: Intracortical microstimulation (ICMS) is a promising technique for delivering somatosensory feedback from neuroprostheses. ICMS parameters are typically adjusted by matching psychophysical performance obtained from mechanical stimulation of the skin and the electrical stimulation of the cortex (Berg et al., IEEE Trans. Neural Syst. Rehabil. Eng., 21:500-7, 2013). Here, we specifically matched the probability of correct decisions in a yes/no detection task. 3 male Wistar rats were trained to detect bursts of mechanical sinusoidal vibrations (frequency: 40 Hz, zero-to-peak amplitude: 200 μm, duration: 0.5 s) delivered to the volar surface of their hindpaws. Subsequently, they performed the detection task at 6 intensity levels

(3-200 μm) and 3 frequencies (40 Hz, 60 Hz and 80 Hz). Each condition was repeated 4 times. Psychometric functions were obtained based on hit rates corrected for false alarms. For each rat, the psychometric functions were fitted by a mathematical model based on intensity and frequency variables (R^2 values are 0.88, 0.87 and 0.92 for individual rats). Later, rats were implanted with microwire arrays in the hindpaw representation of the somatosensory cortex and trained to detect trains of biphasic, charge-balanced current pulses (cathodic phase leading, phase duration: 600 μs, frequency: 40 Hz, duration: 0.5 s). Similar yes/no detection tasks were performed with ICMS intensity levels of 2.5-40 μA, and mathematical models were constructed for the corrected hit rates (R^2 values are 0.73, 0.86 and 0.92 for individual rats). By using the models from vibrotactile and ICMS experiments, we calculated psychometric correspondence functions at 5 frequencies (40 Hz, 50 Hz, 60 Hz, 70 Hz and 80 Hz) for each rat. These functions establish a map between vibrotactile and electrical stimulation amplitudes which produce the same corrected hit rate. The psychophysical correspondence was validated in an additional detection task with probe trials containing either a tactile or an ICMS stimulus with some frequencies and amplitudes not tested before. Kolmogorov-Smirnov statistic was used to test the null hypothesis that vibrotactile and ICMS stimuli produce similar psychometric curves in the validation experiments. According to the results, we could not reject the null hypothesis (all p values >0.3 for five frequencies and three rats). Therefore, the approach based on psychophysical correspondence functions seems to be useful for determining the amplitude parameters of ICMS in a cortical neuroprosthetic application.

Title: High frequency electrical stimulation: effect of spatial location on retinal ganglion cell responses *In vitro*

Authors: *J. W. MORLEY[1], C. Y. YANG[2], D. TSAI[3], T. GUO[2], G. J. SUANING[2], S. DOKOS[2], N. H. LOVELL[2];
[1]Med., Western Sydney Univ., Sydney, Australia; [2]Univ. of New South Wales, Sydney, Australia; [3]Columbia Univ., New York, NY

Abstract: Retinal prostheses allow electrical stimulation of surviving retinal ganglion cells (RGCs) following photoreceptor degeneration due to diseases such as retinitis pigmentosa. Recently, high frequency stimulation (HFS) has been used to excite or inhibit responses of ON and OFF RGCs in the retina by modulating the stimulus amplitude. It is a promising technique for achieving preferential RGC activation that may enhance the quality of phosphene perception in clinical applications. HFS-based preferential activation has relied on careful placement of small electrodes close to the RGC soma. It was unclear how well the technique would scale-up for clinical settings, due to the inability in an implant to precisely place electrodes relative to individual RGCs. In this study, we placed our stimulating electrode at locations around the soma and examined how RGCs responded to HFS. Retinae from wild-type C57BL/6 female or male mice aged 4–8 weeks were used, and RGC responses were recorded with whole-cell patch clamp recording. All procedures were reviewed and approved by the UNSW Animal Care and Ethics Committee. The stimulating electrode was 25µm diameter, and HFS pulses were delivered with cathodic-first, charge-balanced biphasic waveforms at 2kHz for 300ms. Cathodic and anodic pulse duration was 100µs, with cathodic-anodic inter-phase duration of 140 µs and anodic-cathodic inter-pulse duration of 160µs. The stimulation amplitudes ranged from 5µA to 120µA, in steps of 5µA. We also simulated the experiments using morphologically- and biophysically-accurate computational models, performed and analyzed in NEURON 7.2 and Matlab R2010a (Mathworks). In the in vitro experiments we observed the characteristic non-monotonic response curves of RGCs to increasing amplitude of HFS. This response was maintained even when the stimulating electrode was moved away from the axon initial segment of the RGC under study. When the stimulating electrode was moved away from the RGC soma the amplitude required to reach maximum spike rate increased, and when positioned on the side of the soma opposite the axon, the stimulus amplitude required to reach maximum spike rate was significantly higher compared to when the electrode was located on the axonal side of the soma (Kruskel-Wallis, $P<0.0001$). The computational models also produced non-monotonic response curves similar to those observed in the in vitro experiments. Our results show that HFS-based stimulation of RGCs results in characteristic response curves that are not overtly sensitive to electrode placement relative to the axonal initial segment, suggesting the generalizability of the HFS-based preferential activation technique.

Title: Exploration patterns in a visual prosthesis simulation

Authors: ***N. J. KILLIAN**[1,3], M. J. KYADA[4], J. S. PEZARIS[2,3];
[1]Neurosurg., [2]Dept. of Neurosurg., Massachusetts Gen. Hosp., Boston, MA; [3]Dept. of Neurosurg., Harvard Med. Sch., Boston, MA; [4]Dept. of Behavioral Neurosci., Northeastern Univ., Boston, MA

Abstract: Understanding the patterns of visual exploration used in the reduced acuity vision available through a visual prosthesis provides important insights for device design, and improving accessibility to visual information for recipients. As part of the preparations for implanting a visual prosthesis, we have trained three monkeys (*Macaca mulatta*) to recognize letters of the Roman alphabet using simulated artificial vision, using a task that we have previously shown humans are highly skilled at without any training. Here, we have examined the eye movement patterns of the three monkeys during the cue exploration phase of the simulated artificial vision task. We found that the animals' overall performance on the two-alternative forced-choice task improved as they honed their usage of eye movements to explore cue images. In particular, saccade rates increased during learning and higher saccade rates were correlated with greater performance throughout most of the learning time course. Each animal employed unique global patterns of eye movements that were established at the outset of training, suggesting the distinct exploration styles were a result of innate biases rather than high-level strategies. Each animal had their own preferential viewing regions for each individual letter, such as vertices and openings in curves that were largely independent of the viewing condition (letter size, number of phosphenes being simulated). Viewing of these specific regions was detected on all conditions down to the lowest phosphene densities and at all but the smallest font size, suggesting that the animals recognized individual letter forms even in the hardest conditions where performance above chance was barely detectable. The animals performed better when making more saccades within the cue image region and when fixations had higher microsaccadic jitter. Furthermore, the fastest-learning animal used an exploration style characterized by a high saccade rate and high microsaccadic jitter. Our results suggest that training visual prosthesis recipients to explore with a high saccade rate, high jitter style, or artificially mimicking this style through modifications of stimulation patterns, may assist in learning to use phosphene vision for symbol recognition.

Title: The potential for evoking visual perception using epicortical microelectrodes: micro-stimulation of primary visual cortex in nonhuman primates

Authors: *D. OSWALT[1], D. ZHOU[2], D. TOBEY[2], P. DATTA[2], N. TALBOT[2], R. GREENBERG[2], L. RIETH[3], R. SHARMA[3], P. HOUSE[4], B. GREGER[1];
[1]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ; [2]Second Sight Med. Products, Sylmar, CA; [3]Blackrock Microsystems, Salt Lake City, UT; [4]Univ. of Utah, Salt Lake City, UT

Abstract: Electrical stimulation of primary visual cortex is a potential means to restore limited vision to those with profound blindness. Research on restoring vision by cortical stimulation has historically focused on stimulation via epicortical macroelectrodes or intracortical microelectrodes. Epicortical macroelectrodes, those with diameters greater than 2mm, required high levels of current to evoke a visual percept, yielding unnatural sensations and a concern for initiation of seizure activity. Intracortical microelectrodes allowed for greater spatial resolution and lower stimulation thresholds. However, the intracortical placement of a microelectrode array presents surgical challenges and may engender a greater tissue response than epicortical placement. Epicortical microelectrodes may strike a balance between spatial resolution, surgical access, and longevity that maximizes utility to patients.
A 96-channel intracortical microelectrode array (Blackrock Microsystems) and a 47-channel epicortical microelectrode array (Second Sight) were implanted in a nonhuman primate at the right occipital pole and sagittal fissure respectively. The epicortical array was designed with 200um diameter disk electrodes organized into 14 banks of four concentric rings. Inter-electrode spacing was 100um within each bank and 0.5mm to 1.5mm spacing between banks. Photic stimuli were presented to the nonhuman primate at 15 retinotopic points while recording cortical activity. Electrical stimulation consisted of 200ms trains of 0.2ms biphasic pulses. Stimulation was applied monthly via the intracortical array and daily via the epicortical array.
Electrode impedances in the intracortical array fluctuated following implantation and with stimulation (80kΩ-800kΩ). Excluding a few aberrant measurements, electrode impedances on the epicortical array have remained within tolerance (8kΩ-11kΩ) on single disk electrodes. Previously visual percepts have been evoked with simulation as low as 18uA via intracortical microelectrodes (Torab 2011), however, stimulation of a few hundred micro-amps via several electrodes was routinely required (Davis 2012). In the current study, preliminary results indicate the nonhuman primate may perceive a visual sensation with 150uA-300uA electrical stimulation

using epicortical microelectrodes.
Epicortical microstimulation of primary visual cortex may evoke visual percepts within safe levels of current injection, and potentially provide a more practical alternative to intracortical arrays.

Title: Addition of pupil diameter measurements increases brain computer interface performance.

Authors: *K. A. FERCHO[1], E. BURNISON[2], E. K. HANSON[3], L. A. BAUGH[1];
[1]Basic Biomed. Sci., [3]Communication Sci. and Disorders, [2]Univ. of South Dakota, Vermillion, SD

Abstract: When patients suffer from severe motor disabilities, such as those that often accompany amyotrophic lateral sclerosis (ALS), alternative forms of communication may be required to maintain well-being and offset the loss of verbal and/or gesture communication. Although great progress has been made in the development of brain computer interfaces (BCI), improvements are still necessary in the usability, accuracy, and speed of these systems before they can be widely adopted within patient populations. Previous research has shown that pupil diameter not only modulates in response to levels of light and emotionally arousing events, but also in response to a wide range of mental functions including decision making. More recently, the use of pupil diameter has been shown effective as a form of simple no/yes communication within patients with locked-in syndrome. In the present study, we hypothesized that the inclusion of pupil diameter, as recorded through an eye-tracking camera, would increase the accuracy and reduce the classification time associated with the use of a P300 BCI speller. Twenty-five healthy participants identified target letters presented in random sequence while both 9-channel electroencephalography and binocular eye-tracking were performed. As expected, pupil diameter varied as a function of the presence of the target letter, with a mean response of approximately 2mm of pupil dilation occurring during the presence of the target letter. Offline classification algorithms correctly identified target trials with a mean accuracy of 65%, based on P300 data alone. As hypothesized, classification accuracy significantly increased when moment-to-moment pupil diameter was included in the algorithm. This study verifies the utility of including pupil

diameter to create a hybrid brain computer interface application, a particularly appealing option as many alternative communication devices include basic eye-tracking equipment that can readily access this novel source of information. Furthermore, as pupillary response is preserved in patients in a complete locked-in state, when combined with traditional EEG-based BCIs, increased accuracy and ease of use may be possible in cases of severe motor disability. This is especially important as current alternative communication methods require an increase in usability before widespread adoption within patient populations is possible.

Title: Threshold manipulation of retinal ganglion cells using precondition anodic stimulation.

Authors: *Y.-C. CHANG, J. D. WEILAND;
Biomed. Engin., USC, Los Angeles, CA

Abstract: Retinal prosthetic implants have shown potential to restore partial vision to patients blinded by retinitis pigmentosa or age-related macular degeneration, via a camera-driven multielectrode array (MEA) that electrically stimulates surviving retinal neurons. Commercial epi-retinal prosthesis use charge-balanced symmetric cathodic-first biphasic pulses to depolarize retinal ganglion cells (RGCs) and bipolar cells (BCs), resulting in the perception of light in blind patients. However, the potential for asymmetric pulse and the order of both phases has not been fully studied. To investigate RGC activation in response to epi-retinal stimulation, we developed an adeno-associated viral (AAV) vector incorporating the genetically encoded calcium indicator GCaMP6f for labeling a majority of RGCs in mice. The virus was administered through intravitreal injection and the optimal time window for in vitro electrophysiological studies is determined 3-4 weeks later by observing fluorescence of retinal cells in situ, through a

customized fundoscope. At the optimal point, the retina was dissected and maintained in vitro as a wholemount. We then used calcium imaging to record the neural activity from RGCs at single cell resolution in wholemount retinas while applying the electrical stimulation through a MEA with transparent indium tin oxide electrodes. Results show that the spatial pattern of RGC activation can be influenced by the choice of pulse paradigms. Compared with supra-threshold charge balanced symmetric biphasic pulses with cathodic first phase that excite most of RGC in the effective region, symmetric pulses with anodic first phase can inhibit the activation of most RGCs. However, an asymmetric biphasic pulse consisting of an anodic first phase of relatively long duration and low amplitude and a cathodic second phase of short duration and high amplitude has a lower activation threhosld, compared to a biphasic, symmetric, cathodic first pulse. Extending the duration of anodic phase with sub-threshold amplitude slightly hyperpolarizes the membrane potential of RGCs. This has the effect of making the cells highly sensitive to stimulation, thus amplifying the depolarizing effect of a cathodic pulse. These findings support the possibility to manipulate the electrical stimulation thresholds and responses of RGCs through asymmetric pulses.

Title: Neuronal responses in the primary somatosensory cortex during reach-to-grasp movements using native and robotic arm

Authors: *H. MAO[1], S. N. FLESHER[2], R. A. GAUNT[3], A. B. SCHWARTZ[4];
[1]Systems Neurosci. Inst., [2]Bioengineering, [3]Physical Med. and Rehabil., [4]Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Primary somatosensory cortex (SI) receives afferent input from the peripheral sensory apparatus and responds with high fidelity according to characteristics of the stimulus such as location and modality. In addition to this well-recognized afferent driving of SI, we are interested in the possibility of non-peripheral activation of SI cells during movement. While operating a

robot arm via a brain-computer interface (BCI), movement commands from motor cortex are used to control the device and interactions between the robot hand and environment are monitored via visual feedback, which might have the potential to drive SI responses. Thus, this paradigm provides a unique opportunity to study SI activity during motor control but without peripherally driven somatosensory feedback. Two sets of microelectrode arrays were implanted in two hemispheres of a non-human primate. Each set had one array (88 electrodes) placed in the upper arm area of the primary motor cortex (MI) and one array (32 electrodes) in the hand and finger representation of SI. The subject was first trained to perform a reach-to-grasp task using his native arm. Action potentials from arrays contralateral to the performing arm were recorded for this hand-control (HC) experiment. In the BCI experiment, neural activity from the MI array was used to control the robot arm to perform the same reach-to-grasp task. Simultaneously recorded SI activity (in the same hemisphere as the MI array) and kinematics of the robotic arm were saved for offline analysis. An accelerometer, attached to the arm contralateral to the recorded units, was used to determine whether movement of the arm might be generating peripheral sensation during the task. Trials contaminated by movements of the native hand were excluded from analysis for the BCI experiment. In the HC experiment, the overall activity of SI neurons was depressed during reaching, began to increase before object contact, and sharply peaked shortly after contact. In the BCI experiment, 9 out of 29 SI neurons showed modulation around object contact. These included 7 cutaneous and 2 proprioceptive units with receptive fields in the fingers. Most of these units had a peak in activity around object contact or during grasping shortly after initial contact. One, a cutaneous unit, was most active when the robot hand started to close around the object at the end of reaching. Object-related activity peaks during the BCI tasks were broader than those of the same neurons in the HC tasks. These results show that SI can be modulated during motor control by both peripheral and non-peripheral input.

Title: Comparing perceptual latency of microstimulation in human somatosensory cortex to peripheral sensory input

Authors: *J. M. WEISS[1,2], M. KRYGER[1], S. FLESHER[2,3], D. J. WEBER[2,3], J. L. COLLINGER[1,2,3,4], R. A. GAUNT[1,2,3];
[1]Physical Med. and Rehabil., [2]Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA; [3]Ctr. for the Neural Basis of Cognition, Pittsburgh, PA; [4]DVA, Pittsburgh, PA

Abstract: We have recently demonstrated that intracortical microstimulation (ICMS) of human primary somatosensory cortex (S1) can evoke tactile percepts with naturalistic qualities, suggesting that ICMS could be an effective way to provide somatosensory feedback. We expect that the perceptual latency of ICMS needs to be similar to that of natural somatosensory input to be useful for motor control. While animal work has suggested that these latencies are indistinguishable [Romo 2000], these results have yet to be verified in humans. Here we compare the simple reaction times (RTs) of a human participant in response to ICMS in S1 and electrical and mechanical stimulation of the hand.

Under an Investigational Device Exemption, a person with a C5/C6 spinal cord injury was implanted with four microelectrode arrays, including two arrays in S1. Reaction times were measured for single-electrode ICMS of S1 and compared to that of vibrotactile or surface electrical stimulation of the hand in a region with spared sensation. Stimulation amplitudes and electrode/vibrotactor locations were matched to produce perceptually similar experiences from ICMS and peripheral stimulation. After a variable delay, the subject was randomly presented with either ICMS or peripheral stimulation and responded using a bite switch as quickly as possible. All stimuli were presented at 100 Hz for 500 ms. Catch trials in which no stimulus was delivered were randomly interleaved.

RTs to ICMS and peripheral stimulation were similar but highly variable. A total of 176 trials were acquired over three sessions comparing ICMS and vibrotactile RTs. Across the sessions, the median ICMS RT was 28 ms longer than the vibrotactile RT ($p < 0.01$, Wilcoxon rank sum). However, vibrotactile RTs were highly variable between days, ranging from 55 ms shorter than ICMS to 129 ms longer. An additional 144 trials over three sessions were acquired comparing ICMS and electrical RTs. Across the sessions, the median ICMS RT was 21 ms longer than the electrical RT ($p < 0.05$), and ranged from 69 ms longer than electrical to 9 ms shorter. Considering RTs from all six sessions and stimulus modalities (ICMS vs. peripheral stimulation), a multi-factor ANOVA revealed that day-to-day variability was significant ($p < 0.001$), but stimulus type was not ($p = 0.168$). Across all sessions, the participant failed to respond to 2.2% of stimulus trials and erroneously responded to 3.1% of catch trials.

These data suggest that the difference in RT between single-electrode ICMS and natural sensory input is small, although additional data are required to account for the day-to-day variability.

Title: A sensory substitution system for providing grasping force and hand opening feedback from a sensorized myoelectric hand

Authors: ***A. E. PENA**[1], L. RINCON-GONZALEZ[1], D. AGUILAR[1], J. ABBAS[2], R. JUNG[1]; [1]Florida Intl. Univ., Miami, FL; [2]Arizona State Univ., Tempe, AZ

Abstract: Current myoelectric prosthetic limbs are limited in their ability to provide direct sensory feedback to their users. Increased reliance on visual cues and attentional demand by the amputee can impact their ability to perform several daily life activities. We are investigating a non-invasive approach for providing sensory feedback through vibrotactile stimulation. Previous studies have taken advantage of the "referred sensations" in the residual limbs, placing tactors directly on the locations where the sensation is felt as if it was coming from the phantom fingers. While this approach can be effective, it requires costly prosthetic socket modifications to embed the tactors and not all amputees experience referred sensations. Though many sensory substitution studies have been done, none have shown significant performance improvements in control of myoelectric hands. For this study we have developed a wearable system that delivers vibratory patterns mapped to the sensor outputs of an instrumented myoelectric hand to deliver grasping force and hand opening (position) information. The feedback system uses a single tactor to convey force and an array of five tactors to convey position.
Initial studies with 6 able-bodied subjects were performed to validate the feedback system. During these studies, the tactors were placed on the lateral surface of the upper arm. We investigated whether subjects could discriminate and identify 5 different levels of force and position independently. In 3 blocks of randomized stimulation trials, subjects were instructed to report the level of force and position perceived while receiving no visual feedback from the hand. Performance was assessed using success rate during the third block. On average, subjects had a success rate of 79±10.9% and 84±12.7% at identifying discrete force and position levels, respectively. These results suggest that this sensory substitution system could be used to deliver grasping force and position feedback. Future work will investigate the effect of substitute sensory feedback on the users' ability to control force and position outputs of a myoelectric hand.

Title: Intracortical microstimulation of human somatosensory cortex elicits cutaneous percepts

Authors: ***S. N. FLESHER**[1], J. L. COLLINGER[2], S. T. FOLDES[2], J. M. WEISS[1], J. E. DOWNEY[1], E. C. TYLER-KABARA[3], S. J. BENSMAIA[5], A. B. SCHWARTZ[4], M. L. BONINGER[2], R. A. GAUNT[2];

Abstract: Dexterous object manipulation requires cutaneous sensory feedback. In its absence, simple tasks are very difficult. In prosthetic limbs controlled through brain-computer interfaces (BCIs), providing somatosensory feedback could be an important step to improving function as vision provides impoverished cues about object interactions. Intracortical microstimulation (ICMS) of primary somatosensory cortex (S1) is a potential method to restore this sensory channel, particularly in people that cannot benefit from stimulation of the peripheral nervous system. Under an Investigational Device Exemption, a 28 year old participant with a chronic spinal cord injury was implanted with 2 intracortical microelectrode arrays (MEAs) in motor cortex and 2 MEAs in area 1 of S1. Locations of the S1 MEAs were based on presurgical imaging with the goal of eliciting percepts that project to the fingers of the right hand. Electrodes were stimulated at supraliminal intensities and the participant described the locations and qualities of evoked percepts. Projected fields were located on the proximal pads of digits 2-5. Sensations were evoked on 59 of 64 electrodes, and no painful sensations or paresthesias were reported. We tested whether the subject could use this spatial information to identify which of four fingers on a robotic limb was touched by converting robot finger torque to stimulus intensity. The load-bearing finger was identified with 84.3% accuracy (54 trials).
We measured detection thresholds using a two-alternative forced choice task and found the

median detection threshold to be 34.9μA, with upper and lower quartiles at 60.0 and 24.8μA, respectively. Thresholds were generally stable over 11 months. Of the 32 electrodes with 3 or more measured thresholds 7 changed significantly over time, 3 of which had a negative slope, suggesting thresholds were not globally increasing.
We measured the discriminability of ICMS trains differing in amplitude and found the just noticeable differences to be 15.4 ± 3.9 μA (mean ± s.d.) and independent of the magnitude of the reference stimulus. In magnitude estimation experiments, we found that perceived intensity increased linearly with stimulation amplitude (R2 = 0.98) for 5 electrodes tested.
In summary, percepts were evoked at somatotopically appropriate locations with intensities that scaled linearly with amplitude over a wide range. These properties of evoked percepts can be used to convey location and intensity of object contact, key types of information for guiding interactions with objects. Providing artificial somatosensory feedback to BCI users could improve the user's control and experience with the prosthetic device.

Title: Investigation of peripheral nervous system interfaces for motor decoding and somatosensory stimulation.

Authors: *J. M. BUIL[1], H. SCHERBERGER[2];
[1]Neurobio. Lab., Deutsches Primatenzentrum GmbH, Goettingen, Germany; [2]Neurobio. Lab., Deutsches Primatenzentrum GmbH, Göttingen, Germany

Abstract: Until recently, neural interface research for (bidirectional) prosthetic use has focused to a large extent on direct interactions with the brain. An alternative approach is to interface at the peripheral nervous system (PNS) instead. Transverse Intrafascicular Multichannel Electrodes (TIMEs) are thin film, polymide, electrode arrays that are inserted transversally through the nerve. These allow the recording and stimulation of individual fascicles in the peripheral nerves. To investigate if these PNS interfaces are suitable for bidirectional prosthetic use, we implant

multi-channel TIME electrodes in the medial and ulnar nerve in the upper limb of a rhesus monkey (Macaca mulatta) and assess if we can decode motor activity from them and stimulate the nerve in order to evoke somatosensation.
Purpose-bred macaque monkeys (*Macaca mulatta*) are trained in a delayed grasping task to grasp a wide range of different objects (42 objects with equal weight but different size and shape). Simultaneously activity of the median and ulnar nerve is recorded as well as the hand and arm kinematics with a 27 DOF electromagnetic hand tracking system. Decoders are trained to decode both grip type (Bayesian decoder) and hand kinematics (Kalman filter) from the neural activity.
For the somatosensory discrimination task, a rhesus macaque is trained to perform a two-alternate-forced choice task in which it receives vibrational or electrical stimulation to the median and ulnar side of the hand, respectively, by applying vibration to the index or little finger, or electrical stimulation to the median or ulnar nerve. It is required to indicate, by pressing a button, which side of the hand was stimulated more intensely. Observing the monkey's behavior will show how strong the electrical stimuli are perceived compared to the vibrational stimuli.
A short-term implantation experiment showed that the implantation technique of TIME electrodes in the PNS of rhesus macaques is feasible, including the placement of a subcutaneous cable and a cranial connector; no signs of loss of hand function were observed post-surgery. Neural activity was recorded over a period of two weeks, in which single unit spikes have been observed, and it was shown that the electromagnetic field, generated by the hand tracking system, did not affect the signal quality, neither concerning the noise level nor the ability to detect spike information. This makes us believe that hand tracking is possible during neural PNS recordings. Investigation of TIMEs in non-human primates provides valuable information regarding the recording and stimulation capabilities of these PNS interfaces prior and in addition to human studies.

Title: Quantification of tactile sensory content in multielectrode array recordings from finger area of macaque motor cortex

Authors: *K. E. SCHROEDER[1], Z. T. IRWIN[1], A. J. BULLARD[1], D. E. THOMPSON[6], J. BENTLEY[7], P. G. PATIL[7,8,1], C. A. CHESTEK[1,2,3,4,5];

Sch., Ann Arbor, MI

Abstract: Challenges in the control of dexterous upper-limb brain-machine interfaces (BMIs) have prompted renewed interest in the amount and nature of sensory information encoded in primary motor cortex (M1). Signals used for motor decoding also contain sensory information, which can interfere with prosthetic performance in contexts where sensation is most important, such as object manipulation. Previous single unit studies in monkeys showed M1 is responsive to tactile stimulation, as well as passive and active movement of the limbs. Recent work in this area has quantified proprioceptive responses of chronically recorded neurons, so here we examined to what extent tactile somatosensation of the hand and fingers is represented in M1 array recordings. We recorded multi- and single units from macaque M1 while gently brushing individual finger pads at 2 Hz. Units displaying significant differences in firing rates between individual fingers ($p<.05$) were found in four animals. Many units exhibited cosine-like tuning across multiple digits, similar to motor tuning profiles. Enough sensory information was present in M1 to correctly decode stimulus position from multiunit activity significantly above chance levels (ranging from 60-90% correct across four animals for a 1 of 3 classification). Additionally, preliminary examination of unit tuning during tactile and proprioceptive inputs indicates cells are often tuned differently in different contexts. The depth and widespread presence of sensory tuning found in these M1 populations implies that more careful and comprehensive training of decoders in the presence of sensory stimuli will be needed for the refinement of BMI for dexterous grasping.

Title: Neural speech recognition: Continuous phoneme decoding using spatiotemporal representations of human cortical activity

Authors: *D. A. MOSES[1,2,3], N. MESGARANI[2,3], M. K. LEONARD[2,3], E. F. CHANG[1,2,3]; [1]Bioengineering, UC Berkeley - UC San Francisco, San Francisco, CA; [2]Neurolog. Surgery, [3]Ctr. for Integrative Neurosci., UC San Francisco, San Francisco, CA

Abstract: The superior temporal gyrus (STG) and neighboring brain regions play a key role in human language processing. Previous studies have attempted to reconstruct speech information from brain activity in the STG, but few of them incorporate the probabilistic framework and engineering methodology used in modern speech recognition systems. In this work, we describe the initial efforts toward the design of a neural speech recognition (NSR) system that performs continuous phoneme recognition on English stimuli with arbitrary vocabulary sizes using the high gamma band power of local field potentials in the STG and neighboring cortical areas obtained via electrocorticography. The system implements a Viterbi decoder that incorporates phoneme likelihood estimations from a linear discriminant analysis model and transition probabilities from an n-gram phonemic language model. Grid searches were used in an attempt to determine optimal parameterizations of the feature vectors and Viterbi decoder. The performance of the system was significantly improved by using spatiotemporal representations of the neural activity (as opposed to purely spatial representations) and by including language modeling and Viterbi decoding in the NSR system. These results emphasize the importance of modeling the temporal dynamics of neural responses when analyzing their variations with respect to varying stimuli and demonstrate that speech recognition techniques can be successfully leveraged when decoding speech from neural signals. Guided by the results detailed in this work, further development of the NSR system could have applications in the fields of automatic speech recognition and neural prosthetics.

Title: Muscle contraction is significantly associated with proprioception restored with electrical nerve stimulation with a Flat Interface Nerve Electrode (FINE)

Authors: *M. SCHIEFER[1,2], I. CUBEROVIC[1,2], E. L. GRACZYK[1,2], D. J. TYLER[1,2]; [1]Biomed. Engin., Case Western Reserve Univ., Cleveland, OH; [2]Louis Stokes Cleveland Dept. of Veterans Affairs Med. Ctr. (LSCDVAMC), Cleveland, OH

Abstract: Amputees lack a sense of proprioception of the prosthetic limb, requiring visually monitoring of limb motion and object interactions. A subject with a trans-radial amputation was implanted with a sensory restoration system. The system has 8-channel Flat Interface Nerve Electrodes (FINEs) positioned around the median, radial, and ulnar nerves in his residual arm. FINE leads are routed to a percutaneous site through which we interface our programmable stimulator with his nerves. The subject undergoes experiments during which he reports the perception in his phantom hand, including its position, during electrical nerve stimulation. We observed that muscle contraction accompanies a sensation of movement in the phantom hand. We investigated the effect of electrical stimulation on the perceived position of the thumb and index finger. To assess phantom digit position, the subject was fitted with a calibrated CyberGlove, which measures the angle of the fingers' joints. When presented with electrical stimulation, the subject mirrored his phantom hand's position with his contralateral hand. Surface electrodes were positioned over the locations in his residual arm where muscle contraction was observed and electromyograms (EMGs) were recorded. EMGs were filtered, rectified and integrated, and normalized by the maximum voluntary contraction. Finally, the subject described the sensation to each stimulus that was presented. During one set of trials, biphasic stimuli with constant amplitude (0.7 mA) and frequency (100 Hz) were delivered to the median nerve. The pulsewidth (PW) of the stimulus had one of four envelopes: flat; a linearly increasing PW followed by a linearly decreasing PW; a linearly increasing PW that plateaued; a linearly increasing PW followed by abrupt cessation of stimulation. The stimulus duration varied between 1-5 seconds. During a second set of trials, the flat PW envelope was applied while PW varied between 120 μs (sensory threshold) and 255 μs. Results support initial observations that

proprioception occurs only when EMG was observed ($p<0.001$). As duration and PW increased, EMG and perceived motion increased. In 25% of trials, EMG was recorded while no movement was reported. In 75% of trials, both EMG and proprioception were concomitant. The shape of the PW envelope was an excellent predictor of joint motion. Results suggest that proprioceptive sensation is due to muscle contraction, but because 25% of trials had EMG alone, muscle contraction may not be the sole driver of proprioception. This is further supported by results from a second subject who has never reported proprioception and in whom muscle contraction has never been observed.

Microtechnology Dept. of Microsystems Engin. Univ. of Freiburg - IMTEK, Freiburg, Germany

Abstract: Recently, several groups reported the possibility to effectively restore the natural hand sensory information in trans-radial amputees, by using intraneural, epineural and wire peripheral neural interfaces. In particular, we showed that intraneural peripheral stimulation could provide sensory information about grasping force, object shape, and stiffness to an amputee during the real-time control of a dexterous hand prosthesis in a one-month trial implemented by using non-portable devices for recording and stimulation. Here we show the results of a six-month implant of transversal intraneural multifascicular electrodes (TIMEs) in median and ulnar nerves of a trans-radial amputee. Moreover, we developed a fully portable system for recording and stimulation, which enabled the user to perform ecological tasks in unstructured environments. During the stimulation sessions, the map of the different sensations elicited in the phantom hand and palm was obtained by changing the stimulation parameters (amplitude, pulse width and

frequency) for all 56 contacts of the TIMEs. Sensations were mainly reported as touch-like pulsations, vibrations, and electroparesthesia. Moreover, when different channels were coupled together it was possible to obtain different, more complex sensations. The physiological plausibility and homologous nature of elicited sensations have been confirmed by EEG recordings. The information acquired with the sensation map was used to implement a bidirectional control of hand prosthesis. This setup has been used then, to evaluate the capability of the user to produce different force levels, to perform manipulation tasks (e.g., a blindfolded box and block test) and everyday activities tasks. The participant showed good ability to produce high and low force levels, and performed very well during blindfold manipulation tasks.Finally the users was able to step out from the laboratory and perform different tasks using the induced feedback.The next steps towards the close-to-natural replacement of lost hands are to extend the types of sensations, which can be elicited and to develop a fully implantable device.

Title: Determining the role of TRP channels in inspiratory burst generation

Authors: K. E. DORST, *M. C. D. PICARDO, C. A. DEL NEGRO;
Applied Sci., Col. of William and Mary, Williamsburg, VA

Abstract: We aim to understand the neural origins of breathing in mammals. The neurons that generate the breathing rhythm are located in a region of the medulla called the preBötzinger Complex (preBötC). These rhythmic neurons in the preBötC arose from progenitors that have expressed the embryonic transcription factor Dbx1. Dbx1-derived preBötC neurons also generate Ca^{2+}-activated non-selective cationic current (I_{CAN}), which is hypothesized to give rise to inspiratory drive potential, i.e. the envelope of depolarization underlying inspiratory bursts. The inspiratory drive potential of preBötC rhythmic neurons can be altered through manipulations

affecting I_{CAN}, such as blocking the current by external flufenamic acid (FFA) or preventing its activation via intracellular BAPTA dialysis. However, the underlying molecular component that is involved in inspiratory burst-generation in these neurons remains unknown. Transient receptor potential (TRP) ion channels are likely candidates of I_{CAN} generation in the preBötC based on previous evidences. For many years, we focused our efforts on the Trpm4 as the putative ion channel responsible for generating the inspiratory drive potential. Trpm4 has been previously shown to be present in the preBötC, and possesses properties that best suit the channel underlying inspiratory drive potentials.
However, recent data acquired from single-cell RNA sequencing (RNAseq), immunohistochemistry, and electrophysiological experiments suggest that Trpm4 may not be the main ion channel that underlies inspiratory behavior. Whole-cell *in vitro* experiments using newborn mouse brainstem slices revealed that the selective Trpm4 antagonist, 9-phenanthrol, produced minor to no attenuation of inspiratory drive potential in Dbx1-derived preBötC neurons. In comparison, experiments using FFA have shown a greater extent of inspiratory drive potential attenuation in these neurons. RNAseq results show that the Trpm4 gene is not as highly expressed as a few other TRP genes. Immunohistochemical staining have also indicated the relatively minimal expression of Trpm4 proteins in Dbx1-derived preBötC neurons. These findings lead us to suggest that Trpm4 may not be a major contributor in generating inspiratory drive potential, and that there is another ion channel of interest. Further electrophysiological and immunohistochemistry experiments are needed in order to determine if our new candidate channel is the molecular component that we seek to identify.

Title: Ca^{2+}-activated K^+ (BK) channels contribute to the ATP excitation of inspiratory rhythm generating networks *In vitro*

Authors: V. JALUBULA, Y. ZHANG, A. K. KATZELL, V. RANCIC, *A. L. REVILL, K. BALLANYI, G. D. FUNK;
Dept. of Physiol., Univ. of Alberta, Edmonton, AB, Canada

Abstract: The hypoxic ventilatory response is biphasic. An initial carotid-body mediated increase is followed by a secondary, centrally-mediated respiratory depression that can be life-threatening in premature infants. During hypoxia ATP is released in the ventral respiratory column, including the preBotzinger Complex (preBötC, key site of inspiratory rhythm generation), where it evokes a $P2Y_1$ receptor-mediated increase in inspiratory frequency that attenuates the secondary depression. In other systems, $P2Y_1$ receptors are coupled to the Gαq-signaling pathway, which involves phospholipase C- and inositol trisphosphate-mediated release of Ca^{+2} from intracellular stores. My objectives were to test whether the $P2Y_1$ receptor-evoked frequency increase depends on release of Ca^{+2} from intracellular stores and then to identify the downstream ion channel(s) that mediate the actions of $P2Y_1$ receptors in the preBötC. Rhythmically-active medullary slices from neonatal rats were loaded with the Ca^{+2} indicator Fluo-4 (via pressure injection) and fluorescence monitored with multiphoton microscopy. Inspiratory neurons, identified by rhythmic Ca^{+2} fluorescence oscillations in phase with inspiratory-related bursts recorded from the XII nerve, responded to the $P2Y_1$ receptor agonist, MRS2365 (100 μM, 10 s), with 2-3 fold increases in intracellular Ca^{+2}. Depletion of intracellular Ca^{+2} stores via bath and local application of SERCA blockers, Thapsigargin (200 μM) and Cyclopiazonic acid (100 μM), blocked the MRS2365-evoked increase in intracellular Ca^{+2} and reduced the MRS2365-evoked frequency increase by 58 ± 9% and 28 ± 7% of control, respectively. I then tested involvement of ion channels known to be modulated by $P2Y_1$ receptors or intracellular Ca^{+2}. I compared MRS2365-evoked frequency increases before and after bath or local application of $BaCl_2$, Apamine, Iberiotoxin and trimethylamine to block G protein-coupled inwardly rectifying potassium channels (GIRK), SK channels, and BK channels, respectively. None of these drugs significantly attenuated the MRS2365 frequency increase. In contrast, Paxilline, a type 2 BK channel blocker, applied at 20 and 1 μM attenuated the MRS2365 response by 46 ± 11% and 32 ± 5% of the control response, respectively. Multiphoton Ca^{+2}-imaging revealed that Paxilline did not affect intracellular Ca^{+2}. Thus, it is unlikely that the effects of Paxilline were due to potential off-target actions on SERCA. These data suggest that $P2Y_1$ receptor mediated increases in inspiratory related frequency in vitro depends partly on release of Ca^{+2} from intracellular stores and activation of BK channels. Title: ATP excites the preBötzinger Complex network *In vitro* via activation of a $G_{\alpha q}$-signaling pathway

Authors: *Y. ZHANG[1], T. ALVARES[1], A. V. GOURINE[4], S. KASPAROV[5], G. D. FUNK[1,2,3]; [1]Dept. of Physiol., [2]Women and Children's Hlth. Res. Inst., [3]Neurosci. and Mental Hlth. Inst., Univ. of Alberta, Edmonton, AB, Canada; [4]Dept. of Neuroscience, Physiol. & Pharmacol., Univ. Col. London, London, United Kingdom; [5]Sch. of Physiol. & Pharmacol., Univ. of Bristol, Bristol, United Kingdom

Abstract: The ventilatory response to hypoxia comprises an initial increase in ventilation followed by a secondary depression that can be life-threatening in premature infants. Astrocytes sense hypoxia and release ATP. ATP released within the ventral respiratory column, including the preBötzinger Complex (preBötC, critical site for inspiratory rhythm generation), during hypoxia attenuates this depression. Our working hypotheses are that ATP released from preBötC astrocytes during hypoxia 1) excites local inspiratory neurons directly via $P2Y_1$ receptor (R)-dependent activation of $G_{\alpha q}$-signaling pathway and 2) acts in an autocrine/paracrine manner to enhance gliotransmission, which further depolarizes inspiratory neurons. Using 700 μm rhythmically-active medullary slices from neonatal rats, we first tested the effects of U73122 (phospholipase C inhibitor), 2-APB (inositol triphosphate receptor inhibitor) and chelerythrine (protein kinase C inhibitor) on the $P2Y_1R$ excitation of the inspiratory network. Bath application and local injection into the preBötC of U73122 (20 μM) shortened the duration of MRS2365 ($P2Y_1R$ agonist, 100 μM)-evoked frequency increase of inspiratory-related activity recorded from XII nerve rootlets by 42.8 ± 11.8% (n=9), but did not affect the peak frequency. In contrast, bath application of 2-APB (100 μM) and chelerythrine (10 μM) reduced the MRS2365-evoked frequency increase by 32.6 ± 8.8% (n=5) and 31.1 ± 4.2% (n=8) respectively. We then compared ATP (5 mM) currents evoked in inspiratory neurons before and after intracellular dialysis of the

same drugs. Intracellular dialysis of U73122 (2 μM, n=7), 2-APB (50 μM, n=5) and chelerythrine (10 μM, n=8) attenuated ATP-induced inward currents in inspiratory neurons by 38 ± 4.3%, 32.6 ± 12.6% and 20.6 ± 4.6%, respectively. Intracellular dialysis of endoplasmic reticulum Ca^{2+}-ATPase blocker thapsigargin (4 μM, n=10) and cyclopiazonic acid (20 μM, n=9) also attenuated the ATP currents by 22.6 ± 5.2% and 21.6 ± 3.5% respectively. Our second objective was to determine if the ATP excitation of inspiratory neurons includes an astrocytic glutamate component. We compared ATP currents evoked in inspiratory neurons before and after bath application of glutamate R antagonists AP5 (100 μM) and CNQX (10 μM) (in 0.5 μM TTX). AP5 and CNQX had no effect on ATP currents (n=8). These data suggest that i) ATP excitation of the preBötC network is produced, at least in part, via activation of a $G_{\alpha q}$-signaling pathway in inspiratory neurons and ii) neuronal excitation by ATP does not include a glial-derived glutamatergic component.

Title: Optogenetic dissection reveals principles underlying respiratory frequency control

Authors: *J. CREGG[1], K. CHU[1], T. E. DICK[2], L. T. LANDMESSER[1], J. SILVER[1]; [1]Neurosciences, [2]Pulmonary, Critical Care, and Sleep Med., Case Western Reserve Univ., Cleveland, OH

Abstract: Central neural networks operate continuously throughout life to control respiration, yet mechanisms regulating ventilation frequency are not understood. Inspiratory rhythm is generated by a *purely excitatory* network within the preBötzinger complex (preBötC) of the ventrolateral medulla. Working models predict that preBötC burst frequency is controlled by a balance of excitatory and inhibitory synaptic inputs, where excitation increases and inhibition decreases inspiratory rate. We tested assumptions of this model using an optogenetic approach. We found that in the absence of inhibitory synaptic transmission, excitatory network activity can generate rapid inspiratory bursting, with an upper frequency limit of ~35 min^{-1}. Interestingly, selective stimulation of excitatory Phox2b+ neurons generated inspiratory rates reaching twice this frequency—as high as ~70 min^{-1}—suggesting that inhibitory neurons are critical for rapid inspiratory bursting. In support of this, we found that blocking inhibitory synaptic transmission

completely abolished *Phox2b::ChR2* mediated increases in inspiratory frequency. To investigate inhibitory mechanisms that might contribute to rapid inspiratory bursting, we selectively stimulated Vgat+ neurons and found that phasic stimulation of inhibitory neurons can actually drive rapid inspiratory rates through post-inhibitory rebound excitation. Blocking post-inhibitory rebound abolished *Phox2b::ChR2* mediated increases in inspiratory frequency. To examine the source of phasic inhibition which generates rapid inspiratory bursting, we tested the hypothesis that Phox2b+ neurons initiate expiratory bursting, but via inhibitory synaptic coupling, cause inspiratory bursting through post-inhibitory rebound excitation. Indeed, we found that stimulation of Phox2b+ neurons resulted in late expiratory bursting with ~110 ms latency, followed subsequently by inspiratory bursting (~390 ms latency). These results demonstrate that—at least at high respiratory frequencies—inspiratory rhythm is generated by dynamic inhibitory interaction between two or more medullary nuclei rather than the dominant excitatory pacemaker activity of the preBötC. Additionally, these data indicate that inhibitory neurons are essential for generation and maintenance of fast inspiratory rhythms.

Title: Optogenetic analysis of neuronal network of medullary respiratory center in brainstem-spinal cord preparations from transgenic newborn rats expressing Archaerhodopsin in Phox2b positive cells

Authors: *H. ONIMARU[1], K. IKEDA[2], M. OGAWA[3], K.-I. IHARA[4], K. KOBAYASHI[4], K. KAWAKAMI[5];
[1]Showa Univ. Sch. of Med., Tokyo, Japan; [2]Div. Biol, Hyogo Col. Med., Hyogo, Japan; [3]Dept Dev Physiol, NIPS, Okazaki, Japan; [4]Dept Mol Genet, Fukushima Med. Univ., Fukushima, Japan; [5]Div. Biol, Jichi Med. Univ., Tochigi, Japan

Abstract: Preinspiratory (Pre-I) neurons in the parafacial respiratory group (pFRG) compose one of the respiratory rhythm generators in the medulla of the newborn rat. A subgroup of pFRG/Pre-I neurons express the transcription factor Phox2b. To analyze detailed neuronal mechanisms of respiratory rhythm generation using optogenetics, we made transgenic (Tg) newborn rats in which Phox2b positive cells expressed Archaerhodopsin-3 (Arch). Phox2b_tTA-2A-Cre Rec BAC rats were mated with CAG-loxP-Stop-loxP-Arch/Rosa BAC rats. We found specific expression of Archaerhodopsin-3 in Phox2b positive cells when CAG-loxP-Stop-loxP-Arch/Rosa BAC male rats were mated with Phox2b_tTA-2A-Cre Rec BAC female rats, whereas the expression was non-specific in reverse pairings. Brainstem-spinal cord preparations were isolated from 0-4 days old Tg newborn rats deeply anesthetized with isoflurane and were superfused at a rate of 3.0 ml/min with the artificial cerebrospinal fluid, equilibrated with 95% O_2 and 5% CO_2, pH 7.4, at 25-26°C. The preparations were cut transversely at a level just rostral to the anterior inferior cerebellar artery. To examine photostimulation to the pFRG (left side), the medulla was further cut to remove a right half of the pFRG in the most experiments. Photostimulation of the ventral medulla was performed by green laser light (532 nm) through an optic fiber with 1 mm outer diameter. Inspiratory C4 ventral root activity was monitored and membrane potentials of Pre-I or inspiratory neurons were recorded in the pFRG. Continuous photostimulation up to 90 s of the rostral ventral medulla covering the pFRG induced decrease of respiratory rate or complete cessation of respiratory rhythm accompanied with membrane hyperpolarization of pFRG-Phox2b positive Pre-I neurons, whereas the inhibitory effects tended to decline during the continuous photostimulation more than 30 s. We confirmed that this method is useful for analysis of the local circuits of respiratory rhythm generation in the en bloc newborn rat preparation.

Title: Optogenetic stimulation of pre-Bötzinger complex and Bötzinger complex inhibitory neurons reveals a major role of inhibition in respiratory central pattern generation

Authors: *H. KOIZUMI[1], W. BARNETT[2], M. F. TARIQ[1], B. MOSHER[1], T. JOHN[1], R. ZHANG[1], I. A. RYBAK[3], Y. I. MOLKOV[2], J. C. SMITH[1];

Abstract: The architecture of respiratory central pattern generator (CPG) circuits remains not fully understood. Different components of the normal three-phase rhythmic respiratory pattern are postulated to be generated by different neuronal populations distributed within the pre-Bötzinger complex (pre-BötC) and Bötzinger complex (BötC) regions, which contain core circuit components of the CPG. Interacting inhibitory microcircuits in these compartments are proposed to be critical for generating the three-phase rhythmic pattern, but this has not been demonstrated definitively. We applied optogenetic techniques to manipulate activity of pre-BötC or BötC inhibitory neurons to test for perturbations of respiratory neural activity. We employed a transgenic mouse line expressing Cre-recombinase in neurons promoted by the vesicular GABA transporter (VGAT) for inhibitory neuron specific expression of Channelrhodopsin-2 (ChR2). VGAT is expressed in both GABAergic and glycinergic inhibitory neurons. With precisely positioned optical cannulae bilaterally in adult transgenic mouse *in situ* perfused brainstem-spinal cord preparations, we laser (473 nm) stimulated inhibitory neurons in pre-BötC or BötC regions, while recording phrenic and vagus nerve respiratory motoneuronal outflows. Continuous photo-stimulation (20 Hz, pulsed trains) of BötC inhibitory neurons prolonged the duration of the expiratory phase in a laser power dependent manner (0.5-2 mW), and at highest laser power eliminated respiratory oscillations in both phrenic and vagus nerves. Extracellular recordings showed suppression/silencing of inspiratory activity in pre-BötC during the laser stimulation of BötC inhibitory neurons. Continuous photo-stimulation of the pre-BötC increased respiratory frequency by reducing the duration of expiration in a laser power dependent manner (0.5-2 mW). Extracellular recordings demonstrated suppression/silencing of activity of post-inspiratory neurons in BötC during photo-stimulation of pre-BötC inhibitory neurons. We quantitatively reproduced these perturbations in our computational model describing interactions between pre-BötC and BötC circuits by selective graded stimulation of the corresponding inhibitory populations. Our experimental data together with computer simulations indicate a major role of BötC and pre-BötC inhibitory neurons in controlling respiratory phase durations and three-phase respiratory pattern generation in a manner consistent with mutual inhibitory interactions.

Title: Optogenetic inhibition of Dbx1 preBötzinger complex neurons suppresses breathing in mice

Authors: ***N. C. VANN**, F. D. PHAM, C. A. DEL NEGRO;
Col. of William and Mary, Williamsburg, VA

Abstract: Breathing is an essential and incessant behavior for humans and all terrestrial mammals. Inspiratory breathing movements emanate from neural rhythms generated in the preBötzinger complex (preBötC) of the ventral medulla, wherein interneurons derived from Dbx1-expressing precursors (i.e., Dbx1 neurons) are hypothesized to comprise the core oscillator circuit. Here we test this Dbx1 core hypothesis using intersectional mouse genetics. We expressed the proton pump Archaerhodopsin (Arch) in Dbx1 neurons to transiently inhibit those in the preBötC via bilateral 589-nm laser pulses, while simultaneously monitoring respiratory rhythm in vitro or breathing behavior in vivo. In a slice model that spontaneously generates inspiratory rhythm and motor output, Arch activation resulted in a 6 mV hyperpolarization of Arch-expressing Dbx1 neurons in patch-clamp recordings as well as ~25 s cessations of inspiratory motor output. In vagus-intact adult mice, Arch activation reduced respiratory frequency and prolonged inspiratory cycle time. Furthermore, Arch activation caused apneas lasting as long as ~18 s in anesthetized mice. These data are consistent with the Dbx1 core hypothesis, specifically indicating that Dbx1 neurons comprise the core oscillator for inspiratory breathing movements. Breathing behavior is unique in that the genetic origin of a key rhythmogenic population is known, which provides a well-defined target for detailed investigations that elucidate the cellular, synaptic, and molecular-level mechanisms underlying respiration in mammals.

Title: Adenosine inhibits the preBötzinger complex inspiratory network during the first two weeks of postnatal development

Authors: *R. J. REKLOW, G. D. FUNK;
Dept. of Physiol., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Acute exposure to moderate hypoxia evokes a biphasic ventilatory response, comprising of an initial increase in ventilation within the first minute followed by a secondary depression over the next several minutes that can be life-threatening in premature infants. The initial increase is primarily attributed to activation of the carotid body chemoreceptors while the secondary depression is believed to be primarily central in origin. The hypoxic depression of breathing is strongly implicated in life-threatening apneic events that occur in premature infants, cardiovascular diseases that accompany obstructive sleep apnea and may be a factor in SUDEP (sudden unexplained death in epilepsy). Despite its clinical significance, underlying mechanisms are poorly understood. The increased level of extracellular adenosine (ADO) during hypoxia is implicated in the ventilatory depression but data are ambiguous, likely reflecting variability in the magnitude of the hypoxic stimulus, as well as developmental and species differences in the extent of the secondary depression and its underlying mechanisms. In adult sheep and rats, a suprapontine A2a receptor-mediated activation of GABAergic neurons is implicated. In neonatal rats, a direct A1 receptor-mediated inhibition of the brainstem respiratory network also appears to contribute. The ADO inhibition in rats disappears at 3 days postnatal (P3), suggesting that this may contribute to the greater depression in neonates. The aim of this study was to test the hypothesis that the ADO sensitivity of preBötC network decreases during postnatal development. ADO was locally applied to the preBötC (functionally identified by a strong Substance P evoked

frequency increase) of rhythmically-active medullary slices isolated from mice ranging in age from P0-12. At P0-5, ADO (500 μM, 30 s) inhibited inspiratory-related frequency by approximately 30%. Similar inhibitory effects were observed between P6-12. The $P2Y_1$ receptor agonist, MRS2365 (100 μM, 10 s), increased frequency by 2-3 fold at all ages (P0-12), indicating that the sensitivity of the respiratory network to $P2Y_1$ receptor-mediated excitation also persists over this developmental window. These data suggest that ADO-mediated inhibition of the preBötC inspiratory rhythm generating network may contribute to the hypoxic respiratory depression during the first two weeks of development. In addition, if extracellular ADO is derived from the degradation of extracellular ATP that is released during hypoxia, the secondary depression will be determined by the interaction between the excitatory effects of ATP at P2 receptors and inhibitory effects of ADO at P1 receptors.

Abstract: Respiratory movements in mammals are produced by the brainstem respiratory central pattern generator (CPG). Core structures of the respiratory CPG are the pre-Bötzinger (pre-BötC) and Bötzinger (BötC) complexes whose network interactions control respiratory oscillations. The normal breathing rhythm (eupnea) includes three phases of the cycle: inspiration, post-inspiration (post-I), and the second phase of expiration (E2). Synaptic inhibition in the CPG circuits has been proposed to be essential for generating this eupneic pattern. However, the importance of inhibitory interactions in the respiratory CPG as well as types of inhibitory neurotransmitters involved has been established based on pharmacological and modeling studies. As a first step in deciphering the CPG inhibitory circuits, we employed lentiviral vector-based gene transfer to express either channelrhodopsin (ChR2) or archaerhodopsin (Arch) photo-sensitive channels in glycinergic neurons of pre-BötC in Wistar rats (confirmed using immunocytochemistry *post hoc*), and we used optical control for either ChR2-mediated excitation (480 nm) or Arch-mediated inhibition (530 nm) to stimulate/inhibit these neurons, respectively, while recording from multiple respiratory motor outputs simultaneously in the *in situ* perfused juvenile rat brainstem-spinal cord preparation. Optogenetic excitation of pre-BötC glycinergic neurons significantly increased respiratory frequency due to the disappearance of E2. Optogenetic inhibition also increased the respiratory frequency, but unlike optical excitation, activation of Arch suppressed the post-I phase. We used a well-established computational model of the respiratory CPG to mechanistically explain these increases in respiratory frequency and perturbations of the three-phase pattern. In the model, we found that similar perturbations could be induced by altering the activity of the inhibitory population of pre-BötC inspiratory neurons. Simulated excitation of this population up to tonic spiking completely suppressed the activity of BötC E2 neurons and, thus, augmented oscillation frequency. In contrast, inhibiting this population disinhibited both post-I and E2 expiratory populations causing tonic discharge, thus eliminating phasic post-I activity and creating conditions for endogenous bursting of excitatory inspiratory neurons at a higher respiratory frequency. In summary, we explicitly demonstrated the functional importance of glycinergic interneurons in the pre-BötC for generation of eupnea and provide mechanistic insights for these responses using mathematical modeling.

Title: Breathing responses produced by selective optogenetic activation of rostral ventrolateral medullary catecholaminergic neurons are dependent on the integrity of PreBotzinger complex

Authors: M. R. MALHEIROS-LIMA[1], L. T. TOTOLA[1], M. V. G. LANA[2], E. CONSTANZI-STRAUSS[3], B. E. STRAUSS[2], A. C. TAKAKURA[4], *T. S. MOREIRA[5];

Abstract: Optogenetic stimulation of the catecholaminergic C1 neurons produces vigorous cardiorespiratory stimulation. We also demonstrated that depletion of C1 neurons attenuates breathing responses induced by hypoxia. The Pre-Bötzinger complex (PBC) is a specific group of neurons located in the ventrolateral medulla that is critical for respiratory rhythmogenesis. Our hypothesis is that the PBC contributes to breathing responses caused by selective activation of C1 neurons. To explore the specific contribution of the C1 neurons to breathing control, we used an optogenetic approach to activate these cells *in vivo*. PRSx8-ChR2-eYFP, a lentiviral vector that expresses channelrhodopsin-2 (ChR2) under the control of the catecholaminergic neuron-preferring promoter PRSx8, was injected into the rostral ventrolateral medulla (RVLM: 2-3 unilateral injections; 100-150 nl/site) of the male Wistar rats (240-280g). After 3 weeks, mean arterial pressure (MAP) and electromyography recording of diaphragm (Dia_{EMG}) were evaluated in urethane anesthetized and artificially ventilated rats. Photostimulation of ChR2-transduced RVLM neurons (473 nm, 20 Hz, 10 ms, 9 mW) was performed before and after unilateral injection of the ionotropic glutamate antagonist, kynurenic acid (kyn: 100 mM - 50 nl) in the PBC. After 3 weeks, ChR2 was largely confined to TH-expressing neurons (87%). The ChR2-expressing neurons were non-GABAergic and non-glycinergic. Photostimulation of ChR2-transduced RVLM neurons increased MAP (143±27, vs. baseline: 131±25 mmHg) and Dia_{EMG} freq (45±3, vs. baseline: 37±3 bpm). Unilateral injection of kyn in the PBC blocked the increase in Dia_{EMG} freq (0±0 vs. saline + laser: 24±6%) without changing the increase in MAP (18±5, vs. saline + laser: 12±4 mmHg) elicited by photostimulation of C1 neurons. Our results suggest that the increase in breathing produced by photostimulation of RVLM-C1 neurons can be caused by a direct glutamatergic activation of PCB. These results provide the most direct evidence that the C1 neurons have a role on breathing control

Title: Defining the respiratory role of preBötzinger Complex Dbx1-derived and somatostatinergic neurons *In vivo*

Authors: *Y. CUI[1,2], K. KAM[1], D. SHERMAN[1], W. A. JANCZEWSKI[1], Y. ZHENG[2], J. L. FELDMAN[1];

Abstract: To fully understand the neural control of breathing, the functional roles of distinct neural subpopulations of preBötzinger Complex (preBötC), a medullary nucleus critical for generation of respiratory rhythm, must be identified. Normal breathing in rodents requires activity of glutamatergic Dbx1-derived ($Dbx1^+$) preBötC neurons expressing somatostatin (SST). We combined *in vivo* optogenetics and pharmacology in channelrhodopsin 2 (ChR2)-expressing transgenic mice to determine firing patterns of preBötC $Dbx1^+$ and SST^+ neurons and the effects of precisely phase-timed photoactivation of these neurons on breathing. In transgenic adult mice expressing ChR2 in $Dbx1^+$ neurons (Dbx1-ChR2), photostimulation: i) during expiration evoked ectopic inspiratory bursts, and; ii) during early inspiration augmented inspiratory bursts; these effects were associated with excitation of preinspiratory and inspiratory neurons. In transgenic mice expressing ChR2 in SST^+ neurons (SST-ChR2), photostimulation: i) during early inspiration evoked augmented inspiratory bursts, and; ii) during expiration delayed the subsequent inspiration; these effects were associated with excitation of preBötC inspiratory and postinspiratory neurons. Inhibitory photoresponses were largely eliminated by blocking synaptic inhibition within preBötC or by local viral infection to limit ChR2 expression to preBötC SST^+ neurons. We propose that preinspiratory preBötC $Dbx1^+$ neurons are essential elements of the inspiratory rhythmogenic kernel and that inspiratory preBötC $Dbx1^+$ and SST^+ neurons primarily serve a premotor patterning role by activating downstream premotoneurons to shape inspiratory motor output. Moreover, in confirmation of published data, we conclude that postsynaptic inhibition within the preBötC is not essential for rhythmogenesis, but is critical for fine tuning breathing by broadening the dynamic range of inspiratory burst amplitude, stabilizing breathing

rhythm in the presence of significant perturbations, and, when inhibitory neurons are acutely activated, inducing apneas, such as needed during swallowing and breathholding.

Title: Imaging of dendritic calcium transients in preBötzinger neurons in organotypic slice cultures.

Authors: *W. S. PHILLIPS[1,2], C. A. DEL NEGRO[2], J. C. REKLING[1];
[1]Univ. of Copenhagen, Kobenhavn N, Denmark; [2]Dept. of Applied Sci., Col. of William & Mary, Williamsburg, VA

Abstract: The rhythm for breathing is generated by a network of excitatory interneurons in the preBötzinger complex (preBötC) of the ventral medulla. Rhythmic build-up of excitatory activity within this network results in an envelope of synaptic drive that is integrated into characteristic firing patterns recorded at the soma of preBötC neurons. Postsynaptic membrane properties are capable of amplifying excitatory synaptic input, but the extent to which dendrites actively or passively remodel EPSPs prior to their arrival and integration at the soma - and whether such a process selectively favors a more robust response to synchronized input - remains unclear. Here we use a novel organotypic brainstem-slice culture preparation, which retains the preBötC, to indirectly investigate voltage responses within dendrites of rhythmically active preBötC neurons. These cultured brainstem slices maintain a bilaterally synchronous pattern of inspiratory-like activity, and preBötC neurons exhibit electrophysiological properties consistent with those recorded and documented using acute slice preparations—a well-established experimental model for 25 years. Reduced light scattering and slice depth conferred via culturing has allowed us to image fluorescent calcium dynamics along extended dendritic segments during both rhythmic behavior and in response to current injection. Using wide-field fluorescence microscopy and whole-cell patch-clamp recording, we observed invasive dendritic calcium transients detectable

over 150 µm from the soma during inspiratory-like bursts of preBötC network activity. By comparing the dynamics of network-evoked dendritic calcium activity to that evoked by current injection under various conditions we aim to elucidate the role of dendrites in synaptic integration serving inspiratory burst generation in the preBötC.

Title: The consequence of antiepileptic drug treatment on the respiratory activity generated in the PreBötzinger Complex

Authors: *H. KOCH[1,2], J. BRANDES[2,1], L. RÜSCHSTROER[2,1], H. LERCHE[2,1];
[1]Univ. Tübingen, Tübingen, Germany; [2]Hertie Inst. for clinical brain research, Tübingen, Germany

Abstract: Sudden Unexpected Death in Epilepsy (SUDEP) is the major source of death in patients suffering from therapy-resistant epilepsy. Although the mechanism of action is not entirely understood, respiratory dysfunction after generalized tonic-clonic seizures seems to play a major role. Risk factors include polytherapy with several antiepileptic drugs (AEDs). Therefore, we hypothesized that AEDs critically alter the central respiratory response to hypoxia, as induced by periictal respiratory disturbances, and contribute to fatal apnea in SUDEP patients. As a model, we used isolated transversal brain stem slices containing the pre Bötzinger Complex of neonatal and juvenile mice (P3-P14). This nucleus is essential for inspiration and contributes to respiratory rhythm generation. In vitro, it continues to generate rhythmic activity which closely resembles eupneic breathing. We recorded the activity of the PreBötzinger Complex (preBötC) under normoxic (95% O_2) and severely hypoxic (under 1% 0_2) conditions. Control conditions without medication were compared to conditions where one of the common AEDs Lamotrigine, Levetiracetam and Carbamazepine had been added to the artificial cerebrospinal fluid that surrounded the slice. None of the medications displayed a significant impact on either fictive sighs or fictive eupneic breathing activity. However, both Lamotrigine and Carbamazepine significantly reduced the frequency of or completely abolished fictive gasping during hypoxia. Furthermore, they delayed the resumption of eupneic breathing during recovery

from hypoxia under normoxic conditions. Levetiracetam, in contrast, did not show such an effect. As a conclusion, AEDs which alter sodium currents might impair the preBötC-mediated central response to hypoxia. This could lead to increased vulnerability for SUDEP in patients who continue to suffer from seizure-induced apneas despite medication with AEDs.

Title: PreBotzinger Complex SST^+ neurons modulate breathing rhythm and pattern

Authors: *R. P. DE SOUSA ABREU[1,2], J. L. FELDMAN[1];
[1]Neurobio., UCLA, Los Angeles, CA; [2]Fundação Champalimaud, Lisbon, Portugal

Abstract: Within the respiratory rhythm generator, the preBötzinger Complex (preBötC), a specific subset of glutamatergic neurons that expresses the inhibitory peptide somatostatin (SST) is critical for breathing. In rats, these neurons constitute approximately 10% of the preBötC and project extensively to a broad range of respiratory-related regions (e.g., Bötzinger Complex and RTN/pFRG). We investigated the modulatory role of these neurons on breathing, in freely moving mice.

We used optogenetics to acutely manipulate the activity of preBötC SST^+ neurons and investigate their impact on preBötC rhythmic activity (preI and inspiratory), respiratory-modulated motor output (e.g., genioglossus and abdominal muscle activity) and, ultimately, breathing, in both anesthetized and behaving mice. To elucidate the mechanisms underlying modulation, we examined phase response curves (PRCs), in some cases during distinct external challenges (e.g., anesthetic depth, hypoxia, and hypercapnia). In freely moving mice, a chemogenetic approach was also implemented to investigate the impact of preBötC SST^+ neurons on breathing at a different timescale, i.e., when these neurons are activated over a period of hours.

In freely moving mice, we found that preBötC SST^+ neurons can rapidly and transiently modulate breathing shape and frequency in normoxia, hypoxia and hypercapnia. In anesthetized

mice, PRCs of preBötC neuronal activity revealed that preBötC SST^+ neurons do not appear to be rhythmogenic but rather powerful respiratory modulators. Further investigation of PRCs revealed differences across the respiratory cycle (e.g., Inspiration vs. Expiration) and during distinct respiratory network states of excitability. Moreover, it appears that the mechanisms underlying modulation are nonlinear, perhaps threshold-based.
We propose that the changes in breathing, which include the shape (e.g., peak airflow amplitude) and timing (e.g., expiratory duration; T_E), resulted from phase- and excitability-dependent modulation of rhythmogenic processes. For example, activation of pattern-generating mechanisms and consequent recruitment of inspiratory, but not expiratory, muscle activity, could explain the generation of sigh-like events by photostimulation. In contrast, effects on T_E may result of activation of sub- or supra-threshold (below or above bursting threshold) mechanisms that determine rhythm (increase T_E) or pattern (decrease T_E) generation, respectively.
Overall, our study suggests that preBötC SST^+ neurons play an essential role in rapid respiratory responses, a unique property necessary for a robust yet labile breathing behavior.

Title: Unbuckling the Buccal oscillator in the American Bullfrog

Authors: *M. I. BAGHDADWALA, R. J. A. WILSON;
Physiol. and Pharmacol., Hotchkiss Brain Institute, Univ. of Calgary, Calgary, AB, Canada

Abstract: The American Bullfrog is a remarkable model organism to study the neural circuits underlying respiratory rhythm generation. It exhibits a breathing pattern that can be divided into four distinct ventilatory phases: lung-priming, lung-powerstroke, buccal-dilation, and buccal-constriction. We recently established that lung-priming and lung-powerstroke are generated by two separate burst generating substrates in the brainstem—the Priming Area and Powerstroke Area—located in rhombomere 4-5. The neural origin of the two phases of buccal, on the other hand, remains elusive. Our previous experiments suggest that a discrete, bilaterally iterated,

Buccal Area located in rhombomere 7-8 is responsible, at least in part, for generating the biphasic buccal rhythm. However, whether any additional burst generating substrates are involved is yet unknown. To further investigate the generation of biphasic buccal rhythm, we developed an isolated 'buccal-segment' preparation guided by a high resolution extracellular survey of unit activity in the buccal-generating region. **Extracellular survey:** We high-frequency stimulated the vagus (cranial nerve 10) and hypoglossal (CN12) nerve roots bilaterally under High Mg^{2+} saline to excitotoxically kill their motor nuclei. This was done to eliminate any motor neuron activity in close proximity to the Buccal Area. Following this, we extracellularly explored this region to map out patterns of unit activity. Our results showed that multiple separate loci had unit activity correlated to buccal bursts. This suggests that there might be several regions around the previously identified Buccal Area involved in the generation of buccal bursts. **Isolated 'buccal-segment' preparation:** Guided by the survey, we developed a reduced 'buccal-segment' preparation consisting only of the vagus and hypoglossal motor nuclei and nerve roots which, when exposed to 100nM AMPA, produced buccal bursts on both nerves. We further transected the brainstem at various levels and discovered that a central transection between vagus and hypoglossal nerve roots could sometimes produce two independently rhythmic slices suggesting that the buccal rhythm might be generated by multiple burst-generating substrates. **Significance:** We have previously suggested that the Buccal Area in frogs is an evolutionary homolog of the mammalian preBötzinger complex. Both are located in rhombomere 7, are resilient oscillators, staunchly insensitive to CO_2, and co-opted for sniffing. Our discovery that the buccal rhythm might be a multi-substrate phenomenon provides a novel insight into the evolution of breathing.

Title: Kolliker Fuse orchestrates timing of abdominal nerve bursting

Authors: *W. H. BARNETT[1], A. P. ABDALA[2], J. F. R. PATON[2], D. B. ZOCCAL[3], Y. I. MOLKOV[1];

Abstract: A hallmark of the respiratory reflex response to hypercapnia is the emergence of active expiratory pattern in the abdominal motor output (AbN). This pattern consists of late-expiratory (late-E) bursts attributed to the recruitment of expiratory neurons in the parafacial respiratory group (pFRG) putatively driven by chemosensitive cells in the retrotrapezoid nucleus (RTN). Evidence suggests participation of other cellular groups in control of AbN late-E activity generation. Late-E activity is abolished by systemic application of riluzole, indicating potential involvement of the persistent sodium current. However, there is no direct experimental evidence for the presence of persistent sodium channels in pFRG late-E neurons. In this scenario, we suggest that riluzole dependence of late-E activity is mediated by excitation from pre-inspiratory/inspiratory (pre-I/I) neurons of pre-Bötzinger complex (pre-BötC), which are known to contain persistent sodium channels. It has been previously suggested that the pFRG late-E population is suppressed by inhibition from post-inspiratory (post-I) neurons of the Bötzinger complex under eupneic conditions. Therefore, areas that control post-I activity, such as the Kölliker-Fuse (KF) nucleus, may be involved in the control of hypercapnia-induced late-E activity. Here, we explore the role of the KF nucleus and the pre-BötC pre-I/I neurons in modulating late-E respiratory activity. Based on model simulations, we propose that pre-I/I neurons in the preBötC are stimulated by RTN chemosensitive neurons during hypercapnia and which then drive late-E activity in pFRG neurons. Assuming that the KF area provides excitatory drive to BötC post-I inhibitory neurons, our model predicted that during hypercapnia: 1) KF inhibition lower the recruitment threshold of late-E activity; 2) KF excitation prevents emergence of late-E activity. These modeling predictions were tested experimentally in the *in situ arterially perfused* rat. We found that: i) inhibition of KF with isoguvacine (10mM) advanced by 1s the onset of late-E bursts in AbN after exposure to hypercapnia (8% CO2); and ii) disinhibition of KF with gabazine (100μM) greatly attenuated AbN late-E activity. The model suggests that the pre-BötC pre-I/I neurons are an important source of excitatory synaptic inputs to the pFRG expiratory neurons. Moreover, KF-driven inhibitory inputs to the pFRG, possibly through the post-I BötC neurons, may determine the presence and/or onset timing of AbN late-E bursts during hypercapnia.

Title: Acetylcholinesterase and respiration: where this essential enzyme is required?

Authors: A. NERVO[1], C. REYMOND[1], F. NACHON[1], G. CALAS[1], *E. KREJCI[2];
[1]Inst. de Recherche Biomédicale des Armées, Bretigny, France; [2]COGNAC G, UMR 8257 CNRS, Paris, France

Abstract: Acute intoxication by pesticides (carbamates or organophosphates (OP)) or nerve agents affects several vital functions until death by asphyxia. The key target of these reactive molecules are cholinesterases, mainly acetylcholinesterase (AChE), whereas butyrylcholinesterase (BChE) appears more as a scavenger for these compounds. Both enzymes hydrolyze acetylcholine (ACh) and the well-known consequences of the inhibition of cholinesterases result presumably from the consecutive excess of ACh. However, it remains unclear where ACh is toxic. Indeed, deficit of AChE in the brain, when its anchoring protein PRiMA is absent, leads to a huge excess of ACh measured by microdialysis in the brain. PRiMA KO mice adapt well to this excess by the decrease of muscarinic receptors but remain as sensitive as WT mice to AChE inhibitors. Deficit of AChE in the skeletal muscle of AChE1iRR mice leads to muscle weakness and AChE1iRR mice are highly sensitive to OP intoxication, suggesting that AChE in the muscle may also serve as scavenger of OP. To explore where and how ACh could be toxic we have recorded the modifications of body movements and air exchanges of mice in two chambers plethysmography apparatus during the respiration. We used KO or Ki mice in which AChE is not properly localized, or in which nicotinic ACh receptors are absent. For each genotype, the nasal and thoracic flow parameters were recorded before and after intoxication with different inhibitors of cholinesterases such as paraoxon (model of OP pesticide), physostigmine or neostigmine (two carbamates that cross or not the blood brain barrier). We will present how the double chambers plethysmography helps to identify different alterations of respiration. All the inhibitors used block dramatically the respiration, even when the inhibitor does not cross the blood brain barrier. All the mice lacking of AChE in brain or in skeletal muscle are affected by these inhibitors. We will discuss how these results challenge the canonical view that AChE acts essentially to terminate the synaptic transmission at cholinergic synapses.

Title: Parametrization of a closed-loop adaptive controller for respiratory pacing in a rodent model

Authors: *R. SIU[1], B. HILLEN[1], A. THOTA[1], S. RENAUD[2], J. ABBAS[3], R. JUNG[1]; [1]Florida Intl. Univ., Miami, FL; [2]IMS Lab., Univ. de Bordeaux, Bordeaux, France; [3]Arizona State Univ., Tempe, AZ

Abstract: Spinal cord injury at the cervical level can cause damage to the descending respiratory pathways, which can lead to a significant reduction in ventilatory capabilities. Individuals with impaired ventilatory capacity are often dependent on ventilators to achieve proper respiration. Respiratory pacing via electrical stimulation of the phrenic nerve or of the diaphragm has been shown to enhance quality of life compared to mechanical ventilation, by improving speech, preventing social stigma, and improving mobility. However, commercially-available respiratory pacing devices require initial manual specification of stimulation parameters and frequent adjustment to achieve and maintain suitable ventilation and ventilatory efficiency over long periods of time. We have developed a closed-loop neuromorphic controller capable of meeting the ventilatory demands of the user despite changes in muscle and electrode properties, as well as other extrinsic factors. Optimization of key parameters can increase stability and efficiency of the controller when considering its closed-loop implementation. Therefore, we conducted simulations based off rat experimental data to determine the range of relevant parameters over which the controller could achieve and maintain a root-mean-squared error (RMSE) of less than 5% within a period of 50 breathing cycles.

The controller's amplitude modulation algorithm is composed of a neural network in which an error signal at specific time points in the breathing cycle modifies connection weights for neurons that were active in the recent past. Based on prior work with this algorithm, it is expected that controller performance would be most affected by learning rate, number of neurons active at any time-point, and the length of the window used to average past activation values in the update algorithm. As a first step, the controller was tasked with matching a stimulation profile obtained from rat experimental data in which the controller was able to match a desired volume profile. The software-based controller was developed in LabVIEW. Learning rate was assessed for values of 0.0001 to 0.004, number of active neurons from 1 to 19, and past activation window length from 2 to 20 time steps. A limit of 50 cycles was allowed for

adaptation time. Simulations showed that the optimal parameters were a learning rate of 0.002 – 0.004 with 3 – 9 active neurons and 2 – 4 time steps for the past activation window length. These results were then validated in acute animal studies (n=4) in which 6 active neurons and a window of 4 past activations showed the best performance by maintaining RMSE values between 5% and 10% over periods of 100 breathing cycles or more.

Title: Developmental nicotine exposure alters the frequency of miniature inhibitory post-synaptic currents in hypoglossal motoneurons.

Authors: *L. B. WOLLMAN[1], R. B. LEVINE[2], R. F. FREGOSI[3];
[1]Physiol., The Univ. of Arizona, Tucson, AZ; [2]Neurosci., [3]Physiol., Univ. of Arizona, Tucson, AZ

Abstract: Prenatal nicotine exposure with continued exposure through breast milk over the first week of life (developmental nicotine exposure, DNE) is known to cause complex changes in hypoglossal motoneurons (XII MNs) including altered responses to inhibitory neurotransmitters and increased density of $GABA_A$ receptors on these neurons. Here we test the hypothesis that DNE alters the amplitude and frequency of spontaneous, action potential mediated, and miniature GABA inhibitory post-synaptic currents (IPSCs) recorded from XII MNs in neonatal rats. We did whole cell patch clamp recordings from XII MNs in medullary slices (700 micron thick) from DNE pups and control pups. Cells were voltage clamped at -55mV and spontaneous GABA IPSCs (sIPSCs), including both action potential mediated events and miniature events, were recorded in the presence of the glutamate receptor antagonist 6-cyano-7-nitroquinoxaline-2,3-dione (CNQX) and the glycine receptor antagonist Strychnine. Miniature GABA IPSCs (mIPSCs), representative of random quantal release of neurotransmitter, were recorded in the presence of CNQX, Strychnine, and the voltage-gated sodium channel antagonist Tetrodotoxin (TTX). Our results are as follows: 1) DNE does not alter the amplitude (Control {n=4} 21.4±2.7 pA, DNE {n=4} 22±2.1 pA) or frequency (Control {n=4} 366.4±107.6 counts/min, DNE {n=4}

311.5±82.8 counts/min) of GABA sIPSCs. 2) DNE does not alter the amplitude (Control {n=6} 14.6±1.6 pA, DNE {n=6} 15.3±1.4 pA) of GABA mIPSCs. 3) DNE did increase the frequency of GABA mIPSCs (Control {n=6} 26.5±9.1 counts/min, DNE {n=6} 59.2±21.3 counts/min). These results show that DNE alters the random, quantal release of GABA onto XII MNs by a currently unknown mechanism.

Title: Role of potassium conductances in shaping excitability in hypoglossal motoneurons in developmental nicotine exposure model

Authors: M. CHOLANIAN[1], R. B. LEVINE[1], *R. F. FREGOSI[2];
[1]Univ. of Arizona, Tucson, AZ; [2]Univ. Arizona, Tucson, AZ

Abstract: Developmental nicotine exposure (DNE) in rodents is a widely accepted model for studying neurotoxic effects of nicotine exposure *in utero*. Chronic nicotine exposure causes widespread desensitization of nicotinic acetylcholine receptors (nAChRs) in multiple brain regions, including brainstem neurons involved in the control of breathing. Our previous studies showed that DNE decreased excitatory synaptic input in hypoglossal motoneurons (XIIMNs) of neonatal rats and altered their excitability. Here we hypothesize that one of the major underlying mechanisms behind DNE-induced changes in excitability involves alterations in multiple potassium conductances. We have used whole-cell patch-clamp electrophysiology in a medullary slice prepared from neonatal rats to study the effect of DNE on K^+ conductances. We recorded from rhythmically active XIIMNs in an external solution containing 9mM K+ and non-rhythmically active XIIMNs in separate slices using a 3mM K+ external solution. Interestingly, DNE caused an increase in both early and sustained K^+ currents, as compared to XIIMNs from slices prepared from control animals. This effect was only observed, however, in the rhythmically-active XIIMNs. The K+ currents were not affected significantly by DNE in the non-rhythmically active XIIMNs. These results suggest that DNE affects distinct K^+ conductances in rhythmically-active XIIMNs.

Title: Neuromodulation of limb proprioceptive afferents decreases apnea and stabilizes blood pressure (BP) in premature neonates

Authors: *K. KESAVAN[1], D. M. CORDERO[2], R. M. HARPER[3];
[1]Pediatrics, Univ. of California, Los Angeles, CA; [2]Pediatrics - Neonatology, [3]Neurobio., UCLA, Los Angeles, CA

Abstract: Background: Apnea of Prematurity (AOP) and intermittent hypoxia are common, affecting the majority of premature infants. Repeated episodes of hypoxemia during apneic episodes causes marked increases in sympathetic nerve activity, leading to substantial changes in BP. Adult patients with recurrent apneas and chronic IH exhibit increased sympathetic nerve activity and elevated plasma catecholamine levels. To date, the effects of on-going acute effects of such IH episodes on BP have not been systematically studied in premature neonates. It is important to maintain BP within the limits of cerebral autoregulation for optimal cerebral protection. In a pilot study, we found that neuromodulation of limb proprioceptive afferents using a vibration device was associated with fewer breathing pauses, IH episodes, and bradycardic episodes. Therefore, we hypothesized that, with proprioceptive stimulation decreasing apneas and improving oxygenation, we will reduce the associated BP changes.
Objective: The objective is to support breathing and maintain BP in premature infants by using a non-invasive vibratory device placed over limb proprioceptor fibers, an intervention using the principle that limb movements trigger reflexive facilitation of breathing.
Methods: Premature infants (23 -34 wks gestational age), with clinical evidence of AOP episodes were enrolled 1 week after birth. Small vibration devices were placed on one hand and one foot and activated in a 6 hour ON/OFF sequence for a total of 24 hours. Heart rate, respiratory rate, oxygen saturation (SpO_2) and BP, inferred from pulse transit time and calibrated by cuff measures, were continuously collected.
Results: 1. Fewer breathing pauses occurred during vibration periods, vs baseline ($p<0.05$).
2. Significantly fewer SpO_2 declines occurred with vibration ($p<0.05$), vs control periods.
3. Significantly fewer bradycardic events occurred during vibration periods, vs no-vibration

periods ($p<0.05$).
4. Acute falls in mean BP after apnea occurring during control periods were substantially reduced during vibration periods.'
Conclusions: Proprioceptive afferent activation reduced apnea and O_2 desaturation epochs, an outcome that also diminishes IH episodes and accompanying BP changes. Large BP changes pose a risk for impaired perfusion to brain structures. This low-cost neuromodulatory procedure using vibration to proprioceptive nerves has the potential to provide a non-invasive intervention to stabilize BP in premature neonates, thereby improving neurological outcomes.

Title: Identification of cortical drive to arm muscles during arm cycling by analysis of power spectrum

Authors: *T. C. RICHARDS[1], S. CHAKRABARTY, Sr[1], K. POWER[2];
[1]Univ. of Leeds, Leeds, United Kingdom; [2]Sch. of Human Kinetics and Recreation, Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: Cortico-muscular and intermuscular coherence studies have sought to relate activity in the sensorimotor cortex to activity in the muscle, or to identify muscles sharing common cortico-motoneuronal drive. Coherence is most commonly discussed in the context of three distinct bands: alpha (α) at 8 - 12 Hz, beta (β) at 15 - 30 Hz, and gamma (γ) at 30 - 100 Hz. Cortico-muscular coherence in the β-band is thought to reflect coupling of cortical oscillations to the spinal motoneuron pool during sustained contractions. Less commonly, coherence has been observed in the α-band, also during sustained contractions, and in the γ-band during dynamic movements. Cortico-muscular coherence within these bands is often assumed to reflect efferent activity of direct projections from the motor cortex to the spinal motoneurons. It has recently been demonstrated that TMS (transcranial magnetic stimulation) evoked responses increased in biceps brachii during arm cycling compared to an intensity-matched tonic contraction (Forman et al., 2015). The increased amplitude of the evoked response was attributed to increased cortical

neuronal excitability. By generating power spectrum of the EMG response, we will identify TMS induced changes in the frequency components of the response in this dataset (n = 10). In this context TMS evoked muscle activity reflects activity in any single and or combination of frequency bands previously reported in coherence studies. Forman, D. et al. 2015. Corticospinal excitability of the biceps brachii is higher during arm cycling than an intensity-matched tonic contraction Corticospinal excitability of the biceps brachii is higher during arm cycling than an intensity-matched tonic contraction. *Journal of Neurophysiology* [online]. Title: The effects of waveform and current direction on test-retest reliability of transcranial magnetic stimulation

Authors: *P. DAVILA PEREZ[1], A. JANNATI[1], M. SHAFI[1], J. CUDEIRO[2], A. PASCUAL-LEONE[1];
[1]BIDMC - Harvard Med. Sch., Boston, MA; [2]Univ. of A Coruña, A Coruña, Spain

Abstract: Objective: When using transcranial magnetic stimulation (TMS), different waveforms (monophasic vs. biphasic) and induced current directions in the primary motor cortex (posterior-to-anterior [PA] vs. anterior-to-posterior [AP]) may stimulate different cortical neural components. We assessed the effects of these factors on the test-retest reliability of single- and paired-pulse neuronavigated TMS protocols.
Methods: Twenty-six healthy participants between the ages of 18 and 35 (12 males, 22 right-handed) completed two sessions (intersession interval range 1-70 days; median = 10.5 days), assessing resting motor threshold (RMT), amplitude of motor evoked potentials (MEPs) (averaged over 10 pulses), contralateral cortical silent period (cSP), short-interval intra-cortical inhibition (SICI), long-interval intra-cortical inhibition (LICI), and intracortical facilitation (ICF). Estimates obtained for LICI, SICI and ICF were calculated as a percentage of baseline MEP amplitude, averaged over 40 pulses. Ten, nine, and seven subjects underwent two sessions of PA, AP, and biphasic stimulation, respectively. Neuronavigated TMS was performed with a MagPro X100 device and a Cool-B65 figure-of-eight coil (outer diameter 75mm), and Brainsight TMS neuronavigation system using a brain MRI template. MEPs were measured with a

PowerLab 4/25T data acquisition device. Analyses included individual and average absolute intraclass correlation coefficients (ICCs) using a two-way mixed-effects model.

Results:

		Individual ICC			**Average ICC**	
	Monophasic PA	Monophasic AP	Biphasic	Monophasic PA	Monophasic AP	Biphasic
RMT	0.67	0.98	0.90	0.81	0.99	0.95
Baseline MEPs	0.50	0.44	-0.16	**0.66**	0.61	-0.37
cSP	0.73	0.53	0.63	0.84	0.69	0.77
SICI	0.53	0.36	0.48	0.69	0.52	0.65
LICI	0.52	**0.93**	0.68	0.68	0.96	0.81
ICF	-0.13	0.06	**0.77**	-0.29	0.11	0.87
Note: Bold ICC values were significantly higher compared with a different waveform or current direction. The alpha level was 0.05.						

The average ICC for baseline MEP with PA pulse (0.66) was significantly higher than with biphasic pulse (-0.37), p=0.026. The individual ICC for LICI with AP pulse (0.93) was significantly higher than with PA pulse (0.52), p=0.04. The individual ICC for ICF with biphasic pulse (0.77) was significantly higher than with PA pulse (-0.13), p=0.006.

Conclusions: These results demonstrate the significant effect of waveform and current direction on test-retest reliability of TMS measures, thereby emphasizing the importance of choosing the appropriate parameters for a given single- or paired-pulse TMS protocol. Furthermore, these results allow for deeper understanding of the underlying neurophysiological mechanisms of TMS measures.

Title: Probing causal relevance of oscillatory power and phase for corticospinal excitability in humans: a new experimental tacs-tms paradigm

Authors: *L. SCHILBERG, T. ENGELEN, T. DE GRAAF, T. SCHUHMANN, A. SACK; Maastricht Univ., Maastricht, Netherlands

Abstract: TMS measures of motor cortex excitability (Motor Evoked Potentials; MEPs, induced by single TMS pulses over primary motor cortex) are widely applied to study both brain function and plasticity in healthy and patient populations. Unfortunately these measures are subject to substantial and largely unexplained within- and between-subject variability, which affects reliability of MEPs as a measure of cortical excitability in research and clinical settings. Two candidate causes of trial-by-trial MEP fluctuations are the power and phase of cortical oscillations at the time of stimulation. Yet to test their functional relevance is challenging. It would require experimental control over both the power and phase of local oscillations in relation to TMS pulse timing. Transcranial alternating current stimulation (tACS) allows periodic electrical stimulation of human cortex, effectively enabling control over oscillations. TACS over M1 at 20Hz, a dominant frequency at sensorimotor areas, has been shown to increase corticospinal excitability. Alpha frequency (~10Hz) reflects pulsatile cortical inhibition and has been shown to mediate the inhibitory effects of patterned TMS, depending on the temporal relation between TMS pulses and oscillatory phase. To disentangle and evaluate the effects of oscillatory power and phase in cortical excitability, we applied a novel method in which TMS was phase-locked to tACS. We applied single TMS pulses at 8 equidistant phases of a signal entraining motor cortex oscillations (electrodes at M1 and Pz, 1mA current peak-to-peak, 36.5 minutes stimulation), at either alpha (10Hz), beta (20Hz), or sham tACS frequency. TMS intensity was 120% resting motor threshold, and single pulses were on average 6.75 seconds apart. TMS-induced MEPs were recorded with electromyography (EMG) from the targeted right first dorsal interosseous (FDI) muscle. A causal role of phase should lead to an oscillatory pattern of MEPs across the 8 TMS-tACS phase bins, while a causal role of power is tested by

comparing mean MEP from forty TMS-only trials before and after the tACS manipulation. By applying phase-locked tACS and TMS at the same location, a direct assessment of causal relevance of both power and phase of cortical oscillations can be made, which in the future can lead to a more reliable measure of motor cortex excitability.

Title: Corticospinal excitability during normal gait at varying speeds and inter-limb velocities: a transcranial magnetic stimulation study.

Authors: *L. KOGAN, V. GRITSENKO, S. YAKOVENKO;
West Virginia Univ., Morgantown, WV

Abstract: Periodic movements are generally produced by oscillatory activity within dedicated neural elements, termed central pattern generators (CPGs). Our previous modeling work put forth the hypothesis that CPGs involved in gait in humans are driven by signals corresponding to limb velocity, which are high-level representations of desired whole-limb dynamics. Additionally, humans are sensitive to changes in inter-limb velocity during normal gait, and can sense a change in heading without access to visual information. This suggests that gait and inter-limb velocity may be represented within the visuomotor pathways, including the primary motor cortex (M1). The purpose of this work was to test this hypothesis in healthy human volunteers walking on a split-belt treadmill. Subjects walked at various speeds in tied-belt (identical left and right belt speeds) and split-belt regimes (with an inter-limb velocity differential). The acceleration of the treadmill was constant between conditions to allow the subjects to smoothly transition between target velocities. During the experiment, inter-limb velocity was varied sequentially and in randomized order. Eight surface EMG signals were recorded from representative muscles of each leg to allow for comparison between stimulated and contralateral limb response. Corticospinal excitability was measured using single-pulse transcranial magnetic

stimulation of M1 using a threshold value determined for each subject at rest. Integrated motor evoked potential (MEP) amplitudes were compared between baseline values collected during walking in different locomotor phases and under each condition. These normalized values representing corticospinal excitability were then compared across gait speeds and inter-limb velocities, and results were summarized across all subjects. We found that corticospinal excitability was modulated by gait velocity.

Title: Sequence of forelimb muscle activations during symmetric and asymmetric locomotion in rats

Authors: *E. M. SALIDO, K. TUNTEVSKI, S. YAKOVENKO;
Exercise Physiol., West Virginia University, Ctr. For Neurosci., Morgantown, WV

Abstract: Complex movements like reaching to a lever or locomotion are generated by a sequence of muscle actions. The leading theory is that CNS solves the problem of multiple possible control strategies using a subset of actions, termed motor primitives or synergies. The organization of neural and muscle motor primitives at different levels of CNS and how they subserve complex movements remain open fundamental questions. Previously, we have documented the activation sequence of forelimb muscles in cats (Yakovenko et al., 2011). While this animal model has been instrumental in understanding sensorimotor control, new genetic techniques and the development of multielectrode arrays for cortical recording and stimulation encourage transferring behavioral methodology to rodent models. To this purpose, we have developed the precise foot placement locomotor task that allows assessing skilled locomotor movements in rats (Tuntevski et al., 2016). We expected to find a similar sequence of muscle activations in rats walking on pegs as in cats reaching to a lever or stepping over obstacles (Yakovenko & Drew, 2016). Rats were trained to walk on peg walkway configured to produce either symmetric or asymmetric locomotor tasks where animals have to overstep with their left or right limbs. After brief training, selected forelimb muscles were bilaterally implanted with intramuscular electromyography (EMG), Teflon-insulated stainless steel wire pairs. After a week

of recovery, we recorded synchronized EMG and ground reaction forces (GRF) measured with the array of force sensors embedded into walkway pegs. The corresponding signals were digitized and filtered offline. Using supervised automatic threshold detection method (Yakovenko et al., 2005), we have marked locomotor events corresponding to stance and swing onsets for both forelimbs during consistent stepping behavior. The kinematic onset of swing phase was identified as the onset of deflection in GRF. The period between two successive onsets or offsets was defined as the cycle duration. EMG profiles normalized to the cycle duration were analyzed in all locomotor conditions. Average activity phase was determined for each muscle using inter-trial variability to mark onset and offset of EMG bursts. This data was used in the phase-space analysis of muscle activations. The sequence of activation was similar to that observed in cats during locomotion with and without obstacles. Moreover, the phase of bursts and their duration were modulated in the asymmetric tasks. These findings support the hypothesis that the profiles of muscle activations are qualitatively similar across quadrupeds during precise locomotor tasks.

Title: Linear vs nonlinear control of populations of motor neurons during voluntary contractions

Authors: *F. NEGRO[1], A. DEL VECCHIO[2], J. L. DIDERIKSEN[3], F. FELICI[2], D. FARINA[4]; [1]Inst. of Neurorehabilitation Systems, Univ. Med. Ctr. Göttingen, Goettingen, Germany; [2]Dpt. Ctr. Goettingen, Goettingen, Germany

Abstract: During voluntary contractions, motor neurons are controlled by the synaptic input generated by spinal and supraspinal centers. Measuring the correlation between populations of motor neuron spike trains *in vivo*, it has been recently demonstrated that this input is largely common across motor neuron pools [1]. Because of commonality, populations of motor neurons

substantially attenuate uncorrelated synaptic input (synaptic noise) by the averaging process performed in the generation of the neural drive to muscles [2]. Therefore, groups of motor neurons act as ideal amplifiers tuned on the common components of the synaptic input they receive and the neural drive to muscles almost perfectly reflects these components. Distributing correlated synaptic input to populations of motor neurons solves in a simple way the problems of non-linearity and noise at the individual neural level. Furthermore, due to the filter characteristics of muscle contraction, the "effective" neural drive resides in the low-frequencies (0-8 Hz). This view is partly in contrast with the possibility that high frequency neural oscillations may modulate force output [3]. In this study, we show that, although high frequency oscillations can be demodulated in low-frequency components that contribute to the effective neural drive to muscles, this mechanism cannot be use for accurate force control. First, a theoretical analysis based on a simplified integrate and fire model of motor neurons showed that input components modulated by high-frequency carriers are distorted when demodulated in the low-frequency band. Further, a numerical model comprising 445 motor neurons [4] that received both low-frequency input and the same input modulated by a high frequency carrier (20 Hz) confirmed the theoretical predictions. The direct transmission of low frequency components resulted more accurate and effective than that of the demodulated components. Finally, experimentally we found no association between the amplitude of neural drive oscillations in the delta and beta bands for motor units in the tibialis anterior muscle. In conclusion, our results points out that the voluntary control of force can unlikely be achieved by non-linear transmission of modulated high-frequency carriers.

Title: Sarcopenia and connectivity of the aging motor unit

Authors: K. SHETH, 45459[1], V. L. MCGOVERN[1], K. M. CORLETT[1], A. BRATASZ[1], A. BURGHES[1], *W. ARNOLD[2];
[2]Neurol., [1]The Ohio State Univ., Columbus, OH

Abstract: The majority of people over the age of 80 are affected by sarcopenia, or loss of muscle mass and strength, resulting in impaired physical function and increased risk of mortality. Interestingly, after the age of 80 humans may lose up to 50% of their motor neurons. Sarcopenic patients' muscle biopsies show features of denervation and incomplete reinnervation. These findings implicate motor neuron loss as an important factor in the development of sarcopenia. This study was designed to determine the timing of motor unit loss in aging C57BL/6J male mice and to assess the interaction between motor unit function, grip strength and muscle mass. Mice were analyzed longitudinally between the ages of 10-25 months with electrophysiological measures of motor unit function including compound muscle action potential amplitude (CMAP) and motor unit number estimation of the triceps surae muscles, grip strength, and magnetic resonance imaging of triceps surae volume (MRI). CMAP amplitudes at 10 months(50.7±12.4mV; mean±standard deviation), 13 months (43.6±11.2mV), 15 months (47.5±6.7mV), and 17 months (45.3±5.7mV) were unchanged, but beginning at 20 months CMAP amplitudes are reduced (36.1±6.1mV) ($p<0.05$). Similarly, motor unit number estimation is stable at 10 months (341±93), 13m(302±98), 15 months(314±51) and 17 months (271±51), but beginning at 20 months, motor unit number estimation shows reduction (225±77) ($p<0.05$). Forelimb grip was reduced at 24 months (95±15g, $p<0.05$) compared with baseline measures at 15 months (124±21). However, all limb grip did not show significant reduction. Compared to baseline MRI volume at 17 months (21.05±1.11mm^3), measures at 19 months (19.46±1.85mm^3) were unchanged, but reduced at 25 months (18.97±1.02 mm^3, $p<0.05$). Histology of motor neurons, muscle, and axons is in progress to explore the linkage between functional and cellular loss. Our data demonstrate that motor unit loss occurs prior to deficits in grip strength, suggesting that motor unit loss may be an important and early determinant of aging-related sarcopenia. Deeper understanding of the neurological mechanisms of sarcopenia will enable development of effective treatment for this prevalent condition in aging demographics.

Title: Grouping and averaging motor unit data obscures the adaptations of motor unit firing rates during muscle fatigue

Authors: *J. C. KLINE[1], C. J. DE LUCA[1,2], P. CONTESSA[1];
[1]Delsys, Inc, Natick, MA; [2]Dept. of Biomed. Engin., Boston Univ., Boston, MA

Abstract: Muscle fatigue is accompanied by adaptations in the firing rate and recruitment behavior of motor units. Both our own [1] and independent studies [2] have reported that, as a muscle fatigues during repeated or sustained sub-maximal voluntary contractions, active motor units increase their firing rates and new motor units are recruited. Yet these adaptations remain disputed by some [3] who report the opposite changes in firing behavior: namely that motor unit firing rates decrease with fatigue. Such differing results are typically reported in studies that group motor unit data across different subjects, contractions, and force levels. Although this practice has been suggested to obscure the firing behavior of individual motor units [4], the consequences of grouping motor unit data during fatigue have never been empirically investigated. Therefore we set out to evaluate the influence of different practices of analyzing motor unit data on the observed firing behavior during a fatigue protocol of repeated voluntary isometric contractions of the Vastus Lateralis muscle. When we assessed the behavior of individual motor units in individual subjects, we found that motor unit firing rates progressively increase during fatigue. But when the same motor unit data was analyzed using three different practices commonly applied in fatigue studies, we found that: 1) grouping and averaging motor unit firing rates within a contraction falsely indicates that the firing rates decrease with fatigue; 2) grouping motor unit data across subjects obscures specific adaptations in firing behavior unique to each subject; and 3) analyzing motor unit firing rates as a function of recruitment threshold falsely indicates that firing rates decrease due to the fatigue-induced decrease in recruitment threshold [5]. To mitigate this error we analyze the firing rates of individual motor units as a function of action potential amplitude. Each of these practices proved to obscure the actual increase in the firing rate among individual motor units as the muscle fatigued. We have previously explained the increase in firing rates as the result of increasing excitation to the

motoneuron pool to compensate for the diminishing force twitch of the muscle [1]. Contrary to opposing explanations, ours is supported by empirical observations of the actual firing behavior of individual motor units. References: [1] **Adam and De Luca.** *J Appl Physiol*, 2005. Title: Fatigue is characterized by a compensatory interaction between motor unit firing behavior and muscle force

Authors: *P. CONTESSA[1], C. DE LUCA[2,1], J. KLINE[1];
[1]Delsys Inc, Natick, MA; [2]Boston Univ., Boston, MA

Abstract: Previous studies have reported various adaptations in motor unit firing behavior during muscle fatigue, including a decrease [1] and an increase [2] in motor unit firing rates. The inconsistency among previous studies is derived primarily from the limited number (typically 1-5 per contraction) of motor units available for analysis using intramuscular electromyographic (EMG) techniques, and from the practice of grouping motor unit data from different subjects and contractions.
To establish a more clear understanding of the adaptations of motor unit firing rates during fatigue, we investigated the firing behavior of motor units in individual subjects and contractions during a fatigue protocol in the Vastus Lateralis muscle. Five healthy young (24-33 years old) subjects performed voluntary isometric contractions sustained for 60 s at a target level of 30% maximal voluntary contraction force and repeated to the endurance limit. Surface EMG decomposition technology [3] provided the firing behavior of 1,890 motor units. From these data

we found that to perform the target contractions as the muscle fatigued: 1) motor unit firing rates increased; 2) new motor units were recruited; and 3) motor unit recruitment thresholds decreased. The degree of the adaptations was subject-specific, but the behavior was consistent in all subjects. Importantly, in spite of these adaptations, the fundamental motor unit control scheme did not change. Earlier-recruited motor units displayed higher-firing rates than later-recruited ones in all contractions, indicating the Onion-Skin property of motor unit firings [4] was maintained during fatigue. The direct relationship between motor unit recruitment thresholds and action potential amplitude, known as the Size Principle [5], was also preserved throughout the fatigue protocol.

We compared our empirical findings with those obtained from simulation of the fatigue protocol [6]. The agreement between our empirical and simulated data indicated that the fatigue-induced adaptations in motor unit firing behavior can be explained by adjusting the operating point of the excitation to the motoneuron pool to compensate for the decrease in muscle force-twitch that is reported to occur during fatigue [7]. Yet, throughout these complementary adaptations, the control properties that govern motor unit firing behavior remained invariant with muscle fatigue.

Title: Motor point stimulation as a tool to modify spinal neural circuits

Authors: T. YAMASHITA[1,2], A. BERGUQUIST[1], T. YOSHIDA[1,2], *K. MASANI[1,2];
[1]Toronto Rehab Inst., Toronto, ON, Canada; [2]Ibbme, Univ. of Toronto, Toronto, ON, Canada

Abstract: The motor point is the most sensitive location to generate contractions as it contains a high density of terminal motor axon branches when delivering transcunateous electrical stimulation over the muscle belly. It is known that motor point stimulation (MPS) induces a different recruitment curve from those generated by peripheral nerve stimulation (PNS). For example, when PNS is applied to the tibial nerve at the popliteal fossa, progressive increases in stimulation intensity results in the emergence and growth of the soleus H-reflex, concurrent with the M-wave, followed by H-reflex plateau and subsequent decline, while the M-wave amplitude increases unabated; Such reductions in H-reflex amplitude with increases in stimulation intensity are thought to be due to occlusion by back propagating (antidromic) action potentials along motor axons. In contrast, when MPS is applied to the ankle plantarflexors, progressive increases in stimulation intensity most commonly results in the emergence and growth of the M-wave, unaccompanied by the H-reflex. This implies that for a given stimulation intensity, MPS activates a substantially greater proportion of motor versus sensory axons compared to PNS. Such preferential motor axon activation during MPS may represent a unique modality to investigate and modify spinal neural circuitry via the antidromic volley. For example, our previous study showed that, when PNS was applied to the plantarflexors at various inter-stimulus intervals relative to MPS, the H-reflex was strongly inhibited with inter-stimulus intervals below 200 ms, suggesting that the MPS evoked antidromic volleys caused strong inhibition of the H-reflex through spinal circuits and not through direct antidromic occlusion. Here, we applied MPS to modify spinal circuitry via spike timing-dependent plasticity (STDP). Participants were seated on a chair with a torque sensor measuring ankle plantarflexion torque. PNS and MPS were repetitively applied 100 times at a specific inter-stimulation interval, where the antidromic firing of MPS was calculated to invade the motoneurone cell body 2-ms before Ia-afferent activation induced by PNS (estimated H-reflex inhibitory latency according to STDP). Comparing pre- and post-recruitment curves, the maximum amplitude of the H-reflex was reduced by 26%. On the contrary, when PNS or MPS alone was applied, there were no changes in the maximum amplitude of the H-reflex. These results suggest that paired associative stimulation involving PNS and MPS successfully modified spinal H-reflex circuitry. As such, we believe that MPS provides a unique modality to investigate and modify spinal neural circuitry.

Title: Task dependent change in Rectus Femoris activity in normal participants

Authors: *P. SRIYA, T. RICHARDS, S. ASTILL, S. CHAKRABARTY;
Sch. of Biomed. science, Fac. of Biol. Sci., Leeds, United Kingdom

Abstract: The Rectus Femoris (RF) muscle is a bi-articular muscle that performs both leg flexion and extension. Given this, the RF, along with the vastus lateralis (VL) and medialis (VM) must exhibit a task dependent shift in their role during leg flexion and extension. Thus the aim of this study was to examine if RF, VL and VM act as agonists during a simple isometric task. Surface electromyography (sEMG) were recorded from Rectus femoris (RF), Vastus medialis (VM), Vastus lateralis (VL), and Semitendinosus (ST) simultaneously in 2 healthy young males while they performed isometric contractions of Quadriceps muscles at four different angles (0, 20, 60, 90 degrees). Activity in these muscles was compared using amplitude and waveform correlations, allowing quantification of the RF- VL, RF-VM and RF-ST interactions at the knee. Preliminary results suggest activity in RF increased with that in VL and VM at both 20 and 60 degrees but not at 0 or 90, suggesting it acts as an agonist at 20 and 60 but not at 0 and 90 degrees. However, ST and RF did exhibit antagonistic interactions at 0 and 20 degrees while being similar at 90 degrees. This might suggest that local interactions between RF and the other muscles are task dependent rather than being defined by their anatomical arrangement.

Title: Characterization of arm muscle activity during arm cycling at different workloads

Authors: *C. P. CHAYTOR[1], M. R. MONKS[1], D. A. FORMAN[1], J. M. BYRNE[1], A. LOUCKS-ATKINSON[1], K. E. POWER[1,2];
[1]Sch. of Human Kinetics and Recreation, [2]Fac. of Med., Mem. Univ., St John's, NL, Canada

Abstract: Arm cycling is commonly used in rehabilitation settings for individuals with upper- and/or lower-limb motor impairments. It is thought to induce neural plasticity that may lead to

increases in motor function in the affected limb(s). Arm cycling studies typically use absolute workloads for all participants whereas it is standard practice in studies using isometric contractions for participants to contract at relative intensities based on their isometric maximal voluntary contraction. This allows comparison between participants based on relative force outputs. The same does not occur during arm cycling studies. Thus, the objective of this study was to characterize arm muscle activity during arm cycling at different relative workloads. Participants (n=11) completed a 10-second maximal arm ergometry sprint to determine peak power output (PPO) followed by 11 randomized trials of 20-second arm cycling bouts ranging from 5-50% of PPO (5% increments) and a standard 25W workload. Electromyography (EMG) was recorded from the biceps brachii and triceps brachii bilaterally in 11 participants. Ln-ln regression models indicated a slight ns difference in the slopes for biceps brachii between flexion and extension, but not for triceps brachii. RM ANOVA models on ln-EMG found a positive highly significant main effect of workload ($p < .001$) up to 35% but did not differ between flexion and extension for either biceps brachii ($p = .143$) or triceps brachii ($p = .089$) above 35% of PPO. lnEMG was significantly larger in flexion than extension for biceps brachii ($p < .001$) but not triceps brachii ($p = .306$). These results demonstrate that there is a linear relationship between lnEMG and workload up to 35% of PPO in both biceps and triceps brachii. In addition, the slopes of the lnEMG/PPO relationship are not different between phases (i.e. flexion and extension) as intensity increases up to 35% in the biceps brachii and triceps brachii.

Title: Neuronal circuits involved in the reflex activity of pubococcygeus muscle motoneurons of female rats

Authors: *O. LARA GARCIA[1], M. LARA GARCÍA[2,3], D. PÉREZ HERNÁNDEZ[2], M. MARTÍNEZ-GÓMEZ[3,4], E. CUEVAS[3], P. PACHECO[2,4];

Veracruzana, Xalapa, Mexico; [3]Ctr. Tlaxcala Biologia de la Conducta, Univ. Autonoma de Tlaxcala, Tlaxcala, Mexico; [4]Inst. de Investigaciones Biomédicas, UNAM, Mexico, Mexico

Abstract: Neuronal circuits which activity depends of hormonal actions participate in multifunctionality of pelvic striated muscles involved in micturition, defecation and copulatory behavior of female mammals. Thus, pubococcygeus muscle (Pcm) reflexively responds to perigenital tactile stimulation, particularly to pressure of the clitoris and during proestrous but diestrous conditions their motoneurons actively respond with intense after-discharges. Hence, in order to identify the neuronal components involved in its motoneuronal activity, we decided to use EMG multiunit activity recordings (EMA) during clitoral pressure or by electrical stimulation of the dorsal nerve of the clitoris (DNC). In i.p. urethane anesthetized adult female Wistar rats the EMA from both Pcms were bilaterally recorded with bipolar stainless steel electrode (0.1 mm diameter). The DNC stimulation was done through bipolar stainless steel electrodes. Results: Slow sweeps recordings showed that the EMA was compound of discharges with different amplitudes and frequencies. During clitoris stimulation a phasic "on", tonic "on", phasic "off" and tonic "off" (after discharge) were obtained. Occasionally, it was possible to record the axon and its corresponding innervated muscular fiber potentials which presented 1.2 msec of separation. Fast sweeps showed that discharges recorded after cesation of clitoris pressure were compound of groups of potentials with different discharge duration. Stimulation of the DNC evoked 8 and 10 msec latency potentials in the ipsi and contralateral Pcms respectively. Pulses at 10, 20 and 30 per sec produced synchronized and non-synchronized responses of both muscles. Discussion: Present results show that the Pcm motoneurons reflexively respond with a single or repetitive activity through interneuronal excitatory actions. The latency obtained by the DNC stimulation suggests that clitoris activates Pcm motoneurons through circuits that could be implicating the sensory neuron and 3-4 interneurons. It is likely the existence of two interneuronal polysynaptic circuits, one related with the phasic "on" and "off" responses and the other with the repetitive tonic "on" and "off" responses. Furthermore, the prolonged hyperactivity recorded could represent hormonal influence on this reflex. Conclusion: The EMA signals obtained represent multiple and concurrent motor unit activity that provides information concerning Pcm motoneuronal grouped activity present in: a) postural maintenance of the tail in the midline during copulatory behavior; b) intravaginal pressure increase during mating; and c) opening facilitation of the urethra during micturition.

Title: Sex differences in the control of vastus medialis and vastus medialis oblique

Authors: Y.-L. PENG[1], M. S. TENAN[2], *L. GRIFFIN[1];
[1]Kinesiol & Hlth. Edu, Univ. Texas Austin, Austin, TX; [2]Human Res. & Engin. Directorate, U.S. Army Res. Lab., Aberdeen Proving Ground, MD

Abstract: It is unresolved as to whether the vastus medialis (VM) and vastus medialis oblique (VMO) can be controlled independently, though they are known to have different pennation angles and possibly different functions. Weakness of the VMO relative to the vastus lateralis in women has been proposed to explain the high prevalence of knee pain in women compared to men. VMO training is commonly recommended in clinical practice, though it is unclear whether the VMO can be activated preferentially from the VM. The aim of this study is to determine if VM and VMO activation is varied between sexes and if control of the two muscles is different between rehabilitation exercises. Thirteen men and thirteen women performed isometric straight leg raises in two hip positions, neutral hip rotation (SLR-NR) and 30 degrees hip lateral rotation (SLR-LR). Participants performed isometric ramp contractions at a rate of 7.5% maximal voluntary contraction (MVC) per second up to 75% MVC. Bipolar intramuscular fine-wire electrodes were inserted into the VM and VMO and single motor unit action potentials were delineated. Recruitment threshold forces (RT) and initial motor unit firing rates (IFR) were measured. Linear mixed models and Tukey post hoc tests were used to assess significant differences. A total of 654 motor units were analyzed. There were significant main effects of Muscle ($p = 0.03$) and Task ($p < 0.01$) for RT. Holding all other factors constant, the VMO was recruited earlier than the VM (11.9 ± 1.2 vs. 14.8 ± 1.2 % MVC). Motor units were recruited earlier during SLR-NR compared to SLR-LR (11.5 ± 1.2 vs. 15.2 ± 1.2 % MVC). Significant main effects of Task ($p = 0.01$) and Sex ($p = 0.04$) were found for IFR. Motor units were recruited 0.5 Hz ± 0.2Hz faster ($p = 0.01$) during SLR-NR compared to SLR-LR. Women activated their motor units 1.2 Hz ± 0.6 Hz faster than men ($p < 0.05$). Thus, the VM and the VMO can be activated differentially and their motor unit recruitment properties are affected by sex and exercise type.

Title: Pattern of masseter muscle activity during chewing with dental implants

Authors: *A. GRIGORIADIS, M. TRULSSON;
Dent. Med., Karolinska Institutet, Huddinge, Sweden

Abstract: Objectives
Jaw actions adapt to the changing properties of food that occur during a masticatory sequence. In the present study, we investigated how the time-varying activation profile of the masseter muscle changes during natural chewing and how it is affected by food hardness in subjects with implant-supported bridges.
Methods
We recorded surface electromyography of the masseter muscle together with the movement of the lower jaw in ten participants with implant-supported bridges in both jaws (mean age 67) and ten with natural dentition (mean age 71) when chewing gelatin-based model food of two different hardness. The muscle activity and the jaw kinematics were analyzed for the different phases of the chewing cycles in the beginning (three cycles) of the masticatory sequence.
Results
For the dentate group, the increase in the excitatory drive of the masseter muscle was biphasic during the jaw-closing phase showing an early and a late component. The transition between the two components occurred approximately at the time of tooth-food contact. The implant group, on the other hand, lacked to late component in the beginning of the masticatory sequence. Except for amplitude scaling, food hardness did not appreciably affect the muscle's activation profile for any of the groups.
Conclusions
When chewing food during natural conditions, subjects with implant-supported bridges lack the ability to generate a late excitatory component at food contact in the beginning of the masticatory sequence. We propose that the absence of tooth-food contact information from periodontal mechanoreceptors lead to this impairment. The temporal profile of muscle activity was virtually identical when chewing hard and soft food for both groups, implying that the principal effect of food hardness was due to scaling in the magnitude of activity.

Title: Differences in force steadiness and EMG amplitude during a dorsiflexion steadiness task in young and older adults

Authors: *J. J. PETERSON, K. G. KEENAN;
Univ. of Wisconsin - Milwaukee, Milwaukee, WI

Abstract: Background: Functional limitations, including walking, climbing stairs, and maintaining balance, become increasingly prevalent as adults age. Performance on force steadiness tasks has been related to functional limitations in older adults. However, the underlying neural mechanisms driving the change in performance with aging are unclear. Changes in electromyogram (EMG) amplitude may be related to performance, and although EMG amplitudes are frequently increased in older vs. young adults, few studies examine the relationship between force steadiness and increased EMG amplitude in older adults. This may be due to the inherent variability of using single bipolar EMG to estimate muscle activity. High-density surface EMG can increase the accuracy of muscle force estimation compared to single bipolar EMG. Therefore, the purpose of our study was to examine the differences in force steadiness and EMG amplitude between young and older adults during a 5% MVC dorsiflexion task, and to examine the relationship between force steadiness and EMG amplitude.
Methods: 18 young (26.5 ± 4.7 yrs) and 18 older (74.1 ± 7.4 yrs) adults performed a dorsiflexion task while seated on a bench with the left knee extended and ankle in a neutral position. Participants performed a series of MVCs followed by two 30 s trials at 5% MVC. Performance was quantified as the coefficient of variation of force. High-density surface EMG was collected from tibialis anterior (TA) using a 64-channel electrode (OTBioelettronica, Torino, IT). EMG recordings were visually inspected, rectified, normalized to MVC, and averaged across channels. Results reported as mean ± standard deviations.
Results: Force fluctuations increased for the older adults compared with the young adults (4.2 ± 2.0% and 2.2 ± 1.2%, respectively, $p = .008$). EMG amplitude increased for the older adults compared with the young adults (15.7 ± 5.5% and 9.5 ± 2.8%, respectively, $p < .001$). Moreover, there was a positive relationship for older adults between the coefficient of variation of force and EMG amplitude during the steadiness task ($R^2 = .36$; $p = .009$). The relationship was not significant for young adults ($p = .16$).
Conclusions: Over-activation of TA was related to worse performance on a dorsiflexion force

steadiness task in older adults. As previous studies using single bipolar EMG electrodes have failed to report this relationship, high-density surface EMG may be more accurately representing global muscle activity and its changes with advancing age. Future work should examine if the over-activity in TA in older adults is due to malfunction within the neuromuscular system or a compensatory mechanism to improve performance.

Title: Precision and accuracy in human motor control

Authors: *A. KUMAR[1], Y. TANAKA[2], J. GRIGORIADIS[1], M. TRULSSON[1], P. SVENSSON[1];
[1]Karolinska Institutet, Huddinge, Sweden; [2]Dept. of Prosthodontics, Gerodontology and Oral Rehabil., Osaka Univ. Grad. Sch. of Dent., Osaka, Japan

Abstract: Background: Accuracy is measured by the degree of closeness of measurements of a quantity to that quantity's true value. While, precision is related to reproducibility and repeatability. We have compared the capacity to maintain an accurate and precise isometric contraction force with the teeth and fingers.
Aim: To investigate if targeting two different force levels with teeth and fingers affect the accuracy or precision of task performance and further investigate the optimization of target forces in terms of accuracy and precision due to repetition of the task.
Methods: Eighteen healthy volunteers (mean age 27 ± 4) participated in two experimental sessions. During each session, the participants were asked to target two different force levels (0.5 N and 5 N; randomized; displayed on a computer screen) by holding a force transducer with their anterior teeth or with their thumb and forefinger. During a single trial, the participant held the force transducer with a steady force (hold force) of either 0.5/5 N for about 3-5 s and subsequently increased the rapid ramp force to target a peak of 10 N (peak force). The accuracy (i.e., deviation from the target force) and the precision (i.e., coefficient of variation) were calculated and compared across the finger and teeth and across the different force levels. The participants performed 10 series of the task (with 10 trials in each series) with a total repetition of 400 trials during the entire experiment.
Results (preliminary): The deviation from the target (accuracy) for the hold force was

significantly higher when the participants targeted 0.5 N with teeth than when targeting 0.5 N with the finger ($P<0.001$) or 5 N with both the finger and the teeth ($P<0.001$). Further, the deviation from the target was significantly higher in all the series when targeting a hold force of 0.5 N than all the series when targeting 5 N ($P<0.001$). Moreover, the deviation from hold force (5 N) or the peak force (10 N) was significantly higher during the first series than the subsequent last five series ($P<0.001$). However, there were no significant interaction when the precision of task performance (assessed in terms of coefficient of variation) was analyzed for the teeth or finger with two different hold force levels and peak force.
Conclusion: Different force levels affect the accuracy but not the precision of task performance further the optimization of target forces is more obvious when targeting higher forces (5 N) than lower forces (0.5 N). Although the two words precision and accuracy can be synonymous in colloquial use, they could be deliberately distinguished in the context of the scientific method.

Title: Characterization of arm muscle activity during asynchronous and synchronous arm cycling using different forearm positions

Authors: *A. P. HYNES[1], C. P. CHAYTOR[1], L. R. ALCOCK[1], D. C. BUTTON[1,2], K. E. POWER[1,2];
[1]Sch. of Human Kinetics and Recreation, Mem. Univ. of Newfoundland, St John's, NL, Canada; [2]Fac. of Med., Mem. Univ. of Newfoundland, St. John's, NL, Canada

Abstract: The purpose of this study was to characterize the muscle activation of the arm during arm cycling using different modes (i.e. asynchronous and synchronous) and forearm positions (i.e. pronated, neutral and supinated). Ten participants attended two sessions: (1) a familiarization session and (2) a testing session consisting of a warm-up followed by 12 randomized cycling trials (flexion/extension x ASY/SYN x pronated/neutral/supinated). The average rectified electromyography (EMG) of the biceps brachii (BB) and triceps brachii (TB) was recorded from the dominant arm throughout arm cycling and analyzed. Made relative to a

clock face with reference to the elbow joint, flexion was defined as from 3 to 9 o'clock as the hand crank moved towards the body and extension from 9 to 3 o'clock as the hand crank moved away from the body. Separate three-way ANOVAs were performed for BB and TB. Significant main effects for biceps brachii EMG were observed based on cycling phase (flexion > extension, p=0.001), forearm position (supinated > neutral > pronated, p=0.009) and cycling mode (synchronous > asynchronous, p=0.01). Within the flexion phase of arm cycling, BB EMG was higher as the forearm position moved from a pronated to a supinated position. There was no significant difference between the average rectified EMG in the neutral and supinated positions (p=0.536), however, both were significantly greater than the pronated position (supinated vs pronated, p=0.033; neutral vs pronated, p=0.005). BB EMG was significantly greater during synchronous compared to asynchronous arm cycling (p=0.01). There was no effect of forearm position or cycling mode on BB EMG during the elbow extension phase of arm cycling. TB EMG was not affected by phase, mode or forearm position. Though mechanisms associated with the observed changes in EMG were not assessed in the present study, the higher EMG of the BB as the forearm changes from a pronated to supinated position may reflect its biomechanical advantage as an elbow flexor as the forearm becomes supinated. Higher EMG during synchronous versus asynchronous arm cycling may reflect changes in motor control strategies associated with supraspinal and/or spinal factors.

Title: Chronaxie of motor responses to S3 sacral nerve stimulation in sheep

Authors: D. DINSMOOR, M. CUTINELLA, J. AGRAN, *X. SU;
Medtronic, Minneapolis, MN

Abstract: Sacral neuromodulation (SNM; InterStim® therapy) at the third sacral foramen (S3) is an FDA-approved therapy for urinary urge incontinence, urgency-frequency and fecal incontinence. The recommended pulse width for SNM is 210 μs, but the strength-duration (SD) response developed from S3 neurostimulation has not been fully elucidated in the literature to-date. Using fully implanted, commercialized systems in a SNM sheep model, we evaluated electromyography (EMG) of the external anal sphincter (EAS) across different pulse widths.

Seven trials of six S3 nerve roots from four adult, female Polypay sheep were used for this study. Under propofol anesthesia (i.v., 6 mg/kg) in combination with 1-3% isoflurane, sheep were implanted with stimulation leads (Medtronic Model 3889) at S3 and two sensing electrodes (Medtronic Model 4351) at both the 3 and 9 o'clock positions of the EAS. The motor responses to SNM with different stimulation pulse widths were randomly examined using variable intensities from 0.1 V to 10 V. Stimulations triggered the EAS contractions. Response thresholds were obtained from both visual detection and EMG waveform analysis against the stimulus intensity. The strength-duration responses as ascertained both visually and from the EAS EMG were fitted with a monoexponential nonlinear regression; the resulting time constants (chronaxie) were of 74.35 ± 0.001 μs and 62.03 ± 0.001 μs, respectively. The rheobase values were 0.48 ± 0.29 V and 0.48 ± 0.12 V, respectively. The maximal values to minimal pulse width were 1.85 ± 0.39 V and 1.62 ± 0.22 V, respectively. These data suggest that a similar motor response may be evoked in the EAS at pulse widths much shorter (62 μs - 74 μs) than the 210 μs typically used with SNM. Shorter pulse widths translate directly to increased energy savings in the neurostimulator. Future studies are needed, however, to determine if the therapeutic efficacy of SNM in patients with incontinence at shorter pulse widths is equivalent to that at 210 μs.

Title: Emg regression as a measure of the contribution of central signals to force perception

Authors: ***S. TOMA**[1], F. LACQUANITI, 00173[2];
[1]Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ. - Tempe Campus, Tempe, AZ;
[2]Systems Med., Univ. of Rome Tor Vergata, Roma, Italy

Abstract: It has been largely established that force estimation mainly relies on motor commands underlying force production, i.e., the so-called 'sense of effort'. Despite the large body of work investigating the relative contribution of descending and ascending signals in force perception, very few attempts have been made to link a measure of neural output (i.e., electromyography, EMG) to psychophysical performance. We propose that the strength of correlation between EMG activity amplitude and perceptual estimates can be interpreted as an estimate of the contribution of central signals to force perception. The current study was designed to quantify this correlation by recording EMG activity from eight arm muscles while participants performed a quasi-isometric force detection task. We used a method to quantify muscular activity ("*muscle-metric function"*) that could be directly compared to the description of participants' psychophysical judgment about the stimulus force. The muscle-metric curve was obtained by means of muscles averaged activity logistic regression. We found that muscle-metric absolute thresholds and the shape of the muscle-metric curves were closely related to those provided by the psychophysics. Moreover, the logistic regression of the distribution of just 3 of the 8 muscles considered was able to predict approximately 60% of the perceptual decisions total variance. Another important result is that the inter-subjects differences in participants perceptual absolute threshold revealed strong correlation with the thresholds extracted from the muscles-metric curve and participants' joint torques. Overall, our findings provide insights into the role played by descending motor commands in the performance of a force estimation task.

Title: Static synergy patterns used to model time-varying functional task muscle activation of the hand.

Authors: *N. M. COLE[1,2], A. B. AJIBOYE[1,2];
[1]Biomed. Engin., Case Western Reserve Univ., Cleveland, OH; [2]FES Ctr. of Excellence, Rehab. R&D Service, Louis Stokes Cleveland Dept. of Veterans Affairs Med. Ctr., Cleveland, OH

Abstract: A long standing theory of motor control is that the neuromotor system simplifies control of multi-degree-of-freedom (DOF) movements by recruiting coordinated patterns of

muscle activation (muscle synergies), which are combined to produce motor output. Previous studies have extracted synergy patterns from animal models and human subjects. It has been shown that muscle synergies can be extracted from a subset of hand postures and used to reconstruct a larger variety of hand shapes. The hypothesis of this study was that the multiple degrees of freedom in muscle activation in the human hand can be reduced to a set of static synergistic activations from a sample of electromyographic (EMG) data and those synergies can be scaled to produce a variety of time-varying functional output. In able-bodied persons, we recorded EMG from twelve intrinsic and extrinsic hand muscles. Each subject performed static hand postures and dynamic functional tasks with object manipulation. Synergies were extracted from average EMG recordings during static hand postures using a cross-validated NNMF decomposition algorithm. For each subject, the synergy model was used to reconstruct time-series EMG data. It has been concluded that a static synergy model extracted from hand postures can explain the temporal changes in muscle activation during functional tasks.

Title: Neural control of forelimb locomotor behaviors

Authors: A. ISLAM, T. PENG, ***P. SHAH**;
Stony Brook Univ., Stony Brook, NY

Abstract: Abundant evidence has established the existence of shared neural circuitry for different rhythmic hindlimb locomotor behaviors. However, whether common neural elements also control rhythmic forelimb locomotor movements remains largely unexplored. Understanding the neurophysiology of different functional forelimb motor behaviors will prove valuable in strategizing therapies for the recovery of hand function after neurotrauma. The primary goal of the present study is to determine the neuronal motor control of rhythmic forelimb movements - treadmill stepping (TM), overground walking (OG) and horizontal ladder walking (LD) - in adult rats. We hypothesized that neural mechanisms controlling rhythmic walking on the TM would be similar to that documented during OG and LD walking. Healthy adult rats were implanted with EMG electrodes in the deltoid (DEL), bicep, pronator, flexor

digitorum super-ficialis, and extensor digitorum (ED). Kinematic features of locomotor behaviors (TM, OG and LD) were captured using an advanced 3D Motion Analysis system while collecting EMG data. Burst characteristics (mean and peak amplitudes, burst duration), patterns and timing of muscle activity were analyzed from raw EMG signals. Cross-correlogram histograms examined synchronization of motor unit activity between TM and OG (low speed TM vs high speed, LSHS; low speed TM vs OG, LSOG; high speed TM vs OG, HSOG) for the DEL and ED. Bandpass EMG signals generated from one step cycle from each of the locomotor behaviors were used to construct correlogram histograms (total of ten individual steps). Our preliminary data show that the burst duration and amplitude between the three behaviors (TM, OG and LD) vary between muscles, but the order of muscle activation patterns is preserved such that there is a highly sequential pattern of proximal to distal muscle activation during TM, OG and LD. Additionally, center peaks appeared in the histograms for all correlation analyses. The width of the central synchronous peak in the cross-correlation histogram was broader in the DEL muscle than the ED between LSHS (average ± SD peak width = 31± 4.82ms vs 14.56± 2.59ms), LSOG (34.56 ± 3.97ms vs 29.33 ± 10.34 ms) and HSOG (33.22 ± 3.14ms vs 24 ± 5.91ms) conditions. These findings reveal that there is some degree of common neuronal drive to motoneurons during the TM and OG walking conditions. Moreover, there is also greater relative contribution of direct common inputs to the ED motoneurons during the two behaviors in comparison to the DEL. These data are novel and suggest that common neuronal drive regulates rhythmic forelimb locomotor behaviors in awake adult rats.

Title: Impaired oral motor control due to anesthesia during intraoral manipulation of food

Authors: *J. GRIGORIADIS, A. KUMAR, P. SVENSSON, K. SVENSSON, M. TRULSSON; Dept. of Dent. Med., Karolinska Institutet, Huddinge, Sweden

Abstract: Background: Mastication is a complex intermittent rhythmic act in which the tongue, facial and jaw muscles act in coordination with each other, to position the food morsel appropriately in between the teeth, break it down into smaller pieces and prepare it for swallowing. The fine-tuned coordination of tongue, facial and jaw muscles is achieved by the ability of the central nervous system to receive and integrate sensory information from various types of orofacial mechanoreceptors, including the periodontal mechanoreceptors (PMRs). Sensory information from PMRs surrounding the roots of natural teeth is important for optimizing the positioning of food, force levels and adjustment of force vectors during precision biting.
Aim: The aim of the experiment was to test the hypothesis; if decreased inputs from the PMRs, due to anesthesia, would perturb the oral fine motor control and the related jaw movements, during the intraoral manipulation of food morsels.
Material and Methods: Thirty healthy volunteers (16 female; mean age 27 (range 19-40)) with a natural dentition were equally divided into experimental and control groups. The participants in both the groups were asked to manipulate and split a spherical chocolate candy (diameter: 10mm, weight: 0.84 ± 0.01g) into two equal halves (ideal split) with the anterior teeth, thirty times each before and after an intervention. The intervention was made in the experimental group by anesthetizing the upper and lower front teeth. The control group continued the performance of the behavioral task without any intervention. During the experiment we evaluated the performance of the split and recorded the vertical jaw movement, electromyographic activity of masseter muscle and sound related to the cracking of the candy. We assessed the performance i.e., deviation from ideal split and the duration of jaw movements during the tasks.
Results: Preliminary results indicate that the participants in the experimental group showed a significant decrease in performance ($P<0.001$) while no difference was observed in the control group ($P=0.566$). However, there were no robust changes in the duration of jaw movements, due to anesthesia ($P>0,050$).
Conclusion: Sudden deprivation of sensory information from PMRs impairs oral fine motor control during intraoral manipulation of food, however, no significant changes in duration of jaw movements where observed. Our results maybe important because we have previously observed smaller duration of jaw movements in oral prosthetic rehabilitated patients in comparison to natural dentate individuals.

Title: Assessing movement variability with quantitative motion capture in able-bodied individuals performing the Jebsen Taylor Hand Function Test

Authors: L. WOZNICZKA[1,2], S. WANG[2,3], *K. KONTSON[2], E. CIVILLICO[2];
[1]Univ. of Marquette, Milwaukee, WI; [2]U.S. Food and Drug Admin., Silver Spring, MD; [3]Univ. of Maryland, College Park, MD

Abstract: The Jebsen Taylor Hand Function Test (JHFT), which is widely used in clinical settings to assess hand function, consists of seven standardized tasks based on activities of daily living. Although originally developed for individuals with neurological and musculoskeletal conditions, JHFT has also been utilized in the upper limb amputee population to evaluate rehabilitation progress and functional performance. Currently, the standard endpoint for each JHFT task is completion time. For upper limb prosthetic users, it is also important to assess *how* the subject performs each task: the completion time endpoint for JHFT is not sufficient to evaluate the potential compensatory movements (CMs) employed by subjects due to the loss of distal degrees-of-freedom in the arm. Through the use of motion capture technology, quantitative information on how the subject moves (i.e. movement quality) can be used to measure performance in a way that is potentially more clinically meaningful than completion time alone. To better understand the applicability of motion capture and variability in movement quality for each task in able-bodied individuals, five able-bodied subjects were recruited for a pilot study. Using a Vicon motion capture system with eight Bonita B10 infrared cameras, 27 markers on the upper body of each subject were tracked. Each subject performed two trials of the seven JHFT tasks with the dominant hand. Inter-subject variability for each task was determined by normalizing all subject trials with respect to completion time and calculating the maximum standard deviation for a particular task. The following angles were analyzed: wrist flexion, ulnar deviation, and internal rotation; elbow flexion; shoulder flexion, abduction, and internal rotation. Preliminary results indicate that shoulder flexion and abduction varied greatly between subjects during Task 1 (writing) and Task 5 (stacking checkers). There was high variability in shoulder abduction, but not shoulder flexion, while subjects performed Task 3 (picking up small objects) and Task 4 (simulated feeding). Wrist angles and elbow flexion were fairly consistent across all subjects for all of the JHFT tasks, with the exception of Task 2 (page turning). In future studies,

the utility of the motion capture in capturing compensatory movements will be assessed using able-bodied subjects performing these tasks with DOFs artificially reduced to more closely approximate the movements of an upper limb prosthesis user. The mention of commercial products, their sources, or their use in connection with material reported herein is not to be construed as either an actual or implied endorsement of such products by the DHHS.

Title: Principles of auditory processing in sensory and premotor structures of the songbird forebrain

Authors: *E. SOYMAN, D. S. VICARIO;
Rutgers Univ., Piscataway, NJ

Abstract: Sensory and motor brain structures are known to work in collaboration during speech perception, although their specific functions and the nature of the connectivity between them remain controversial. The present study exploits the special features of the songbird vocal communication system to explore the participation of auditory and vocal premotor structures in auditory processing of vocal signals. We simultaneously recorded the neural responses to auditory stimulation in both the higher-order auditory area NCM and premotor area HVC of the songbird brain in awake zebra finches (*Taeniopygia guttata*) using silicon probes to test multiple sites in each structure. Bird's own song (BOS) and various conspecific songs (CON) were presented in both blocked and shuffled sequences. The neural responses showed plasticity in the form of stimulus specific adaptation, although the dynamics were markedly different between the two structures. In NCM, the decrease in response with repetition of each stimulus was gradual and long-lasting. In contrast, HVC responses to CON stimuli decreased rapidly but transiently, as reflected by differential dynamics in the blocked versus shuffled stimulus presentation sequences. Responses to BOS in HVC decreased much more gradually than CON responses. Furthermore, the quality of neural representations and discrimination, as assessed by computing the mutual information between stimuli and neural activity, was higher in NCM than in HVC. Conversely, the internal functional connectivity, as analyzed by estimating the coherence

between the recording sites, was greater in HVC than in NCM. The cross-coherence between the two structures was limited to low frequencies (<18 Hz). An intriguing finding was that, in HVC, CON stimuli with high acoustic similarity to BOS elicited auditory responses that were more differentiated from BOS, compared to CON stimuli with low BOS-similarity. Our findings converge on the conclusion that auditory communication signals are processed according to very different, but complementary, principles in the two structures. NCM activity is governed by functionally heterogeneous neurons and/or neural subpopulations that reliably represent different parts of complex auditory stimuli at fine temporal resolutions; NCM thus is likely to play an important role in stimulus recognition and long-term memory formation. In contrast, HVC responses are globally synchronous and do not differentiate well between different stimuli; however, they show strong temporal and/or contextual sensitivity. These findings may inform study of the contributions of auditory and motor pathways to human speech processing.

Title: Effects of complex acoustic contexts on stimulus encoding in songbird auditory forebrain

Authors: *M. DONG, D. VICARIO;
Psychology, Psychology, Rutgers Univ., Piscataway, NJ

Abstract: An auditory stimulus can convey different information, depending on its timing and acoustic relationship to preceding stimuli. For example, oddball effects that depend on the relative frequency of two different stimuli have been demonstrated with simple sounds. The present study extends that approach to a novel paradigm that uses complex vocalizations from different acoustic categories (zebra finch and canary song syllables) as stimuli to investigate the effects of context-dependent encoding. We used multiple electrodes to record multi-unit neural activity in the auditory forebrain (Field L and area CLM) of awake male zebra finches in response to a sound presented in two different contexts. A zebra finch syllable (Target) was first presented in a sequence with 7 other zebra finch syllables as context; and then with 7 different canary syllables as context. All stimuli were played in a shuffled order with equal probability at an ISI of 1.2 secs.

The results show that the same Target syllable induced higher responses in the canary context than in the zebra finch context. This suggests that neural responses to a stimulus are "context"-dependent and is consistent with the stimulus-specific adaptation (SSA) hypothesis from oddball experiments. However, the current experiment differs from oddball experiments in two ways. First, most oddball experiments used pure tones as stimuli but we used complex stimuli. Second, oddball experiments using two stimuli show that a given stimulus elicits stronger neural responses as an oddball with low probability than as a standard with high probability. Our results show that neural responses differ depending on the type of context stimuli even though the probability of Target occurrence remains the same. This suggests an influence of the acoustic contrasts between syllables from different natural categories, independent of relative stimulus probability. Therefore, the current experiment expands our understanding of how the nervous system dynamically processes auditory information, which may be important for context-dependent tasks that depend on sequential information and use complex sounds, such as speech processing.

Title: Mechanisms underlying the social enhancement of vocal learning in songbirds

Authors: *Y. CHEN, L. E. MATHESON, J. T. SAKATA;
McGill Univ., Montreal, QC, Canada

Abstract: Social processes profoundly influence speech and language acquisition. Despite the importance of social influences, little is known about how social interactions modulate vocal learning. Like humans, songbirds learn their vocalizations during development, and they provide an excellent opportunity to reveal mechanisms of social influences on vocal learning. Using yoked experimental designs, we analyzed the degree to which attention, multisensory stimulation, the structure of tutor vocalization, and reciprocal interactions mediated social influences on vocal learning. We demonstrated that social interactions with adult tutors for as

little as one day significantly enhanced vocal learning. Social influences on attention to song appeared central to the social enhancement of learning because socially tutored birds were more attentive to the tutor's songs than passively tutored birds and because variation in attentiveness and in the social modulation of attention significantly predicted variation in vocal learning. Attention to song was influenced both by the nature and amount of tutor song: pupils paid more attention to songs that tutors directed at them and to tutors that produced fewer songs. Tutors altered their song structure when directing songs at pupils in a manner that resembled how humans alter their vocalizations when speaking to infants, that was distinct from how tutors changed their songs when singing to females, and that could influence attention and learning. Furthermore, social interactions that rapidly enhanced learning increased the activity of noradrenergic and dopaminergic midbrain neurons. These data highlight striking parallels between humans and songbirds in the social modulation of vocal learning and suggest that social influences on attention and midbrain circuitry could represent shared mechanisms underlying the social modulation of vocal learning.

Title: Experimental evidence for innate biases in vocal sequencing learning

Authors: *L. JAMES, J. T. SAKATA;
McGill Univ., Montreal, QC, Canada

Abstract: Understanding how animals, including humans, learn and produce species-typical vocal sequences remains a fundamental question in neuroscience, ethology, and linguistics. Across languages, particular word and sound sequences are substantially more prevalent than others, and many have postulated that this results from innate sensory, motor, or cognitive biases (e.g., theories of universal grammar). However, there are no rigorous experimental tests of innate biases in vocal sequence learning across development. Zebra finches are a powerful animal model to experimentally assess innate predispositions underlying vocal sequence learning because they, like humans, learn their vocalizations during development. The songs of individual zebra finches consist of syllables arranged in a single stereotyped sequence (motif), and these

sequences vary extensively across individuals. In order to experimentally test the hypothesis that intrinsic biases guide vocal sequence learning, we tutored naïve juvenile zebra finches (i.e., raised in the absence of song; n=47), with randomized sequences of five species-typical syllables. All birds were tutored with the same five syllables and with all 120 possible five-syllable sequences in equal proportion. Because the stimuli do not provide any bias in sequencing, consistencies across tutored birds in the sequences produced would reflect intrinsic predispositions. Consistent with intrinsic biases in vocal learning, we found significant similarities in the sequencing of syllables across birds. For example, we observed significant biases in the location of individual syllables within a song motif (e.g., beginning, middle, or end). Additionally, we found directional biases between pairs of syllables wherein transitions from one syllable to the other were significantly more common than the reverse direction. These results provide strong experimental support for the hypothesis that sensory and/or motor systems are endowed with intrinsic biases that guide vocal sequence learning.

Title: Representation of calls in the activity of neurons in the songbird premotor nucleus hvc

Authors: *K. MURPHY, J. F. PRATHER;
Univ. of Wyoming, Laramie, WY

Abstract: Calls are vocalizations produced by both male and female songbirds. Although calls are shorter in duration than songs and have a less complex acoustic structure, portions of calls have been shown to be learned. Lesion and electrophysiological studies have indicated that nuclei in the song motor pathway (HVC and RA) are necessary for call vocalizations, however it remains unknown to what degree calls may be represented in activity of cells within the anterior forebrain pathway (HVC cells that project to Area X). This study investigated the role of HVC_{INT} and HVC_X neurons in both production and perception of call vocalizations. Individual HVC_X or HVC_{INT} neurons were recorded in awake and freely behaving adult male Bengalese finches (*Lonchura striata domestica*) using a miniature motorized microdrive. Neurons were identified through bipolar antidromic stimulation delivered to Area X. To determine the activity of cells

during call production and perception, calls were recorded through a microphone and played back through a speaker. A majority of HVC_X neurons were active in association with auditory playback of the bird's own call (BOC). This result indicates that the song learning pathway receives auditory activity associated with calls. These initial findings reveal that the song system is no longer involved in just song production and learning, but instead is a vocal communication system that contains representations of both songs and calls. In ongoing experiments, we are addressing the degree to which HVC_X neurons are selectively responsive to BOC versus other call stimuli such as heterospecific calls or conspecific female calls. In our recordings from HVC_{INT}, all cells that we sampled were active prior to call production. This could indicate that either HVC_{INT} neurons are active in driving the vocalization of calls (e.g. through precise regulation of HVC_{RA} neurons) or HVC_{INT} neurons are relaying a motor copy (e.g. corollary discharge) of the call from the HVC_{RA} neurons to a sensorimotor network. Together, these results indicate that call-related activity is present in HVC_X and HVC_{INT} neurons and support the role of the song system in representing the sounds used communication that include both songs and calls.

Title: Anatomical links between auditory perception and motor behavior in female mate choice

Authors: *J. L. DUNNING[1], S. MAZE[2], E. J. ATWOOD[2], K. MURPHY[2], J. F. PRATHER[2]; [1]Zoology and Physiol., [2]Univ. of Wyoming, Laramie, WY

Abstract: Females of many species use male courtship displays as a proxy of male fitness to inform decisions of mate choice. Female mate choice has been studied extensively in songbirds, in which females evaluate the quality of male songs for the purpose of choosing a mate. Female songbirds are superb in their abilities to discriminate amongst songs and will exhibit copulatory behaviors (i.e. copulation solicitation displays (CSDs) and calls) in response to songs played through a speaker, even when no male is physically present. It remains unknown, however, how perception of song quality influences expression of copulatory behaviors. Studies of female responses to song have implicated specific auditory cortical regions, such as the caudal

mesopallium (CM), in the expression of female mate preferences. Here we examined the projections from CM in female Bengalese finches (*Lonchura striata*) using an anterograde neural tracer. Our results demonstrate a novel projection from CM to the robust nucleus of the arcopallium (RA) as well as a region we suspect to be the ventral intermediate arcopallium (AIV). Ongoing experiments with dual tracers are examining the AIV projections more carefully. These arcopallial projections may enable CM to influence brain regions implicated in female courtship behaviors. In zebra finches, AIV projects to the ascending auditory stream, which in turn projects to the mediobasal hypothalamus (MBH), a region associated with female CSDs. In female Bengalese finches, RA projects to the dorsomedial nucleus of the intercollicular complex (DM), a site necessary for female call production. In addition, DM has recently been shown to project to the cloaca via the respiratory premotor nucleus retroambigualis (RAm) in canaries. Together, these data reveal putative pathways through which CM may influence both CSDs and calls in response to preferred song(s). To address the functionality of the projections emanating from CM in driving female courtship behaviors, we have begun using an adeno-associated virus (AAV) encoding the channelrhodopsin protein (ChR2) to selectively and reversibly manipulate CM neurons as female songbirds are engaged in evaluation of song quality. Our preliminary results demonstrate that CM displays robust expression of ChR2 and an increased firing rate in response to 420nm light. We are presently beginning tests of our expectation that manipulations of CM while females are listening to song will induce changes in female courtship behaviors via the projections of CM to the arcopallium.

Title: Mismatch response in auditory area of freely-moving songbird

Authors: *C. MORI, K. OKANOYA;
Grad. Sch. of Arts and Sci., The Univ. of Tokyo, Tokyo, Japan

Abstract: Mismatch negativity (MMN) is a component of the event related potentials (ERPs) that occurs in humans in response to unexpected and rare stimuli. The presentation of an oddball sequence of stimuli, infrequent sound (deviant) embedded in frequent regular sounds (standard), results in an evoked response. Several animals, including primates and rodents, show mismatch responses similar to that of humans. In this study, we investigated intracranial mismatch response from field L and the caudomedial nidopallium (NCM), in a songbird forebrain area, a brain structure considered to be analogous to parts of the primary auditory cortex in mammals. Songbirds communicate with each other by vocalization and develop a complex vocal pattern through vocal learning. Java sparrow, a species of songbird, is highly social and maintains communication with flock members using frequently repeated contact calls. It is crucial for Java sparrow to process repeated vocal signals and detect novel ones. We recorded local field potentials from Java sparrows by chronically implanted electrodes with wireless transmitter under freely moving condition. The auditory evoked potentials were recorded in passive listening. Pure tones (1-8 kHz) of 50 ms duration with 10 ms onset and offset ramps were presented at about 60-70 dB through a speaker placed near the perch. Three sound sequence designs (flip-flop sequence, many-standard sequence, and cascade sequence) were utilized to test whether the songbird auditory was capable of evoking human-like MMN.Significant negative and positive field potentials were observed between 50-250 ms after the onset of the deviant sound. We expect that songbird has a potential to be useful animal models that will contribute to the further understanding of neural mechanism of auditory sensory memory processing. Title: Mechanism and function of physiologically heterogeneous cell types in caudolateral mesopallium

Authors: *A. N. CHEN[1,2], C. D. MELIZA[3];
[2]Neurosci. Grad. Program, [3]Psychology, [1]Univ. of Virginia, Charlottesville, VA

Abstract: The avian caudal mesopallium is one of the first regions in the auditory system responsible for selective, invariant representations of learned conspecific song. Using whole-cell electrophysiological recordings from caudolateral mesopallium (CLM) in zebra finches (*Taeniopygia guttata*), we have identified several putative classes of neurons by spike shape, frequency-current relationships, and firing patterns. A small proportion of cells had narrow spikes (NS; 9%) and little to no frequency adaptation, characteristics of inhibitory interneurons. The remaining putatively excitatory cells exhibited broad spikes and a range of phasic and tonic firing patterns that could be clustered into separate groups. Some neurons were regular-spiking (RS; 16%), with tonic, moderately adapting spiking responses to prolonged depolarizations. The predominant majority of neurons displayed a phasic firing pattern, responding only at the onset of depolarizing step currents. Within this group of cells we distinguished transient-spiking neurons (TS; 29%), which fired 3-5 action potentials at depolarization onset, followed by subthreshold oscillations, and onset-spiking neurons (OS; 46%), which fired only a single action potential at depolarization onset. Some neurons were filled with biocytin to reconstruct cell morphology; phasic neurons tended to have smaller, less elaborate dendritic trees. All four classes of neurons were present in adults and juveniles, but TS and OS neurons were more common in adults. Firing patterns are intrinsic, as they persisted in the presence of fast synaptic transmission blockers. Some TS cells became regular-spiking when treated with 4-AP but not other potassium-channel blockers, suggesting that a low-threshold outward current is responsible for phasic firing in these cells, as is also seen in vestibular ganglion cells and inferior colliculus in mammals. Based on linear and dynamical systems models fit from responses to complex, broadband current stimulation, phasic neurons are likely to function as coincidence detectors in processing complex auditory stimuli such as birdsong.

Title: Song exposure affects HVC ultrastructure in juvenile zebra finches

Authors: H. G. KHALED[1], Z. HUANG[3], R. H. R. HAHNLOSER[3], *S. M. H. GOBES[2]; [2]Neurosci., [1]Wellesley Col., Wellesley, MA; [3]ETH, Zurich, Switzerland

Abstract: Zebra finch song learning bears many similarities to human language learning, and thus the zebra finch is a useful model for understanding the biological processes involved in vocal skill acquisition. Song exposure in juvenile zebra finches triggers rapid spine enlargement and spine stabilization in HVC, an important brain area for adult song production. However, it is currently unknown whether in conjunction with learning-related spine changes there are also associated changes in synaptic structure and morphology. We paired juvenile male zebra finches with an adult bird (tutor) for various durations of time during the song-learning period. Birds were sacrificed at 59 days post-hatching and tissue from HVC was collected. Samples were processed for electron microscopy and imaged with a focus ion beam scanning electron microscope (FIB/SEM). Synapses in HVC were manually identified, and classified by subtype (symmetric or asymmetric) and shape (concave or convex). All identified synapses were segmented in 3D using ilastik, an interactive machine learning tool for image processing. Degrees of synapse curvature were quantified using EspINA, which enables measurement of synapse morphometric features. Comparisons of HVC synapse volumes and synapse curvatures were made among experimental groups that varied in their experience with tutor song. We found that asymmetric synapse volumes are significantly larger in bird groups exposed to song as compared to song isolates. Transient changes in synapse curvature emerged rapidly following tutor song exposure: the convexity difference between symmetric and asymmetric synapses significantly increased after one day of tutoring and decayed back to pre-tutoring levels within 3 weeks of first exposure. Overall, our results suggest that synapse morphology in the zebra finch HVC depends on tutor song exposure.

Title: Motor and sensory coding in duetting wrens

Authors: E. S. FORTUNE[1], N. DAY[2], P. RIVERA[1], *M. J. COLEMAN[3];
[1]Dept. of Biol. Sci., New Jersey Inst. of Technol., Newark, NJ; [2]Dept. of Integrative Biol. and Physiol., Univ. California Los Angeles, Los Angeles, CA; [3]Keck Sci. Dept., Claremont McKenna, Pitzer and Scripps Colleges, Claremont, CA

Abstract: Male and female plain-tailed wrens (Pheugopedius euophrys) coordinate the production of syllables to generate a duet song that sounds as if a single bird is singing. We are interested in how these birds use both autogenous (self-generated) and heterogenous (other-generated) sensory feedback to coordinate motor patterns necessary for the production of duet songs. To do so, we examined patterns of action potentials in HVC, a site of sensorimotor integration for song control, both in awake and anesthetized birds. Chronic neurophysiological recordings were made using multiunit electrodes that were implanted in each bird. To compare activity between males and females during singing, we analyzed multiunit recordings. However, within a bird, we isolated single units to examine temporal patterns of activity to determine the roles of putative interneurons and projection neurons. We found that female activity was more tonic and male activity more phasic during duet production. The activity of putative interneurons appeared to encode both autogenous and heterogenous feedback, whereas the activity of putative projection neurons was correlated with the motor output of the animal. To examine the sensory responses in the birds, we subsequently anesthetized each bird with urethane and conducted playback experiments. We found that neurons in HVC of males and females exhibit similar response patterns to sensory playback of different song types. We predict that these common sensory codes contribute to the timing of the motor activity while the birds are singing their duet.

Title: Early auditory experience does not affect c-Fos expression in catecholaminergic neurons in response to socially modulated song

Authors: *H. J. BARR[1], Y. CHEN[1], S. C. WOOLLEY[2];
[1]Integrated Program in Neurosci., [2]Biol., McGill Univ., Montreal, QC, Canada

Abstract: Attribution of social salience to sensory information is a critical step in neural encoding of information and, across vertebrates, catecholaminergic systems appear to participate in assigning this salience. In songbirds, individuals often show strong biases for particular songs and catecholaminergic inputs into the auditory system have been postulated to shape neural responses to song. We have recently found that early exposure to song shapes auditory processing of song as well as behavioral preferences. For example, females raised in isolation of adult male song (isolate-reared) do not show species-typical preferences for courtship over non-courtship song, and it is uncertain whether they are able to discriminate between these two types of song. One possibility is that deficits in catecholaminergic responses to song contribute to this altered behavioral perception. To investigate this, we exposed both normally- and isolate-reared female zebra finches to either courtship or non-courtship songs and examined whether early life song exposure affected the activity of midbrain catecholaminergic neurons in response to contextually different song stimuli. Using immunocytochemistry, we quantified the degree of colocalization of cells expressing tyrosine hydroxylase (TH; the rate-limiting enzyme in the synthesis of catecholamines) and c-Fos (an immediate early gene and marker of neuronal activity) in three key catecholaminergic nuclei: the Locus Coeruleus (LoC), ventral tegmental area (VTA), and central gray (GCt). We found that while c-Fos expression in TH neurons was increased by song playback relative to silence, it was not significantly modulated by either early exposure to song or the type of song stimuli. These findings suggest that in normally-reared birds, differences in social salience of courtship and non-courtship song are not reflected in differences in c-Fos expression in midbrain catecholaminergic neurons. Furthermore, the finding that isolate-reared birds show similar levels of c-Fos expression in catecholamine neurons to normally-reared birds suggests that perhaps their initial appraisal of the general salience of song is comparable. Differences in song discrimination and preference could thus be modulated by more fine-tuned catecholaminergic activity at sites of auditory processing or by other neuromodulatory systems.

Title: Parental experience counts in a socially monogamous songbird: enhanced neural and behavioral responses to fledgling begging calls in male and female parents

Authors: *B. A. BELL, N. NARAYANAN, D. S. VICARIO;
Psychology, Rutger's Univ., Piscataway, NJ

Abstract: Animals invest heavily in pair bonds and offspring, and benefit if they are able to recognize their mates and family if they become separated. This study investigates how experience modulates the neural memory for auditory signals that can be used in individual recognition, with a focus on parent-offspring interactions in the zebra finch (ZF), a socially-monogamous species with bi-parental care. Male ZFs learn a single song early in life that is used as a social signal in adulthood. Each male's song contains unique variations that enable the song to be used as a recognition signal. In addition to songs, ZFs produce a 'long call' that is used in social situations, such as when birds are separated and want to locate one another. During the juvenile period (before long calls develop), ZFs produce another type of call, a short, high-frequency fledgling call (FC). FCs signal to parents that offspring need to be fed, and elicit a direct behavioral response. Thus, FCs are a behaviorally-relevant category of vocalization for ZF parents of both sexes, but may be meaningless to adult ZFs that have not yet mated and produced offspring (virgins). Although adult ZFs show behavioral and neuronal memories for the songs and long calls of familiar individuals, the neural processing of and behavioral responses to FCs have not been thoroughly examined.
Neural processing of these socially-relevant stimuli was assessed in the NCM and CMM regions of the avian auditory forebrain, in parents and virgin subjects. In addition, parental behaviors elicited by FCs were tested in a novel paradigm. Finally, the behavioral and neural data collected from parents were used to determine whether ZF parents can discriminate between the FCs of their own vs. unfamiliar fledglings. Results show that neural responses to FCs are stronger in parents of both sexes than in virgins. This may be due to differences in neural tuning that include

higher best frequencies in parents, perhaps reflecting a shift toward the high frequencies of FCs. Parents also show a neuronal memory for the calls of their own fledglings. In the behavioral paradigm, FC playback elicited parental behaviors more frequently in parents than in virgins. However, results also showed unexpected sex differences in the frequency of parental behaviors (nest-box entries, food-collected, etc.), as well as in the lateralization for parental-enhancement of neural responses to FCs. These sex differences support the hypothesis that maternal and paternal care develop through different neural mechanisms and establish the ZF as a valuable model for investigating how parental experience affects neural and behavioral processing in both female and male parents.

Title: Statins affect the quality of auditory memories and performance on a behavioral discrimination paradigm in an avian model.

Authors: D. VALIVETI, S. SRINIVASAN, *D. S. VICARIO, M. L. PHAN;
Rutgers The State Univ. of New Jersey, Piscataway, NJ

Abstract: The rise in childhood obesity has led to increased hypercholesterolemia (high cholesterol) and other risk factors in children normally associated with adult cardiovascular diseases. HMG-COA reductase inhibitors (statins) have been recommended for the management of high cholesterol in children. However, oral statins may affect cholesterol synthesis in the CNS, disrupting brain growth and maturation. We have developed the zebra finch (ZF) as a model system to examine potential cognitive and neural effects of statins in juveniles and adults by assessing song learning, auditory memory and performance on an auditory discrimination paradigm. Songbirds learn their vocalizations as juveniles through a process of vocal imitation similar to human speech learning. A songbird auditory region, the caudomedial nidopallium (NCM) is a specialized forebrain area that stores a memory of the tutor's song and subserves song discrimination.

Male ZFs received either oral simvastatin (40 mg/kg) or vehicle daily from ages 45±5 post-hatch days (phd) until the termination of the experiment (180 ± 5 phd). To test the hypothesis that statins impair auditory discrimination performance in adulthood, the birds were trained to peck for a food reward in response to a Go stimulus and to withhold responding from a NoGo stimulus. Vehicle treated birds reached criterion in ~2 weeks (M= 14.5 ± 1.9 days). In contrast, none of the statin treated birds learned the task well enough to reach the accuracy criterion (80% correct across two 100 trial sessions).
To test the hypothesis that chronic statin exposure impairs learning and memory, we then recorded simultaneously from multiple electrodes in NCM in the same birds in an awake restrained preparation. We compared multi-unit responses to novel and familiar songs (that had been presented 20h earlier). Response differences were quantified as Relative Response Strength (RRS) to provide a measure of long-lasting familiarity; the higher the RRS, the stronger the memory. RRS was significantly lower in statin-treated birds than in those that received vehicle alone ($p < 0.05$). Together, these results suggest that oral simvastatin treatment, given in therapeutic dosages chronically across development and into adulthood, produces deficits in learning and memory in adults.

Title: Zebra finches still recognize their tutor song after manipulation of temporal structure

Authors: *C. MOL[1], G. J. L. BECKERS[1], R. W. J. KAGER[2], J. J. BOLHUIS[1];
[1]Dept. of Psychology, [2]Dept. of Language, Literature and Communication, Utrecht Univ., Utrecht, Netherlands

Abstract: There are remarkable behavioral, neural and genetic parallels between birdsong and human speech and language. Song development in the zebra finch (*Taeniopygia guttata*) is a commonly used model for human speech development. Young male zebra finches learn their song by imitating the song of an adult bird (a 'tutor') during a sensitive period early in life,

comparable to speech acquisition in human infants. During vocal learning, zebra finches also form a memory of their tutor song, which they can still recognize when adult. However, it is not known which acoustic features of the tutor song are memorized during development, and are important for recognition in adult birds. Zebra finches typically sing a stereotyped motif consisting of a sequence of complex syllables separated by brief silent intervals. Within syllables, often several song elements can be distinguished based on rapid temporal or spectral changes. As a comparison, human infants use the temporal structure of speech, such as silent intervals, to parse continuous speech and to recognize linguistically relevant speech units. The aim of our study is to investigate whether the temporal sequencing of syllables, elements and silent intervals in a tutor song is important for song recognition in zebra finches. We assessed recognition of a tutor song using an auditory discrimination paradigm without reinforcement, in which adult zebra finches (raised by their parents) were exposed to playbacks of their tutor song and an unfamiliar song. Zebra finches typically respond differently towards tutor and unfamiliar song, which can be used as a behavioral measure for song recognition. In a previous study, we demonstrated that zebra finches were still able to recognize their tutor's song after systematically changing the temporal order of syllables within these songs. In the current study, we altered the temporal structure of silence intervals within a tutor song, such that: (1) all inter-syllable silence intervals were removed, (2) silence between song elements, within syllables was added, or (3) a combination of these two manipulations was applied. We found that adult zebra finches still recognized their tutor's song after all of the silence interval manipulations. Taken together, we conclude that zebra finches can recognize their tutor's song despite various and drastic manipulations of song temporal structure, and that therefore temporal integration of acoustic features over relatively brief song segments is sufficient for recognition.

Title: Matching tutors to students: efficient two-stage learning and birdsong

Authors: *T. TESILEANU[1], B. OLVECZKY[2], V. BALASUBRAMANIAN[3];
[1]Initiative for the Theoretical Sci., CUNY Grad. Ctr., New York, NY; [2]Ctr. for Brain Science, Dept. of Organismic and Evolutionary Biol., Harvard Univ., Cambridge, MA; [3]Dept. of Physics and Astronomy, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Existing models of birdsong learning assume that the outflow of the song-specialized basal ganglia (LMAN) plays the role of experimenter: it introduces vocal variability required for trial-and-error reinforcement learning. Recent data, however, suggests that LMAN activity also provides a corrective bias that drives short-term improvements in song that are later consolidated in the robust nucleus of the arcopallium (RA). This learning process is thought to occur through heterosynaptic plasticity, in which the strengths of HVC-RA synapses are modulated by activity at the LMAN-RA synapses. Here we develop a new model of such two-stage learning in which the teacher circuit (LMAN in the bird) provides both variability for experimentation and an instructive signal to the student circuit (RA in the bird). We demonstrate that for such learning to be efficient, the instructive signal should be adapted to the specific dynamics of the plasticity mechanism in the student. As an example, we show in our model that an adapted LMAN can effectively train RA to move from juvenile to adult patterns of firing, mimicking what is seen in songbirds. Specifically, using a stochastic gradient descent approach, we show that to guide RA effectively, the signal from LMAN should respond to an integral of the motor error on a timescale that is related to the parameters of the RA plasticity rule. We test this prediction in simulations using both a rate-based approximation and spiking neurons. Our results indicate that when LMAN uses an integration timescale that is significantly different from the one implied by our analysis, learning is slowed down or even abolished. Assuming that over evolutionary timescales circuits in the brain have adapted to learn more efficiently, our model predicts the structure of signals from LMAN. These predictions can be directly tested by recording activity in LMAN. We also demonstrate how the variability observed in the firing patterns of LMAN neurons can be used in a reinforcement learning paradigm to enable LMAN to build its teaching signal. Two-stage learning, in which one brain area learns information about the world and then, over longer timescales, transfers this knowledge to downstream circuits, has been observed in other parts of the brain. Our model can be applied generally to settings where a tutor circuit (such as LMAN in the bird) is used to teach a student circuit (such as RA) to produce a desired output under the drive of a conductor (such as HVC).

Title: Mechanisms for category learning in songbirds

Authors: *T. SAINBURG[1], T. Q. GENTNER[2];
[1]Psychology, UCSD, LA Jolla, CA; [2]Psychology, UCSD, San Diego, CA

Abstract: My current project is to explore cognitive and physiological mechanisms which underlie acoustic category acquisition where explicit feedback only exists at the sequence level, or does not exist at all. Using an operant conditioning paradigm, combined with recent innovations in deep generative neural networks, we aim to isolate both unsupervised learning, and supervised learning where feedback exists only at the sequence level as exists in phoneme sequences in language. More specifically, we are training a VAE on Starling motifs to compress motif representations into a 2 Dimensional latent space. We are then drawing a circle in part of that latent space using samples points, arbitrarily dividing that circle in half, and calling half of those motifs 'A', and half of those motifs 'B'. Using this arbitrary division in the latent space of our network, we manipulate the information available to the bird to categorize motifs A vs B. We create three conditions:

Sequence Level Feedback (covert supervision): Classifying sequences (AB and BA vs AA and AB), the birds are provided feedback at the level of the sequence (left or right peck), where learning to divide A and B is necessary to correctly predict a reward. Specific instances of motifs (e.g. A31) are picked at random from an a-modal distribution (A24 is just as likely as A1)

Distributional (no supervision): While the bird is performing a cover task (classifying sequence loudness), a bird is experiences the same sequences as in I but with no feedback that provides information about phoneme category boundaries. Instead, the distribution of motifs (A and B) are gaussian, where motifs at the boundary between A and B have low probability (A24 is much more likely than A1)

Mixed Feedback: The bird performs the same task as in A, motifs are selected from a gaussian probability distribution function (A24 is much more likely than A1).

The purpose of this study is to create a controlled condition in which we can isolate the two leading theories in phonetic category learning: distributional learning where categories are learned using unsupervised clustering and covert reinforcement learning in which categories are learned using explicit feedback which occurs at the level of the sequence. Likely, phoneme categorization uses a combination of these two mechanisms, but a biological substrate for feedback learning in sequences has yet to be identified. This work would both demonstrate the plausibility of these mechanisms in sequence-component category learning, and enables further investigation into the computations which underlie feedback in sequence learning.

Title: Early auditory experience modifies neuronal firing properties of neurons in zebra finch auditory cortex

Authors: *T. KUDO, Y. YAZAKI-SUGIYAMA;
OIST, Okinawa, Japan

Abstract: Juvenile, male zebra finches learn to sing based upon auditory experience with adult conspecifics during a limited time window called the critical period. They first hear and memorize tutor songs (normally their fathers') during a sensory learning period (<~50 days). Then they match their own vocalizations to memorized tutor songs using auditory feedback. We recently reported that early tutor song experience shapes neuronal auditory responsiveness in the caudomedial nidopallium (NCM), homologous to the mammalian higher auditory cortex (Yanagihara and Yazaki-Sugiyama, 2016). Here we examined development of neuronal properties with tutor song experience during the sensory learning period (between post-hatching day [PHD] 20, 40, and 60) in male and female NCM using whole-cell patch clamp *in vitro*. We found three types of neuron in NCM with distinctive spontaneous firing rates; silent, low frequency (< 7 Hz), and high frequency (> 9 Hz). High-frequency neurons were found only at PHD 20 and 40. The proportion of low-frequency neurons increased from PHD 20 to PHD 40, then decreased to the PHD 20 level by PHD 60 in both males and females. Some low- and high-frequency neurons showed tonic bursts during spontaneous firing (burst type neurons) in both sexes, but the percentage of burst neurons increased at PHD 40 only in males, returning to the PHD 20 level by PHD 60. When juvenile birds were isolated from their fathers at PHD 10, which extends the sensory learning period, high-frequency neurons could be found even at PHD 60. Also the proportion of low-frequency neurons and the ratio of burst-type neurons were higher at PHD 60, compared to normal juveniles, i.e. they are more like PHD 40 in normal juveniles. These findings suggest that early song experience modifies NCM neuronal properties, especially firing properties that might be necessary for song memory formation.

Title: Relationship between song acoustic similarity and neural activity in female zebra finches

Authors: *R. TABATA, M. INDA, K. HOTTA, K. OKA;
Grad. Sch. of Sci. and Technology, Keio Un, Yokohama, Japan

Abstract: Zebra finches (*Taeniopygia guttata*) are songbirds, and they are known as an animal model of language learning. High order auditory areas in the zebra finch are analogous parts of the mammalian auditory cortex, so how acoustic information is encoded in these areas is crucial for understanding the neural bases of acoustic information processing. In particular, caudomedial nidopallium (NCM) in male zebra finch is related to the perceptual discrimination and memorization of birdsong. Previous study has reported the number of ZENK-expression cells in this area. ZENK, one of immediate-early genes, is commonly used as an index of neural activity. ZENK expression level was highest when they were exposed to conspecific song, in comparison with heterospecific song or pure tones (Mello *et al.*, 1992). In NCM of female zebra finch, song stimulus from her mate or unfamiliar directed song for courting induced the number of ZENK-expression cells (Woolley and Doupe, 2008). The number of ZENK-expression cells increased by unfamiliar directed song in comparison with mate's directed song. This result suggests that NCM detects whether the song is familiar or unfamiliar. However, how each single cell responses change temporally to each song is still unknown, because neural activities have been only estimated by the total number of ZENK expression cells previously. Here, we conducted electrophysiological experiments in NCM and NCL (NCM n=18, NCL n= 14) by using extracellular recording technique, and recorded temporal neural activities of single cell, induced by her pair's (familiar) or non-pair's (unfamiliar) directed songs. Pair-bonding is defined as occurrence of clumping behavior, and allopreening, following 8-13 days after male and female housing together. Spike sorting analysis was carried out by custom-developed MATLAB (MathWorks) code. Spike candidates were detected from recorded data and analyzed by principal component analysis, after detected waveforms were classified into several clusters by using k-means clustering. Neural activity is estimated as spike rate and spike precision; spike rates are detected during each song stimulus and spike precisions are average of inner products between trials during song stimulus. We detected that spike rates and spike precisions in NCM and NCL by pair's directed song are significantly higher than non-pair's directed song. Moreover, these neural activities are correlated with the similarity of several acoustic features between pair's and non-pair's directed songs. These results indicate that these neural indices

represent whether the song is familiar or unfamiliar and the song familiarity is caused by the acoustic similarity.

Title: Auditory neural activity in zebra finch forebrain depends on acoustic strucures of syllables

Authors: *M. INDA, R. TABATA, K. HOTTA, K. OKA;
Keio-Univ. Biophysics and Neuroinformatics Lab., Yokohama/Kanagawa, Japan

Abstract: Zebra Finch (*Taeniopygia guttata*) is a kind of songbirds. Male songs have stereotyped sequences of syllables which contain various acoustic characteristics. The male birds sing their own songs to court to females, and the females decide mating partners by their own preferences. Therefore, the auditory discrimination by difference of song structures is important ability for songbirds. The song discrimination system has been considered to be function of neurons in the avian forebrain, especially, higher-auditory regions. The caudal medial mesopallium (CMM) is a one of these regions, which is known to discriminate between conspecific and heterospecific songs. However, it doesn't discriminate between unfamiliar and familiar songs (Woolley and Doupe, 2008). This previous work only evaluated the neural responses to clearly different sound stimuli, thus we focused on song structures to clarify the details of song discrimination system. We mimicked syllable acoustic structures; 'Pitch' or 'Mean Frequency', by using pure tones with unchanging temporal characteristics to keep syllable sequences. In addition, we made syllable-shuffled song to disrupt syllable sequences. All motifs of these songs were divided into two parts 'first half' and 'second half' by syllable types, and these of natural song was exchanged for synthetic songs to investigate a factor of song discrimination. Furthermore, we prepared another synthetic song whose positions of 'first half' and 'second half' were exchanged. We recorded neural activities of CMM as spike sequences when these sounds were presented to female zebra finches. CMM neurons in females were more selective to the male songs comparing to tones mimicked 'Pitch', even though they were mixed in the same song. In contrast, these neurons did not show significantly different neural activities between the male songs and shuffled ones. These results indicate that these neurons discriminate between songs and the others by their acoustic structures. Meanwhile, these neurons were also significantly and selectively responded to 'second half' of songs. Syllables in 'second half'

induced higher mean frequencies and entropies than the ones of ‘‘first half’. We conclude that in CMM, there are some neurons that discriminate songs by not syllable sequence but these acoustic structures.

Title: G protein-coupled estrogen receptor 1 (GPER) is found in the plasma membrane and cytoplasmic fractions of tissue from the arcuate nucleus of the hypothalamus

Authors: *M. FERI[1], J. PHAN[2], K. SINCHAK[3];
[1]Biol. Sci., California State Univ. Long Beach, Long Beach, CA; [2]Biol. Sci., [3]California State University, Long Beach, Long Beach, CA

Abstract: In the ovariectomized (OVX) rat primed with 2μg estradiol benzoate (EB), sexual receptivity (lordosis) can be facilitated within 30 minutes after the infusion of non-esterified 17β-estradiol (E2) into the arcuate nucleus of the hypothalamus (ARH). Our lab has shown that the E2 rapid facilitation of lordosis is mediated by G protein-coupled estrogen receptor (GPER). We have observed that GPER are coexpressed in ARH orphanin FQ (OFQ; aka nociceptin) neurons and induce the release of OFQ to facilitate lordosis (Long et al., 2014, Horm Behav 66:63). However, it is unclear whether the GPER signaling is initiated at the level of the plasma membrane or in the cytoplasm. Within the ARH we have observed that immunopositive GPER staining is located in the cytoplasm closely associated with the nucleus. Others have observed GPER in the plasma membrane of hippocampal tissue (Funakoshi, 2006). We tested the hypothesis that GPER are localized in the plasma membrane and the cytoplasm of the ARH. ARH block dissections were collected from OVX Long Evans rats treated with 2μg EB or oil. ARH plasma membrane and cytosolic fractions were produced using a Plasma Membrane Protein Extraction Kit (Abcam). GPER levels in plasma membrane and cytosolic fractions were

determined by western blot analysis. A band corresponding to the weight of GPER was observed for both plasma membrane and cytosolic fractions. Plasma membrane preparations lacked positive LIM kinase-staining indicating that the preparations were not contaminated with cytoplasmic fractions. Conversely, flotillin 1 was not observed in the western blots of cytoplasmic fractions free of plasma membrane contamination. These findings indicate that E2 may initiate signaling via ARH GPER at either the levels of the plasma membrane or intracellularly within the cytoplasm. Further, the SERMs tamoxifen and ICI 182,780 that antagonize classical estrogen receptors (α & β), activate GPER. Thus, understanding when and which GPER signaling pathways is mediating estrogenic signaling will be important for understanding estrogenic action throughout the cycle and better direct estrogenic therapies.

Title: Dopamine receptor D1 and D5 do not form physical complexes with Src kinase on the plasma membrane to mediate actions of progesterone signaling in the arcuate nucleus of hypothalamus

Authors: *J. PHAN[1], J. RODMAN[2], K. SINCHAK[2];
[1]Biol. Sci., [2]California State University, Long Beach, Long Beach, CA

Abstract: Classical progesterone receptor-B (PR-B) are necessary for progesterone facilitation of sexual receptivity (lordosis) and are upregulated by estradiol priming (EB). Infusion of progesterone in the arcuate nucleus of the hypothalamus (ARH) of estradiol-primed ovariectomized rats facilitates behavior within 30 minutes. These rapid actions of progesterone are mediated by extranuclear classical progesterone receptor which inhibit ARH β-endorphin neurons and induce lordosis. We have shown PR-B expressed in β-END neurons and present on plasma membrane from ARH neural tissue. Further, we have shown that this PR complexes and signal through Src to facilitates sexual receptivity. This PR-Src signaling are interdependent with

dopamine receptor (D1/D5) signaling--antagonizing one, blocks facilitation of lordosis by the other two. However, it was unclear which dopamine receptor, D1 or D5, associated with the PR-Src signaling. We have shown through immunohistochemistry that PR and D1 are colocalized and expressed in β-END neurons in the ARH. However, coimmunoprecipitation revealed D1 did not complex with either PR or Src on the plasma membrane. Thus, we tested the hypothesis that Src forms complexes with D5 in ARH plasma membrane. To test this, ovariectomized rats were treated with EB or EB + progesterone and plasma membrane and cytosolic fractions were extracted from ARH block dissections. Western blot analysis revealed Src and D5 were present in the ARH. However, coimmunoprecipitation experiments indicated that Src and D5 do not form complexes either. Our results suggest that rather than physically interacting with D1 or D5, Src may be regulated through the G protein subunit associated with the dopamine receptor to modulate the rapid actions of progesterone signaling through PR-Src complexes.

Title: Subpopulations of arcuate nucleus β-endorphin neurons express G protein-coupled estrogen receptor 1 and estrogen receptor-α

Authors: *T. CHUON[1], S. HUERTA[1], J. RODMAN[1], K. SINCHAK[2];
[2]Biol., [1]California State University, Long Beach, Long Beach, CA

Abstract: Sequential activation of estrogen receptor (ERα) and G protein-coupled estrogen receptor 1 (GPER; aka GPER30) over 48 hours induces sexual receptivity (lordosis) in ovariectomized rats (Long et al., 2014, Horm Behav 66:63). It is becoming more apparent that rapid extranuclear signaling and classical genomic signaling are important for synchronizing reproductive behavior and physiology. Estradiol, acting through ERα, initially inhibits lordosis via activation of β-endorphin (β-END) neurons in the arcuate nucleus of the hypothalamus (ARH). Meanwhile, estradiol is also upregulating systems, presumably via ERα as well, to

deactivate β-END neurons and facilitate lordosis. For example, in ARH β-END neurons, estradiol increases expression of opioid receptor-like (ORL)-1 along with its cognate ligand orphanin FQ (OFQ; nociceptin) in presynaptic neurons. Subsequently, estradiol acts rapidly via GPER to facilitate lordosis. In estradiol benzoate (EB, 2μg) primed ovariectomized (OVX) rats, ARH infusion of non-esterified 17β-estradiol (E2) 48 hours later will facilitate lordosis in 30 minutes. Our behavioral data and immunohistochemical colocalization of GPER in ARH OFQ neurons indicate this E2 acts via GPER directly in ARH OFQ neurons. Given that genomic actions of estradiol appear to be regulating ORL-1 expression in β-END and GPER's effects on regulating β-END activity are presynaptic, we hypothesized that ER-α will be expressed in β-END neurons, whereas GPER colocalization with β-END will be minimal. Double-label immunohistochemistry showed that β-END expresses both ERα and GPER. However, there seems to be a higher percentage of β-END immunopositive staining colocalized with ERα than GPER. These results are congruent with our previous findings: ERα has transcriptional effects in β-END neurons, and GPER is presynaptic to β-END in OFQ neurons.

Title: Tamoxifen and ICI 182,780 activation of G protein-coupled estrogen receptor 1 (GPER) acts through orphanin FQ (nociception) neurons to rapidly facilitate sexual receptivity

Authors: *S. M. CHOKR, N. LONG, A. CHHAN, K. SINCHAK;
Biol. Sci., California State Univ. Long Beach, Long Beach, CA

Abstract: Estradiol can facilitate sexual receptivity (lordosis) by sequential activation of estrogen receptor-α (ERα) and G protein-coupled estrogen receptor 1 (GPER; aka GPER-1, GPER30; Long et al., 2014, Horm Behav 66:63). In the ovariectomized (OVX) rat, a priming dose of estradiol benzoate (2 μg; EB) initially activates β-endorphin (β-END) neurons in the arcuate nucleus of the hypothalamus (ARH) that project to the medial preoptic nucleus (MPN) to activate μ-opioid receptors (MOP), which inhibits lordosis. Subsequently, 47.5 hours after EB, infusion of non-esterified 17β-estradiol (E2) into the ARH reduces MPN MOP activation and facilitates lordosis within 30 minutes. This E2 acts through GPER and activates the orphanin FQ-opioid receptor-like-receptor-1 (OFQ-ORL-1) system to reduce the release of β-END into the MPN. Our lab has previously shown that GPER are expressed in 85.7% of ARH OFQ neurons. Thus, E2 appears to act directly through GPER in OFQ neurons to release OFQ and facilitate lordosis. We previously showed that the selective estrogen receptor modulators (SERMs), tamoxifen (TAM) and ICI 182,780 (ICI), facilitate lordosis and deactivate MPN MOP within 30 minutes through a GPER dependent pathway, similar to E2. Therefore, we hypothesized that infusion of TAM or ICI in the ARH of an EB-primed OVX rat will rapidly deactivate MPN MOP and facilitate lordosis via activation of the OFQ-ORL-1 system. As expected, infusion of either TAM or ICI into the ARH 47.5 hours after EB priming facilitated sexual receptivity within 30 minutes. Further, pretreatment with UFP-101, an ORL-1 selective antagonist, blocked TAM and ICI facilitation of sexual receptivity. These data indicate that, like E2, TAM and ICI rapidly induces ARH GPER signaling that induces the release of OFQ to facilitate lordosis by deactivation of β-END neurons. This GPER signaling is likely acting directly to induce ARH OFQ release which activates ORL-1 to inhibit β-END release. Understanding the regulation of GPER pathway activation by common anti-estrogen therapies TAM and ICI is important for better directing SERM therapies.

Title: Measuring the tonic and phasic release of dopamine during sexual behavior in female hamsters using fixed potential amperometry

Authors: *B. T. HIMMLER[1], K. M. MOORE[1], L. E. BEEN[3], B. A. TEPLITZKY[2], R. L. MEISEL[1];
[1]Dept. of Neurosci., [2]Dept. of Biomed. Engin., Univ. of Minnesota, Minneapolis, MN; [3]Dept. of Psychology, Haverford Col., Haverford, PA

Abstract: In studying the neurobiology of sexual behavior, the majority of research has focused on the male experience, with little research focusing on the female experience. In contrast, reproductive success in most mammalian species, depends on a specific pattern of vaginal stimulation during mating, i.e., sexual selection. In many species, including hamsters, females behaviorally regulate the receipt of penile intromissions from the male. Past research has shown that sexual behavior in females is rewarding, a consequence of mating that is mediated by the release of dopamine in several brain areas, including the nucleus accumbens (NAc). However, the exact mechanisms involved with the receipt of intromissions and the release of dopamine is unknown. The objective of this study was to use Fixed Potential Amperometry in order to investigate the tonic increase of dopamine seen during sexual behavior in females, and also to investigate if there is a time-locked phasic pattern between intromissions during mating and with the release of dopamine in the NAc. In order to test this, adult female hamsters received bilateral ovariectomies and a carbon fiber electrode was sterotaxically lowered into their NAc. Females were then treated with estrogen and progesterone to induce sexual receptivity, and were tested with a stimulus male partner. Our preliminary results reveal a tonic increased release of dopamine in the NAc during mating bouts as well as a phasic time-locked release of dopamine with intromissions. These results have broader implications for how sexual experience may produce a vulnerability for drug addiction.

Title: Investigation of glutamate neurotransmission in the copulatory reward of sex behavior in female Syrian hamsters

Authors: *K. M. MOORE, R. L. MEISEL;
Dept. of Neurosci., Univ. of Minnesota Dept. of Neurosci., Minneapolis, MN

Abstract: The long-term focus of research in our lab has been to understand the neural underpinnings of sex behavior. Although dopaminergic signaling traditionally has been the focus of research in natural reward, glutamatergic neurotransmission, despite its involvement in synaptic plasticity in learned and motivated behaviors, has been largely ignored. The present study utilized enzymatic biosensing and immunohistochemistry to elucidate the effects of male copulatory behavior on glutamate release and activation in multiple regions of the female brain. Our enzymatic biosensor recordings suggest that the pattern of glutamatergic neurotransmission in different brain regions in the female hamster may be responsible for encoding distinct properties of the female's copulatory interaction with the male. Specifically, patterns of glutamate release in the prefrontal cortex (PFC) appear to encode overall bouts of male copulatory behavior, which we hypothesize may be responsible in signaling to downstream regions responsible for copulatory reward. In contrast, recordings in the nucleus accumbens (NAc) have revealed transient glutamate release in response to individual penile intromissions, which we hypothesize may signal reward so that future receptivity to this reproductively necessary behavior is reinforced. We next examined the underlying circuitry by which this activation takes place. We first determined potential sex-activated afferents to the NAc using stereotaxic injections of the monosynaptic retrograde tracer Choleratoxin subunit B and subsequent staining for cFos, a marker of neuronal activity. We confirmed that sex behavior increased activity in the NAc core as revealed through increased levels of cFos expression, and found that retrogradely labeled afferents in the PFC were also activated, corroborating the findings from our biosensor recordings. To further investigate this circuitry, we are currently using an inhibitory designer receptor exclusively activated by designer drug (DREADD) to selectively silence accumbal-PFC innervation during sex behavior, and will examine the impact of this manipulation on both cellular activation as well as reward-related behavioral conditioning to repeated sex experience.

Title: RU-486 enhances 8-OH-DPAT's inhibition of female rat sexual behavior

Authors: *R. S. HORNUNG[1], L. UPHOUSE[2];
[2]Biol., [1]Texas Woman's Univ., Denton, TX

Abstract: Gonadal hormones are critical for initiation of female rat sexual behavior. Estradiol is more important but progesterone allows expression of the entire repertoire of sexual activity. Neurotransmitters also influence the expression of sexual behavior and 5-HT_{1A} receptors have received special attention since 5-HT_{1A} receptor agonists inhibit the behavior. Both estradiol and progesterone reduce the effectiveness of the 5-HT_{1A} receptor agonist, 8-OH-DPAT [(±) -8-hydroxy 2-(di-*n*-propylamino) tetralin]. Mechanisms responsible for estrogen's reduction include a decline in 5-HT_{1A} receptor signaling but progesterone's role is not clear. Progesterone also reduces the effects of restraint on sexual behavior and the 5-HT_{1A} receptor has been implicated in this behavioral decline. Since the antiprogestin, RU-486 [(11β-(4-dimethylamino)phenyl-17β-hydroxy-17(1-propynyl)estra-4,9-dien-3-one)], attenuated the effect of progesterone, the intracellular progesterone receptor was implicated. By extension, the intracellular progesterone receptor may be involved in progesterone's reduction of sexual inhibitory effects of 5-HT_{1A} receptor agonists, but the effect of RU-486 has not been examined. The current project was designed to test this hypothesis. However, it has been reported that RU-486 blocks the serotonin transporter. To rule out the possibility that RU-486 was acting by such a mode, and independent of the intracellular progesterone receptor, RU-486 was administered before or after progesterone treatment. Ovariectomized Fischer rats were primed with 10 µg estradiol benzoate and 500 µg progesterone. RU-486 (5 mg/rat) was administered either 1 hr before progesterone (to block intracellular progesterone receptor-mediated events) or 4 hr after progesterone (when intracellular progesterone receptor-mediated events should have occurred). Prior to injection with 0-100 µg/kg 8-OH-DPAT, all females showed high lordosis frequency and lordosis quality. However, proceptivity was significantly reduced by RU-486 given before (Chi Square, $p \leq 0.05$), but not after, progesterone. RU-486 treatment before progesterone also enhanced the response to 8-OH-DPAT so that lordosis inhibition was evident at lower doses of the drug (ANOVA, $p \leq 0.05$). Comparable enhancement was not evident when RU-486 was given 4 hr after progesterone. Therefore, the intracellular progesterone receptor may be required for progesterone to reduce the sexual inhibitory effects of 5-HT_{1A} receptors.

Title: Melanocortin 4 receptors expressed only on sim1 neurons are sufficient for male sexual behavior

Authors: *E. SEMPLE, J. HILL;
Univ. of Toledo, Toledo, OH

Abstract: Sexual dysfunction affects 20-30% of men in the United States and world-wide. Unfortunately, sexual dysfunction is poorly understood, and existing treatments that target the periphery are often ineffective. Preclinical data has shown that central melanocortins, released by pro-opiomelanocortin (POMC) neurons in the arcuate nucleus of the hypothalamus (ARC), can lead to male erection and increased libido in rodents. When the melanocortin 4 receptor (MC4R) is knocked out globally, male mice show erectile dysfunction. The paraventricular nucleus of the hypothalamus (PVN), a known projection target of POMC neurons, expresses a high concentration of MC4 receptors. We hypothesize that the PVN is a key site of melanocortin-mediated regulation of male sexual behavior. To test this hypothesis, we compared the sexual behavior of tbMC4R/Sim1-cre mice to MC4R null mice and wild-type controls. The tbMC4R/Sim1-cre mouse model utilizes the cre-lox system to express MC4R only on Sim1-cre neurons, which are primarily found in the PVN. These mice were paired with a sexually experienced female and their behavior was filmed between 8pm and 2am. The behavioral videos were scored based on male sexual behaviors such as mounting, intromission, and ejaculation. Because MC4 receptors are also known to play a role in metabolism, a metabolic profile was obtained from these mice through the use of GTT, NMR, and weight gain. Expression of MC4R only on Sim1 neurons reversed the sexual deficits seen in MC4R null mice to those of controls, despite a similar metabolic profile to MC4R null mice. This study implicates MC4R on Sim1 neurons, likely in the PVN, in the central neurocircuitry underlying sexual behavior.

Title: Prenatal exposure to diazepam or flunitrazepam produces sexual behavior modifications of male mice

Authors: *M. MARQUEZ-OROZCO[1], A. MARQUEZ-OROZCO[2], G. DE LA FUENTE-JUAREZ[2], L. A. I. HERNANDEZ-ALVAREZ[3];
[2]Embryology, [1]Univ. of Mexico (UNAM), Mexico, Mexico; [3]Educ. and Res., Hosp. Gen. Zona Norte de Puebla, Mexico, Mexico

Abstract: Studies performed in our laboratory have shown testicular alterations and dimorphic behavioral modifications in mature male mice exposed prenatally to diazepam (DZ), with facilitation patterns in females and copulatory alterations in males. Thus, the aim of this work was to assess sexual behavior of male mice exposed *in utero* to 1 mg/kg of DZ or to a single dose (2.5 mg/kg) of flunitrazepam (FLU) in an attempt to find a biological gradient. One group of CD-1 strain female mice (DZ) was sc. treated with DZ from 6^{th} to 17^{th} days of gestation, other group of dams (FLU) were exposed to a single dose of FLU on the 6^{th} day of gestation. The control groups (C) received saline solution. The spontaneous offspring male sexual activity to receptive females was tested in 3 sessions (1/week) on 6th month of age. Tested were performed during the dark stage of the photoperiod and video recorded under red light. Pre-copulating and copulating activities were evaluated. Assessment of copulatory stage included: mount (ML), intromission (IL) and ejaculation (EL) latencies, mount series with intravaginal penetration (MSWIP) or without it (MS), mount series with ejaculation (MSWE) and the number of interruptions of penile penetrations as falls, pauses or breaks were determined. DZ males exhibited a significant larger incidence of falls and breaks during MSWIP, nevertheless FLU males also showed a higher tendency to breaks. This may be explained by a motor coordination failure that depends of cerebral cortex, which in turn we have found to be affected by prenatal exposure to DZ in previous works. Prenatally treated males showed greater proportion of ejaculations, which may compensate the modifications of motor pattern. Data were statistically processed by frequency analysis test, Odds Ratio (OR) in 2x2 tables of Manttel-Haenzel's X^2 test, Cornfield confident limits, Student's *t* test and X^2 test for *K* independent groups with contingency C coefficient, using a software package with confidence level $\alpha = 0.95$. Results show a biological gradient to prenatal benzodiazepines (BDZ) exposure that may be correlated to modification of density of central receptors to BDZ during development and suggest a permanent modification in the GABAergic neurotransmission substrate mediated by CNS.

Abstract: In former work, effects of prenatal exposure to diazepam (DZ) on sexual behavior of adult mice have been found. The aim of this work was to assess sexual behavior during reproductive span of CD-1 strain male mice exposed in utero to DZ. One group of female mice was treated with DZ (2.5 mg/kg/day; sc.) from 6th to 17th days of gestation and a control group received saline solution. The spontaneous offspring male sexual activity to receptive females was tested in 3 sessions (1/week) twice, on the 6th month of age and later on the 27th. Tests were performed during the dark stage of the photoperiod and video-recorded under red light. Pre-copulating and copulating activities were evaluated. Pre-copulating consisted in slow movements, interest, recognition and olfaction of females, self-licking and auto-exploration, olfaction of female genitals and rubbing. Assessment of copulatory stage: mount intromission and ejaculation latencies, mount series with intravaginal penetration or without it, mount series with ejaculation and number of interruptions of penile penetration were determinate. During copulating stage adult DZ-treated males showed greater incidence of interruptions of intravaginal penetration, while senile DZ-treated males had lower latencies of mount series and greater proportion of ejaculations (α=0.95).Both adult and senile DZ-treated males exhibited a significant larger incidence of falls and pauses during mount series with intromission. Data were statistically processed by frequency analysis test, Odds Ratio (OR) in 2x2 tables of Manttel-Haenzel's X^2 test, Cornfield confident limits, Student's *t* test and X^2 test for *K* independent groups with contingency C coefficient, using a software package with confidence level $\alpha = 0.95$. Results suggest a permanent modification in the GABAergic neurotransmission substrate mediated by CNS and show long-lasting effect of prenatal exposure of DZ on sexual behavior.

Title: The converging roles of progesterone receptor, dopamine receptor, and neuronal activation in the medial amygdala to mediate female sexual motivation

Authors: *S. A. RUDZINSKAS, S. JURADO, J. A. MONG;
Univ. of Maryland Baltimore, Baltimore, MD

Abstract: The neural mechanisms which mediate sexual motivation in women are not well understood. Previous work in our laboratory investigating mechanisms underlying methamphetamine (MA)-facilitated female sexual motivation have given us new insights into the neural circuitry and components contributing to sexual motivation in the normal female brain. Using cFos and lesion studies in a rodent model, we have demonstrated that the medial amygdala (MeA) is the crucial mediator of MA's ability to increase sexual motivation in females. These studies resulted in the novel finding that MA, in the absence of hormones, could increase progesterone receptor (PR) in the MeA. This is significant since dopamine and dopamine receptor 1 (D_1R) activation have been previously demonstrated to initiate PR signaling via ligand independent activation. Furthermore, a PR antagonist RU486 infused into the MeA after MA administration blocks MA's ability to increase sexual motivation. Taken together, this evidence led us to hypothesize that D_1R mediated PR upregulation in the MeA is responsible for increasing both sexual motivation and cFos activation of this nucleus. To test the behavioral aspect of this hypothesis, we designed a lentivirus containing an ubiquitin-PR-GFP-construct to ubiquitously overexpress PR. This virus was stereotaxically injected into the MeA two weeks prior to sex behavior testing, during which proceptive, or sexually motivated, behaviors and receptive events were recorded for 15min following exposure to a novel male. Our preliminary results suggest that PR upregulation in the MeA significantly increases overall number of proceptive behaviors in a hormonally-primed female rat. In fact, specific proceptive behaviors such as hops and darts also show significant increases, with no significant changes to non-

proceptive behaviors. To test whether PR upregulation may account for the increases in cFos in the MeA after MA, we are currently administering RU486 to rats 30min prior to progesterone on the final day of the MA-binge, and quantifying changes in cFos activation after RU486 using immunohistochemistry. Our future studies will aim to further link the role of PR, D_1R, and cFos neural activation play in the MeA to mediate sexual motivation.

Title: Neural estrogen receptor alpha and beta signalling pathways in mice

Authors: *S. MHAOUTY-KODJA;
CNRS UMR 8246, INSERM U1130, UPMC, Paris, France

Abstract: Estrogens through their nuclear receptors play a key role in the regulation of neuroendocrine functions and behaviors related to reproduction in both males and females. In males, estradiol derived from neural aromatization of gonadal testosterone acts perinatally in the neural structures underlying these responses to induce their irreversible organization. It is also necessary during adulthood in their activation and maintenance. In females, ovarian estradiol liberated during the postnatal period is required in pubertal maturation and feminization of neural structures involved in the expression of female sexual behavior. As for males, estradiol is also important during adulthood in the regulation of neuroendocrine and behavioral responses related to reproduction. In order to precise the neural roles of estrogen receptor alpha (ERalpha) and beta (ERbeta) in these neuroendocrine and behavioral responses, we recently generated mouse lines lacking each of these receptors in the nervous system. This restricted mutagenesis does not interfere with their peripheral functions. We recently showed that neural ERbeta invalidation delays pubertal maturation in females, but does not interfere with the organization and activation of sexual behavior in both males and females (Naulé et al., 2015; 2016). We recently assessed the effects of ERbeta invalidation on aggressive behavior by using the resident-intruder test in males. We will also present the first results we obtained on the recently generated mouse model lacking neural ERalpha gene. This characterization included behavioral (mating, olfactory preference, aggressive behavior…) and neuroanatomical analyses in brain areas underlying

sexual and aggressive behaviors. The goal of this study is to get a precise view of the neural phenotypes induced by these gene invalidations. This will allow then a detailed molecular analysis of these signaling pathways in the relevant brain areas underlying neuroendocrine and behavioral responses related to reproduction in both males and females.

Title: Disruption of conditioned sexual inhibition in male rats: alcohol and cue effects on nucleus accumbens GABA release.

Authors: *K. GERMÉ[1], J. ALVAREZ-BARKHAM[2], L. CUSACK[2], L. R. GOSSIP[2], H. S. POUPEL[2], H. RAJABI[2], J. G. PFAUS[2];
[1]Dept. of Biol. / Ctr. for Studies in Behavioral Neurobio., [2]Psychology, Concordia Univ., Montreal, QC, Canada

Abstract: Sexual inhibition can be induced in male rats when they are given access on alternate trials to a sexually nonreceptive female scented with a neutral odor (almond) and an unscented receptive female. On a final choice test with two receptive females, one scented and the other unscented, males show a conditioned avoidance of the scented female. An acute systemic treatment with a low dose of alcohol (0.5g/kg) before the final test disrupts this preference and those males show greater numbers of Fos-immunoreactive cells in the nucleus accumbens (NAc) when exposed to the odor alone. We have previously shown that males receiving this low dose of alcohol (0.5 g/kg) display an increase in both dopamine (DA) and serotonin (5-HT) concentrations in the NAc, however in alcohol-treated males only, the cue increased DA but not 5-HT. As GABAergic neurotransmission is a major target of ethanol effects, we examined here the effects of the same low dose of alcohol on extracellular concentrations of GABA in the NAc in the presence of an inhibitory cue. Sexually naïve male Long-Evans rats were conditioned for sexual inhibition to an odor (almond) using our established paradigm and injected with saline or alcohol (0.5g/kg) before the final choice test. Males were then implanted with microdialysis probes aimed at the NAc and given access to the odor under the influence of saline or alcohol. The alcohol alone had no effect on GABA concentrations. However, in the presence of the

inhibitory cue, there was an increase in GABA concentrations in NAc in alcohol-treated but not in the saline-treated rats. These data suggest that, as with DA transmission, enhanced transmission of GABA in the NAc is involved in sexual disinhibition in male rats.

Title: Cellular substrates for interactions between neuropeptide Y (NPY) and corticotropin-releasing factor (CRF) in the rat locus coeruleus

Authors: *M. J. WARNER, B. A. S. REYES, E. J. VAN BOCKSTAELE;
Pharmacol. and Physiol., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Neuropeptide Y (NPY) transmission in the brain mediates behavioral responses to stress, anxiety and stress resilience. This neuropeptide is abundant in the central nucleus of the amygdala (CeA), a limbic region that sends CRF projections to noradrenergic neurons of the locus-coeruleus (LC). The LC-norepinephrine (NE) system contains the largest cluster of noradrenergic neurons within the brain and provides the major source of NE throughout the neuraxis. From a functional perspective, the amygdalar-LC circuit is thought to mechanistically link limbic and arousal centers in response to stress. Several lines of evidence have proposed that NPY and CRF are strategically positioned to interact with each other. While previous independent studies have described the anatomical organization of NPY and CRF in the CeA and its influence on LC-NE neuronal activity (Enman et al., 2015; SFN abstract), the cellular substrates for interactions between NPY and CRF in the rat LC remain largely unknown. In the present study, we investigated anatomical substrates for interactions between NPY and CRF using immunofluorescence and immunoelectron microscopy in the male rat LC. Forty-micron thick tissue sections from the LC were collected and processed for immunocytochemical detection of NPY, NPY receptors (Y1r or Y2r) and CRF using commercially available antibodies that underwent rigorous specificity testing. Immunofluorescence microscopy showed that individual CRF-immunoreactive fibers within the LC exhibited labeling for NPY. Ultrastructural analysis using immunogold-silver labeling for CRF and immunoperoxidase labeling for NPY

confirmed that CRF and NPY co-exist in single axon terminals in the LC. Furthermore, immunogold-silver labeling of Y1 or Y2 and immunoperoxidase labeling for CRF revealed that CRF is presynaptically distributed in axon terminals that directly contact Y1-labeled dendrites while CRF and Y2r co-exist in the same axon terminals. On occasion, CRF-labeled axon terminals contacted Y2-labeled dendrites. Taken together, these findings indicate multiple sites of interaction between CRF and NPY in the LC.

Title: Activation of amygdalar corticotropin releasing factor and brainstem enkephalinergic afferents to the locus coeruleus in female rats following social stress

Authors: *B. A. REYES[1], H. GUAJARDO[2], E. C. DUFOURT[1], R. J. VALENTINO[2], E. J. VAN BOCKSTAELE[1];
[1]Pharmacol. & Physiol., Drexel Univ., Philadelphia, PA; [2]Anesthesiol. and Critical Care Med., Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Stress-related psychiatric diseases are nearly twice as prevalent in women compared to men. We demonstrated sex differences in signaling of the corticotropin-releasing factor (CRF) receptor in the locus coeruleus (LC) that can increase female vulnerability to stress-related psychopathology. Sex differences in afferent regulation of the LC could also affect stress vulnerability.We recently showed in male rats that social stress differentially engages CRF neurons in the central nucleus of the amygdala (CeA) and opioid-containing neurons in the nucleus paragigantocellularis (PGi) that project to the LC depending on coping strategy as determined by their latency to assume a defeat posture. Using the same model of social stress, the present study was designed to examine engagement of these neural circuits following social defeat in female rats. Female Sprague-Dawley rats were injected with the retrograde tracer, Fluorogold (FG) into the LC. Three days following the FG injection, rats were subjected to repeated (5 days) resident-intruder stress or control manipulation and perfused 90 minutes after

the last session. Sections through the lower brain stem and forebrain were collected and processed for immunocytochemical detection of c-fos, a marker of neuronal activity, FG and CRF or enkephalin (ENK). Cell counts revealed that while c-fos expression in the PGi was comparable among all groups, significant increases in c-fos expression were observed in the CeA of rats that have a short latency to defeat (SL) rats ($P < 0.05$) when compared to control and long latency (LL) rats. Triple labeling of c-fos, FG and CRF revealed that 82% of c-fos and FG-immunoreactive neurons in the CeA of SL rats also expressed CRF, which was significantly higher ($P < 0.01$) when compared to control and LL rats. In the PGi, approximately 34% of c-Fos and FG-immunoreactive neurons of LL rats also expressed ENK,which was significantly higher ($P < 0.05$) when compared to SL rats. These preliminary results indicating that repeated social stress engages divergent circuitry to regulate the LC in female rats with different coping styles is consistent with previous findings in males and suggests that coping strategy rather than sex is an important determinant of this regulation.

Title: Simultaneous acute stresses impair memory enduringly via novel convergent actions of multiple stress hormones

Authors: *Y. CHEN[1], J. MOLET[1], J. C. LAUTERBORN[2], B. H. TRIEU[2], J. L. BOLTON[2], K. P. PATTERSON[2], C. M. GALL[2], G. LYNCH[2,3], T. Z. BARAM[1,2];
[1]Pediatrics, [2]Anatomy/Neurobiology, [3]Psychiatry and Human Behavior, Univ. of California Irvine, Irvine, CA

Abstract: Terrorist attacks, natural disasters and battles confront us with simultaneous physical, emotional and social stresses. However, despite vast information about effects of individual acute or chronic stresses on the brain, it is unknown if multiple concurrent short stresses

influence crucial brain functions, if these problems persist, and the nature of the responsible mechanisms. Whereas an individual short stress did not affect memory, here we show that concurrent stresses lasting 1-2 hours provoked profound and enduring spatial memory deficits in mice. These stemmed from disrupted hippocampal synaptic plasticity due to loss of functional excitatory synapses. The effects of the concurrent stresses were recapitulated by combined actions of the canonical stress hormone corticosterone and the hippocampal peptide corticotropin-releasing hormone. Together, these hormones disrupted synaptic function and integrity via convergent mechanisms on dendritic spine scaffolding. Accordingly, blocking the actions of both hormones, but not of each, within the brain of stressed mice abrogated the memory problems. The inability of the mammalian brain to preserve memory when challenged with multiple simultaneous acute stresses might be adaptive.

Title: Mood, stress and longevity: convergence on Ankyrin 3

Authors: *A. NICULESCU[1], S. RANGARAJU[3], D. LEVEY[2], K. NHO[2], H. LE-NICULESCU[1], A. SAYKIN[2], D. SALOMON[3], M. PETRASCHECK[3];
[1]Psychiatry, [2]Indiana Univ. Sch. of Med., Indianapolis, IN; [3]The Scripps Res. Inst., La Jolla, CA

Abstract: Antidepressants have been shown to improve longevity in C. elegans. It is plausible that orthologues of genes involved in mood regulation and stress response are involved in such an effect. We sought to understand the underlying biology. First, we analyzed the transcriptome from worms treated with the antidepressant mianserin, previously identified in a large-scale unbiased drug screen as promoting increased lifespan in worms. We identified the most robust treatment-related changes in gene expression, and identified the corresponding human orthologues. Our analysis uncovered a series of genes and biological pathways that may be at the interface between antidepressant effects and longevity, notably pathways involved in drug

metabolism/degradation (nicotine, melatonin). Second, we examined which of these genes overlap with genes which may be involved in depressive symptoms in an aging non-psychiatric human population (n=3,577), discovered using a genome-wide association study (GWAS) approach in a design with extremes of distribution of phenotype. Third, we used a convergent functional genomics (CFG) approach to prioritize these genes for relevance to mood disorders and stress. The top gene identified was ANK3. To validate our findings, we conducted genetic and gene expression studies, in C.elegans and in humans. Taken together, these studies uncover ANK3 and other genes in our dataset as biological links between mood, stress and longevity/aging, that may be biomarkers as well as targets for preventive or therapeutic interventions.

Title: The role of $Ca_v1.2$ in mediating susceptibility to chronic stress in the prefrontal cortex

Authors: *C. C. BAVLEY, A. M. RAJADHYAKSHA;
Pediatric Neurol., Weill Cornell Med., New York, NY

Abstract: Chronic stress increases the risk for developing neuropsychiatric disorders, particularly in genetically vulnerable individuals. Single nucleotide polymorphisms (SNPs) in the gene *CACNA1C*, which codes for the $Ca_v1.2$ subunit of the L-type Ca2+ channel (LTCC), has been associated with several stress-related disorders, including bipolar disorder, schizophrenia, and major depressive disorder. The prefrontal cortex (PFC) is responsible for cognitive and emotional processing, and deficits in the functional connectivity of the PFC have been associated with most neuropsychiatric disorders. The PFC is particularly susceptible to the effects of chronic stress, displaying changes in gene expression, dendritic spine morphology and synaptic plasticity. Additionally, carriers of the risk-conferring SNPs in *CACNA1C* show alterations in PFC structure and function, suggesting a critical role of $Ca_v1.2$ in maintaining

functionality of this region. Here we demonstrate that chronic stress increases $Ca_v1.2$ protein expression in the PFC of mice, and that $Ca_v1.2$ heterozygous mice are resilient to the effects of chronic stress on anxiety-like behavior and working memory, demonstrated in the elevated plus maze and y-maze spontaneous alternation tests, respectively. Current experiments are examining the molecular mechanisms downstream of $Ca_v1.2$ within the prefrontal cortex that may mediate these stress-induced behavioral deficits. Understanding how $Ca_v1.2$ regulates susceptibility to chronic stress will help further our understanding of $Ca_v1.2$ signaling, as well as improve our understanding of the role of $Ca_v1.2$ in the development of stress-related neuropsychiatric disorders.

Title: Effects of social housing on measures of stress in male and female Syrian hamsters

Authors: *A. P. ROSS, A. NORVELLE, D. C. CHOI, J. C. WALTON, H. E. ALBERS, K. L. HUHMAN;
Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Although Syrian hamsters are thought to be naturally solitary, research from our laboratory suggests that hamsters prefer social interaction and that this interaction can induce a conditioned place preference. We have also demonstrated, however, that social defeat stress stimulates stress hormone release and promotes hyperphagia and weight gain in male hamsters. In contrast, it has also been proposed that single housing of female hamsters leads to stress-induced anorexia. Thus, there are conflicting ideas about whether group housing or single housing is more stressful to hamsters. The purpose of this study was to compare a variety of stress endpoints in singly housed and group housed males and females. Male (n = 20) and female (n = 20) hamsters were housed singly or in groups of 5. After 4 weeks, the hamsters were euthanized by rapid decapitation and trunk blood was collected at lights on, a time that is at the nadir of the daily glucocorticoid rhythm. Fat pads, thymus and adrenal glands were extracted and weighed. Serum was collected, and cortisol was measured using a radioactive immunoassay. We found that group-housed females weighed more than any other group. In addition, both group-

housed females and males had significantly more fat than did singly housed animals. Interestingly, there was no effect of housing on basal cortisol concentration or adrenal gland weight. There was, however, an effect of housing on thymus gland weight, such that the thymus glands of group-housed animals was less than that of singly-housed hamsters, but this effect was only significant when thymus weight was normalized to body weight. Together, these data suggest that while different housing protocols can impact aspects of hamster physiology, neither group nor single housing is a strong stressor for Syrian hamsters. Title: Acute and repeated exposure to social stress alters gut microbiota composition in Syrian hamsters.

Authors: *K. A. PARTRICK[1], B. CHASSAING[2], A. T. GEWIRTZ[2], K. L. HUHMAN[3]; [2]Biol., [1]Georgia State Univ., Atlanta, GA; [3]Neurosci., Georgia State Univ., Altanta, GA

Abstract: Recent data indicate gut microbiota can affect their host's brain and behavior. In humans, social stress is the primary form of stress experienced, and this exposure promotes a wide variety of gastrointestinal and neuropsychiatric illnesses. It is still not known if alterations in gut microbes are involved in these outcomes. Syrian hamsters are ideal subjects for social stress research because they are territorial and aggressive and rapidly form stable dominant/subordinate relationships. Importantly, their agonistic interactions are highly ritualized and thus rarely result in physical injury, making it possible to focus on psychological effects of social stress. The purpose of this study was to determine if exposure to social stress in hamsters alters gut microbiota and if gut microbiota composition can predict the outcome of an agonistic encounter. Hamsters were paired for 15 min on Day 1, leading to rapid formation of a dominance hierarchy. Animals were then paired twice a day on Days 2-5. Fecal samples were collected before and after the initial interaction on Day 1 and again on Day 5. Microbiota composition was

assessed via 16S mRNA Illumina sequencing on fecal samples. After the first interaction, a decrease in alpha diversity was observed in both dominant and subordinate animals, with this decrease being more pronounced after repeated interactions. Importantly, beta diversity analysis revealed distinct clustering, reflecting alterations of microbiota composition, between hamsters undergoing social interaction versus their controls. Linear discriminant analysis (LEfSe) identified specific microbiota members that drove those differences. Bacteria from the order Lactobacillales, linked to reduced inflammation and anxiolytic effects, were significantly reduced following social stress in both dominants and subordinates. Differences between these two groups were also seen including Bifidobacterium, linked to anxiolytic effects, and Clostidiacea, linked to gastrointestinal disease, which were significantly altered only in winners (dominants). Importantly, LEfSe analysis on samples collected before social interaction revealed some microbiota were powerful predictors of whether an animal achieved dominant or subordinate status. Together, these data suggest that agonistic social interactions impact gastrointestinal health in both winners and losers, and that the state of the microbial community before social stress may predict the outcome of dominant/subordinate relationships. Title: Sex differences in the effects of arginine vasopressin (AVP) in the anterior hypothalamus (AH) on resilience to social stress in Syrian hamsters

Authors: *J. I. TERRANOVA[1,2], N. HARDCASTLE[1,2], K. L. HUHMAN[1,2], H. E. ALBERS[1,2]; [1]Neurosci. Inst., Georgia State Univ., Atlanta, GA; [2]Ctr. for Behavioral Neurosci., Atlanta, GA

Abstract: Syrian hamsters readily establish dominance relationships that are formed and maintained by agonistic behaviors such as aggression and social communication. Hamsters that

lose agonistic encounters subsequently abandon territorial aggression and become more susceptible to subsequent social stress, whereas animals that have dominant experience become more resistant to social defeat stress. Dominant male hamsters have increased arginine vasopressin (AVP) 1a receptors, whereas subordinate males have decreased AVP cell bodies in the hypothalamus, a critical brain region that mediates aggressive behavior. Thus, the purpose of this project is to test the hypothesis that neural systems that increase aggressive behavior promote resistance to social stress, whereas neural systems that reduce aggressive behavior decrease resistance to social stress. Interestingly, AVP microinjection into the anterior hypothalamus (AH) *facilitates* aggression in male hamsters but *inhibits* aggression in female hamsters. Therefore, we also tested the hypothesis that there is a marked sex difference in how susceptibility to social stress is mediated. Hamsters were singly housed for two weeks and implanted with unilateral guide cannula aimed at the AH. The week following surgery, hamsters were handled daily and the estrous cycle was monitored in females. During the testing week, hamsters experienced a single 15 min defeat in the home cage of a sex-matched resident aggressor (RA). Females were defeated and tested during diestrus. Twenty-four hours later, hamsters were microinjected with saline vehicle or 0.9 μM AVP and placed in a neutral arena with an unfamiliar RA behind a mesh cage. Time spent avoiding the RA and time spent investigating the RA was quantified. There was a trending interaction of drug treatment and sex on avoidance duration ($p = 0.137$) and a significant interaction of drug treatment and sex for investigation duration ($p < 0.05$). Females who received AVP in the AH spent less time investigating the RA than control females (Controls: 201.37 ± 19.25 seconds; AVP: 108.59 ± 26.49 seconds) and more time avoiding the caged RA than control females (Controls: 55.76 ± 17.70 seconds; AVP: 148.03 ± 26.34 seconds). There was no effect of AVP treatment on male avoidance or investigation. These data support the hypothesis that neural systems that decrease aggressive behaviors increase susceptibility to social stress. Furthermore, there are sex differences in the contributions of these neural systems. (This work is supported by NSF IOS-0923301 and NIH MH062044. Title: An acute social defeat stressor during puberty increases susceptibility to conditioned defeat in adulthood

Authors: *A. M. ROSENHAUER, K. E. MCCANN, A. NORVELLE, K. L. HUHMAN; Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Syrian hamsters readily display territorial aggression and, if they lose an agonistic encounter, show striking reductions in aggressive behavior and increases in submissive behavior, a distinct behavioral change termed conditioned defeat. This model is particularly useful because the behavioral change occurs after a single defeat in both males and females. Additionally, this stressor is primarily psychological with no tissue damage or inflammation, and therefore, makes an ideal model for studying social stress. Although our lab has made significant progress delineating the neural circuit involved in conditioned defeat, all research to date has been in adults. However, social stress is also common during human adolescence, and stress experienced during puberty is a known risk factor for the development of stress-induced disorders in adulthood. In this project, we expanded the conditioned defeat model to include social defeat in early puberty. We found that hamsters exposed to a single, 15 min social defeat on P35 exhibited significantly increased social avoidance 24 hrs later when compared to no defeat controls, ($F(1,54) = 40.072$, $p < .001$). When these hamsters were tested for territorial aggression on P64, all animals attacked an intruder placed in their home cages. Pubertal stress and no defeat control animals were then subjected to a single 15 min social defeat in adulthood (P65) and were tested for social avoidance on P66 to determine if the pubertal social defeat increased vulnerability to social stress in adulthood. Indeed, hamsters that experienced pubertal social stress responded to the adult social defeat with increased social avoidance when compared with hamsters that were only defeated in adulthood or with no defeat controls ($F(2,81) = 8.214$, $p = .001$). Thus, a single social stressor in puberty increased susceptibility to acute social stress in adulthood. It is possible that the rapid changes occurring within the brain during puberty may constitute a stress-sensitive period resulting in this enhanced vulnerability. This pubertal social defeat and adult re-defeat protocol is a promising model with which to explore the long term effects of adolescent social stress and may shed light on how stress during development contributes to the increased risk of developing psychopathology in adulthood. We are currently using this behavioral protocol to examine the role of DNA methylation following adolescent stress to test if inhibiting DNA methylation blocks the increased stress responsivity later in life. Title: Prenatal exposure to social stress alters adult response to social stress in Syrian hamsters

Authors: *A. NORVELLE, G. M. F. JONES, A. M. ROSENHAUER, K. E. MCCANN, K. L. HUHMAN;
Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Maternal stress can have long lasting cognitive, emotional and physical effects on the offspring of stressed mothers. The majority of the relevant studies in this area have used relatively severe, non-social stressors to induce behavioral change in the offspring. Additionally, many studies have indicated that stress-induced alterations in maternal behavior is a critical mechanism underlying these behavioral changes. The purpose of this project was to assess the utility of our hamster social defeat model as an alternative with which to examine the effect of mild social stress of dams on the behavior of their offspring. Syrian hamsters are an ideal species with which to study the effects of social stress because both males and females are highly aggressive and will readily defend their home cage from an intruder. Yet when a hamster loses an agonistic encounter, it will abandon territoriality and will instead display social avoidance. In the current study, 6 of 12 females were defeated 3 times for 15 min in early pregnancy (prenatal days 2, 4 and 6) by larger, ovariectomized females. Following parturition, maternal behavior was scored for 7 days. Surprisingly, we observed no difference between groups in maternal behavior including licking and grooming or pup contact time. The pups of all 12 dams were weaned at P25 and were group housed until P60 whereupon they were singly housed. Half of the offspring of both groups of dams were defeated and all offspring were tested for avoidance behavior with a caged, non-threatening intruder. Defeated males of non-stressed dams avoided more than no defeat controls ($t(11)=2.5$, $p=0.03$). Male offspring of stressed dams did not show the same effect ($t(13)=1.53$, $p=0.15$). This change in stress responsivity cannot be attributed to differences in maternal behavior. There were no differences in the behavior of female offspring of stressed or non-stressed dams. These data suggest that males may be more susceptible to prenatal stress. This sex difference is consistent with the increased prevalence of specific neurodevelopmental disorders in males, including autism and schizophrenia. Supported by NIH R01MH062044 to KLH. Title: Gene expression and network analyses in the basolateral amygdala dominant and subordinate Syrian hamsters

Authors: *K. E. MCCANN, D. M. SINKIEWICZ, K. L. HUHMAN;
Neurosci. Institute, Ctr. for Behavioral Neurosci., Georgia State Univ., Atlanta, GA

Abstract: Social stress is the most common stressor experienced by humans and is a risk factor for developing a number of neuropsychiatric illnesses, including anxiety and mood disorders. Hamsters are ideal for modeling social stress because both males and females readily exhibit intraspecific aggression. After losing one agonistic encounter, however, both males and females abandon all territorial aggression and become highly submissive, a behavioral shift termed conditioned defeat. Our laboratory has made significant progress in delineating the neural circuitry and many of the neurochemical correlates of conditioned defeat and have demonstrated that the basolateral amygdala (BLA) is a critical component of this neural circuit. The purpose of this project was to sequence the BLA transcriptome of dominant and subordinate animals and to compare their gene expression to one another and to same-sex controls. We examined genes associated with learning and memory, mood and anxiety disorders, and social behavior. Several genes that had lower expression in animals that experienced an agonistic encounter have been linked to bipolar disorder (Akap5), general mood disorders (Aldh1a1), anxiety (Kif13a), and depression (Mgat5). Other genes linked to major depressive disorder (Gad2, Gria2), PTSD (Dicer1), and anxiety (Spock3) had higher expression in dominant and/or subordinate animals when compared with controls. Next, we used a weighted gene co-expression network analysis to determine the similarity in gene expression patterns of dominant, subordinate, and control samples and graphed the connectivity of the samples based on overall gene expression patterns. All samples from subordinates grouped closely together, suggesting overall gene expression patterns in the BLA were consistent in this group, regardless of sex. Samples from dominants and controls, however, were intermixed, and overall expression patterns in these groups were not distinct from one another, again independent of sex. This is not surprising given that the

behavioral phenotype of controls is aggressive, closely resembling that of dominants. We are now examining specific gene network patterns to further define the similarities and differences of gene expression in males and females of different social status. Title: Prelimbic and infralimbic cortical TrkB signaling differentially regulates conditioned defeat learning

Authors: *D. C. CHOI[1], K. A. PARTRICK[2], A. M. ROSENHAUER[2], K. L. HUHMAN[2]; [1]GSU Neurosci. Inst., Atlanta, GA; [2]GSU, Atlanta, GA

Abstract: Social defeat stress is well established to result in pervasive changes in social avoidance and behavioral adaptations that parallel the development and symptoms of depression and other psychiatric disorders. In order to identify targets for the treatment of these mental health disorders, our laboratory utilizes social defeat stress to elucidate the specific circuitry and mechanisms that regulate these long-lasting behavioral changes. The medial prefrontal cortex (mPFC) is known to regulate emotional learning and to modulate conditioned defeat learning. Previous work has also found BDNF in the prelimbic cortex (PL) and infralimbic cortex (IL) subregions of the mPFC are critical for consolidation of fear learning and extinction, respectively (Choi et al 2010, Peters et al., 2010). The purpose of this study was to test the hypthothesis that BDNF/TrkB signaling in the PL and IL differentially regulate conditioned defeat learning. Hamsters were implanted with cannulae targeting either the PL or IL and microinjected with BDNF (0.4ug/100 nl saline) or vehicle 30 min prior to a 15 min defeat stress by a resident aggressor. The following day, the defeated hamsters were tested for defeat-induced social avoidance with a confined resident aggressor in a novel testing arena. During this test, animals previously infused with BDNF in the PL demonstrated a robust attenuation in avoidance relative to vehicle -infused controls. In contrast, the animals infused with BDNF in the IL had greater

avoidance behavior relative to vehicle controls. These data suggest that TrkB signaling in the PL and IL have opposing roles in modulating conditioned defeat learning. With the specificity and solubility limitations of currently available TrkB receptor antagonists, we are now beginning to investigate the necessity of PL and IL TrkB signaling in social stress-induced behavioral change utilizing $TrkB^{F616A}$ mutant mice. These mice have a single point mutation within the TrkB receptor, resulting in its being highly sensitive to inhibition by small PP1-derivative molecules, in particular, 1-NM-PP1. Future experiments will also utilize site-specific inducible knockdown of BDNF gene expression in BDNF floxed mice to test whether PL and IL BDNF expression is critical for conditioned defeat learning. Title: Transcriptional regulation of corticotropin-releasing factor gene expression

Authors: *L. AGUINIGA[1], D. J. KLUMPP[2];
[2]Urology, [1]Northwestern Univ., Chicago, IL

Abstract: Corticotropin−releasing factor (CRF) has been well established as a key mediator of stress responses and voiding control, where increased CRF levels in Barrington's nucleus induce urinary retention and bladder dysfunction. Arachidonic acid (AA) metabolites have been shown to modulate CRF expression, however the transcriptional mediators of this modulation are unknown. We are investigating the role of PPARgamma and Ahr in AA−dependent CRF induction. We used MIRAGE software to identify candidate transcription factor binding sites in a 1kb region of the human CRF gene promoter. We identified a peroxisome proliferator−activated hormone response element (PPRE) and two Xenobiotic Responsive Element (XRE) sites as candidate mediators of AA−dependent CRF induction. Site−directed mutations of the PPRE and XRE sites were generated in a CRF−luciferase reporter plasmid. We evaluated expression of WT and the mutants in HEK 293T cells for their responses to AA. We

also transfected in transcription factors AhR and PPAR and evaluated AA−dependent CRF induction. Mutation of XRE1 resulted in significantly decreased basal CRF expression, while mutation of XRE2 or PPAR had modest effects. However upon AA induction, the PPRE mutant had increased CRF expression compared to WT, whereas XRE1 had decreased expression. The double mutation of XRE1 and XRE2 resulted in decreased responsiveness to AA. Co−transfection with PPAR had modest effects; however, AhR resulted in a significant increase in AA−dependent CRF expression. Over−expression of AhR and PPAR resulted in inhibition of AhR−dependent CRF induction. These results suggest AhR binding to the XRE sites modulates AA−dependent CRF gene expression. Continued studies using animal models will examine the role of such factors in modulating voiding in response to stress.

Abstract: Collapsin response mediator protein 2 (CRMP2) was originally identified as an intracellular mediator for the repulsive axon guidance molecule, Semaphorin3A. CRMP2 plays a key role in axon guidance, dendritic morphogenesis, and cell polarization. CRMP2 is implicated

in various neurological and psychiatric disorders. However, *in vivo* functions of CRMP2 remain unknown. We generated CRMP2 gene-deficient (*crmp2*$^{-/-}$) mice to examine their behavioral phenotypes. During 24-h home cage monitoring, the activity level during the dark phase of *crmp2*$^{-/-}$ mice was significantly higher than that of wild-type (*WT*) mice. Moreover, the time during the open arm of an elevated plus maze was longer for *crmp2*$^{-/-}$ mice than for *WT* mice. The duration of social interaction was shorter for *crmp2*$^{-/-}$ mice than for *WT* mice. *Crmp2*$^{-/-}$ mice also showed mild impaired contextual learning. Because the mechanisms that contribute to the response to methamphetamine may be relevant to a variety of psychiatric disorders, we examined the methamphetamine-induced behavioral change of *crmp2*$^{-/-}$ mice. Methamphetamine-induced hyperlocomotion was observed in both *WT* and *crmp2*$^{-/-}$ mice, but *crmp2*$^{-/-}$ mice showed drastic behavioral changes compared to *WT* mice. *Crmp2*$^{-/-}$ mice also showed altered expression of proteins involved in GABAergic synapse, glutamatergic synapse and neurotrophin signaling pathways. In addition, SNAP25, RAB18, FABP5, ARF5, and LDHA, which are related genes to schizophrenia and methamphetamine sensitization, are also altered in *crmp2*$^{-/-}$ mice. Our study implies that dysregulation of CRMP2 may be involved in pathophysiology of neuropsychiatric disorders.

Title: Acute ketamine reverses changes in glutamate release and related molecular mechanisms induced by chronic stress

Authors: *L. MUSAZZI[1], P. TORNESE[1], N. SALA[1], M. SEGUINI[1], M. MILANESE[2], T. BONIFACINO[2], D. BONINI[3], G. RACAGNI[1], A. BARBON[3], G. BONANNO[2], M. POPOLI[1]; [1]Univ. of Milano, Milano, Italy; [2]Univ. of Genova, Genova, Italy; [3]Univ. of Brescia, Brescia, Italy

Abstract: Increasing evidence has associated dysfunction of the glutamate system with the pathophysiology of neuropsychiatric disorders. Consistently, the NMDA receptor antagonist ketamine (KET) was demonstrated to induce rapid and sustained antidepressant effects.
Using a chronic mild stress (CMS) model of depression, we studied the effects of chronic stress and KET on glutamate release and related molecular mechanisms in the hippocampus (HPC) and prefrontal/frontal cortex (PFC/FC) of rats. Sucrose preference test was used to distinguish stress resilient (CMS-R) from vulnerable rats (CMS-V).
A significant increase of basal glutamate release from superfused synaptic terminals was measured in HPC and PFC/FC of CMS-V; acute KET restored glutamate release to control levels. Moreover, CMS significantly increased the levels of synaptic mineralocorticoid receptor levels, and decreased total and synaptic metabotropic glutamate receptor 2 expression, selectively in CMS-V. These changes were reversed by acute KET treatment. Finally, a significant reduction in dendritic trafficking of total BDNF and BDNF-6 splice variant transcripts was measured in CA1 and PFC/FC of both CMS-R and CMS-V, and in CA3 of CMS-V. KET partly reversed these changes.
These results suggest that chronic exposure to stress induces significant functional and molecular alterations, which are modulated by KET. Further investigation of the mechanisms underlying individual vulnerability to stress could help to clarify the neurobiological underpinnings of depression and fast-antidepressant effect.

Title: Engineered transcription factors targeted to the Fosb gene are sufficient to model the epigenetic and transcriptional phenomena that underlie stress-related behaviors

Authors: *P. J. HAMILTON[1], E. A. HELLER[4], D. D. BUREK[2], S. I. LOMBROSO[2], S. T. PIRPINIAS[2], M. FARIS[2], J. D. KOURIS[2], A. D. AVAKIAN[2], H. M. CATES[2], R. L. NEVE[5], E. J. NESTLER[3];

Abstract: Multiple studies have implicated genome-wide epigenetic remodeling events in brain reward regions following stress exposure. However, only recently has it become possible to target a given type of epigenetic remodeling to a single gene of interest, in order to probe the causal relationship between such regulation and neuropsychiatric disease (Heller et al., *Nat Neurosci*, 2014). Here, histone post-translational modifications were targeted specifically to the *Fosb* gene locus using engineered zinc-finger proteins (ZFPs). *Fosb*-ZFPs were fused to either the transcriptional repressor, G9a, that promotes histone methylation or the transcriptional activator, p65, that promotes histone acetylation. These ZFPs were expressed selectively in D1 vs. D2 medium spiny neurons (MSNs) using Cre-dependent viral expression in the nucleus accumbens (NAc) of mice transgenic for Cre-recombinase in these MSN subtypes. We find that *Fosb*-targeted histone acetylation in D2-MSNs and *Fosb*-targeted histone repressive methylation in D1-MSNs promotes susceptibility to social stress, while *Fosb*-targeted histone methylation in D2-MSNs and *Fosb*-targeted histone acetylation in D1-MSNs promotes resilience to social stress. Thus, we observe that cell- and gene-specific targeting of histone modifications *in vivo* is sufficient to model natural transcriptional phenomena that underlie stress-related behaviors. In light of these findings, we are broadening our technical repertoire to include CRISPR/Cas9 technology, in an effort to model other transcriptional events that underlie stress-related behaviors. To this end, we designed guide RNAs to target nuclease dead Cas9 (dCas9) fused to novel effector domains to the *Fosb* gene locus. We observe that dCas9 fused to the transcriptional activator, VP64, or the transcriptional repressor, KRAB, and targeted to specific locations in the *Fosb* promoter is sufficient to regulate *FosB* and *deltaFosB* mRNA levels, in both cultured cells and the NAc. These results suggest the validity in engineering ZFPs and dCas9 as DNA-binding factors to induce transcriptional events that control stress responses.

Abstract: In the limbic brain, mineralocorticoid receptors (MRs) and glucocorticoid receptors (GRs) both function as receptors for glucocorticoids. MR and GR mediate distinct effects on cellular physiology via transcriptional mechanisms, but how target gene specificity comes about has remained enigmatic. We have detected DNA binding sites of MR and GR in the hippocampus of rats injected IP with corticosterone (3 mg/kg), using chromatin immunoprecipitation followed by sequencing (ChIP-Seq), in order to identify the extent of MR/GR binding selectivity and underlying mechanisms.
This dataset revealed 918 MR- and 1450 GR-specific binding sites. *De novo* motif analysis resulted in a similar binding motif for both proteins at 100% of the target loci, which matched the known glucocorticoid response element (GRE). An additional motif was found next to the GRE, that co-occurred near all MR-specific binding sites, but was absent for GR-specific or MR-GR overlapping sites.
Members of the NeuroD family of bHLH proteins were hypothesized to bind this additional motif and affect MR/GR signalling. Neurod1, Neurod2 and Neurod6, showed hippocampal expression and could act as DNA-binding transcriptional coactivators of MR/GR at the GRE in reporter assays in non-neuronal cells. Both N-terminal and C-terminal lacking receptor truncates could be potentiated, suggesting NeuroD factors interact with proteins in the MR/GR signalling complex rather than the receptors themselves. In conclusion, a NeuroD factor binding to an additional motif near the GRE seems to result in MR selective signaling in the limbic brain.

Title: Mild chronic unpredictable stress is not sufficient toinduce depressive-like symptoms in rats

Authors: *C. J. FONTAINE, C. CHIU, S.-Y. YAU, A. R. PATTEN, B. R. CHRISTIE;
Div. of Med. Sci., Univ. of Victoria, Victoria, BC, Canada

Abstract: Depression is a mental disorder that is characterized by affective, cognitive, and physiological impairments that affects over 100 million people worldwide. Chronic unpredictable stress (CUS) is a common model for the induction of depression, however the initial development of depression-like symptoms under mild conditions remains controversial. In the present study we have used a mild CUS protocol for 2 or 4 weeks to examine key changes to gross physiology that have been associated with depression. These included monitoring for changes in body and adrenal gland weight, as well as for changes in systemic corticosteronelevels and levels of glutathione and adiponectin in the brain. We hypothesized that a depression-like state would be associated with reductions in body weight, glutathione and adiponectin as well as increases in adrenal gland weights and circulating corticosterone levels. Neither 2 nor 4 weeks following mild CUS is sufficient to produce depressive-like symptoms as described above. Interestingly, in contrast to our predictions, we saw increases in glutathione and adiponectin in the hippocampus following 2 weeks of CUS. Our data provide evidence for potential protective and compensatory actions of glutathione and adiponectin in the hippocampus under mild stress conditions.

Wuerzburg, Wuerzburg, Germany; [2]Dept. of Psychiatry, Psychosomatics and Psychotherapy, Ctr. of Mental Hlth., Wuerzburg, Germany; [3]Dept. of Psychiatry, Psychosomatics and Psychotherapy, Div. of Mol. Psychiatry, [4]Dept. of Psychiatry, Psychosomatics and Psychotherapy, Univ. Hosp. of Wuerzburg, Wuerzburg, Germany

Abstract: Anxiety and depressive disorders result from a complex interplay of genetic factors, cellular signaling, personality traits as well as stressful life events and are common mutual comorbidities. Regulator of G protein signaling 2 (Rgs2), a protein negatively regulating G protein coupled receptor signaling by increasing the GTPase activity of the Gα protein subunit has been reported to be involved in human and rodent anxiety.
Here we investigate, whether homozygous Rgs2 deficient ($Rgs2^{-/-}$) mice show behavioral alterations related to human anxiety and depressive disorders.
Innate anxiety was evaluated using elevated plus maze, dark/light box and open filed tests. $Rgs2^{-/-}$ mice showed significantly increased avoidance behavior in all three tests, indicating heightened innate anxiety. Pavlovian fear conditioning (FC) revealed significantly faster learning in the conditioning session as well as significantly augmented short-term fear memory in context and cue tests 24 h later in $Rgs2^{-/-}$ mice. Long-term fear memory and extinction assessed by cue and context tests one and two weeks after conditioning, revealed faster extinction in $Rgs2^{-/-}$ mice. Acute stress via FC did not augment anxiety-like behavior but provoked locomotor suppression for both genotypes indicating increased cautious behavior. Chronic mild stress (CMS) potentiated anxiety-like behavior in wildtype mice in dark/light box and showed a gender specific effect in $Rgs2^{-/-}$ mice. While CMS led to an increase in anxiety-like behavior in male $Rgs2^{-/-}$ mice, female mice exhibited reduced anxiety-like behavior and increased locomotor activity. $Rgs2^{-/-}$ mice exhibited depressive-like behavior in forced swim test compared to wildtype controls, but CMS did not alter immobility times.
Expression of Rgs2 was analyzed 1h and 6h after FC. Mild dynamic changes of Rgs2 expression in wild type mice were detected, suggesting Rgs2 to act as an inducible modulator (intermediate early gene) in G protein pathways involved in fear memory. MicroRNA expression patterns were analyzed using small RNA sequencing in selected brain regions 1h and 6h after FC. Moreover,

Rgs2$^{-/-}$ mice showed significantly decreased levels of monoaminergic neurotransmitters as well as decreased expression of *ADRA2A, ADRA2B*, *ADRA2C, DRD2* and increased expression of *GABA2* and *DRD2* suggesting a regulatory influence of Rgs2 on the monoaminergic system. In conclusion, downregulation of Rgs2 leads to increased innate anxiety as well as learned fear and may result from deregulation of monoaminergic signaling.

Title: Molecular fundamentals of the impaired epinephrine response following recurrent hypoglycemia: a clue from microarray analysis

Authors: *B. B. NANKOVA[1], J. KIM[2], N. KUDRICK[2], E. F. LAGAMMA[3];
[1]Pediatrics & Biochem & Mol Biol, New York Med. Col. Dept. of Pediatrics, Valhalla, NY; [2]Pediatrics, The Regional Neonatal Center, Maria Fareri Children's Hosp. at Westchester Med. Ctr., Valhalla, NY; [3]Pediatrics & Biochem & Mol Biol, New York Med. Col. Dept. of Pediatrics and The Regional Neonatal Center, Maria Fareri Children's Hosp. at Westchester Med. Ctr., Valhalla, NY

Abstract: An attenuated sympathoadrenal response to hypoglycemia is a major component of Hypoglycemia-associated autonomic failure (HAAF), a well-known neuroendocrine complication in children and adults on insulin therapy for type 1 and type 2 diabetes. The molecular mechanisms underlying this defect are still elusive. Recently we reported an initial rise in tyrosine hydroxylase activity and gene transcription during HAAF, suggesting intact CNS - adrenal synaptic signaling. Yet, epinephrine responses were impaired and this correlated with reduced adrenal capacity to produce catecholamines indicating that peripheral components of the sympathoadrenal system may be directly affected by recurrent hypoglycemia (RH). We hypothesized that both, extensive cholinergic signaling between the splanchnic nerve fibers and

the adrenal medulla and cellular endoplasmic reticulum (ER) stress caused by prolonged/repeated glucose withdrawal, contribute to the defective adrenal epinephrine release (and production) in HAAF. To gain further insight into the molecular mechanism(s) mediating the blunted epinephrine responses following RH we utilized global gene expression profiling approach. SD rats were subjected to insulin-induced RH or received saline injections. After the antecedent treatments and overnight fast all animals underwent a hypoglycemic-hyperinsulinemic clamp (target glucose levels 45mg/dL). Set of animals from each group (n>6) were sacrificed before or during the clamp, total RNA isolated from individual AM samples and subjected to microarray analysis. Differentially expressed genes (DEGs) were identified and ranked according to significant up- or down-regulation of twofold or more (*P≤ 0.05). Based on comparison analysis of DEGs, sets of genes unique for RH were revealed. A complementary bioinformatics analysis confirmed activation of the unfolded protein response (UPR) - common cellular defense mechanism which allows for recovery of ER homeostasis, cell adaptation and survival, or in case of chronic or severe stress favors induction of apoptosis and cell death. Furthermore, the data point to at least three additional pathway/process networks altered in the AM following RH which may contribute to the impaired epinephrine secretion in HAAF: increased neuropeptide (PENK, NPY, GAL) signaling; altered ion homeostasis (Na+, K+, Ca^{2+}) and downregulation of multiple proteins involved in Ca^{2+}-dependent exocytosis. Given the pleiotropic effects of the UPR in different organs, involved in maintaining glucose homeostasis these findings indicate a plausible additional mechanism for maladaptive responses to recurrent hypoglycemia.

Title: Acute stress is not acute: early and sustained effects of acute stress

Authors: *M. POPOLI[1], L. MUSAZZI[1], P. TORNESE[1], N. SALA[1], G. TRECCANI[1,2], D. TARDITO[1], M. SEGUINI[1];
[1]Univ. Degli Studi Di Milano, Milano, Italy; [2]Aarhus Univ., Aarhus, Denmark

Abstract: Compelling evidence has shown that stress destabilizes structure and function of limbic/cortical areas, and represents a risk factor for stress-related neuropsychiatric disorders. In recent studies, our group contributed to the understanding of essential destabilizing effects of stress in prefrontal cortex (PFC). We showed previously that acute inescapable footshock (FS)-stress rapidly enhances depolarization-evoked glutamate (Glu) release/transmission in PFC, by increasing corticosterone (CORT) levels, stimulation of CORT synaptic receptors, and rapid (non-genomic) enhancement of the readily releasable pool (RRP) of presynaptic vesicles in perforated synapses, mediated by synapsin I phosphorylation. Moreover, we showed that stress at the same time dramatically increases (+42%) the total number of non-perforated synapses in prelimbic PFC. In addition, we observed significant atrophy/remodeling of apical dendrites as early as 24 hours after stress, sustained for up to 14 days. These findings provided new evidence that acute stress has both early and sustained effects on structure and function of excitatory circuitry. We show now that hyperactivation of glutamate release/transmission in PFC lasts for at least 24 hours after acute stress, with increased Glu release and RRP (up to 24 h), and synapsin I phosphorylation (up to 6 h). Mineralocorticoid receptor expression level in presynaptic membranes increased immediately after the stress protocol, while glucocorticoid receptor increased after 6 h.
In order to identify epigenetic changes responsible for early and sustained changes in synapses/circuitry, we measured the expression of 21 microRNAs (miRNAs), selected for their implication in the modulation of synaptic plasticity and antidepressant effect, in the PFC immediately after 40 minutes of acute FS-stress. We found 4 miRNAs significantly downregulated. Bioinformatic analysis results highlighted enrichment of miRNA targets in different pathways, some of them related to neuronal functions, synaptic plasticity and the stress response. Expression changes in gene targets were validated by qPCR and Western blot. Overall, our results show that acute stress may exert sustained effects in PFC, with relevance to stress-related disorders, such as depression, anxiety and PTSD.

Title: Effects of acute systemic corticosterone treatment on clock gene expression in the male rat brain

Authors: *M. J. HARTSOCK, A. C. TOMCZIK, A. M. JANAS, L. E. CHUN, E. R. WOODRUFF, R. L. SPENCER;
Univ. of Colorado Boulder, Boulder, CO

Abstract: Daily oscillations in gene expression, or circadian clocks, are present in cells throughout the body and serve to optimize cell function. These clocks consist of positive arm genes *Bmal1* and *Clock*, whose protein products induce transcription of negative arm genes *Per* and *Cry*. PER and CRY proteins then feed back to inhibit the positive arm, creating a molecular oscillation with a period of ~24 h. In mammals, the hypothalamic suprachiasmatic nucleus (SCN) is a uniquely light-responsive brain region that entrains peripheral clocks to the solar day. The SCN regulates diurnal release of adrenal glucocorticoid hormones (CORT), which mediate circadian entrainment of many tissues in the periphery. Circadian clocks are also present in extra-SCN brain regions that receive no direct input from either light or the SCN, and it has been hypothesized that these extra-SCN brain clocks may also depend on CORT as a critical circadian entraining factor. Notably, the clock gene *Per1* has a CORT receptor response element in its promoter region, a potential mechanism for such entrainment. Presented here are two experiments examining whether CORT alone is sufficient to induce *Per1* expression in brain regions important for emotion control in male Sprague-Dawley rats maintained on a 12:12h light:dark cycle. In the first experiment, rats underwent adrenalectomy (ADX) or sham surgery, and ADX rats received CORT in the drinking water to maintain circadian CORT elevations at the start of the active phase, when water consumption is greatest. Five days later, all rats were administered CORT (2.5 mg/kg, ip) or vehicle during the inactive phase and killed 60 min later. Acute CORT increased *Per1* mRNA in the hypothalamus and neocortex, but only in ADX rats. In the second experiment, rats underwent ADX and were then supplemented with CORT in the drinking water for the first 2 h of the active phase. Three days later, rats were administered CORT (2.5 mg/kg, ip), vehicle, or no injection during the active or inactive phase and killed 30 min later. Acute CORT increased *Per1* mRNA in the neocortex in both CORT and vehicle-treated rats, but not in rats receiving no injection, suggesting that the stress of injection was sufficient to induce *Per1* expression even in the absence of stress-induced CORT levels. No time of day effects were observed. Our results align with our past work showing that 30 min of acute restraint stress rapidly increases *Per1* mRNA in the rat hypothalamus and neocortex, but that this induction is abrogated by ADX only in the hypothalamus. These findings suggest that acute stress may induce *Per1* expression differently in different brain regions, through both CORT-dependent and CORT-independent mechanisms.

Title: Characterization of glucocorticoid-induced loss of DNA methylation of the stress gene Fkbp5 in neuronal cells

Authors: *O. H. COX, H. SONG, N. GADIWALLA, J. MENZIES, R. LEE;
Psychiatry, Johns Hopkins Univ., Baltimore, MD

Abstract: Exposure to stressful and traumatic events especially during neurodevelopment leads to increased susceptibility to neuropsychiatric diseases. Emerging evidence suggests that exposure to stressful events is associated with molecular changes in genes that mediate or are targets of glucocorticoid (GC) signaling. In particular, the *FK506* binding protein 5 (*FKBP5*), a major regulator of the stress response and intracellular GC signaling, has been implicated in anxiety, depression, PTSD, and bipolar disorder. It has been shown to undergo epigenetic and transcriptional changes following exposure to stress. However, mechanisms that govern these changes are largely undetermined. To model the effect of GC exposure on the brain, the HT-22 mouse hippocampal cell line was treated with GCs for 7 days. Following treatment, cells were examined for epigenetic and transcriptional changes. *Fkbp5* exhibited a loss of DNA methylation and an increase in expression. The methylation marks persisted for one month following initial GC exposure in the absence of additional GCs, whereas expression returned to baseline levels soon after the initial exposure period. We then examined whether the GC-induced loss of methylation in the neuronal cells involved cell division. Interestingly, cells treated with mitomycinC or nocodazole, which inhibit cell division, prevented most of the GC-induced loss of methylation, implicating cellular division in GC-induced DNA methylation loss. We then characterized the functional significance of the GC-induced loss of DNA methylation. In the cell line, previous 7-day exposure to GCs caused a more robust expression of *Fkbp5* (45% increase over previously unexposed, p=0.008) when GCs were introduced a second time. Similarly, an *in vitro* reporter assay consisting of a CpG-free plasmid, *Fkbp5* intronic GRE (GC response element), and the luciferase gene showed significantly higher luminometric activity when the GRE was unmethylated (303% increase over the methylated GRE, p=0.0005). This suggests that previous exposure and loss of methylation can result in greater activation of *Fkbp5* in response to GC exposure. We are currently testing the interaction between the promoter and the GRE in the presence of GCs and are characterizing the role of the methyltransferase DNMT1 in the observed GC-induced methylation loss of *Fkbp5*. In summary, GCs can lead to persistent changes in DNA methylation and potentially affect gene function during second exposure events, conveying

future “risk” to a previously exposed individual. These findings may provide an important mechanistic understanding of the consequences of stress exposure in psychiatric disorders.

Title: Environmentally malleable epigenomic regions in the mammalian brain

Authors: *S. ODELL[1], S. L. KLEIN[2], A. SHARMA[2], E. MITCHELL[2], M. TOTH[2];
[2]Pharmacol., [1]Weill Cornell Med. Col., New York, NY

Abstract: Environmental experience can shape behavioral responses via gene expression through epigenetic mechanisms, including DNA methylation and histone modifications. Early life adversity is a form of environmental experience that has long been studied in both humans and rodent models, due to its neuropsychiatric consequences in adulthood. Previously, the approach to investigate the epigenetics of early life adversity has been limited to the investigation of candidate genes. Our current work took an unbiased approach, looking at genome-wide changes in methylation in response to environmental challenge by enhanced reduced representation bisulfite sequencing (eRRBS). In order to specify the epigenetic signatures of early life adversity in mice, we used various pre/postnatal environmental insults including maternal anxiety (5-HT1AR deficit elicits anxiety-like behavior), maternal infection (injection of 50μg/mg of LPS once a day from E16 to E18), and maternal separation (3 hours/day from P3 to P14). In addition displaying model specific behaviors, all three of these adverse life situations lead to innate fear/anxiety in adult mice, demonstrated by decreased entrances and time spent in the open arms of the elevated plus maze, a behavior linked to the ventral dentate gyrus (vDG). Likewise we found these models share common epigenetic signatures in the vDG, defined as early life adversity differentially methylated regions (ELA-DMRs). We identified over a hundred ELA-DMRs, 200-300bp long regions in the mouse genome whose cytosine methylation status are inherently labile and responds with permanent changes in methylation to

at least two different early life adverse situations. We found our ELA-DMRs to have intrinsic DNA methylation-dependent enhancer-like activity in vitro by luciferase reporter assay. Further, network analysis reveals ELA-DMRs to be embedded in synaptic related genes, including enrichment in cytoskeletal rearrangement, synaptic plasticity cytoskeletal reorganization, transcription and apoptosis pathways. Further, *DNMT3a* knockout studies reveal that methylation patterns of ELA-DMRs in the vDG are *DNMT3a* dependent as well as developmentally delayed compared to global biomodal methylation. In conclusion our analysis provide evidence that ELA-DMRs and their experience dependent methylation shift is a strong candidate in connecting environmental input to gene expression and ultimately synaptic, neuronal network and behavioral changes.

Title: Physiological variations in the number of hypocretin and histamine producing neurons

Authors: R. MCGREGOR, L. SHAN, M.-F. WU, *J. M. SIEGEL;
Dept Psychiat, Univ. California Los Angeles, North Hills, CA

Abstract: Waking and sleep states are the result of the coordinated activities of different neuronal systems. Amongst them, arousal promoting cell groups like hypocretin (Hcrt) and histamine producing neurons play a critical role in waking whereas melanin concentrating hormone (MCH) expressing neurons are involved in sleep regulation. Consistent with their role in modulating each state, Hcrt and histamine neurons show the highest levels of activity during the active phase whereas the peak activity of MCH neurons has been reported to be prior to and during the inactive phase. In spite of the extensive evidence indicating circadian modulation of these systems, studies have so far assumed that the number of detectable neurons in each neurochemical group remains constant through the different behavioral states. To measure any variation in the number of immunohistochemically detectable neurons, we sacrificed groups of animals at 5 h into the light phase or 5 hours into the dark phase. We then processed the tissue for Hcrt, histidine decarboxylase (HDC) and MCH. We observed that the animals sacrificed during the dark phase showed a significantly greater number of Hcrt and histamine neurons compared to the animals sacrificed during the light phase. We did not observe differences in cell

size between conditions in Hcrt and HDC cells. The increase in Hcrt cell number was largely restricted to the medial hypothalamus. In contrast, we did not observe differences in the number of MCH neurons between the circadian phases. However, there was a significant increase in MCH cell size during the light phase. To further explore if there were more "undetected" Hcrt and MCH neurons we used colchicine to inhibit axonal transport. We observed that animals that received colchicine had a substantially greater number of Hcrt containing neurons compared to the highest number observed under physiological conditions. But we did not see an increase in the number of MCH cells with colchicine. This study shows that the cell number of Hcrt and HDC expressing neurons changes across the 24 hour period. We also find that the control of cell size and number varies across transmitter groups. Furthermore, we observed, as revealed by colchicine administration, that there is a greater number of neurons capable of Hcrt production than previously thought. These results have important physiological implications as well as suggesting the possibility of treatment of certain pathologies like narcolepsy, characterized in human by the loss of Hcrt neurons, by increasing peptide production in these "hidden" Hcrt neurons.

Title: Orexin neurons are inhibited by local GABAergic neurons

Authors: *L. FERRARI, D. PARK, E. ARRIGONI;
Neurol., Beth Israel Deaconess Med. Ctr. - Harvard Med. Sch., Boston, MA

Abstract: The Basal Forebrain (BF) is a crucial region of the wake promoting systems in the brain and it contains a variety of cells including neurons that produce acetylcholine, glutamate and GABA. Recent work has shown that selective activation of GABAergic neurons in the BF through chemogenetics techniques produced sustained wakefulness associated to fast cortical rhythms in freely behaving mice (Anaclet et al., 2015 and Xu et al., 2015). The downstream circuit through which these neurons are able to produce wakefulness it is still unknown. Our

hypothesis is that BF GABAergic neurons can promote wakefulness by means of inhibition of GABAergic neurons in the Lateral Hypothalamus (LH), thus dis-inhibiting wake promoting neurons in the LH, such as orexin neurons. In this work we applied channelrhodopsin circuit assisted mapping (CRACM) to study if LH GABAergic neurons are able to directly inhibit orexin neurons. To test the presence of a functional connectivity between LH GABAergic neurons and orexin neurons we stereotaxically injected vGAT-cre mice in the perifornical region with a cre-dependent AAV ChR2 and an AAV-h-orexin-tdTomato (Saito et al. 2013), this resulted in the expression of channelrhodopsin (ChR2) in GABAergic cells and Td-tomato in orexin neruons. Four weeks after the AAV injections we prepared coronal brain slice and performed whole-cell recording from Td-tomato positive cells (orexin neurons) while stimulating local GABAergic neurons expressing ChR2 with blue light pulses. Photostimulation of perifornical GABAergic neurons expressing ChR2 evoked inhibitory postsynaptic current (IPSC) in 6 out of 9 orexin neurons. These photoevoked IPSCs were blocked 20uM of the $GABA_A$ receptor antagonist Bicuculline. In this work we have demonstrated that GABAergic neurons in the perifornical region inhibit orexin neurons through release of GABA and activation of postsynaptic $GABA_A$ receptors. We propose that LH GABAergic neurons inhibit wake active orexin neurons during sleep. During wakefulness LH GABAergic neurons are inhibited by wake promoting BF GABAergic neurons resulting in the dis-inhibition of the orexin neurons.

Title: Orexin gene transfer in pons projecting amygdala neurons suppresses cataplexy induced by predator odor in narcoleptic mice

Authors: *M. LIU[1], P. SHIROMANI[1,2], C. BLANCO-CENTURION[1], D. PELLURU[1], R. KONADHODE[1];

[1]Psychiatry and Behavioral Sci., Med. Univ. of SC, Charleston, SC; [2]Ralph H. Johnson VA Med. Ctr., Charleston, SC

Abstract: Narcolepsy, a sleep disorder associated with a massive loss of orexin neurons, is characterized by poor wake maintenance and sudden attacks of flaccid paralysis known as cataplexy. In both human and animal narcoleptics, cataplexy attacks could be triggered by strong emotions. The amygdala is important for regulating strong emotional responses and the loss of orexin may be critical for triggering cataplexy. We have shown that cataplexy attacks induced by predator odor can be blocked by orexin gene transfer into the amygdala in orexin-knockout mice. To further identify the specific amygdala-involved circuit responsible for emotion-induced cataplexy, we selectively expressed orexin in the amygdala neurons projecting to pons. In orexin-KO mice, recombinant adeno-associated viral vectors with Cre-driven expression of the mouse prepro-orexin gene, or GFP gene (rAAV-DIO-orexin or rAAV-DIO-GFP), were microinjected into the central nucleus of amygdala (CeA). Simultaneously rAAV-mCherry-IRES-WGA-Cre was injected into pontine areas including vlPAG and LC. Four weeks later sleep was recorded for 12h at night (no-odor). Subsequently mice were exposed to 1ml coyote urine upon lights-off, followed by 12h night sleep recording (odor night). Narcoleptic symptoms were assessed using Sleepsign software and video recordings. In rAAV-DIO-GFP control group, coyote urine odor dramatically triggered cataplexy attacks when compared to no-odor night ($n=7$, $p<0.05$). In rAAV-DIO-orexin group, Cre-driven orexin expression in CeA neurons significantly suppressed predator odor-induced cataplexy ($n=7$, $p<0.05$, compared to control group), while there was no significant effects on spontaneous cataplexy ($n=7$, $p>0.05$, compared to control group). These results indicated that amygdala-pons circuit mediates the emotion-induced cataplexy and could be served as a surrogate circuit to treat emotion-induced cataplexy.

Title: An *In vitro* study of pre and post synaptic cholinergic control of hypoglossal motor neurons in adult mice

Authors: *L. ZHU, L. L. FERRARI, D. PARK, N. L. CHAMBERLIN, E. ARRIGONI; Neurol., Beth Israel Deaconess Med. Center/ Harvard Med. Sch., Boston, MA

Abstract: In REM sleep, cranial respiratory muscles undergo a suppression of activity, with the genioglossus (GG) muscle showing the most dramatic suppression. A current hypothesis is that the loss of GG activity during REM sleep is mediated by a combination of 1) monoaminergic disfacilitation and 2) a direct cholinergic inhibition of hypoglossal motor neurons. Strikingly, blockade of cholinergic receptors in the hypoglossal motor nucleus fully restores REM sleep GG activity (Grace et al., 2013), suggesting that a cholinergic-mediated inhibition of hypoglossal motor neurons is largely responsible for the REM sleep suppression of GG activity. Previous *in vitro* electrophysiological work showed that hypoglossal motor neurons are excited by the cholinergic agonist carbachol via nicotinic receptors (Chamberlin et al., 2002). This work was conducted in neonatal rats, whereas, all the *in vivo* work has been done in adult animals.
In the current study, we tested the pre- and post-synaptic cholinergic control of hypoglossal motor neurons in brain slices from adult mice. We recorded from hypoglossal motor neurons in medullary slices of 18 6-8 week-old mice using whole-cell voltage-clamp mode. We found that bath application of the nonselective cholinergic agonist carbachol (15μM) (at -60mV in TTX) produced an outward (inhibitory) current mediated by muscarinic receptors in hypoglossal motor neurons. This inhibition was followed by a larger inward (excitatory) current mediated by nicotinic receptors.
We also expressed channelrhodopsin2 (ChR2) in glutamatergic hypoglossal premotor neurons of the intermediate medullary reticular formation (IRt) in 15 adult vglut2-cre mice. We photostimulated IRt axons/terminals with blue-light pulses and recorded photo-evoked excitatory postsynaptic current (EPSCs) in hypoglossal motor neurons. We found that photostimulation of the glutamatergic IRt input evoked AMPA-mediated EPSCs with short latency in hypoglossal motor neurons. Bath application of carbachol strongly inhibited the IRt glutamatergic excitation to hypoglossal nucleus via muscarinic receptors. Our results provide a possible mechanism for cholinergic inhibition of the hypoglossal motor neurons in REM sleep. We propose that direct cholinergic inhibition of hypoglossal motor neurons together with the cholinergic presynaptic suppression of the excitatory drive from the IRt hypoglossal premotor neurons can be responsible for the reduction in activity of hypoglossal motor neurons in REM sleep.

Title: Malapropros noradrenaline impairs hippocampal plasticity and prevents memory consolidation

Authors: *M. A. FRAZER[1], A. SERGEEVA[2], B. GROSS[2], D. BAUER[2], K. SWIFT[2], G. POE[2]; [2]Anesthesiol., [1]Univ. of Michigan, Ann Arbor, MI

Abstract: The noradrenergic neurons of the locus coeruleus, which supply the forebrain with norepinephrine, fall silent prior to sleep spindle initiation, and are inhibited from firing during REM sleep. This decrease in noradrenaline allows for the depotentiation of previously potentiated circuits and overall bidirectional synaptic plasticity, resulting in the ability of new associations and information to be integrated into an existing memory network. However, some disorders, such as post traumatic stress disorder (PTSD), display a heightened noradrenergic system during sleep, resulting in aberrantly high levels of noradrenaline during sleep. It has been shown previously that high NE at the synapse results in hippocampal memory impairment, and we hypothesize that this impairment is due to NE acting to prevent depotentiation, leading to inflexible synaptic connections which precludes the incorporation of new memories into old schema during reconsolidation. We exogenously amplified the noradrenergic system during sleep and measured effects on hippocampal encoding during reversal learning, errors in memory consolidation, and effects on sleep spindles and REM architecture. Rats were instrumented for noradrenergic microinfusions to the hippocampus during sleep after learning, and were tested for the ability of to flexibly encode in an altered environment and for reversal learning and familiar reconsolidation. Aberrant presence of noradrenaline resulted in a hippocampal spatial map inflexible to novel information and impaired reversal learning, as evidenced by changes in hippocampal place cell stability and coherence. Reactivation episodes were also analyzed, and found to be altered in rats with inappropriately timed NE presence.

Title: CGRP neurons in the external lateral parabrachial nucleus and the pathways regulating hypercapnia induced cortical EEG arousal.

Authors: *S. KAUR, J. L. WANG, P. M. FULLER, C. B. SAPER;
Neurol., Beth Israel Deaconess Med. Ctr. and Harvard M, Boston, MA

Abstract: We have reported that glutamatergic signaling from neurons in the lateral parabrachial region mediates cortical arousal to hypercapnia. This region contains a population of neurons in the external lateral subnucleus (PBel) that express calcitonin gene-related peptide (CGRP) which has extensive forebrain projections and which we hypothesized may be necessary relay for the hypercapnic signal to cause arousal. To test this hypothesis, we conducted optogenetic inhibition of CGRP-PBel neurons and their terminal fields. To selectively inhibit CGRP-PBel, CGRPCre-ER mice (n=16) were injected on one side of the brain with an adeno-associated virus containing the gene for archaerhodopsin T TP009 (ArchT; n=12) in a Cre-inducible FLEX cassette AAV-FLEX-ArchT-GFP that expressed ArchT in CGRP positive PBel cells. In n=4 CGRPCre-ER mice, the control vector with no gene for ArchT (AAV-FLEX-GFP) was injected. On the other side we deleted the CGRP neurons by injecting a Cre dependent virus expressing the diphtheria toxin subunit A (AAV-FLEX-DTA) in all mice (n=16). All mice were instrumented for sleep recording and received unilateral implantation of an optic fiber above the PB. We investigated EEG arousals to 10% CO2 given for 30s every 300s, with and without inhibition of the PBel with a 593nm laser light. Laser light was on for 60 sec, beginning 20s prior and extending 10s after the CO2 stimulus. In 8 CGRP-Cre ER mice where the optical fiber targeted CGRPPBel, 593nm light increased the arousal latency significantly ($F_{3, 17}$= 31.2; P< 0.001) by fourfold 69.7 ± 6.7s (compared to no laser control-16.8 ± 0.6s) and in 49.8 ± 4.9% of the trials mice did not wake up to CO2 stimulus ($F_{3, 17}$= 31.1; P<0.001). To conduct optogenetic inhibition of the terminal fields of the CGRP-PBel neurons, CGRP-Cre ER mice were injected bilaterally with AAV-FLEX-ArchT-GFP in the PBel. The terminal fields of CGRP-PBel neurons such as central nucleus of amygdala (CeA) and substantia innominata in the basal forebrain (BF) were injected unilaterally (left side) with either 3% Ibotenic acid or combination of AAVCre + AAV-Flex-DTA (1:1) that caused unilateral cell deletion in the injected areas and the other side was implanted with optical fiber. Laser light induced Inhibition of the terminal fields at CeA (n=6) and BF (n=5), also increased the arousal latency to 30s CO2 significantly ($F_{3, 17}$= 22.0; P<0.001) to 48.2 ± 6.8 s and 54.7 ± 1.1 s ($F_{1, 7}$= 25.8; P<0.001) respectively. This inhibition of terminals in the CeA and BF also showed 32.55 and 52.4% of the trials respectively that failed to arouse to CO2. These results suggest that CGRP-PBel neurons mediate cortical EEG arousals to hypercapnia by its projections to the BF and CeA.

Title: Activation of NOS1 neurons of the caudal hypothalamus produces prolonged wakefulness

Authors: *N. P. PEDERSEN[1,2], C. B. SAPER[3,4], P. M. FULLER[3,4];
[1]Neurol., Emory Univ., Atlanta, GA; [2]Emory Epilepsy Service, Atlanta, GA; [3]Neurol., Beth Israel Deaconess Med. Ctr., Boston, MA; [4]Harvard Med. Sch., Boston, MA

Abstract: The caudal hypothalamus is a long-appreciated component of the arousal system, but the precise neuronal populations, anatomical pathways and mechanisms underlying this are unknown. We recently showed that glutamate neurons of this region are wake-promoting when activated. A subpopulation of caudal hypothalamic glutamate neurons express nitric oxide synthase (NOS1). By stereotaxic microinjection of an adeno-associated viral vector into the the caudal hypothalamus, we were able to conditionally transduce the excitatory designer receptor (hM3-Dq) in NOS1 neurons in a NOS1-Cre mouse. After activation, mice showed prolonged wakefulness up to 6 hours. These results recapitulate the effects of activation of glutamate neurons of this region, suggesting that this NOS1 subpopulation of neurons may represent the wake-promoting subpopulation of caudal hypothalamic glutamate neurons. These neurons are a candidate component of the ascending arousal system.

Title: Sleep and wake differentially affect superficial and deep layers of mouse cortex

Authors: K. PEELMAN[1], C. M. FUNK[1], A. V. RODRIGUEZ[1], S. HONJOH[1], G. TONONI[1], *C. CIRELLI[2];
[1]Psychiatry, UW-Madison, Madison, WI; [2]Univ. of Wisconsin Madison Dept. of Psychiatry, Madison, WI

Abstract: Cortical neurons tend to fire tonically during wake, while in NREM sleep they alternate between periods of strong firing and phases of neuronal silence. Several previous studies have found the mean cortical firing rate to be higher in wake and REM sleep than in NREM sleep. These general features of cortical neuronal activity have been described across many areas in both excitatory and inhibitory (fast spiking) neurons. It is also known that the sleep/wake effects on cortical activity can vary depending on neuronal subtypes, and that firing rates during wake are higher in the deep layers than in superficial layers. However, it is unclear as to whether sleep affects neuronal firing across layers in the same way. Here, we studied how wake, NREM sleep, and REM sleep influence the activity of single units in superficial and deep layers of several primary (V1, M1, S1) and secondary (V2, M2) cortical areas. Sleep/wake chronic polygraphic recordings were performed in freely-moving adult male mice (n=15) implanted with silicon probes spanning all cortical layers. Spike sorting was performed offline by superparamagnetic clustering of wavelet coefficients on multiunit clusters obtained over the light cycle, the major sleep phase in mice, and only well-isolated, stable single units were assessed. In excitatory cells (n=64), we found a significant decline in mean NREM firing relative to both active wake and REM sleep in both the superficial ($p<0.05$, paired t-test) and deep layers ($p<0.005$, paired t-test). The change in mean neuronal firing from active wake to NREM sleep was significantly more pronounced in the deep layers, which showed a 48% ± 17% (mean ± std) decrease in mean NREM firing relative to wake, whereas the superficial layers showed a 26% ± 19% decrease (super vs. deep NREM modulation, $p<0.005$, unpaired t-test). This pattern was prevalent across all cortical areas studied. By contract, preliminary observations in putative inhibitory neurons (n=14) showed comparable levels of decline in NREM sleep relative to active

wake across layers. Thus, across many cortical areas, the NREM sleep-dependent decline in excitatory neuronal activity is more pronounced in deep than in superficial layers.

Title: Sleep-wake discharge activity of neurons in the parafacial zone in rats

Authors: *M. ALAM, A. KOSTIN, D. MCGINTY, R. SZYMUSIAK, N. ALAM;
Res. Service, VA Greater Los Angeles Healthcare Syst., North Hills, CA

Abstract: Introduction: Recent studies suggest that the medullary parafacial zone (PZ) plays a role in sleep-regulation. GABAergic neurons in the PZ express sleep-associated Fos-immunoreactivity and cell-specific lesions of this area cause suppression of nonREM sleep, but do not effect REM sleep. While these findings suggests that PZ neurons may be nonREM-sleep active, the activity profiles of PZ neurons across spontaneous sleep-wake cycles, especially during nonREM versus REM sleep remain unknown. The present study determined the discharge activity of PZ neurons during spontaneous sleep and waking in freely behaving rats. Methods: Male Sprague-Dawley rats were surgically implanted with EEG and EMG electrodes for chronic recording of sleep-wake states. Five pairs of 20um microwires were implanted through the barrel of a mechanical microdrive into the PZ for recording extracellular activity of the neurons across its dorsal-ventral extent. All recordings were conducted early in the light phase of a 12:12 light-dark cycle. Following isolation of single units, the discharge activity was recorded through 3-5 sleep-wake cycles. Results: Extracellular discharge activity was recorded from 41 neurons in the PZ. Based on their nonREM/wake, nonREM/REM, and REM/wake discharge ratios and a minimum 25% change criterion, a majority of neurons (n=22; 54%) were sleep-active. These included: a) 20 neurons that exhibited increased discharge during both nonREM (51±3%) and REM sleep (43±7%) as compared to waking. The mean nonREM/REM discharge ratio of these neurons were 1.09±0.05; and b) two neurons that exhibited >2 fold increase in discharge during REM sleep as compared to both waking and nonREM sleep. Wake-active neurons constituted 27% of the recorded neuronal population and included both wake/REM-active (n=7) and wake-

active (n=4) neurons. State-indifferent neurons constituted 20% (n=8) of the recorded neurons. Conclusion: These preliminary findings show that while PZ neurons exhibit several sleep-wake discharge profiles, a majority are sleep-active. These finding are consistent with a role of the PZ in sleep-regulation.

Title: Sleep restores slow intrinsic timescales of cortical dynamics after sustained wakefulness in rats

Authors: *C. MEISEL, D. PLENZ;
NIMH, Bethesda, MD

Abstract: Sleep is crucial for daytime functioning and well being. These observations suggest that sleep plays an important role in organizing cortical networks toward states where information processing is optimized. The neuronal correlates underlying the changes in cortical information processing, however, have been difficult to identify. The general idea that computational capabilities are maximized nearby critical states related to phase transitions or bifurcations led to the hypothesis that brain networks operate at or close to criticality. One of the important implications of being near criticality is that system dynamics recovers more slowly from small perturbations, a phenomenon called critical slowing down. The observation of slow timescales in brain dynamics at different spatial scales has recently led to a growing interest in understanding their underpinnings and how they might benefit optimal brain function and cognition, for example in terms of integrating information and improving the signal-to-noise ratio in short-term memory or decision-making processes at the neuron network level. Whether these slow timescales governing cortical dynamics change in a wake-time dependent way which could account for reduced network function, however, is still an open question.
Here, we show that cortical time scales change systematically at the network level during the wake/sleep cycle. While wake shortens timescales, sleep recovers slow dynamics.
We implanted microelectrode arrays into superficial layers of prefrontal cortex for chronic recordings of LFP and multiunit activity in the awake, behaving rat. Rats were sleep deprived for 6 h followed by a recovery sleep. We observed spiking activity to exhibit long timescales

characterized by a slow decay in the autocorrelation function which became progressively faster during sleep deprivation. Concomittantly, the recovery from large network synchronization events became faster with time awake as measured in spiking data and LFP. All observed changes were reversed by sleep. Experimental findings during sleep deprivation were closely matched by a neural network model which is gradually tuned away from an order-disorder phase transition.
Our results indicate that the long timescales at which cortex normally operates, are progressively disturbed during sustained wakefulness while sleep recovers them. Interpreted in a dynamical systems framework these observations provide support for an interesting hypothesis for a network-level function of sleep: to reorganize cortical networks towards a critical state and thereby ensure optimal function for the time awake.

Title: Reduced effective connectivity between the frontal cortex and striatum during sleep

Authors: *M. J. REDINBAUGH[1], G. E. SPENCER[1], I. N. PIGAREV[2], Y. B. SAALMANN[1]; [1]UW Madison, Madison, WI; [2]Inst. for Information Transmission Problems (Kharkevich Institute), Russian Acad. of Sci., Moscow, Russian Federation

Abstract: Consciousness plays a pervasive role in how we function, and yet it remains unclear what neural mechanisms maintain consciousness and allow for transitions between awake and unconscious states. Mounting evidence associates loss of consciousness with decreased frontal-parietal and cortico-thalamic information transmission. However, not much is known about how deep brain structures influence this breakdown. The dorsal striatum is connected with frontal cortex and the thalamus through cortico-striato-thalamic loops, and lesion evidence implicates the striatum in alterations of the sleep/wake cycle, including sleep fragmentation. We hypothesize that the breakdown in communication in cortico-cortico and cortico-thalamic

circuits associated with loss of consciousness also occurs in cortico-striatal circuits. Thus, the striatum may influence thalamo-cortical processing across the sleep/wake cycle.
We performed simultaneous neural recordings (n=52) from the frontal eye field (FEF) and caudate nucleus (CN) in two cats during awake (task-free resting state), slow-wave sleep (SWS), and rapid-eye movement (REM) states. We recorded spikes and local field potentials (LFPs) in each brain area using a bipolar electrode configuration. To measure effective connectivity, we electrically stimulated FEF while recording from CN. To monitor the level of consciousness, we recorded the EEG across two exposed skull screws and tracked eye position. All recordings in awake, SWS and REM states took place under the same conditions: head-stabilized cats sat comfortably in a dark room (lights off) with no sensory stimulation. We analyzed neural data during stable eye epochs (excluding periods around eye movements).
Both FEF and CN LFPs had greater delta (1-4Hz) power in SWS relative to wake and REM, and greater gamma (>30Hz) power in wake and REM relative to SWS. There was also increased coherence between the LFPs in FEF and CN in the delta and alpha (8-13Hz) ranges during SWS (cf. awake and REM). Importantly, stimulating FEF elicited greater spiking activity in CN during the awake state compared with SWS. This suggests perturbed information transmission between FEF and CN during SWS.
Our results show that disruption of the pathway between cortical and striatal regions occurs during SWS. The mechanism underlying this disruption involves altered inter-areal synchrony, including unfavorable phase delays between regions, which interfere with the efficacy of information transmission. We suggest that the striatum, via cortico-striato-thalamic loops, plays a role in modulating thalamo-cortical processing and, consequently, the level of consciousness.

Title: Basal forebrain cholinergic neurons are vital for sleepiness observed after alcohol consumption

Authors: *A. SHARMA, R. SHARMA, P. SAHOTA, M. THAKKAR;
Res., Harry S Truman Mem. Veterans' Hosp., Columbia, MO

Abstract: Purpose: Corticopetal wake-promoting basal forebrain region (BF) is implicated to mediate sleepiness following alcohol intake. However, the specific phenotype of the neuronal population mediating this effects is unknown. Since the BF cholinergic neurons are sole supplier of cholinergic inputs to several forebrain regions, including the cortex, we hypothesized that the cholinergic neurons of the BF may have a critical role in alcohol induced sleepiness.
Methods: To test our hypothesis, adult male Sprague-Dawley rats were instrumented with sleep recording electrodes and bilateral guide cannulas targeted toward the cholinergic zone of the BF. To verify alcohol induced sleep promotion, rats were administered alcohol [35% (v/v); 3 g/Kg; intragastric] at dark onset (pre-lesion). Subsequently, the animals were divided into two groups.
Lesions: Selective lesion of the BF cholinergic neurons was performed by bilateral administration of immunotoxin, 192-IgG-Saporin (0.28 μg/0.5μL/side) in the BF.
Shams: Bilaterally infusion with artificial cerebrospinal fluid (0.5μL/side).
Rats were left undisturbed for 3 weeks. Subsequently, alcohol induced sleepiness was re-examined (post-lesion) as described above. On completion, rats were euthanized, brains removed and processed for ChAT immunohistochemistry in the BF to verify selective lesion of the cholinergic neurons.
Results: ***Pre-Lesion:*** Robust sleep promotion was observed following alcohol administration.
Post-Lesion: As compared to controls, rats in the lesion group took significantly ($p<0.05$) longer time to fall asleep and spent significantly less time asleep following alcohol administration.
Conclusions: Our results suggest that the cholinergic neurons are the mediators of sleepiness following alcohol intake.

Title: Electrical stimulation of the nucleus of the solitary tract: effects on electroencephalographic spectral power and the sleep-wake cycle in freely moving cats

Authors: *D. MARTÍNEZ-VARGAS, A. VALDÉS-CRUZ, V. M. MAGDALENO-MADRIGAL, R. FERNÁNDEZ-MAS, S. ALMAZÁN-ALVARADO;
Lab. de neurofisiología del control y la regulación, Inst. Nacional De Psiquiatría, México D.F., Mexico

Abstract: The nucleus of the solitary tract (NTS) plays a determinant role in the antiepileptic effects of vagus nerve stimulation (VNS). One mechanism underlying the efficacy of VNS is the induction of cortical changes detected by electroencephalography (EEG), which can be mediated by the NTS through its projections to the cerebral nuclei responsible for modulating cortical activity. The NTS may alter the sleep-wake cycle and could alter cortical EEG activity by lesion or chemical stimulation in animals under acute conditions. Despite the key role of NTS on EEG and sleep-wake in acute conditions the effect of electrical stimulation of the nucleus of the solitary tract (ENTS) in freely moving animals is unknown. The aim of this work was analyze the effects of ENTS on the EEG spectral power and sleep-wake cycle in freely moving cats. Seven adult male cats were implanted stereotaxically into both lateral geniculate bodies of the thalamus, both amygdalae, right hippocampi and the left NTS. Also stainless steel epidural electrodes were implanted in the left (Cx Pf-L) and right (Cx Pf-R) pre-frontal cortices to record the EEG. The activity of EEG, hippocampus, amygdala, electromiogram and electrooculogram was recording. All of the animals underwent eight recording sessions of 23 hours; two sessions were conducted at baseline (BL), and six were conducted while ENTS was applied. The BL recordings were conducted firsty and the day after the BL recordings were finished, the stimulation threshold for the NTS was determined. The next day the recordings with ENTS began. In each recording, ten trains of stimulation (1 min On /5 min Off; pulse square waves, 0.5-ms; 30-Hz frequency and, intensity 200-400 μA) were applied to the awake cats starting at 10:00 a.m. Changes induced by ENTS on sleep-wake cycle and EEG spectral power of the Cx Pf-L, Cx Pf-R of the bands at 0.5-3.5 Hz, 3.5-8 Hz, 8-12 Hz, 12-14 Hz and 14-26 Hz during the 23 hours of recording were analyzed. ENTS increases the band power from 3.5-8 Hz, 8-12 Hz and 14-26 Hz for twelve hours. Furthermore, the ENTS modified the architecture of the sleep-wake cycle, the ENTS led to increases in the percentage and total time of wakefulness during the first six hours after ENTS. Following these effects, increases in the percentage and total time of rapid eye movement (REM) sleep values were observed. ENTS produces a long-lasting increase in the bands power of EEG at 8-12 Hz and 14-26 Hz, which favors wakefulness and REM sleep in freely moving cats. These effects are attributed to the possible influence of the NTS on the thalamocortical system, locus coeruleus and parabrachial nucleus that are involved in the regulation of wakefulness and REM sleep.

Title: Peripheral tumors disrupt normal sleep/wake states in mice

Authors: *J. C. BORNIGER, A. H. HINZEY, N. ZHANG, Y. M. CISSE, W. H. WALKER, II, M. M. GAUDIER-DIAZ, U. J. MAGALANG, M. B. LUSTBERG, R. J. NELSON, A. C. DEVRIES;
Neurosci., The Ohio State Univ. Wexner Med. Ctr., Columbus, OH

Abstract: Adequate sleep is an important component in maintaining health and recovering from infection and injury. Breast cancer (BC) patients frequently experience sleep disruption, potentially exacerbating comorbid conditions and reducing post-treatment quality of life. It is not known whether the psychological burden of a cancer diagnosis, physiological alterations caused by tumors, cancer treatment(s), or other factors are primarily responsible for disrupted sleep in cancer patients. We hypothesized that changes in immune signaling in response to cancer and its treatment alter brain sleep circuitry. To probe this question, we measured sleep throughout the course of tumor development in female mice inoculated subcutaneously with 67NR non-metastatic mammary cancer cells. A subset of mice was challenged with a 6 hr sleep deprivation protocol to examine the effects of tumors on homeostatic responses to sleep loss. Approximately 3 weeks after tumor inoculation, central cytokine transcription was measured in brain regions related to vigilance state regulation (i.e., hypothalamus and brainstem). Peripheral tumors increased and fragmented sleep, particularly during the active phase, and this alteration was accompanied by marked elevation of IL-1β transcription within the brainstem. Furthermore, tumor-bearing mice showed an exaggerated response to sleep loss, sleeping more during recovery. These results suggest that peripheral tumors influence sleep, likely through a mechanism involving IL-1 in the brainstem; future studies are needed to determine whether psychological stress and subsequent treatment with chemotherapy or radiation exacerbates the phenotype we observed.

Title: Altered sleep-wake behavior in a novel murine model of type 2 diabetes and Alzheimer's disease (db/AD mice)

Authors: ***M. SETHI**[1], L. GUERRIERO[1], C. WANG[1], R. BERNAT[4], A. M. HELMAN[2], T. MACHEDA[2], A. AGARWAL[4], M. P. MURPHY[2], M. J. DUNCAN[3], B. F. O'HARA[1]; [1]Dept of Biol., [2]Sanders-Brown Ctr. on Aging, Dept. of Biochem., [3]Dept. of Anat. & Neurobio., Univ. of Kentucky, Lexington, KY; [4]Signal Solutions LLC, Lexington, KY

Abstract: Sleep has been suggested to play a variety of roles ranging from learning, memory consolidation, and clearance of toxic metabolites such as Aβ, in addition to possible roles in basic energy metabolism and functional adaptions related to ecology. Sleep is also essential for optimal cognition over short time periods, but probably also over longer time periods of many years. Increasing data suggest a bidirectional role for sleep and Alzheimer's Disease (AD), with poor sleep promoting AD, and AD increasing sleep disruption. Insufficient sleep is also correlated with increased risk of obesity and diabetes, which in turn are increasingly linked to AD. Previous studies have shown that db/db mice, which have diabetes and obesity, have attenuated sleep wake rhythms in addition to increased sleep fragmentation and overall sleep duration. This is also true of several different AD mouse models. To examine the interaction of these diseases, a mouse model was created that combines the genetic mutations for diabetes (db/db) with a commonly used mouse model of AD (APP-PS1) that contains human autosomal dominant mutations in APP and PS1 that lead to early onset human AD, and AD-like pathology in the mouse. When combined, these mice also display severe cerebrovascular pathology, without increased Aβ deposition (Neidowicz et al., 2014). Cognitive impairments were more profound in these mice compared to db/db and APP-PS1 mice alone. Given the role of sleep in all of these disorders, we are examining multiple sleep and diurnal variables in the combined mouse model (db/AD) and the individual mouse models db/db and APP-PS1, and found significant alterations in normal sleep, and response to sleep deprivation, which may contribute to or interacts with disease pathology. These mice may also provide a useful tool to examine sleep interventions to slow disease progression.

Abstract: The peroxisome proliferator-activated receptor alpha (PPAR) is a member of the nuclear receptor superfamily that has been suggested as a modulator of several physiological functions, including sleep. Endogenous ligands, such as oleoylethanolamide (OEA) activate PPARα leading to increase waking in rats. Although injections of OEA enhance wakefulness, no further evidence is available regarding whether activation of PPARα would modulate wake-related compounds after sleep deprivation. Thus, the aim of this study was to characterize if PPARα was able to promote wake-linked endogenous compounds such dopamine, norepinephrine, serotonin, and adenosine after total sleep deprivation (TSD) collected from nucleus accumbens (AcbC). Male Wistar rats (*n*= 20) were anesthetized, placed into the stereotaxic frame for implantation of a microdialysis guide-cannula aimed to the AcbC, and habituated to the experimental conditions for 7 days in the microdialysis bowl. Artificial cerebrospinal fluid was continuously perfused and dialysates were collected every hour (first 20 min) across the whole study. In the experimental day, TSD was carried out by maintaining rats on constant alertness across 6h from (08:00-14:00h). After TSD, animals received an intraperitoneal injection of vehicle, OEA, Wy14643 (agonist of PPARα), or MK-886 (antagonist of PPARα; 10, 20 or 30mg/Kg, each compound), and dialysates were collected across the next 4h. Samples were injected into HPLC and analyzed for detection and quantification of dopamine,

norepinephrine, serotonin, and adenosine. We found that activation of PPARα by OEA or Wy14643 enhanced wake-linked compounds after TSD. Opposite results were observed if MK-886 was administered. We conclude that nuclear receptor PPARα modulates neurochemical homeostasis after sleep deprivation.

Title: Exploring PPARg as a mediator of diet/energy balance effects on sleep/wake behavior

Authors: *I. J. PERRON[1], K. CHELLAPPA[2], A. PACK[1], S. VEASEY[1];
[1]Ctr. for Sleep and Circadian Neurobio., [2]Inst. for Diabetes, Obesity, and Metabolism, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Our lab has previously found that energy imbalance (brought on by dietary manipulations) profoundly influences sleep/wake architecture in mice, independent of body weight. Specifically, mice in positive energy balance exhibit increases in total sleep time and sleep/wake fragmentation compared to mice in negative energy balance or maintained on a regular chow (RC) diet. Peroxisome proliferator-activated receptor gamma (PPARg) is a nuclear receptor that can directly influence the circadian clock, has elevated hypothalamic expression in obesity, and is sufficient to induce overeating and weight gain when activated. We hypothesize that PPARg within the hypothalamus serves as an energy sensor and contributes to energy balance effects on wakefulness. To determine the role of brain PPARg in mediating positive energy balance-induced changes to sleep, we implanted mice with an ICV guide cannula and EEG/EMG recording electrodes, and then fed them either RC or high-fat diet (HFD) for 4 weeks. After an undisturbed sleep recording (no injection), mice were randomized to the order of receiving two injections, the PPARg antagonist GW9662 (2 ug in 2uL) and vehicle (1:1 DMSO/saline, pH 7.5). These injections were given 3-4 days apart at ZT11 and sleep/wake behavior during the subsequent dark period was scored and analyzed. Our preliminary results

found that GW9662 did not affect sleep or wakefulness in either RC- or HFD-fed mice compared to vehicle. However, the vehicle condition decreased total wakefulness by approximately one hour in RC-fed mice (p=0.088) but not HFD-fed mice (p=0.520) compared to no injection, thus complicating the interpretation of GW9662 results. Thus, in light of the substantial effects of the vehicle on sleep/wake behavior, present attempts are directed towards using Cre/LoxP transgenic mice to test the importance of PPARg in mediating sleep/wake behavior.

Title: pumilio regulates sleep in *Drosophila melanogaster* through suppression of synaptic proteins

Authors: *L. DE JESUS[1], N. RODRIGUEZ[2], J. ALEMAN[2], J. ORTEGA[2], C. PACHECO[2], A. AVALOS[2], J. L. AGOSTO[2];

Abstract: Numerous studies have shown that the brain's information encoding and storage mechanisms involve changes in the number and strength of its synaptic connections. According to the evidence supporting the Synaptic Plasticity Hypothesis (SHY), these changes result in a net increase in synaptic strength during wakefulness and a net depression during sleep. Therefore, SHY proposes that a key function of sleep is to decrease synaptic strength in order to prevent the saturation of the brain's storage capacity. Nevertheless, the mechanisms of how wakefulness increases synaptic strength, how sleep could be induced by such increases, and how synaptic strength is reduced by sleep remain to be elucidated. To answer these questions, we selected the neuronal homeostasis protein Pumilio (*Pum*) whose main function is to repress the translation of many synaptic proteins and decrease neuronal excitably during chronic patterns of neuronal activity. In this study, we show evidence indicating that *Pum* is recruited during sleep deprivation and prevent the uncontrolled synthesis of synaptic proteins at the translational and

transcriptional level. Interestingly, *Pum's* actions are more significant during chronic sleep deprivation (84 hours) than during acute deprivation (12 hours) and has little or no effect on normal daily sleep. At the behavioral level, *Pum* knockdown results in the abolishment, and even the reversal, of compensatory sleep responses to mechanical and pharmacological sleep deprivation. Consistent with the idea that these effects are due to exaggerated translation of synaptic proteins, exaggerating synaptic translation by overexpressing the eukaryotic initiation factor 4E (eIF4E), which is a known target of Pum repression, also decreased the compensatory sleep rebound. Based on these findings, we propose that the
synaptic strengthening, associated with extended wakefulness, triggers neuronal homeostasis mechanisms to avoid the saturation of the brain's storage capacity and induces sleep perhaps by decreasing the excitability of wake-promoting neurons.

Abstract: As a biggest unrevealed issue in sleep biology, the mechanism for homeostatic sleep/wakefulness regulation, as well as the neural substrate for "sleepiness", remains a mystery. To make a breakthrough in this question, we have initiated a large-scale forward genetic screen of sleep/wake abnormalities in mice, based on somnographic (EEG/EMG) measurements, the

gold standard in mammalian sleep/wake assessment. We have so far screened >7,000 heterozygous ENU-mutagenized mice and established 10 pedigrees exhibiting heritable and specific sleep/wake abnormalities. By combining linkage analysis and whole-exome sequencing, we have so far identified three mutations: *Sleepy* and *Sleepy2*, causing marked hypersomnia (increased non-REM sleep), and *Dreamless*, causing short and highly fragmented REM sleep. Since these dominant mutations cause very strong phenotypes, we expect that the mutated genes play central role for regulating sleep/wake amounts. Furthermore, these mutant mice can be a sleep disease model to approach the relationship between sleep and other cognitive and mental functions such as learning and memory, depression, anxiety, sociability and more. Here, we examined the following series of behavioral analyses for both *Sleepy* and *Dreamless* mutant mice: 1) Morris water maze, 2) forced swim test, 3) tail suspension test, 4) open field test, 5) novel object recognition, 6) elevated plus maze, 7) social interaction test, 8) sucrose preference, 9) nest building, and 10) fear conditioning. We detected the significant behavioral phenotypes in both *Sleepy* and *Dreamless* mutant mice. These results of behavioral test battery provide us the landmark information to approach the link between sleep and other cognitive behaviors, as well as the further physiological functions of *Sleepy* and *Dreamless* genes.

Title: Sleep affects operant conditioning memory in *Aplysia* californica

Authors: *A. P. VORSTER[1], J. BORN[2];
[2]Inst. for Med. Psychology and Behavioral Neurobio., [1]Univ. of Tübingen, Tübingen, Germany

Abstract: Sleep is known to support memory consolidation. This has been shown for mammals and, more recently, also for invertebrates such as bees and Drosophila. Here, we investigated

whether sleep affects memory consolidation also in Aplysia californica which has an even simpler nervous system and is a well-studied model of synaptic memory formation. The animals were tested on an operant avoidance learning task ('learning that a food is inedible') three times (Learning, Retrieval 1, Retrieval 2), with a 17-h interval between tests. One group of animals had undisturbed sleep after Learning (sleep group), the other stayed awake, and recovered sleep after Retrieval 1. Compared with the wake animals, the sleep group displayed significantly better performance at Retrieval 1. Moreover, performance was correlated with prior sleep in the sleep group at Retrieval 1 as well as with prior recovery sleep in the wake animals at Retrieval 2.

Abstract: To understand the neural architecture of sleep-wake cycles, we developed a method called CUBIC-MAP to image and analyze mouse brain activity at single-cell resolution. Specifically, we used Arc-dVenus transgenic (Tg) mice, which express the destabilized yellow fluorescence protein Venus under the control of the Arc gene promoter after neural activation. To visualize neural activity during sleep-wake cycles, we sampled Arc-dVenus Tg mice every six hours over 24 hours with chronic administration of two drugs that influence sleep and wake (methamphetamine and haloperidol). Using the CUBIC protocol developed in our laboratory to make tissues such as whole brains transparent, we observed fluorescence expression of Arc-dVenus Tg mice using a light-sheet fluorescent microscope. We developed an imaging and analysis pipeline (CUBIC-MAP) to visualize the link between neural activity and behavior during natural sleep-wake cycles and pharmacologically perturbed sleep-wake cycles. CUBIC-Map enables multiple brain comparisons and reveals the regions that are activated in natural and

pharmacological sleep and wake states. CUBIC-MAP will be a powerful tool not only for sleep-wake cycle research, but also for other applications in neuroscience.

Title: Hypothalamic lipotoxicity coordinates insulin sensitivity inmale offspring of obese rats

Authors: R. CARDENAS-PEREZ[1], L. FUENTES-MERA[2], J. CORONA-CASTILLO[4], L. REYES CASTRO[5], E. ZAMBRANO[5], *A. CAMACHO[3];

Abstract: Hypothalamic endoplasmic reticulum stress (ER) and mitochondria dysfunction contribute to insulin resistance generation during obesity and type 2 diabetes. ER and mitochondria interact through Mitofusin 2 (MTF2), which anchors in the outer mitochondrial and ER membranes regulating energy metabolism. We have reported that saturated lipids modulate hypothalamic MTF2 expression coordinating ER stress response and body insulin resistance (Díaz, B et al. 2015). Here we determine lipotoxic susceptivility of brain cell types coordinating insulin resistance by using in vitro and in vivo neuronal models. We found that lipotoxic insult induced by 24 h saturated fatty acid (palmitic) stimulation to microglia primary cultures promotes inflammation, evidenced by significant TNF alfa release when compare to palmitoleic, oleic and stearic acid. Also, confocal TMRM and ER-Tracker Green analysis in hypothalamic mHypoA-CLU192 cells showed that time-dependent palmitic stimulation induces early (1 h) mitochondrial mass and ER- Tracker reduction, which it is exacerbated at 12h, when we also found decrease in the mitochondrial membrane potential. Furthermore, we found that 24

h palmitic stimulation leads to decrease in 473 serine AKT phosphorylation, an effector of insulin resistance. Prevention of Insulin resistance during palmitic stimulation was performed by pre-incubation of the anti-inflammatory and the ER stress release reagents, sodium salicylate and 4 phenylbutirate, respectively. Finally, by using an in vivo model we demonstrated that maternal obesity in rats during pregnancy and lactation promotes hypothalamic lipotoxic insult affecting male offspring insulin sensitivity leading to plasma glucose increased. We conclude that lipotoxic insult promote time-dependent hypothalamic inflammation, mitochondria and ER dysfunction, which might lead to glucose insensitivity in male offspring.

Title: Paraventricular thalamus drives high fat diet-induced compulsive eating behavior

Authors: *J. CHENG, C. LI, X. MA, Y. HE, H. ZHOU, G. XIAO, Y.-D. ZHOU;
Dept. of Neurobio., Mail Box 22, Zhejiang Univ. Sch. of Medicin, Zhejiang, China

Abstract: Obese individuals exhibited increased activation of brain reward circuitry in response to palatable foods or food-related cues. Overconsumption of palatable foods triggers addiction-like neuroadaptive responses in the brain reward circuit and drives the development of compulsive eating behavior. However, how consumption of the energy-dense foods induces compulsive eating behavior remains unclear. Here, we demonstrated 1-week high-fat diet (HFD) consumption was sufficient to induce compulsive eating behavior in adult C57BL/6J mice. Remarkably, high-fat diet-induced compulsive eating caused a high level of c-Fos activation in the paraventricular nucleus of thalamus (PVT) in mice. Photostimulating PVT ChR2-expressing CaMKII neurons could effectively induce compulsive eating behavior in mice fed with regular chow. In contrast, inhibiting PVT CaMKII neurons by using the Designer Receptors Exclusively Activated by a Designer Drug (DREADD) method in HFD mice reversed their compulsive eating behaviors. Dorsal medial nucleus of the hypothalamus (DMH) was identified as a downstream target of PVT by using the adeno-associated virus anterograde tracing method. We further showed that activation of PVT-DMH pathway drove compulsive eating behavior in mice

fed with regular chow, while specifically inactivating this pathway reduced compulsive eating behavior in HFD mice. We thus conclude that HFD induces compulsive eating behavior by means of activating the PVT-DMH circuit. From an evolutionary perspective, we hypothesize that activation of the PVT-DMH circuit may play an important role in food seeking in a situation where food is scarce, and thus is important for survival. Keywords: Compulsive eating behavior, high-fat diet, paraventricular thalamus. Support: National Natural Science Foundation of China grants (81571125 and 91132712).

Title: Effects of a high-fat diet during gestation on learning/memory processes and leptin receptor expression on the hippocampus of Wistar rat pups

Authors: *N. Y. CORTÉS, C. R. VUELVAS-OLMOS, M. F. PINTO-GONZÁLEZ, O. GONZÁLEZ-PÉREZ, J. L. COLLÁS-AGUILAR, J. GUZMÁN-MUÑIZ, N. A. MOY-LÓPEZ; Neurosci., Univ. of Colima, Colima, Mexico

Abstract: Pregnancy is a critical period during which nutrition is a key factor for maternal and neonatal health. There are many dietary recommendations about pregnant women, however, food with high lipid levels are often preferred, and their consumption during pregnancy could influence on neurodevelopment and cognitive abilities of the neonate later in life. Therefore, our aim was to analyze the effects of a high-fat diet during gestation on spatial learning and memory, and on the expression of leptin receptors on hipocampal CA1 and CA3 areas. To accomplish this, 44 Wistar rats were used, 22 from control group (CG) which mother was fed balanced, diet and 22 from experimental group (EG) from a mother fed a high fat diet (HFD) with 42% more lipids during pregnancy. Weight gain was measured daily on both groups, starting at postnatal 2 (P2). Later, from P29 to P42, spatial learning and memory were evaluated using the Morris Water Maze (MWM). Groups were tested in 1 trial per day for 7 days for spatial learning, while spatial memory was tested after a week of rest on P42, with an only trial. After behavioral tests, brain tissue was obtained and then, hippocampal leptin receptor expression in hipocampal CA1

and CA3 was analyzed by optical density. Results showed a greater weight gain on EG without significantly different from CG. While on MWM, results indicated a significant reduction in escape latency (t=3.67, fd=42, p=0.001) and a better performance in memory (t=3.08, fd=42, p=0.004) in CG compared with EG, implying a decreased performance from rats whose mothers consumed a HFD during pregnancy. As for leptin receptor expression, significantly increased staining was observed on CA3 (U=0.000, p=0.001) and CA3 (U=0.000, p=0.001) hipocampal areas. These results imply that changes in leptin receptors may be caused by maternal nutrition during embryonic development, because HFD could increase adipocyte proliferation, releasing leptin into the bloodstream and interacting with astrocytes, which stimulate the neurons and could cause a decrease in the number of neuronal receptors, which could cause a decrease in hippocampal activity and therefore an affected efficiency on learning and memory processes, as we observed in EG performance in the MWM. Therefore, it is important to emphasize maternal nutrition for the proper neural and cognitive development of the infant.

Title: Silencing hypothalamic inputs to the VTA differentially affects feeding and reward-seeking behavior

Authors: *G. VAN DER PLASSE, K. C. G. DE GIT, E. M. HAZELHOFF, M. C. M. LUIJENDIJK, R. A. H. ADAN;
Translational Neurosci., Brain Ctr. Rudolf Magnus, Univ. Med. Ctr., Utrecht, Netherlands

Abstract: Activity of ventral tegemental (VTA) dopamine (DA) neurons is important for reward-seeking, anticipation and motivated behaviors. These functions are under modulatory control of hypothalamic brain areas that allow flexible engagement of the DA system in behavior. However, despite recent technical advances that have identified specific inputs into the VTA, there is limited knowledge of the function of these projections.
In this study, VTA inputs from the dorsomedial hypothalamus (DMH) and zona incerta (ZI)

were targeted with a combination of CAV2-cre and a viral mediated silencing strategy. This approach induces irreversible silencing of the targeted pathway, rendering DMH-, and ZI inputs to the VTA non-functional.
Following viral expression we assessed the behavioral consequences of inactivation on functions that are known to be mediated by the VTA or hypothalamus. These behaviors include motivation for reward, food preference and locomotion, as well as food intake, body temperature and anticipation to food. Results indicate projection-specific modulation of motivated behaviour and food-intake.

Title: Selective activation of catecholamine neurons in the caudal ventrolateral medulla using DREADD technology stimulates feeding.

Authors: *A.-J. LI, Q. WANG, S. RITTER;
Washington State Univ., Pullman, WA

Abstract: Previous results indicate that catecholamine (CA) neurons in caudal and rostral C1 in the ventrolateral medulla (VLM) are critical for glucoprivic control of feeding and adrenal medullary secretion, respectively. In the present study, we examined projections of Al/C1 neurons within the hindbrain that potentially contribute to glucoprivic feeding. We compared c-Fos expression in the VLM and dorsomedial medulla (DMM) in response to three treatments shown previously to stimulate food intake: selective activation of virally transfected A1/C1 CA neurons, systemic 2-deoxy-D-glucose (2DG) administration, and localized A1/C1 injections of 5-thioglucose (5TG). Designer receptors exclusively activated by designer drugs (DREADD) technology was used for selective activation of CA neurons. For this approach, a Cre-dependent DREADD construct, AAV2-DIO-hSyn-hM3D(Gq)-mCherry, was injected bilaterally into A1/C1 in Th-Cre^{+} rats. Immunohistochemical analysis of mCherry and dopamine beta-hydroxylase co-

expression showed highly selective and effective transfection of CA neurons in the injection sites. Systemic injection of the receptor agonist, clozapine-N-oxide (CNO), increased feeding (but not blood glucose) and activated CA neurons in the AAV-injected sites in VLM. In the DMM of the same rats, however, CNO specifically induced c-Fos expression in non-CA neurons in the subpostrema area (Sub-P) and dorsolateral solitary nucleus (Sol-DL). After systemic 2DG and local A1/C1 5TG injections, CA neurons were activated in the same VLM sites and non-CA neurons were activated in the same Sub-P and Sol-DL regions as seen after CNO injection. However, systemic 2DG and local 5TG injections also induced c-Fos in the hindbrain neurons not activated by CNO. Together these results suggest that (1) activation of A1/C1 neurons is sufficient to stimulate feeding and (2) that Sub-P and Sol-DL neurons are activated by signals originating from A1/C1 neurons and (3) that these downstream DMM sites may contribute to the glucoprivic feeding response and/or additional glucoregulatory responses.

Title: Pancreatic projections of glucose sensing CNS neurons

Authors: *A. ALVARSSON, M. BAYNE, S. A. STANLEY;
Diabetes, Obesity and Metabolism Inst., Icahn Sch. of Med. At Mount Sinai, New York, NY

Abstract: The central nervous system (CNS) plays a complex role in the control of metabolic functions. CNS glucose-sensing neurons respond to blood glucose levels and orchestrate counterregulatory responses to hypoglycemia. Although several brain regions are known to form synaptic connections with metabolic organs, the specific roles of glucose-sensing neurons in such projections have not yet been established. Glucose-sensing CNS neurons also appear to constitute distinct neuronal populations that mediate different physiological functions, but previous studies have been hampered by low expression levels of glucose sensors such as glucokinase (Gck). However, a recently generated transgenic mouse with cre-recombinase

expression in Gck-expressing neurons (Gck-cre/Rosa-tdTomato mice) allows the mapping Gck expression. Here we performed retrograde tracing studies to determine the neural pathways involving Gck-expressing neurons innervating the pancreas using Gck-cre/Rosa-tdTomato mice. PRV-GFP (5x100 nl) was injected into the pancreas of Gck-cre/Rosa-tdTomato mice via a Hamilton syringe. Five to eight days after PRV-GFP injections the mice were perfused and the brains dissected, sectioned and mounted for quantification using an optical microscope. The numbers of PRV-GFP infected neurons and neurons with overlapping Gck and GFP labelling were quantified. GFP labelling was seen throughout the hypothalamus, midbrain, hindbrain and cortex. Overlapping labelling between Gck-expressing and GFP-expressing neurons revealed that subsets of hypothalamic glucose-sensing neurons, particularly in the lateral hypothalamus and paraventricular nucleus of the hypothalamus, form synaptic connections that project to the pancreas. Taken together, these findings suggest that several brain regions, most notably in the hypothalamus, harbor glucose-sensing neurons that form polysynaptic connections to the pancreas, thus potentially playing roles in the control of pancreatic functions.

Title: TrkB-expressing neurons in the paraventricular hypothalamus regulate food intake through specific projections

Authors: *C. E. KINNEY[1,2], J. AN[1], G.-Y. LIAO[1], B. XU[1];
[1]Neurosci., Scripps Florida, Jupiter, FL; [2]Pharmacol. & Physiol., Georgetown Univ., Washington, DC

Abstract: Brain-derived Neurotrophic Factor (BDNF) has recently been shown to play a role in the regulation of energy balance, specifically within the paraventricular nucleus of the hypothalamus (PVH). This nucleus acts as a site of integration for many signals from the periphery as well as within the brain, and as an output nucleus affecting both food intake and energy expenditure. Tropomyosin-related Kinase B (TrkB), the receptor for BDNF, is expressed by neurons in the PVH (PVH^{TrkB} neurons); and we show that loss of TrkB from these neurons in adult mice leads to a rapid & severe hyperphagic obesity phenotype. Furthermore, we use

projection-specific gene deletion to remove these receptors only from PVH^{TrkB} neurons that send axons to a specific downstream target nucleus. Using this method, we show an intermediate hyperphagic obesity phenotype for several projections, including to the parabrachial nucleus (PVH^{TrkB} → PBN) and lateral hypothalamus (PVH^{TrkB} → LH). These findings suggest that multiple projections act in concert to maintain energy balance, rather than a single projection being responsible for energy balance and the rest performing unrelated functions. Thus, targeting the whole population of PVH^{TrkB} neurons for the development of obesity treatments may exhibit efficacy with fewer side effects.

Title: Effects of perinatal undernutrition on pyramidal neurons of the anterior cingulate and its correlation with the maternal response of rats

Authors: *M. ORTIZ VALLADARES, M. REGALADO, C. TORRERO, M. SALAS;
Inst. de Neurobiología, Univ. Nacional Autónoma De México, Querétaro, Mexico

Abstract: Perinatal undernutrition (PU) in the rat elicits long-term physical and behavioral consequences. The physiological and metabolic abnormalities associated with PU have been widely studied, but the negative consequences on the mother-litter behavior are still under investigation. The aim of this study was to analyze the pup retrieval and nest building responses of dams with the PU and its correlation with the morphology of the pyramidal neurons of the anterior cingulated cortex. The experimental underfed (UG) group consisted of undernourished dams fed with a caloric food restriction diet, while the control (CG) was fed ad libitum. At postnatal (PN) day 90 rats were mated, and after birth the retrieval of pups (body area, frequency and latency), and the nest building (shape and size) at PDs 4, and 12 of the lactation period were evaluated. The analysis of the pyramidal neurons was performed by using the Sholl method before the staining with the Golgi-Cox technique. We measured to the perimeter, and area of the perikarya and the dendritic arbor density. At PDs 4, and 12 the UG dams showed significant prolonged retrieving latencies, carrying the pups by improper body areas, and with deficient nest building organization, when compared with the CG dams. At PD 4 the UG dams showed significant reduction in the area and perimeter in the pyramids when compared with the CG dams. Moreover, the UG showed reduced dendritic arborization than the CG of dams. The

deficiencies in the maternal responsiveness of the UG mothers may partly reflect the synaptic and functional alterations at the telencephalic structures of the maternal circuitry, vulnerable to early food restriction in this case the anterior cingulate cortical pyramids. Title: Alterations in cortical thickness are related to the combined effects of age and BMI in adolescence and adulthood

Authors: *M. L. WESTWATER[1], R. VILAR-LÓPEZ[2], K. M. J. DIEDEREN[1], H. ZIAUDDEEN[1], P. C. FLETCHER[1], A. VERDEJO-GARCIA[2,3];

Abstract: Overweight and obesity have been associated with adverse changes in the central nervous system, such as compromised white matter connectivity and reduced grey matter volume in regions involved in feeding behaviour. However, the association between excess weight and brain structure across human development remains understudied. Here, we examine the relationship between age, body mass index (BMI) and cortical thickness (CT) in adolescence and adulthood.
Seventy adolescents (M_{age}= 16.6, SD = 1.46, 35 female) and 75 adults (M_{age}= 33.3, SD = 6.36, 42 female) underwent structural MRI scanning. Exclusion criteria included psychopathology, metabolic syndrome, use of psychotropic medication and morbid obesity (BMI $\geq$ 40). Structural MRI data were collected on a 3T scanner, and FreeSurfer software was used to generate cortical surface reconstructions of MR images and obtain measures of CT. Multiple linear regression was used to examine the effects of age and BMI on global mean CT. As BMI is sex- and age-specific for teens, weight class (lean and excess) was used as a dichotomous variable in the adolescent group. For analyses of local CT, we examined the effects of age, BMI and weight class on thickness at each vertex of the subject's surface. Monte Carlo simulations were applied to

determine significant contiguous clusters that displayed significant ($p < 0.05$) vertex-wise thickness values that differed from zero. Sex, years of education and white matter surface area were entered as covariates in all models.
Among adolescents, we found a significant age by weight class interaction ($p < 0.05$) where excess weight moderated the association between age and global mean CT, resulting in increased CT with excess weight. Local analyses showed a similar interaction in a cluster within the right superiorfrontal cortex ($p < 0.05$), such that excess weight was associated with increased CT in this cluster. In adults, a significant age by BMI interaction ($p = 0.03$) was once again observed but in an inverse relationship: increasing age and BMI were associated with reduced global mean CT. Local analyses revealed reduced CT in four clusters within the left superiorparietal and superiorfrontal cortices ($p < 0.05$) and the right inferiorparietal ($p < 0.01$) and superiortemporal ($p < 0.05$) cortices. In keeping with the global findings, older subjects with higher BMIs showed the greatest reduction in CT in these areas.
Our findings show a differential relationship between increasing BMI and CT in adolescents and adults. The previously reported obesity-related cortical atrophy was observed only in adults, suggesting that excess weight may precede these changes, rather than emerge consequent to them.

Title: Temporal and regional changes in neuroimmune signaling with post-ovariectomy weight gain in rats

Authors: *K. S. CURTIS, K. MCCRACKEN, D. BUCK, W. BLAIK, B. BRANTLEY, R. L. DAVIS;
Dept. Pharmacol & Physiol, Oklahoma State Univ. Ctr. for Hlth. Sci., Tulsa, OK

Abstract: Laboratory rats rapidly and reliably gain body weight after ovariectomy without the need for special diets or genetic manipulations. The predictable time course of weight gain that occurs after ovariectomy allows us to investigate temporal and regional changes in neuroimmune

signaling known to occur in the CNS with obesity. Adult female rats were ovariectomized (OVX) and given *ad libitum* access to standard laboratory chow for 4 weeks (ad lib) or *ad libitum* feeding followed by access to chow for only 2 hours/day during the last 10 days (dieted). Rats (n = 4-5/group) then were euthanized and tissue punches taken from the hypothalamic arcuate (ARC) and paraventricular (PVN) nuclei, and from the hindbrain dorsal vagal complex (DVC). Interleukin-6 and monocyte chemoattractant protein-1 (IL-6, MCP-1) protein were determined by ELISA and toll-like receptor 4 (TLR4) by western blot from these punches. As expected, body weight increased during the 4 week-period in ad lib OVX rats and decreased in OVX rats that were dieted during the last 10 days. IL-6 and TLR4 expression in the ARC and the PVN were similar in the two groups; however, IL-6 levels and TLR4 expression in the DVC were greater in ad lib OVX rats that gained weight compared to dieted rats that lost weight. Expression of MCP-1 in the PVN was less in ad lib rats than in dieted rats, while MCP-1 in the ARC was greater in ad lib OVX rats. In other groups of ad lib and dieted OVX rats (n = 4-5/group), immunolabeling of astrocytes for glial fibrillary acidic protein (GFAP) revealed elevated GFAP in the ARC of ad lib rats that gained weight, compared to dieted rats that lost weight. Together, these findings show that post-OVX weight gain is associated with temporally- and regionally-specific patterns of cytokine/chemokine expression and glial activation. Importantly, examination of neuroimmune signaling comparatively early during this weight gain suggests that changes may occur earlier in the development of obesity than had previously been reported, and follow a regional and/or temporal sequence. For example, increased expression of IL-6 and TLR4 in the DVC may reflect altered signals from the periphery associated with greater food intake and initial weight gain after ovariectomy, whereas further increases in body weight may be necessary for any changes in the ARC and PVN. In contrast, changes in the 'pro-obesity' chemokine, MCP-1, and GFAP in the ARC and PVN suggest that modulation of these factors may contribute to the onset of weight gain. Thus, a temporal and regional sequence of neuroimmune signaling in interconnected CNS areas may be critical in post-ovariectomy weight gain.

Title: Effects of perinatal undernourishment on the maternal kyphotic posture of lactating rats

Authors: *C. A. SALCEDO BARRÓN, M. REGALADO, C. TORRERO, M. SALAS;
Inst. de Neurobiología, Univ. Nacional Autónoma De México, Queretaro de Arteaga, Mexico

Abstract: Among the most representative components of the maternal behavior that meet the purpose of the newborn nutrition, is the maternal kyphotic posture. During this posture the mother maintains an adequate environment for the protection, thermal regulation and breast-feeding of the progeny. Although the effects of perinatal malnutrition on the maternal behavior have been studied, however, little is known on the kyphotic long-term effects and its regulatory mechanisms elicited by perinatal undernutrition (PNU). The aim of this study was to analyze the kyphotic posture in lactating dams with PNU elicited by their own newborn pups. Wistar dams with PNU at 90 days of age were mated and pregnancy was confirmed by vaginal smears. At birth pups were culled to 10 pups per litter with food and water ad lib. Maternal testing was carried out between 1100-1300 h. Before testing the pups were removed for 4 h to increase the motivation for nursing, body weight, and temperature were obtained. During the test (1 h) the maternal response including the kyphotic posture were video-recorded in their home cage at postnatal days 4 and 12. After the test the litter was weighed and the temperature was taken again. The results showed that mothers with PNU significantly reduced the duration of kyphosis (high crouch) than control dams, choosing unconventional postures (prone and partial crouch) for breast-feeding. Moreover, the total nursing duration and licking of the pups were also reduced.
The findings suggest that PNU mothers have deficiencies in the mechanism underlying the kyphosis and/or that the sensory stimuli generated by the own pups to evoke the dam kyphotic position are suboptimal compared with the offspring of control dams. Furthermore, this condition may reflect the suboptimal growth of the progeny of the next generation.

Title: Parcellation of human hypothalamus using high-resolution resting-state fMRI

Authors: *T. OSADA[1], A. OGAWA[1], M. TANAKA[1], M. HORI[2], S. AOKI[2], S. KONISHI[1]; [1]Dept Neurophysiol, Juntendo Univ. Sch. Med., Tokyo, Japan; [2]Dept Radiol, Juntendo Univ. Sch. Med., Tokyo, Japan

Abstract: The hypothalamus is a small structure (approximately 1 cm^3 per hemisphere in humans) that contains several nuclei. Due to its size, the precise functional architecture of the human hypothalamus is not well understood, and higher spatial resolution is required to investigate the hypothalamus using functional MRI. Here, we collected high-resolution functional MRI images (1.25 mm cubic voxel) from six young healthy subjects using multi-band EPI, and delineated boundaries in the hypothalamus using resting-state fMRI. Resting-state functional connectivity has allowed us to parcellate the cerebral cortex into putative functional areas based on the changes in the spatial pattern of connectivity in the cerebral cortex when a seed point is moved from one voxel to another (Cohen et al., Neuroimage, 2008; Hirose et al., Cerebral Cortex, 2013). The boundary mapping method, which has been applied to the 2D cortical surface, was extended to a 3D space in the present study, and the centers of parcellated areas in the hypothalamus were determined. Approximately ten areal centers were identified in the hypothalamus in each hemisphere, and most of them were located symmetrically in the left and right hemispheres. The symmetrical location of the identified centers confirms the reproducibility of the parcellation results. These results suggest the feasibility of the high-resolution 3D parcellation procedures for subcortical structures. It remains to be explored in the future what kind of functions each of the areal centers plays.

Title: Leptin specifies GLP-1 innervation to the paraventricular nucleus of the hypothalamus

Authors: *J. E. BIDDINGER[1], M. M. SCOTT[2], R. B. SIMERLY[1,3];
[1]Developmental Neurosci., Children's Hosp. Los Angeles, Los Angeles, CA; [2]Univ. of Virginia, Charlottesville, VA; [3]USC, Los Angeles, CA

Abstract: The nucleus of the solitary tract (NTS) plays a critical role in the central integration of nutritional signals from visceral organs and is the first central target of gastrointestinal vagal afferents that signal nutritional status from gut to brain. The paraventricular nucleus of the hypothalamus (PVH) receives ascending inputs from the nucleus of the solitary tract (NTS) that function to integrate neuroendocrine responses and autonomic regulation. Neurons that express glucagon-like peptide-1 (GLP-1) are located primarily in the NTS and send dense projections to the PVH. Moreover, nearly all GLP-1 neurons coexpress leptin receptors and are directly responsive to leptin. Although the physiological importance of GLP-1 projections to the PVH is well established, little is known about the development of this pathway and how environmental factors influence innervation of hypothalamic targets by GLP-1 neurons. The fat-derived hormone leptin functions during development to impact the organization of metabolic circuitry, but its possible role in impacting brainstem-hypothalamic connections is unknown. In order to determine if leptin is required for development of GLP-1 projections to the PVH, we used mice that express a fusion protein of synaptophysin and the fluorescent reporter tdTomato under control of the GLP-1 promoter in $Lep^{ob/ob}$ mice. In contrast to projections from the arcuate nucleus to the PVH, leptin-deficient $Lep^{ob/ob}$ mice show an increase in GLP-1 puncta, compared with densities observed in wild-type (wt) controls. To determine the role of leptin on the activity of GLP-1 neurons in the NTS and their postsynaptic neurons in the PVH in response to a visceral stimulus, $Lep^{ob/ob}$ and wt mice received peripheral injections of cholecystokinin (CCK). Compared with saline controls, IP injection of CCK resulted in increased cFos immunoreactivity in GLP-1 neurons and in PVH neurons in $Lep^{ob/ob}$ mice. We next tested the sufficiency of leptin receptors (LepRb) in directing these developmental events and determined that mice with functionally null leptin receptors ($LepRb^{TB}$ mice) also show an increase in GLP-1 fiber density in the PVH, indicating that LepRb are critical for normal development of GLP-1 neural circuitry. These results suggest that leptin acts directly on GLP-1 neurons in the NTS through the LepRb to specify the density of GLP-1 inputs to PVH neurons. Ongoing studies are defining the identity of

PVH neurons that receive enhanced inputs in the absence of leptin and are establishing the resulting physiological impact of these developmental events.

Abstract: Motivational systems are most often studied in behavioral isolation, with strict control over internal and external variables for simplification. In this way the animal is encouraged to express goal-seeking behavior directed toward one goal. Using this strategy, a number of molecularly- circumscribed subsets of neurons have been attributed to govern defined behaviors. Starvation- sensitive Agouti-related peptide (AgRP) neurons expressed in the arcuate nucleus of the hypothalamus (ARC) are both sufficient and necessary to regulate food consumption. Given the strong feeding phenotypes elicited by ARC^{AgRP} activation, it may be possible that these neurons engage multiple motivational systems and serve a more generalized role in facilitating biological demands, beyond the acquisition and ingestion of calories. We sought to investigate the integration and competition between hunger and alternative motivational systems such as anxiety, fear, social interactions, thirst, and learned preferences.

Title: Hindbrain prolactin-releasing peptide (PrRP) neurons are not strongly connected to pre-motor circuits controlling jaw or tongue movements

Authors: *H. ZHENG, A. K. OWEN, J. R. STROTHER, L. RINAMAN;
Dept Neurosci, Univ. of Pittsburgh Dept. of Neurosci., Pittsburgh, PA

Abstract: PrRP is expressed by noradrenergic neurons in the caudal nucleus of the solitary tract (cNTS). In rodents, PrRP neurons express cFos in direct proportion to feeding-induced gastric distension, and central PrRP signaling limits meal size. PrRP neurons innervate brainstem regions that control oral consummatory behaviors, and thus may control feeding motor programs. To test this, transneuronal pseudorabies virus (PRV) transport was combined with immunofluorescent localization of PrRP to determine whether these cNTS neurons are synaptically linked to pre-motor neurons that control tongue or jaw movement. Sprague-Dawley rats were sympathectomized and the chorda tympani nerve severed to prevent central autonomic infection, then were injected with PRV into the anterior tongue or masseter muscles. Rats were perfused 3-4 d later, and brain sections processed to reveal PRV and PrRP. Infected motor neurons occupied the hypoglossal or trigeminal nucleus after tongue or masseter injection, respectively. Infected pre-motor neurons were located bilaterally within the cNTS, area postrema, medullary and pontine reticular formation, midbrain, hypothalamus, and limbic forebrain. Infected cNTS neurons often were intermingled with PrRP-positive neurons, but very few were double labeled. Cell counts in infected and non-infected cases suggest that PrRP immunolabeling was not reduced by PRV replication. We conclude that PrRP neurons are not synaptically linked to pre-motor circuits that control intrinsic tongue movements or jaw closing, although ongoing analysis suggests that PrRP neurons may innervate higher-order, later-infected forebrain pre-motor neurons.

Title: Manipulations of hypothalamic melanocortin circuitry produce lasting changes in body weight

Authors: *S. C. FUNDERBURK[1,2], C. LI[1,2], M. J. KRASHES[1,2];
[1]Natl. Inst. of Diabetes, Digestive, and Kidney Dis., NIH, Bethesda, MD; [2]Natl. Inst. on Drug Abuse, NIH, Baltimore, MD

Abstract: Balanced caloric intake and energy expenditure is critical to survival and optimal health; however, overconsumption and declining physical activity have led to a rapidly worsening obesity epidemic, prompting a need for greater understanding of the neural mechanisms controlling energy homeostasis. Within the arcuate nucleus of the hypothalamus (ARC), agouti-related peptide (AgRP) neurons promote hunger and reduce energy output. Optogenetic activation of ARC^{AgRP} neurons produces rapid, reversible increases in food intake, mediated by direct monosynaptic inhibition of melanocortin receptor 4 (MC4R) satiety neurons in the paraventricular nucleus of the hypothalamus (PVH). Recently, we have demonstrated that brief, repeated activation of ARC^{AgRP} neurons results in long-term increases in body weight, fat mass, food intake and energy expenditure. Likewise, long-term synaptic silencing of downstream PVH^{MC4R} neurons with the tetanus toxin light chain produces similar increases in body weight, fat mass, and food intake. Together, this suggests that repeated short-term activation of ARC^{AgRP} neurons can produce long-term plasticity in feeding neural circuits, likely including PVH^{MC4R} neurons, which can lead to long-term disruptions in energy balance.

Title: GABAergic receptor neurons trigger consumption in *Drosophila melanogaster*

Authors: *S. K. CHEUNG, K. SCOTT;
Univ. of California, Berkeley, Berkeley, CA

Abstract: Animals must regulate the amount of food consumed to ensure the appropriate intake of nutrients. Previous studies indicate that four GABAergic interneurons (DSOG1) in the *Drosophila melanogaster* brain are necessary to inhibit overconsumptive behavior. Here we identify the specific GABAergic receptor that is required for proper control of ingestion in Drosophila. Knockdown of this receptor in a driver line causes overconsumption of tastants, indicating that the line contains a set of neurons that regulates consumption in *Drosophila melanogaster*. These neurons are sufficient to drive consumption, as acute activation promotes consumption in flies. Complementary, acute silencing of these neurons causes decreased consumption of appetitive substances in motivated flies. Our study identifies neurons that are necessary and sufficient for *Drosophila* ingestive behavior and are most likely downstream of DSOG1 neurons.

Title: Obesity is linked to a global increase in cortical Gaussian curvature

Authors: *N. MEDIC[1,2], H. ZIAUDDEEN[1,2], L. RONAN[1], P. C. FLETCHER[1,2];
[1]Psychiatry, [2]Wellcome Trust-MRC Inst. of Metabolic Sci., Univ. of Cambridge, Cambridge, United Kingdom

Abstract: In this study, in two separate datasets of healthy subjects, we explored the association of obesity with global changes in a relatively unexplored measure of cortical morphology: intrinsic or Gaussian curvature. Using surface-based morphometry in FreeSurfer and Caret, we examined cortical thickness, surface area and two measures of cortical curvature: the local gyrification index (LGI) and Gaussian curvature. LGI describes cortical curvature at the centimetre level, and represents the degree of cortical folding. On the other hand, Gaussian curvature constitutes a feature intrinsic to the surface, independent of its spatial conformation, enabling the study of cortical shape at a more subtle, millimetre level. In the first dataset ($N = 52$, 26 lean [BMI $M = 22.08$ kg/m^2, $SD = 1.39$ kg/m^2], 26 obese [BMI $M = 33.73$ kg/m^2, $SD = 2.43$ kg/m^2]; 26 females; age $M = 25.44$, $SD = 5.32$) we found no differences between lean and obese subjects in global cortical thickness, surface area or LGI. However, global Gaussian curvature was increased in obese subjects, both on the pial ($t(47) = 4.27$, $p < .001$) and white matter surfaces ($t(47) = 4.51$, $p < .0001$). We replicated these findings in a larger dataset ($N = 203$, 68 lean [BMI $M = 22.43$ kg/m^2, $SD = 1.54$ kg/m^2], 68 overweight [BMI $M = 27.31$ kg/m^2, $SD = 1.3$ kg/m^2], 67 obese [BMI $M = 35.82$ kg/m^2, $SD = 4.73$ kg/m^2]; 79 females; age $M = 32.27$, $SD = 7.72$): again, we found no obesity-related changes in global cortical thickness, surface area or LGI, and a global increase in cortical Gaussian curvature (compared to lean subjects), both on the pial ($t(197) = 2.81$, $p < .01$) and white matter surfaces ($t(197) = 3.77$, $p < .001$). Overweight subjects from this dataset were not significantly different from their lean counterparts in any of the explored measures. In the second line the analysis (combined datasets), we demonstrated that the effect of obesity on Gaussian curvature is more strongly expressed on the white than the pial surface (surface-by-group interaction $F(2,760) = 20.49$, $p < .0001$). Further, in a post-hoc, exploratory analysis, we found that the obesity-linked increase in Gaussian curvature on the white matter surface is mediated by reduced intensity of the white matter in obese subjects, sampled 1mm below the white matter surface.
In summary, in two independent datasets comprising healthy subjects, we found a consistent and global obesity-linked increase in Gaussian curvature, expressed to a greater extent on the white matter surface, and possibly driven by reduced integrity of the white matter underlying the cortex.

Title: Up-regulation of miR-210 in hypothalamus leads to increases in food intake and body weight in mice

Authors: *K. KIM[1], J. PARK[2], M.-S. KIM[3], H. NAM[2];
[1]Dept of New Biol., [2]DGIST, Daegu, Korea, Republic of; [3]Asan Med. Ctr., Seoul, Korea, Republic of

Abstract: Hypothalamus plays a key role in metabolic regulation and organismal aging. In order to find a link between aging and regulatory RNA molecules we performed comprehensive transcriptome analysis of young and old hypothalamic tissues with interest in differentially expressed microRNAs. MicroRNAs are well known to regulate various functions through direct post-transcriptional repression of their targets in the central nerve system. We focused on miR-210 because our transcriptome data indicate that miR-210 was significantly up-regulated in aged hypothalamus and recent other reports suggest that this miR regulates energy metabolism by repressing mitochondrial regulatory proteins. To better understand significance of this up-regulation in hypothalamus we stereotaxically injected a AAV construct expressing miR-210 into ARC nucleus of 2 month old young mice hypothalamus. Within a month of injection, these injected mice showed significant increases in food intake and body weight, and a noticeable compromise in glucose tolerance compared to age-matched, control mice that received AAV vehicle. We are currently exploring molecular mechanism underlying this metabolic changes caused by this miR and its implication to aging process in hypothalamus and whole body.

Title: A cholinergic basal forebrain feeding circuit modulates appetite suppression

Authors: *A. M. HERMAN[1], J. ORTIZ-GUZMAN[1], I. HERMAN[1], M. KOCHUKOV[2], K. QUAST[2], J. PATEL[3], J. SELEVER[2], J. CARLSON[1], B. ARENKIEL[2];

Abstract: Irregular food intake, either consuming too much or too little, is a primary cause of obesity and other eating and metabolic disorders. Highly coordinated by the brain, food intake must be balanced with energy expenditure in order to maintain proper body weight homeostasis. To date, insight into the neural control of feeding has largely focused on signaling mechanisms classically associated with the hypothalamus, the major center in the brain that regulates body weight homeostasis. However, the role of non-canonical central nervous system signaling mechanisms in regulating feeding behavior has been largely uncharacterized. Acetylcholine has long been proposed to influence feeding behavior, due in part to the functional similarity between acetylcholine and nicotine, the addictive component in tobacco that acts as an appetite suppressant. It is worth noting that nicotine is an exogenous agonist for acetylcholine receptors, suggesting that endogenous cholinergic signaling may play a role in normal physiological regulation of body weight homeostasis. However, it remains unclear if cholinergic neurons in the brain regulate food intake, and how their circuits function to modulate feeding. Here, we report that cholinergic neurons of the basal forebrain potently influence food intake and body weight. While impairment of cholinergic signaling increases food intake and results in severe obesity, enhanced cholinergic signaling decreases food consumption. Accordingly, we found that this cholinergic population modulates appetite-suppression on downstream targets in the hypothalamus. Together, our data pinpoint the cholinergic basal forebrain as a major modulatory center underlying feeding behavior, highlighting a new role of acetylcholine in modulating food intake.

Title: The role of melanocortin-4 receptors in the paraventricular hypothalamic circuits in homeostatic processes of appetite

Authors: *C. LI, M. KRASHES;
NIH/NIDDK, Bethesda, MD

Abstract: Nutrient intake is essential for survival and requires food seeking and consumption behaviors, however overeating has led to a growing obesity endemic. Thus, identifying the neural circuits controlling feeding is imperative. The agouti-related peptide (AgRP) neurons in the arcuate nucleus (ARC) of the hypothalamus promote feeding following acute soma activation. Moreover, stimulation of $AGRP^{ARC}$ terminal fields in the paraventricular nucleus of the hypothalamus (PVH) orchestrates food intake. Using optogenetics, we recently demonstrated that food intake driven by PVH terminal photostimulation of ARC^{AgRP} neurons is mediated by direct inhibitory synaptic connectivity onto satiety-promoting melanocortin-4 receptor (Mc4R) cells. In addition, we have also showed that photoactivation of PVH^{Mc4R} neurons alone promote satiety, reducing food intake in hungry mice, while chemogenetic silencing of this subpopulation increased motivated feeding in calorically replete animals. Currently we are monitoring *in vivo* physiological activity of PVH^{Mc4R} neurons via genetically encoded calcium indicator imaging strategies. Our data directly demonstrate that PVH^{Mc4R} neurons display state-dependent responses. These results strengthen the direct modulation, connectivity and function of the ARC^{AgRP} --> PVH^{Mc4R} circuit, helping reveal the precise wiring diagram of these complex neural networks directing motivated behaviors such as feeding.

Title: How does the brain implement decision-making to eat: implication of the 5-HT4 receptors

Authors: *V. COMPAN;
SCIENCES, Nimes Univ., Nimes, France

Abstract: Adaptive decision-making to eat is crucial for survival but in anorexia nervosa, the brain persistently supports reduced food intake despite a growing need for energy. How the brain persists in reducing food intake to the point of death despite the evolution of mechanisms to ensure survival by governing adaptive eating behaviors remains just as mysterious as the switch from anorexia to bulimia. Neural substrates belong to the reward-habit system and could differ from overeating-induced obesity. The contribution of serotonin receptors in eating is critical in humans and animal models. One possibility is that restrictive food intake critically engages decision-making (goal-directed) systems where the serotonin 4 receptors play a pivotal action in two critical brain structure of the reward system; The nucleus accumbens and the medial prefrontal cortex. These studies introduce the view that a persistent food restriction might mimic some aspects of addiction to drugs of abuse. Furthermore, novel molecular mechanisms influenced by the constitutive activity of the serotonin 4 receptors, in the nucleus accumbens, could underlie the switch from undereating to overeating in animal models.

Title: Intermittent access to palatable food leads to compulsive self-administration subserved by anterior insula to ventral striatal projections

Authors: *S. R. SPIERLING, A. KREISLER, G. DE GUGLIELMO, O. GEORGE, E. ZORRILLA;
The Scripps Res. Inst., La Jolla, CA

Abstract: Palatable foods are hypothesized to elicit neurobehavioral changes known as “food addiction.” Compulsivity, a component of addiction, can be defined as perseveration of behaviors despite incorrect or adverse outcomes. The insular cortex subserves many visceral-emotional functions, including taste processing and implications in drug craving and relapse. The

anterior insular cortex (AIC) sends inputs to the nucleus accumbens core (AcbC), which subserves reward and reinforcement. AIC-AcbC projections have been implicated in compulsive-like drinking in a model of alcohol addiction [Nat Neurosci 2013; 16(8): 1094-100]. In rats, intermittent access to a preferred high sucrose, chocolate-flavored diet (P) leads to binge-like intake [Neuropsychopharm 2008 Feb; 33(3) :524-35]. This study tested the hypothesis that intermittent palatable food access leads to compulsive self-administration that is mediated by AIC-AcbC inputs. Female Wistar rats, matched for food intake and body composition, were assigned to 1 of 4 groups (n=7-10): 1) ad lib chow (C) 2) ad lib P 3) intermittent P for either 30 min or 4) 24 hr on 3 non-consecutive days/week (MWF), with C otherwise. On intermittent P days, all rats performed operant self-administration for food on a fixed-ratio 1 (FR) or progressive-ratio (PR) schedule. Compulsivity was assessed via: 1) PR session breakpoint and 2) FR self-administration despite intermittent footshock punishment. Independent of duration, rats receiving intermittent access to P, but not ad lib access to C or P, showed increased PR breakpoint and FR self-administration despite intermittent footshock, consistent with compulsive self-administration. Intermittent access rats showed a direct correlation of body fat and body weight gain with increased PR breakpoint, linking compulsive eating with weight gain risk. AAV5 virus expressing fluorescently labeled archeorhodopsin 3.0 T or non-opsin virus controls were stereotactically injected into the AIC. Fiber optic cannulae were implanted bilaterally into the AcbC to allow optoinhibition of AIC-AcbC projections. Each rat performed 1 FR and 1 PR session with (optoinhibition) or without (control) laser activation. AIC-AcbC optoinhibition significantly reduced the PR responding of intermittent access rats that developed compulsive-like, elevated PR performance, without affecting the lower PR performance of control ad lib access rats or non-compulsive-like intermittent access controls. FR responding was unaltered by optoinhibition. The results support the hypothesis that AIC-AcbC projections subserve compulsive palatable food self-administration in our intermittent-access model.

Title: The melanocortin_3 receptor controls autoinhibitory feedback from agrp neurons onto mc4r neurons in pvn

Authors: *M. GHAMARI-LANGROUDI;
Mol. Physiol. & Biophysics, Vanderbilt Univ., Nashville, TN

Abstract: The role of the melanocortin-3 receptor in energy homeostasis has remained an enigma. Global deletion of the receptor in the MC3R-/- mouse increases adipose mass in the absence of detectable hyperphagia or hypometabolism. Yet at the same time, the MC3R-/- mouse exhibits reduced fast-induced refeeding, and hypersensitivity to the anorexigenic and weight-reducing effects of cachexia., and MC3R-specific agonists stimulate food intake. Here, we demonstrate that the activation of MC3R stimulates food intake and is a presynaptic receptor on arcuate nucleus AgRP/NPY neurons, and regulates GABA release from these cells onto MC4R PVN neurons, creating an autoinhibitory feedback loop. This study demonstrates that MC3R in fact plays an anabolic role by driving food intake and suppressing energy expenditure. Thus, α-MSH released by POMC neurons to activate MC4R target neurons ultimately inhibits the firing of these same neurons by MC3R-mediated release of GABA onto these same neurons. The role of this regulatory loop in the whole animal is suggested by the fact that melanocortin agonist administration is initially equally effective in inhibiting food intake in WT and MC3R-/- animals, but exhibits more potent and sustained anorexigenic action in the MC3R-/- mouse.

Title: The combination of 5-HTP/carbidopa plus phentermine showed a synergistic effect on weight loss and decreases the locomotor activity induced by phentermine, and neural activity in nucleus accumbens shell correlates with the reduction of locomotor side effects

Authors: *C. I. PEREZ[1], B. KALYANASUNDAR[1], M. G. MORENO[1], S. A. SIMON[2], R. GUTIERREZ[1];
[1]CINVESTAV, Mexico City, Mexico; [2]Dept. of Neurobio., Duke Univ. Med. Ctr., Durham, NC

Abstract: Obesity is a major public health problem.Hendricks et. al., 2009 reported that physicians frequently prescribed a new drug combination of appetite suppressants for the treatment of overweight: phentermine (PHEN) plus 5-hydroxytryptophan/carbidopa (5-HTP/CB). 5-HTP is a precursor of serotonin, carbidopa helps to more 5-HTP available to enter the brain and PHEN acts inhibiting recapture of dopamine. Despite its common practice, it is not known if this combination induces a synergistic effect on body weight-lossand how it modulates single-unit activity in the nucleus accumbens shell (NAcSh).We used a daily i.p injections of PHEN and 5-HTP/CB either alone or in combination for 7 days. We found that the combination of 5-HTP/CB (31 and 75 mg/kg, respectively) plus PHEN (10, 15 and 20 mg/kg) promoted a significantly greater body weight-loss than these appetite suppressants alone. Importantly, this combination reduced locomotors side-effects induced by PHEN alone, especially during the last 4-7 days of daily treatment.These data indicates the existence of a synergistic effect of this combination in body weight and reduction of side-effects.In order to shed light of the neuronal correlates of this synergism, we recorded single-unit activity of NAcSh in rats while they received the combination 5-HTP/CB + PHEN (31, 75 and 15 mg/kg, respectively) and drugs alone. We found that PHEN alone exerts at the population activity level a strong inhibitory imbalance towards inhibition (n=197, inh 61%: act 8%) that correlated with the onset of locomotor side-effects, while 5-HTP/CB alone although it modulated spiking activity in the NAcSh (n=140, inh: 21%: act 21%) it does not induced any inhibitory imbalance at the population activity of the NAcSh and did not induce locomotor activity. PHEN with 5-HTP/CB attenuated the inhibitory imbalance induced by PHEN alone that correlated with the reduction of psychomotor activation induced by PHEN. These data indicates that the combination counterbalanced the inhibitory imbalance induced by PHEN, selectively increasing the percentage of neurons and magnitude of activated responses without altering neurons inhibited by PHEN. To confirm this data, we are now recording neuronal activity using a higher dose of 5-HTP (63mg/kg)/CB +PHEN.Our preliminary results indicate that these combinations of 5-HTP/CB+PHEN further attenuated locomotor side-effects and reversed the inhibitory imbalance induced by PHEN towards activation.This preclinical evidence indicates that this combination produced a synergistic effect in weight loss and found for the first time that NAcSh population activity explained their reduced locomotor side-effects.

Title: Consumption of a high-fat diet increases persistent sodium currents in AgRP neurons in the arcuate nucleus of the hypothalamus.

Authors: *W. WEI[1], A. SMITH[1], K. O'CONNELL[1,2];
[1]The Univ. of Tennessee, Memphis, TN; [2]the Neurosci. Inst., Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Excess food intake is the leading cause of obesity. Although the regulation of food intake is complex and involves multiple brain regions, the control of appetite begins in the arcuate nucleus of the hypothalamus (ARH). Within the ARH, neurons expressing Agouti-related peptide (AgRP) are of special importance, since they play a direct role in regulating appetite and food intake. Our previous work has shown that after high fat diet (HFD) consumption, the spontaneous firing frequency of AgRP neurons increases significantly, with an accompanying change in the action potential waveform. We reasoned that an altered subthreshold 'pacemaker' current might underlie the increased excitability of AgRP neurons after HFD consumption. The persistent sodium current ($I_{Na,P}$) is one of the pacemaker currents in many types of neurons. Using current- and voltage-clamp recording of AgRP neurons in acute brain slices, we compared the amplitude of $I_{Na,P}$ and voltage dependence of $I_{Na,P}$ between lean and HFD fed-mice. We found that application of 10 uM rizulole, a blocker of $I_{Na,P}$, induced membrane hyperpolarization and significantly decreased the firing rate of AgRP neurons from both HFD-fed mice and control diet (CD)-fed mice. Consistent with a increased role for $I_{Na,P}$ in neuronal excitability following consumption of HFD, AgRP neuronal inhibition by riluzole was greater in neurons from HFD mice compared to controls. We also found that the peak amplitude of $I_{Na,P}$ is larger in AgRP neurons from HFD-fed mice than from control mice. Using single-cell RT-PCR, we confirmed expression of Nav1.7 and Nav1.9 subunits in AgRP neurons, both of which exhibit a gating mode that generates a persistent current and may represent a putative molecular correlate of $I_{Na,P.}$ Taken together, HFD consumption leads to a significant increase in the amplitude of $I_{Na,P}$ in AgRP neurons, which may contribute to the mechanism of increased spontaneous firing frequency of AgRP neurons following HFD consumption.

Title: Alcohol injection but not voluntary drinking robustly suppresses appetite in rats

Authors: *N. NELSON;
Neurosci. & Psychology, Univ. of Illinois At Urbana-Champaign, Champaign, IL

Abstract: In addition to being the most commonly abused substance in most parts of the world, alcohol is also a calorie containing (7 kcal/g) but nutritionally poor food source. On heavy drinking occasions, alcohol-derived calories could account for 10 - 27% of the recommended daily energy intake in adults. Consumption of alcoholic beverages has been proposed to be a risk factor for obesity; yet, other researchers believe the contrary. To that end, it is vital to understand the extent to which alcohol administration affects body weight (BW) and appetite. Our prior work revealed that IP alcohol administration dose-dependently reduces food intake, preference for a 45% high fat diet, and weight gain in male *Long-Evans* rats. Here we hypothesize that the effects of alcohol on energy homeostasis would depend on the route and pattern of administration. In experiment 1, male *Long-Evans* rats were injected (IP) on Mon, Wed and Fri (3 weeks) with 3 g/Kg/day (30% V/V in saline) alcohol doses administered all at once (EtOH_S) or in 2 separate 1.5 g/Kg injections that were spaced 3h apart (EtOH_D). In experiment 2, male and female *Long-Evans* rats voluntarily consumed 5% and 10% alcohol solutions sweetened with 0.1% saccharine (a non-calorie sweetener) on Mon - Fri (7.5 h/day) for 1 week and 7 weeks, respectively. Blood alcohol concentrations (BAC) were determined from plasma derived from tail blood in both experiments. Results of experiment 1 indicate that 3 g/Kg/day alcohol led to BACs of 246 ± 40 mg/dL (EtOH_S) and 120 ± 10 mg/dL (EtOH_D) 7.5h after administration and acutely suppressed energy intake and BW in both groups, but to a greater extent in the EtOH_S group. Results of experiment 2 indicate that although male and female rats would voluntarily ingest around 3g/Kg alcohol within 7.5h, acute BW and appetite suppressions were not observed. Furthermore, the pilot data show that BACs at 1h and 9h after alcohol presentation were 79 ± 15 mg/dL and 6 ± 0.1 mg/dL, respectively. Hence, the BAC achieved during voluntary drinking was never as high as those of IP injection. Together, these data show that 3 g/Kg IP alcohol produces robust appetite and BW suppression due to the higher BAC attained than voluntary drinking. Such results suggest that BAC attained and the maintenance of high BAC are the determining factors for how alcohol consumption affects acute appetite and long term energy balance.

Title: The glucose sensitivity of lateral hypothalamic area (LHA) orexin glucose-inhibited (GI) neurons may influence reward-based feeding via modulation of ventral tegmental area (VTA) dopamine (DA) neurons

Authors: S. B. TEEGALA[1], Z. SHENG[1], U. KHAN[1], M. P. THOMAS[2], *V. H. ROUTH[1]; [1]Dept Pharmacol & Physiol, RBHS: New Jersey Med. Sch., Newark, NJ; [2]Biol. Sci., Univ. Northern CO, Greeley, CO

Abstract: Lateral hypothalamic area (LHA) orexin neurons are inhibited by glucose (glucose-inhibited; GI). We found that metabolic state regulates the glucose sensitivity of LHA orexin-GI neurons. Fasting and the "hunger" hormone ghrelin enhance activation of these neurons in low glucose, whereas the satiety hormone leptin does the converse. LHA orexin neurons project to ventral tegmental area (VTA) dopamine (DA) neurons where orexin induces glutamate plasticity. VTA DA neurons are involved in reward-based feeding behavior. We hypothesized that activation of LHA orexin-GI neurons in low glucose persistently enhances glutamate neurotransmission onto VTA DA neurons and reinforces reward-based feeding behavior. We first measured spontaneous N-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor mediated glutamate postsynaptic currents on VTA DA neurons using voltage clamp recording in horizontal mouse brain slices containing the LHA. Lowering glucose from 2.5 to 0.25 or 0.7 mM increased NMDA (n=8; $P<0.001$) and AMPA (n = 7; $P<0.0001$) receptor-mediated current amplitude; effects persisted for at least 1 hour after return to 2.5 mM glucose. When glucose was lowered in the presence of the orexin A antagonist SB334867 (10μM) NMDA current amplitude was not increased (n=5; $P>0.05$). This suggests activation of orexin-GI neurons mediated the effect of low glucose. A 24 hour fast increased the AMPA/NMDA current amplitude ratio, a measure of in vivo glutamate plasticity (n=7, P=0.03). Next, we dialyzed the LHA of rats with glucose concentrations seen in the brain during fasting, euglycemic and hyperglycemic conditions (0.7, 2 and 4 mM, respectively) and measured conditioned place preference (CPP). Rats were food restricted to 85% of their body weight, bilaterally implanted with microdialysis guide cannula aimed 1mm above the LHA (AP: -2.8,

ML: +/- 3.1; DV: -8.1; 15^{o}) and maintained at 85% body weight. They were then conditioned with 5g of a positive reinforcer (chocolate) on alternate days for 6 days using a two compartment CPP apparatus. Chocolate was placed on the side opposite to their initial preference. On day 7, glucose was dialyzed into the LHA and the time spent in each compartment in the absence of chocolate was measured. The difference in time for the chocolate conditioned vs initially preferred compartment was calculated as an index of CPP. There was a significant negative correlation between glucose concentration and CPP ($P<0.05$, $R^2=0.66$, $n=6$). Our data suggest that the glucose sensitivity of LHA orexin-GI neurons may link metabolic status to reward based-feeding by altering glutamate plasticity on VTA DA neurons.

Title: Leptin receptor-expressing neurons in the nucleus of the solitary tract receive mono-synaptic input from CCK-sensitive visceral afferents.

Authors: *D. NEYENS, S. APPLEYARD, H. ZHAO, S. PAGE;
Integrated Physiol. and Neurosci. (IPN), Washington State Univ., Pullman, WA

Abstract: Leptin is an essential anorexigenic hormone that regulates energy homeostasis; it is produced primarily by white adipose tissue and circulates at levels that reflect fat mass. Historically, research has focused on the effects of leptin in the hypothalamus, but leptin has also been shown to act in the brainstem to reduce food intake. The nucleus of the solitary tract (NTS) is an important hub of integration for direct and indirect controls of food intake, as it receives input from visceral afferents in the gut as well as descending input from forebrain structures that control feeding behavior. Injections of leptin into the 4th ventricle or NTS significantly reduce food intake; however, the cellular mechanisms underlying this effect are not well understood. A subpopulation of NTS neurons express leptin receptors (LepRs), but the electrophysiological profile of these LepR-expressing neurons has not been well-characterized. Here we use patch-

clamp techniques and selective stimulation of the vagus-containing solitary tract in horizontal brain slices to characterize how LepR neurons process visceral afferent information. We selectively recorded from LepR-expressing NTS neurons using a transgenic mouse line in which the LepR promoter drives Cre-dependent expression of td-Tomato (LepRCre-tdTomato). The majority of LepR neurons in the NTS receive at least one direct, monosynaptic input from solitary tract afferents, as defined by low jitter or variability (<200 μs) in the latency of evoked excitatory post-synaptic currents (EPSCs) and no failures. Nearly all LepR neurons also received polysynaptic inputs, suggesting these neurons can integrate multiple excitatory inputs following visceral afferent stimulation. The gut peptide cholecystokinin (CCK) significantly increased (~340%) the frequency of spontaneous excitatory inputs onto about half of LepR neurons tested, suggesting that NTS LepR neurons are targets for CCK-sensitive afferents innervating the lower GI tract. Interestingly, almost all LepR neurons (~99%) express post-synaptic NMDA receptors, as indicated by Mg-sensitive currents blocked by the antagonist DCPene (10 μM). NMDARs are critical for vagus-mediated satiety reflexes, and our lab has shown that NMDARs help maintain fidelity of transmission during high-frequency stimulation of the solitary tract. Taken together, these data suggest that LepR-expressing NTS neurons integrate inputs from CCK-sensitive and CCK-insensitive vagal afferents, and NMDAR-mediated currents may be essential to their function in the NTS.

Title: MRAP2 is essential to central ghrelin activity

Authors: *D. SRISAI, J. A. SEBAG;
molecular physiology and biophysics, Univ. of Iowa / F.O.E.D.R.C., Iowa City, IA

Abstract: The Melanocortin Receptor Accessory Protein 2 (MRAP2) is a single-pass transmembrane protein essential for the control of energy homeostasis. MRAP2 is highly expressed in the central nervous system, including the arcuate nucleus of the hypothalamus (ARC) and the paraventricular nucleus of the hypothalamus. It acts by regulating the activity of several central G-protein coupled receptors (GPCR) that control food intake and energy expenditure, including the Melanocortin-4 receptor and the Prokineticin Receptor 1. In this study we identify a role for MRAP2 in the regulation of the Ghrelin receptor GHSR1a. Ghrelin is a

hormone mainly secreted by the stomach that signals hunger to the brain. The ghrelin receptor is mainly expressed in the hypothalamus, especially in AGRP neurons of the ARC, where its activation leads to hunger and increased food intake. Here we demonstrate that MRAP2 KO mice have a defect in hunger sensing and show that fasting fails to activate the orexigenic AGRP neurons in the hypothalamus of mice lacking MRAP2. We also show that MRAP2 is essential for ghrelin-stimulated intracellular signaling and that MRAP2 forms a complex with the ghrelin receptor. Also, whereas the intra-cerebroventricular injection of ghrelin significantly induces food intake in WT satiated mice, the orexigenic effect of ghrelin is largely lost in MRAP2 KO mice. These results suggest that MRAP2 is essential for the central actions of ghrelin and further demonstrate that MRAP2 is a master regulator of the energy homeostasis machinery.

Title: Fasting promotes liver oleoylethanolamide signaling through a histamine-dependent mechanism

Authors: *A. MISTO[1], G. PROVENSI[2], V. VOZELLA[1], B. PASSANI[3], D. PIOMELLI[1,4]; [1]D3, Fondazione Inst. Italiano Di Tecnologia, Genova, Italy; [2]Dept. di Neuroscienze, Psicologia, Area del Farmaco e Salute del Bambino, [3]Dept. di Scienze della Salute, Univ. di Firenze, Firenze, Italy; [4]Dept. of Anat. and Neurobio., Univ. of California, Irvine, CA

Abstract: The fatty acid ethanolamide, oleoylethanolamide (OEA), is a lipid mediator that regulates feeding (Rodriguez de Fonseca et al., 2001; DiPatrizio et al., 2015; Piomelli 2013) and stimulates lipolysis and fatty acid oxidation in adipocytes and hepatocytes (Guzman et al., 2004) through activation of nuclear peroxisome proliferator-activated receptor-alpha (PPAR-α) (Fu et al., 2003). Fasting is accompanied by a substantial elevation in liver OEA levels (Fu et al., 2007), but the biochemical mechanism and physiological implications of this effect are unknown. The neurotransmitter histamine plays an important role in the control of feeding behavior and mediates, in part, the anorexic effects of OEA (Provensi et al., 2014).
In the present report, we show that histamine is obligatory for food deprivation-induced OEA accumulation in mice liver through a mechanism that requires activation of H_1-type histamine receptors.
Male HDC-/- mice (mice deficient in the histamine-synthesizing enzyme histidine

decarboxylase), and wild-type littermates (129/Sv background), male C57BL/6J-Kit$^{W\text{-}v}$/J mice (mice mast cells deficient) and male C57BL/6J mice were subjected to 3 different conditions: a) free-feeding (FF); b) 12h food-deprivation (FD) and c) 1h refeeding after 12h food-deprivation (RF).
Alpha-fluoromethylhistidine (α-FMH), a suicide inhibitor of HDC, was administered by intracerebroventricular (i.c.v.) infusion (5µg/5µl), while histamine receptor antagonists (fexofenadine and famotidine, 10 mg/kg and ciproxifan, 3mg/kg) were administered by intraperitoneal injection during FD or RF. Histamine was administered by intrahepatic (IH) injection (2-4mg/kg for 30min and 1h) during FF. Endogenous OEA, fatty acid 18:1 and N-oleoyl-PE levels were quantified after lipid extraction by liquid chromatography/mass spectrometry.
We found that: 1) fasting stimulates liver OEA mobilization in wild-type mice, but fails to do so in mutant HDC-/- mice; 2) the H_1 receptor antagonist, fexofenadine, prevents the effect of fasting on OEA accumulation in wild-type mice; 3) the H_2- and H_3-receptor antagonists, famotidine and ciproxifan, and i.c.v. infusion of α-FMH do not affect fasting-induced OEA accumulation in wild-type mice; 4) histamine administration stimulates hepatic OEA production in dose-and time-dependent way; 5) histamine effect is selective only for OEA not for oleic acid.
In conclusion, our results suggest that fasting stimulates peripheral histamine-dependent signaling, which promotes OEA mobilization in mice liver through activation of H_1, but not H_2 or H_3 receptors. The mechanism underlying this novel function of histamine is under investigation.

Title: Endogenous cholinergic activation of NTS catecholamine neurons depends on glucose concentration.

Authors: *S. PAGE, S. M. APPLEYARD;
Integrative Physiol. and Neurosci., Washington State Univ., Pullman, WA

Abstract: Visceral afferents carrying satiety information from the gastrointestinal system terminate primarily on neurons in the nucleus of the solitary tract (NTS). Catecholamine neurons in the NTS (NTS-CA) play a critical role in integrating and relaying information regarding satiety, cardiovascular activity, and stress to other brain nuclei. Nicotine is a potent suppressor of appetite, and smoking cessation is associated with heightened appetite and weight gain. We have previously demonstrated that nicotine activates NTS-CA neurons through a pre-synaptic mechanism by binding to nAChRα7, increasing the rate at which glutamate is released from visceral afferent terminals. Further, our lab showed that, similar to the 5-HT3 receptor, activation of visceral afferent terminals through nAChRα7 is rapidly modulated by changes in extracellular glucose concentration. For the current study, we determined whether NTS-CA responses to native cholinergic inputs, which release the endogenous nAChR agonist acetylcholine (ACh), are also regulated by changes in glucose. To study NTS-CA neuronal responses to endogenous ACh, we used a line of transgenic mice that express enhanced green fluorescent protein under the control of the tyrosine hydroxylase promoter (TH-EGFP), and crossed it with a line that expresses light sensitive channelrhodopsin-2 selectively in choline acetyltransferase-positive neurons (ChAT-ChR2). The resulting offspring expressed both transgenes (TH-EGFP/ChAT-ChR2), allowing us to simultaneously identify NTS-CA neurons and photo-stimulate local ACh release during whole-cell recordings. It was found that whole-field laser illumination of horizontal brain slices increased the frequency of glutamatergic spontaneous excitatory post-synaptic currents (sEPSC) in NTS-CA neurons. This response was absent in animals lacking ChR2, and was completely blocked by alpha7 nicotinic ACh receptor (nAChRα7) selective antagonists MG624 (20μM) and methyllycaconitine (100μM). sEPSC responses were reproducible within the same cell by repeating stimulation in 30-second intervals. We found that reducing the concentration of bath glucose from 10mM to 2mM decreased the magnitude of endogenous ACh responses by ~32%. The effect of 2mM glucose on ACh responses was fully reversed by restoring glucose to 10mM. The results of this study indicate that endogenous acetylcholine activates NTS-CA neurons through indirect actions on nAChRα7 to increase glutamate release from pre-synaptic visceral afferent terminals, and that this action is dependent on local glucose levels.

Title: Access to snacks from weaning onward in female rats causes obesity, insulin insensitivity and sustained leptin resistance in adulthood.

Authors: L. N. DELA CRUZ, R. C. CLAWSON, T. J. WENGER, S. T. ALLEN, *H. I'ANSON;
Biol. Department, Howe Hall, Washington & Lee Univ., Lexington, VA

Abstract: Approximately one third of the US adolescent population is obese or overweight. Therefore, we developed a rat model that mimics snacking behavior to investigate the mechanisms leading to childhood obesity. We hypothesized that giving constant access to energy from snacks after weaning causes an early onset of obesity and related disorders. At 22 days of age, we divided 24 weanling female Long-Evans rats into three groups (n=8 per group): chow only (Control), healthy snack (HS), and unhealthy snack (US). HS and US rats were sequentially given a rotation of three snacks at 10am and 3pm daily (HS: Kashi GoLean cereal, unsalted almonds, or Cheerios; US: Keebler's Sandies, Tostitos, and peanut butter chips). All groups received *ad libitum* chow and water. Food intake, snack intake, and body weight (BW) were monitored daily. A leptin challenge was administered at the time of puberty (Days 34-38) and during adulthood (Days 69-73) to investigate possible leptin resistance during development or in response to snacking. To determine insulin sensitivity, a glucose tolerance test (GTT) was performed after an overnight fast on Days 84-85. On Days 90-93, rats were terminated, blood and tissue samples collected, and abdominal fat pads removed and weighed. At this time, HS and US rat BWs were significantly more than Control rats, and US rats grew faster than HS rats. Total caloric intake did not differ between snacking groups, though control rats consumed more calories later in the study. Control rats had significantly less visceral fat than both snacking groups, which had similar fat pad weights. At the time of puberty, neither snacking nor Control rats decreased food intake in response to either leptin dose (1mg/kg or 10mg/kg ip). As adults, only the Control rats decreased their food intake in response to leptin (1 or 5 mg/kg ip). These data suggest that leptin resistance during development may create greater vulnerability to poor dietary choices. Snacking adults remained leptin resistant, likely contributing to their defense of a higher body weight. The GTT resulted in a similar initial insulin release in all groups, but serum insulin levels remained elevated in both snacking groups for more than two hours while insulin in control rats returned to basal levels within thirty minutes of glucose gavage. These data support our hypothesis that constant access to energy from snacking induces early onset of obesity in rats and accompanying markers of metabolic syndrome. Further, we conclude that

young rats, and probably humans, are vulnerable to snacks from weaning due to inherent leptin resistance during development that is sustained into adulthood.

Title: Effects of peripherally and centrally evoked swallow on the jaw-opening reflex responses

Authors: *T. SUZUKI, S. SAKAI, K. TSUJI, J. MAGARA, T. TSUJIMURA, M. INOUE; Div. of Dysphagia Rehabil., Niigata Univ. Grad. Sch. of Med. and, Niigata-Shi, Japan

Abstract: Purpose: We previously demonstrated that the jaw-opening reflex (JOR) response evoked by the low-threshold trigeminal afferents was inhibited during swallowing evoked by superior laryngeal nerve (SLN) stimulation, suggesting that the oral sensory transmission is inhibited by activation of swallowing neural network. The aim of this study was to investigate whether the JOR response was modulated during swallowing evoked by not only peripherally but also centrally evoked swallow. Materials and Methods**:** The experiments were carried out on anesthetized rabbits with urethane (1.0 g/kg, iv). Electromyographic activity was recorded from the digastric and mylohyoid muscles on either side. To evoke the JOR, the inferior alveolar nerve (IAN) was stimulated (single pulse, 0.2msec pulse duration). Stimulus intensity was set at 2.0 times (T) the threshold for evoking the JOR. To evoke swallowing, either the SLN or cortical swallowing area was repetitively stimulated; 30 Hz, 0.2 msec pulse duration for the former and 30 Hz, 0.5msec pulse duration for the latter. Stimulus intensity of SLN and cortex was set between 0.8-4 T and 0.8-1.4 T the threshold for evoking the swallowing at least once for 10 sec, respectively. To reduce the effect of saliva, bilateral submandibular glands were removed and parotid ducts were ligated. In a recording session, the JORs were evoked by the IAN stimulation at 1 Hz for 30 sec. In the middle 10 sec, SLN or cortex was simultaneously stimulated at either intensity. The mean amplitudes and latencies of the JOR were compared among the conditions; before, during and after SLN or cortical stimulation. Results & Discussion**:** Stimulus threshold ranged between 0.05 and 0.17 mA for IAN, between 0.04 and 0.6 mA for SLN and between 0.25 and 1.2 mA for cortex. Amplitude of the JOR was smaller and latency was longer during SLN or cortical stimulation than before stimulation. Furthermore, the inhibitory effects tended to increase as the stimulus intensity of the SLN and cortex increased. The results suggested that the

oral sensory transmission is inhibited during swallowing evoked by either stimulation of SLN or cortex.

Title: Acute hypoglycemic and hyperglycemic states induce specific changes in cervical vagus nerve activity

Authors: *E. A. BATTINELLI[1,3], J. NEWMAN[1], T. TSAAVA[1], H. SILVERMAN[1,3], M. CUCINO[3], C. BOUTON[2], S. S. CHAVAN[1], K. J. TRACEY[1,3];

Abstract: Food intake and energy balance are regulated by crosstalk between the central nervous system and visceral organs. Physiological homeostasis is maintained by reflex mechanisms in which afferent signals are interpreted by the central nervous system and efferent responses are initiated to maintain energy homeostasis. The vagus nerve, with its anatomical distribution and known contribution to metabolic homeostasis, is a conduit that conveys messages regarding changes in peripheral glucose levels to the brainstem. Here, we have recorded and analyzed extraneural activity in the mouse cervical vagus nerve in response to both acute hypoglycemic and hyperglycemic states (a bolus of insulin or glucose, respectively), using both manual and automated wavelet-based analysis techniques. In hypoglycemic animals, a transitory increase was observed in both heart rate and respiratory rate. Whereas in hyperglycemic animals, a transient decrease followed by an increase was observed in heart rate, with no significant changes in the respiratory rate. Administration of insulin and glucose both induced significant increases in vagus nerve activity as compared to quiescent baseline activity, with an average peak rate of 70 events per second during the response compared to the baseline average of ~6 events per second. Induction of acute hypoglycemia induced an immediate response with a latency of 200 seconds that lasted for ~200 seconds. We also observed delayed longer-lasting responses in hyperglycemia (latency of 500 seconds and a total duration of 400 seconds). Together, these studies demonstrate that acute changes in the blood glucose levels mediate

altered heart and respiratory rates associated with specific alterations in the cervical vagus nerve activity.

Title: An inhibitory septum to lateral hypothalamus circuit that mediates stress induced anorexia

Authors: *P. SWEENEY, Z. XU, Y. YANG;
SUNY Upstate Med. Univ., Syracuse, NY

Abstract: Changes in food intake in response to environmental alterations, such as stress, are coordinated by hormonal interactions with the central nervous system. However, the cellular and circuit mechanisms governing stress-induced anorexia are largely underexplored, and effective treatments remain lacking. Here, by using the cell-type-selectivity of genetic methods, circuit mapping, and behavior assays, we decipher a cell-type-specific inhibitory septum to lateral hypothalamus (LH) circuit that contributes to stress-induced suppression of feeding. We find that chemogenetic inactivation of septal GABAergic neurons in the dorsal and medial septum (LSd/MS) attenuates the anorexigenic effects on food intake induced by physical restraint-based stress. Supportively, we find that chemo-/optogenetic activation of LSd/MS GABAergic neurons or their inputs in the LH reduces food intake. Furthermore, we decipher a putative neural circuit that contributes to stress induced anorexia consisting of LSd/MS GABAergic neuronal inputs to a subset of GABAergic neurons localized in the LH, an area involved in homeostatic and hedonic control of energy states. Collectively, our data demonstrate a novel circuit mediating stress-induced anorexia, one that may serve as a therapeutic target for the treatment of emotion-related eating disorders, such as anorexia nervosa.

Title: TNFα contributes to the development of hyperalgesia in overweight ovariectomized rats

Authors: *O. A. JARAMILLO-MORALES[1], J. V. ESPINOSA-JUÁREZ[2], F. J. LÓPEZ-MUÑOZ[2];
[1]Cinvestav, DF, Mexico; [2]Cinvestav, Mexico city, Mexico

Abstract: Menopause is associated with greater perception to pain and an increase in abdominal fat. Additionally, it is known that obesity and overweight is more prevalent in women than in men. Weight gain is related to changes in the perception of pain; however, its mechanism is not clear. **Objective**. The aims of this study were to analyze the behavioral responses of hypoestrogenic, overweight Wistar rats to thermal stimuli and to analyze the leptin and TNFα levels in this population. **Methods**. Animals with hypoestrogenism induced by bilateral ovariectomy were used. Animals received either a hypercaloric diet (30% sucrose) or regular water with standard laboratory food *ad libitum* for 4 weeks; the thermal nociception and body weight were measured during this period. Four weeks after treatment, the TNFα and leptin levels and the abdominal fat weight were measured in both groups. Nociception was assessed using the "Plantar test". **Results.** Overweight ovariectomized Wistar rats displayed significantly higher body weight and abdominal fat weight than did the control group. A hyperalgesic response was observed in animals fed sucrose. Thermal latency was also significantly decreased during the 4th week in these animals compared to that of controls. There were no differences in leptin levels, but the TNFα levels were altered between groups. **Conclusions**. Our data indicate that increased body weight and abdominal fat and increases in TNFα are associated with the hyperalgesic responses observed in ovariectomized overweight female rats.

Title: A genetic approach to pinning down the wanderer: Mapping vagal afferent innervation of the mouse small intestinal mucosa

Authors: *H. SERLIN, E. A. FOX;
Psychological Sci., Purdue Univ., West Lafayette, IN

Abstract: Vagal afferents that supply the small intestine mucosa play a key role in signaling satiation and regulation of digestive functions (e.g., Yox AJP, 260:R503, 1991). Little is known about the morphology or distribution of this innervation. A major obstacle has been selectively labeling a large proportion of vagal mucosal afferents independent of other extrinsic and intrinsic innervation (Fox Auton Neurosci, 126-7:9, 2006). A recent breakthrough revealed that Nav1.8Cre-Tomato control (NavCreTom-CON) mice express Tomato protein in ~80% nodose and dorsal root ganglion (DRG) cells and in mucosal afferents throughout the intestines (Gautron, 519:3085, 2011). Subdiaphragmatic vagotomy in NavCreTom-CON mice (NavCreTom-VGX) resulted in complete loss of this mucosal innervation, suggesting the innervation was all of vagal origin. However, this study relied on visualization of native Tomato fluorescence and qualitative analysis. To quantitatively explore the distribution, more thoroughly evaluate the vagal origin, and examine the morphology of Tomato-containing nerve terminals throughout the entire small intestine, innervation at 13 sites along the small intestine of NavCreTom-CON and NavCreTom-VGX mice were compared. Also, Tomato protein was stained to amplify its native fluorescence signal for more sensitive visualization. CON and VGX tissue was harvested, processed and mucosal innervation quantified in parallel. After perfusion fixation, 1 cm length blocks of small intestine from a random subset of 5 out of the 13 sampling sites from each mouse were harvested, frozen, cross-sectioned, and stained. Several features of nerve terminals in villi or adjacent to crypts were quantified blind. Preliminary data from NavCreTom-CON mice identified a large proximal to distal decrease in the mean number of fibers entering villi (5 + 0.24 vs 1 + 0.11), of fiber line crossings per villus width at villus mid-height (4 + 0.17 vs 0.9 + 0.12), and of crypts in close apposition with nerve fibers (75 + 0.05 vs 25 + 0.02). All of these measures were reduced in VGX mice with only 22% proximal and 13% distal villi exhibiting stained fibers, compared to 92% and 50%, in controls. Interestingly, the remaining fibers in VGX mice showed stable numbers in the 3 measures above along the entire length of the small intestine rather than a proximal-distal gradient (0.4 + 0.07 vs 0.3 + 0.08, 0.3 + 0.08 vs 0.6 + 0.17, 29 + 0.03 vs 13 + 0.02, respectively). These findings suggest labeled afferents in the small intestinal mucosa are mainly vagal in origin. Thus, this mouse model will be

valuable for studying the morphology, plasticity, and function of vagal mucosal afferents at all levels of the small intestine.

Title: Stimulation of AgRP neurons eliminates the effects of appetite suppressing compounds

Authors: R. A. ESSNER, *M. CARTER;
Williams Col., Williamstown, MA

Abstract: To maintain energy homeostasis, the brain controls appetite by detecting circulating anorexigenic (appetite suppressing) and orexigenic (appetite promoting) factors in the bloodstream, and integrating these signals to affect food-seeking behavior. Endogenous anorexigenic hormones include amylin, secreted by the pancreas, and cholecystokinin (CCK), secreted by the small intestine. In addition, exogenous compounds, such as lithium chloride (LiCl), a salt that creates gastric discomfort, and lipopolysaccharide (LPS), a bacterial cell wall component that induces sickness, have appetite suppressing effects. Within the arcuate nucleus of the hypothalamus, agouti-related peptide (AgRP)-expressing neurons make up one key population of orexigenic neurons. Recent studies have shown that optogenetic or pharmacogenetic stimulation of AgRP neurons is sufficient to cause a rapid and reversible increase in food intake in mice. Here, we show that optogenetic activation of AgRP neurons is sufficient to overcome the appetite suppressing effects of amylin, CCK, and LiCl. Interestingly, AgRP neuron stimulation was completely unable to overcome the appetite suppressing effects of LPS. We also show the effects of AgRP stimulation on expression of Fos, an indirect marker of neural activity, in brain regions that suppress appetite following administration of anorexigenic compounds. Taken together, these results show that appetite-suppressing compounds operate in different ways, some of which can be overcome with AgRP neuron stimulation and others that cannot.

Title: Metabolic triglycerides and glucose circadian rhythms are altered by perinatal cafeteria diet in rat

Authors: *D. J. BUSTAMANTE VALDEZ, P. DURAN;
LBAE Biol Cel, Facultad de Ciencias, UNAM, Ciudad de Mexico, Mexico

Abstract: The Hypothalamic Suprachiasmatic Nucleus (SCN) known to be the circadian master clock in mammals also receives humoral and neural information about the metabolic status of the body. The quantity and quality of food intake is related with the correct use of metabolites that are involved in the energy balance. Proper nutrition is one of the factors necessary for the health and development of living beings The intrauterine environment in which grows a fetus is one of the most important factors for the optimal development of this, depends in part on the external stimuli which receive, including the environment nutrition; as an disproportion in the quantity or quality of the nutrients can affect critical periods of development, triggering irreversible physiological or metabolic changes. Epidemiological studies in humans as well in animal models report that an overnutrition due to hypercaloric diets (vgr cafeteria diet) has been associated with predisposition of metabolic syndrome and diseases. The aim of the present study was to evaluate and to establish the differences in the daily profiles, amplitude and acrophase of glucose and plasmatic triglycerides, as well as assess the plasma concentrations of total triglycerides after a test of prolonged fasting in male and female rats of 40 and 90 days of age. Sprague-Dawley female rats were randomly divided in 2 nutritional protocols (control-CO and hypercaloric-low protein malnutrition-MHp) maintained with food and water ad libitum three weeks before mating and during gestation and lactation. All studies were performed in the juvenile male and female offspring. Postnatal body weight and size from birthing trough adulthood were recorded. Results shows that MHp presented a decrease in weight and size, as well as an area significantly lower in the glucose tolerance test from juvenile to adult ages. Preliminary Cosinor analysis of glucose and plasmatic triglycerides daily rhythm shows a reduction in the amplitude and a delay in the acrofase for total triglycerides and glucose for females and males at 40d of age, as well as for total triglycerides daily profile for males of 90d. We performed also a fasting test where a significant reduction of total plasmatic triglycerides in plasma for the MHp was observed. Therefore it can be inferred that the disparity presented in the MHp group in comparison with the CO in the daily rhythm of glucose and triglycerides processes, as well as the delay in the growth

is due to the exposure of hypercaloric and protein known as "cafeteria diet". Therefore nutritional conditions during the early stages of development has an influence on the energy balance in later stages.

Title: Voluntary wheel running and removal produces alterations in locomotor behavior and improvements in diabetic symptoms in mice

Authors: *N. L. ARRUDA, A. HATZIDIS, J. A. HICKS, I. DE PINA MONTEIRO, R. R. GELINEAU, A. V. CUSHMAN, M. H. CHASSE, J. A. SEGGIO;
Dept. of Biol. Sci., Bridgewater State Univ., Bridgewater, MA

Abstract: Both exercise and diet can have profound effects on behavior and health. Consumption of high fat diets can lead to alterations to a variety of different behaviors, including anxiety and locomotion, in addition to producing obesity and other health problems. Alterations to locomotor activity, even under entrained 24 h LD cycles, can produce alterations to feeding behaviors and energy balance, which can exacerbate the negative health consequences of a poor diet. Conversely, exercise has been well characterized to produce healthy outcomes and improve memory; however, the extent to which exercise can alleviate the behavioral and physiological problems caused by poor diet might be small. This study investigated the effects of running wheel access and high fat diet consumption and its subsequent removal on circadian locomotor activity patterns, anxiety behaviors, and diabetic phenotype in B6 mice. These experiments may elucidate whether exercise or calorie reduction has a greater effect on improving health. Mice were placed into either running-wheel cages or cages without a running wheel, and initially, mice were given access to either regular chow or 60 percent fat diet. Measures of health and behavior included: glucose tolerance, body mass, insulin, leptin and triglyceride levels, anxiety behaviors, and circadian locomotion. Baseline measurements for all parameters were taken prior to food switch. After 10 weeks on the high-fat diet, half of the mice given 60 percent fat diet had their diets replaced with regular chow, and after 5 weeks, their behaviors and health parameters were measured again. Prior to the switching of the high fat diet to regular chow, all high fat diet mice exhibited similar levels of insulin and leptin and body mass to each other and were significantly increased compared to mice consuming regular chow. Additionally, wheel running and high fat

diet consumption also produced changes in behavior during the open field, but not the light dark box. Removal of the high fat diet significantly improved body mass, glucose tolerance, and hormone levels compared to mice on continuous high fat diet access. Additionally, open field behaviors and circadian locomotor activity in mice with the food switch exhibited behaviors similar to controls, but different compared to mice continuously fed high fat diet. These results voluntary wheel running can improve, but not completely overcome, the physiological and behavioral deficits caused by high fat diets, and that replacement of a poor diet with a healthier one can produce larger improvements in anxiety and overall health more so than exercise alone.

Title: Morning pulsed leptin infusion reduces body weight but avoids onset of leptin resistance

Authors: P. J. SCARPACE[1], K. Y. E. STREHLER[1], M. K. MATHENY[1], N. KIRICHENKO[1], Y. SAKARYA[1], E. BRUCE[1], C. S. CARTER[2], D. MORGAN[3], *N. TUMER[1];
[1]Pharmacol., [2]Aging, [3]Psychiatry, Univ. Florida, Gainesville, FL

Abstract: Leptin administration results in leptin resistance presenting a significant barrier to therapeutic use of leptin. We hypothesized that pulsed central leptin infusion at specific times of the day would evoke favorable body weight reductions while tempering the development of leptin-induced leptin resistance. Methods: The first experiment examined leptin responsiveness to central leptin infusion, comparing pulsed versus constant infusion of 3 ug/day leptin, and the second experiment compared a 2 hr morning versus a 2 hr evening pulsed central leptin infusion of a submaximal dose of 0.25 ug/day. Leptin-induced pSTAT3 signaling was assessed prior to death. Results: Pulsed infusion of the supramaximal dose of 3 ug/day was not different than constant infusion with both leptin treatments resulting in significant 60 g decreases in body weight and 30% decreases in food intake ($p<0.001$). Both infusions were associated with leptin resistance with 30% and 60% decreases in STAT3 phosphorylation, respectively, for pulse and constant infusions. The 2hr morning pulsed central infusion of the submaximal leptin dose reduced food intake only over the subsequent immediate meal period and was associated with a

30g body weight reduction ($p<0.001$), but resulted in cellular leptin resistance (50% decrease in STAT3 phosphorylation, $p<0.001$). The evening pulsed infusion did not decrease food intake but reduced body weight to same extent as the morning pulsed infusion, yet maintained full leptin signaling. Conclusion: Pulsed infusion of a high dose of leptin induces leptin resistance as does pulsed morning infusion of a submaximal leptin dose. In contrast, a pulsed infusion prior to the dark phase reduces body weight with minimal reduction in food consumption and maintains full leptin signaling. The positive benefit for pulsed delivery remains speculative, yet potentially may provide an alternative mode of leptin therapy.

Title: Dysregulation of gut-brain endocannabinoid signaling and expression of the endocannabinoid system in mice maintained on Western Diet.

Authors: D. ARGUETA, *N. V. DIPATRIZIO;
Div. of Biomed. Sci., Univ. of California Riverside Sch. of Med., Riverside, CA

Abstract: The endocannabinoid (eCB) system is an important regulator of feeding and energy balance. We previously reported that levels of the eCB, 2-arachidonoyl-*sn*-glycerol (2-AG), are elevated in the jejunum mucosa of male rats that were food deprived for 24 h (FD), when compared to ad-libitum free-feeding controls (FF). This local signaling event in the small intestine drives refeeding after a fast and is dependent on cholinergic neurotransmission (DiPatrizio et al, *Amer J Phys* 309 (2015) 805-13). Similarly, it is suggested that oral exposure to dietary fats is a driving force in gut eCB production, which is also regulated by cholinergic signaling (DiPatrizio et al, *Proc Natl Acad Sci USA* 108 (2011) 12904-08). Our current findings reveal that a Western Diet (i.e., high levels of fats and sucrose) induces obesity (DIO, 60 day access) in male mice and is associated with dysregulated 2-AG signaling in jejunum mucosa.

DIO mice exhibit increases in levels of jejunal 2-AG under FF conditions that are comparable to levels found under FD in control mice maintained on standard lab chow. Levels of 2-AG are not increased any further under FD condition, when compared to FF, which provides evidence of impaired fasting-induced eCB signaling in the upper small intestine in DIO. Gene expression analysis (i.e., qRT-PCR) of cannabinoid CB_1 receptors and diacylglycerol lipase – an enzyme associated with the production of 2-AG – reveals an increase in their expression in response to fasting in mice fed a standard diet, an effect absent in DIO mice. Furthermore, FD in lean mice failed to affect levels of 2-AG in plasma. In contrast, FF and FD DIO mice exhibited a large increase in 2-AG levels. Collectively, this work suggests that *(i)* eCB signaling in the gut is initiated under several behavioral and metabolic conditions in rodents, and *(ii)* under conditions of DIO, 2-AG biosynthesis and possibly its signaling capacity at CB_1 receptors are dysregulated. Thus, these investigations advance our understanding of gut-brain eCB signaling and suggest potential new pharmacological avenues for appetite control and the treatment of obesity.

Abstract: The central nervous system maintains body homeostasis and regulates organ physiology. When changes in the environment disrupt this equilibrium, the brain senses the perturbation and coordinates a neurophysiological response to regain homeostasis. Selective regions of brain are activated in response to specific challenges such as pain, tissue injury and inflammation during bacterial infection. The current study was designed to identify specific deep brain regions that are activated in response to systemic inflammation. We used lipopolysaccharide (LPS)-induced endotoxemia to induce systemic inflammation, and immediate early gene *c-fos* expression as a neuronal activation marker to identify the deep brain structures. Adult male BALB/C mice were habituated by daily handling to reduce background c-Fos

expression prior to LPS challenge. Following habituation, animals received intraperitoneal administration of LPS (2 mg/kg), and brain c-Fos expression was analyzed after 90 min by immunohistochemistry. c-Fos immunoreactive cells were observed in nuclear groups of hypothalamus, medulla and pons. These findings suggest that short-term systemic inflammation results in activation of deep brain regions responsible for modulating physiological responses during illness. The future work will generate a detailed map of the specific brain nuclei acutely activated by LPS and compare it to the activation of other pathogen associated molecular patterns.

Title: Catecholaminergic innervation and the neuronal activation of hypothalamic glucose sensitive regions during rapid- and slow-onset hypoglycemia in adult male rats.

Authors: *A. JOKIAHO[1], A. G. WATTS[2];
[1]Dept. of Biol. Sci. Dana and David Dornsife Col., [2]Dept. of Biol. Sci. Dana and David Dornsife Col. of Letters, Arts and Sci., USC, Los Angeles, CA

Abstract: Hypoglycemic counterregulation is mediated by glucosensors located in the hypothalamus, hindbrain, and portal-mesenteric veins. But which are engaged is rate-dependent, with portal vein sensors being obligatory for slow- but not rapid-onset hypoglycemia. Slow-onset hypoglycemia is particularly prevalent with insulin therapy in type 1 diabetes. We have previously shown that hindbrain-to-hypothalamus catecholaminergic (CA) projections are required for sympathoadrenal responses to slow- but not rapid-onset hypoglycemia, and that rapid- but not slow-onset hypoglycemia significantly increases CA/Fos colocalization in the ventrolateral medulla. These results show that the organization of a hypoglycemia-responsive brain networks is rather complex, and involves a set of what are likely parallel but interactive networks, each of which is responsible for controlling epinephrine, glucagon, and glucocorticoid

responses. We now examine how various forebrain cell groups known to be important for glycemic regulation respond to , and how these responses are impacted by removing hindbrain-to-hypothalamus CA projections using injections of the immunotoxin, saporin conjugated to anti-DBH (DSAP) into the hypothalamic paraventricular nucleus (PVH). These injections remove CA inputs to the PVH and other regions within the medial hypothalamus. We then examined whether DSAP lesions affected Fos responses to slow- and rapid-onset insulin-induced hypoglycemia in key forebrain regions. We found that removing CA innervation differentially influences regional hypothalamic Fos responses to slow- and rapid-onset insulin-induced hypoglycemia. Rapid-onset hypoglycemia produced significantly greater Fos activations in the medial and lateral parvocellular and lateral parts of the PVH, parts of the lateral hypothalamus (LHA), the bed nucleus of the stria terminalis that was significantly reduced in all these regions with DSAP lesions. Of particular interest was the altered Fos in LHA regions that contain orexin neurons. We found that 27% of Fos activated neurons colocalized with orexin neurons in rapid-onset hypoglycemia, but this colocalization was significantly reduced by DSAP lesions. Furthermore we used a retrogradely transported polysynaptic neurotropic virus (PRV-152) injected into adrenal gland to show that 25% of PRV-labeled neurons in the LHA colocalized with orexin neurons. These results show that hindbrain-to-hypothalamus CA projections provide hypoglycemia-related information to regions of the forebrain in a rate-dependent way, with orexin neurons playing a particularly prominent role for sympathoadrenal responses.

Title: Combined consumption of alcohol and a high fat diet: sex differences in anxiety, feeding and drinking behavior

Authors: *R. R. GELINEAU, N. L. ARRUDA, J. A. HICKS, I. DE PINA MONTEIRO, A. HATZIDIS, J. A. SEGGIO;
Biol. Sci., Bridgewater State Univ., Bridgewater, MA

Abstract: Poor diets and alcohol are known to affect both behavior and overall health. Additionally, there are sex differences in how males and females respond physiologically and behaviorally to alcohol and high fat diets; however, few studies have examined simultaneous access of moderate alcohol consumption and high fat diet. This project investigated how joint

high fat and ethanol access affected feeding, drinking and anxiety behaviors in male and female B6 mice. Each sex of mice were separated into three groups; 60 percent fat diet, 10 percent fat diet, and regular chow and each group was paired with either water or forced 10 percent alcohol. Weekly body weight, food and fluid intake measurements were recorded. Anxiety behaviors were measured using the open field and light dark box. Hedonic substitution was tested to determine if the addition of a high fat diet would affect alcohol or preference and vice versa. Overall, fluid consumption was greater in mice fed regular chow compared to the 60 percent and 10 percent diets for both sexes. The combined high fat diet and alcohol mice drank more fluid than their water consuming counterparts, a result not seen in regular chow and 10 percent fat diet consuming mice in males. Alcohol drinking females consumed more kilocalories than water drinking females, which then consumed more ethanol than males overall. There is no evidence of hedonic substitution for either sex. In the open field, there were differences between the high fat and regular chow with respect to explorative behaviors, but not between the high fat and 10 percent fat diets for males. For the females, the only behavioral differences were in the open field assay with high fat diet exhibiting reduced velocity than the rest of the groups. Additionally, females consuming high fat diet exhibited increased center zone time compared to both males on high fat diet and females consuming regular chow. There were no differences in the light dark box for either sex. These results suggest that consumption of high fat diets are more powerful in affecting anxiety behavior compared to moderate alcohol consumption. Additionally, males and females respond behaviorally differently to high fat diets and have different alterations in feeding and drinking patterns compared to each other when alcohol is present.

Title: Nucleus tractus solitarius catecholamine neurons contribute to the intake suppressive effects of gastrointestinal satiation signals

Authors: *Z. ONG, H. S. WALD, X. S. DAVIS, H. J. GRILL;
Psychology, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Hindbrain nucleus tractus solitarius (NTS) catecholamine A2 neurons are implicated in food intake inhibitory control. A2 neurons, which express tyrosine hydroxylase (TH), are activated by gastrointestinal (GI) satiation signals, including cholecystokinin (CCK). Saporin toxin conjugated to target these neurons attenuates the intake suppressive effects of exogenous CCK. However, rather than inhibiting the excitability of A2 neurons, saporin conjugation lesions the A2 neurons making the functional effect more difficult to interpret. The present study therefore aimed to refine the procedures and selectively inhibit NTS A2 neurons using DREADDs (Designer Receptor Exclusively Activated by Designer Drugs) to test the hypothesis that NTS A2 neurons mediate the intake inhibitory effects of GI satiation signals. Male TH Cre transgenic rats received bilateral NTS injections of the Cre-dependent inhibitory DREADD, AAV-DIO-hSyn-hM4D(Gi)-mcherry and were trained to consume 12mL of liquid diet Ensure (preload) within 10min to physiologically stimulate endogenous GI signals. Rats were given intraperitoneal injections of 1mg/kg clozapine-N-oxide (CNO; a selective ligand for DREADD) or vehicle (veh) prior to a preload or no preload and subsequent chow intake determined at 30, 60, 90, 120min. Results reveal that preload significantly reduced subsequent chow intake ($p<0.05$ veh-preload vs veh-no preload) and CNO pretreatment attenuated the preload-induced intake suppression at 60min ($p<0.05$ veh-preload vs CNO-preload). Post mortem analysis of injection placements show that the attenuation of preload-induced intake suppression was specific to the inhibition of NTS A2 neurons, as the attenuation was not observed in rats with misplaced DREADD injections. Taken together, results provide support for the hypothesis that NTS A2 neurons participates in the intake inhibitory effects of GI satiation signals. Follow up experiments are underway to examine the contribution of A2 neurons in mediating the intake inhibitory effects of other GI signals, including CCK and glucagon-like peptide 1, to expand the range of effects explored and thereby provide a better understanding of the role of A2 neurons in food intake control. Title: Peripherally injected oxytocin activates vagal afferents to suppress food intake and ameliorates hyperphagic obesity in db/db mice

Authors: *Y. IWASAKI[1], Y. MAEJIMA[1], S. SUYAMA[1], M. YOSHIDA[2], M. KAKEI[2], T. YADA[1];
[1]Jichi Med. Univ., Shimotsuke, Japan; [2]Saitama Med. Ctr., Jichi Med. Univ., Omiya, Japan

Abstract: Oxytocin (Oxt), produced in the paraventricular nucleus and supraoptic nucleus of hypothalamus, regulates food intake. Previous reports have shown that not only central but also peripheral administration of Oxt suppresses feeding and ameliorates obesity. Peripheral oxytocin in circulation little enters the brain due to short half-life and tight restriction by the blood-brain barrier. Therefore, the route through which peripheral Oxt informs the brain is unclear. We investigated whether vagal afferents mediate the sensing and anorexigenic effect of peripherally injected Oxt in mice. First in *ex vivo* study, Oxt depolarized, evoked action potential firings and increased cytosolic Ca^{2+} concentration ($[Ca^{2+}]_i$) in single vagal afferent neurons isolated from the nodose ganglion. The Oxt-induced $[Ca^{2+}]_i$ increases were inhibited by Oxt receptor antagonist. Incidence of Oxt-responses in nodose ganglion neurons was approximately 15%. These Oxt-responsive neurons also responded to anorexigenic hormone cholecystokinin and contained cocaine- and amphetamine-regulated transcript. Next in *in vivo* study, Intraperitoneal (ip) injection of Oxt decreased food intake and increased c-Fos expression in the nucleus tractus solitarius (NTS) of medulla, to which vagal afferents project. The feeding suppression and c-Fos expression in NTS were blunted by subdiaphragmatic vagotomy and capsaicin treatment. In obese diabetic *db/db* mice, leptin failed to but Oxt increased $[Ca^{2+}]_i$ in single vagal afferent neurons. Moreover, single injection or sub-chronic infusion of Oxt decreased feeding and body weight gain in *db/db* mice. These results demonstrate that peripheral Oxt injection suppresses feeding by activating vagal afferents, and that this “peripheral Oxt-vagal afferents-brain” axis is effective for treating hyperphagia and obesity.

Title: Na^+,K^+-ATPase in the hypothalamic arcuate nucleus senses lowering glucose to initiate feeding behavior

Authors: *T. YADA[1], H. KURITA[1], K. Y. XU[2], P. SANTOSO[1], Y. YANG[1], K. DEZAKI[1], M. NAKATA[1];
[1]Physiol., Jichi Med. Univ., Shimotsuke, Japan; [2]Univ. of Maryland Sch. of Med., Surgery, MD

Abstract: Reduction in the blood glucose levels has been considered one of the major metabolic signals that induce appetite under fasting conditions. The glucose-inhibited (GI) neurons in the hypothalamic arcuate nucleus (ARC) are activated by lowering glucose (LG) and suggested to be implicated in feeding. However, their glucose-sensing mechanism and physiological role remain to be determined. We here report that Na^+,K^+-ATPase (NKA) in ARC senses LG to trigger feeding behavior. LG reduced NKA's substrate ATP levels in isolated ARC slices. In ARC GI neurons confirmed by their cytosolic Ca^{2+} ($[Ca^{2+}]_i$) responses to LG, LG also decreased intracellular nicotinamide adenine dinucleotide phosphate ($[NAD(P)H]_i$) level, reflecting reduced ATP production, and increased $[Na^+]_i$, reflecting reduced NKA activity. Intracerebroventricular injection of NKA inhibitor ouabain activated agouti-related protein (AgRP) and neuropeptide Y (NPY) neurons in ARC, and evoked NPY-dependent food intake. Ouabain increased $[Ca^{2+}]_i$ in single NPY/AgRP neurons in ARC. By contrast, specific NKA activator SSA412 counteracted fasting-induced food intake and LG-induced $[Ca^{2+}]_i$ increases in ARC GI neurons. This study reveals novel glucose signalling in ARC that triggers feeding behaviour: LG suppresses NKA activity and thereby activates GI neurons and NPY/AgRP-dependent appetite. This study identifies ARC NKA as the sensor and converter of LG to key neuronal activity and feeding behavior.

Title: Transcriptional alterations in a model of compulsive food taking or abstinence in the presence of contingent footshocks.

Authors: *M. T. MCCOY, N. TERRY, B. LADENHEIM, I. KRASNOVA, S. JAYANTHI, D. WALTHER, J. CADET;
Mol. Neuropsychiatry Res. Br., DHHS/NIH/NIDA/IRP, Baltimore, MD

Abstract: Obesity has reached epidemic proportion worldwide and is a serious risk factor for increased morbidity and mortality. In addition, obesity is, in part, secondary to increased food consumption despite adverse medical consequences. The longstanding aspect of unregulated eating behaviors is probably associated with long-term molecular changes in brain regions that control food intake and/or are involved in regulating rewards. In the present study, male Sprague-Dawley rats were trained to self-administer (SA) palatable food for 9-h per day for 32 days. After this training period, the rats were exposed to contingent footshocks for a period of 18 days. Increasing shocks produced two groups: (1) one group of rats continued to press the lever for food despite footshocks (shock-resistant) and (2) another group that significantly reduce their lever pressing (shock-sensitive). We then used the Affymetrix GeneChip rat transcriptome 1.0 array platform to test for differential transcriptional changes in the nucleus accumbens of these rats. Genes with significant differences between resistant and sensitive rats belong to diverse functional classes including DNA Binding, Oxygen Transport, Signal Transduction, and Synaptic Plasticity. Genes that participate in Cellular Developmental Process, Response to Stress, Response to Oxidative Stress, and Regulation of Cell Death were also over-represented in the comparisons. Thus, this model of food SA with adverse consequences is beginning to provide some insight into the molecular mechanisms involved in compulsive food taking. These discoveries may help to develop approaches to test the role of specific genes in regulating food intake. Title: Regulation of feeding behavior: a new circuit from the raphe nuclei to the hypothalamus

Authors: *C. A. GRILLO[1], C. E. PETYAK[1], B. L. SOMERA[1], V. A. MACHT[1], J. L. WOODRUFF[1], J. R. FADEL[1], L. P. REAGAN[2];

[2]WJB Dorn VA Med. Ctr., Columbia, SC

Abstract: Feeding behavior is an essential activity for maintenance of life. Not surprisingly given this necessity, food intake has evolved to be under the control of multiple peripheral factors interacting with multiple neural circuits. One of those peripheral factors is the adipocyte-derived hormone leptin that is secreted in proportion to fat mass and regulates a broad spectrum of homeostatic functions. Leptin receptors (LepRs) are expressed on neurons of the CNS, mainly in several nuclei of the hypothalamus. The majority of the studies examining the effects of leptin on food intake have focused on the hypothalamus. However, recent reports have suggested that extra-hypothalamic LepRs also regulate food intake. One extra-hypothalamic region which has received recent interest is the raphe. Our studies show that leptin infused directly into the raphe of adult male rats inhibits food intake in a dose-dependent manner. In order to more specifically study the role of LepRs expressed in the raphe upon feeding behavior, we used an optogenetics approach. Infusing a lentivirus, we expressed the light sensitive channelrhodopsin (ChR2) under control of the LepR promoter in the raphe. Selective blue light activation of these neurons inhibited food intake compared to yellow light stimulation used as control. In order to test if this optogenetic approach affected the locomotor activity that could interfere with food intake, we performed an Open Field Test after the light stimulation of the raphe leptin-sensitive neurons, and no changes were observed. We hypothesized that food intake regulation observed depends on activation of raphe leptin-sensitive neurons that send projections to the hypothalamic nuclei. In order to test this hypothesis, we infused the lentivirus containing the ChR2 under the LepR promoter into the raphe and then stimulated with blue light the terminals that reach the arcuate nucleus in the hypothalamus. This terminal stimulation of raphe efferents to the arcuate nucleus significantly inhibited food intake. This later effect had a smaller magnitude than the stimulation of the neuronal bodies located in the raphe, indicating that the arcuate is likely not the only nucleus that receives raphe efferents. Collectively, these data demonstrate that activation of the LepRs expressed in the raphe nuclei inhibit food intake through a circuit that sends projections to the arcuate nucleus.

Title: Regional effects of maternal high fat diet exposure on one carbon metabolism and methylation machinery

Authors: *S. E. MCKEE[1], S. ZHANG[2], L. CHEN[2], J. D. RABINOWITZ[2], T. M. REYES[3]; [1]Univ. of Pennsylvania, Cincinnati, OH; [2]Princeton Univ., Princeton, NJ; [3]Univ. of Cincinnati, Cincinnati, OH

Abstract: Offspring exposed to high fat diet in utero are at an increased risk for the development of metabolic and neurological disorders. To identify potential mechanisms linking early life diet and chronic disease, our lab uses a mouse model in which dams are fed a high fat diet throughout pregnancy and lactation. In adult offspring, we observe global DNA hypomethylation, gene-promoter hypomethylation and dysregulated DNA methyltransferase activity in various regions of the brain important in reward and executive function. These findings suggest that dysregulation in DNA methylation could be a mechanism by which offspring develop increased risk for disease. One carbon metabolism is the critical pathway donating one-carbon units for methylation reactions in the cell. It is well documented that nutrient intake and availability can alter enzymatic functioning and cycling of the one-carbon pathway, which can lead to altered epigenetic gene regulation. It remains undetermined whether perinatal exposure to high fat diet can alter one carbon metabolism and methylation machinery within the brain as a means to program adult disease. To determine this, male and female offspring from dams fed a high fat diet were sacrificed at weaning. Brain, liver and blood were collected to examine gene and protein expression of enzymes within the one carbon metabolism pathway and methylation machinery, activity of methyltranferases, and DNA methylation profiles in these offspring. It is expected that perinatal high fat diet exposure will perturb these systems and program offspring for adult disease.

Title: Preproglucagon neurons in the caudal brainstem contribute to regulation of heart rate and blood pressure

Authors: *M. K. HOLT[1], J. E. RICHARDS[1], F. M. GRIBBLE[2], F. REIMANN[2], S. TRAPP[1]; [1]Neuroscience, Physiol. and Pharmacol., Univ. Col. London, London, United Kingdom; [2]Cambridge Univ., Cambridge, United Kingdom

Abstract: Glucagon-like peptide-1 (GLP-1) is an incretin and neuropeptide best known for its role in glucose homeostasis and appetite regulation. However, in the brain, additional GLP-1 mediated effects are emerging and therefore it may play a more complex role in homeostasis than first anticipated. Activation of brain GLP-1 receptors has been shown to increase energy expenditure, induce nausea and increase heart rate (HR). Within the brain, GLP-1 is produced by preproglucagon (PPG) neurons in the nucleus tractus solitarii (NTS). We have previously shown that PPG neurons project to autonomic control centres throughout the central nervous system, including sympathetic preganglionic neurons in the spinal cord, suggesting GLP-1 may modulate sympathetic activity.

Here we investigated whether HR and blood pressure (BP) are regulated by PPG neurons using implantable biotelemetry BP probes in freely behaving mice. NTS PPG neurons were selectively ablated by injecting a Cre-dependent adeno-associated virus encoding the diphtheria toxin subunit A (DTA) into male transgenic mice expressing Cre recombinase under the control of the glucagon promoter. Following baseline recordings of HR and BP mice were stereotaxically injected with either a DTA or control virus. Recordings of HR and BP were obtained for 24 hours at 4 and 6 weeks post injection.

Successful ablation of NTS PPG neurons was confirmed using immunohistochemistry, and in an additional cohort of mice by an antibody-based assay, which detects active GLP-1. Ablation of PPG neurons reduced active GLP-1 levels in brainstem by 60%, in hypothalamus by >80% and

in the mid thoracic region of the spinal cord by >60% compared to control animals.
Mice with ablated PPG neurons displayed a normal circadian rhythm demonstrating expected increases of HR and BP at the onset of the dark phase. We did not observe an overall change in either HR or BP when comparing post injection recordings to baseline recordings. Mice exhibited a biphasic distribution of HR and BP over 24 hours and HR and BP levels were found to be positively correlated with the activity level of the animal. We analysed HR and BP data from periods of inactivity and found that PPG-ablated mice demonstrated elevated HR (+34±14 bpm) and BP (+5.3±2 mmHg) 4 weeks after viral injection as compared to baseline resting HR and BP. In contrast, control mice exhibited a decrease in HR (-27±11 bpm) without a change in BP (-0.7±0.7 mmHg) when resting.
This study, the first to investigate the role of endogenous, central GLP-1 in cardiovascular control, suggests that NTS PPG neurons may contribute to HR and BP regulation.

Title: Hypothalamic AMPK-induced autophagy increases food intake by regulating NPY and POMC expression

Authors: *T. OH;
Daegu Gyeongbuk Inst. of Sci. & Technol., Daegu, Korea, Republic of

Abstract: Hypothalamic AMP-activated protein kinase (AMPK) plays important roles in the regulation of food intake by altering the expression of orexigenic or anorexigenic neuropeptides. However, little is known about the mechanisms of this regulation. Here, we report that hypothalamic AMPK modulates the expression of neuropeptide Y (NPY), an orexigenic neuropeptide, and pro-opiomelanocortin (POMC), an anorexigenic neuropeptide, by regulating autophagic activity in vitro and in vivo. In hypothalamic cell lines subjected to low glucose availability such as 2-deoxy-d-glucose (2DG)-induced glucoprivation or glucose deprivation, autophagy was induced via the activation of AMPK, which regulates ULK1 and mTOR complex 1 followed by increased NPY and decreased POMC expression. Pharmacological or genetic

inhibition of autophagy diminished the effect of AMPK on neuropeptide expression in hypothalamic cell lines. Moreover, AMPK knockdown in the arcuate nucleus of the hypothalamus decreased autophagic activity and changed NPY and POMC expression, leading to a reduction in food intake and body weight. AMPK knockdown abolished the orexigenic effects of intraperitoneal 2DG injection by decreasing autophagy and changing NPY and POMC expression in mice fed a high-fat diet. We suggest that the induction of autophagy is a possible mechanism of AMPK-mediated regulation of neuropeptide expression and control of feeding in response to low glucose availability.

Title: The hypothalamic corticotropin-releasing hormone system and its involvement in metabolism and energy homeostasis

Authors: *J. RICHTER[1], A. CHEN[1], W. WURST[2], J. M. DEUSSING[1];
[1]Stress Neurobio. and Neurogenetics, MPI of Psychiatry, Muenchen, Germany; [2]Inst. of Developmental Genet., Helmholtz Zentrum München, Munich, Germany

Abstract: The corticotropin-releasing hormone (CRH), family of neuropeptides and their receptors - type 1 (CRHR1) and type 2 (CRHR2) - play a major role in the adjustment of neuroendocrine, autonomic, and behavioral adaptations to stressors. We have revealed that CRH receptors are able to convey differential responses depending on their cellular context and the neuronal circuit they are located. CRH receptors and ligands are expressed throughout the brain and show a differential expression pattern in multiple hypothalamic nuclei, which are involved in the control of hunger and satiety. CRH is strongly expressed in the paraventricular nucleus (PVN), CRHR1 is highly expressed in the arcuate nucleus (ARC) while CRHR2 is strongly expressed in the ventromedial hypothalamus (VMH). There is increasing evidence, that CRH is involved in centrally- and peripherally-controlled metabolic function. And also members of the family of ligands of CRHR2, urocortins, are involved in the regulation of peripheral responses to homeostatic challenges and though, are modulating metabolism and energy balance. More recent studies suggest that urocortins play also a role in the modulation and control of metabolism in the central nervous system. However, until now, there is little knowledge about the pathways and the interaction partners through which CRH receptors mediate their effects on metabolism and

energy balance. To unravel the identity of CRHR-expressing neurons in the hypothalamus and to overcome the lack of valid CRHR antibodies, we used specific reporter mouse lines to visualize on the one hand CRHR1 and CRHR2 positive neurons and on the other hand nuclei-specific markers, e.g. agouti-related peptide (AgRP), proopiomelanocortin (POMC), leptin receptor (LR). We identified, that the majority of CRHR1 neurons in the ARC co-express AgRP and a distinct proportion of CRHR2 neurons is positive for LR. In further work, we aim to identify more specific markers co-expressed with CRHR2 and to unravel the neurotransmitter circuits of CRH receptors in the hypothalamic nuclei by in situ hybridization techniques and to learn more about the connectivities of the hypothalamic CRH system using viral-based tracing methods.

Title: The relationship between neuronal histamine and neurosecretory protein GM in the chick hypothalamus

Authors: *K. UKENA, K. SHIKANO, Y. BESSHO, E. IWAKOSHI-UKENA;
Lab. of Brain Sci, Grad. Sch. of Integ Arts & Sci., Hiroshima Univ., Higashi-Hiroshima, Japan

Abstract: We recently identified two cDNA-encoded paralogous small secretory proteins: neurosecretory protein GL (NPGL) and neurosecretory protein GM (NPGM) in the chick hypothalamic infundibulum. We also detected homologous genes in the vertebrate genome. In a preliminary study, we found that NPGM-producing cells were present among the histaminergic neurons in the rat brain. Although it has been established that histamine is synthesized by the enzyme histidine decarboxylase (HDC) in mammals, the function of HDC and histaminergic

neurons in the avian brain have not yet been characterized. To study this aspect, we first cloned the HDC cDNA from the chicken hypothalamus. We found that the expressed protein possessed a high level of enzymatic activity. Quantitative RT-PCR analysis showed that the HDC mRNA was highly expressed in the hypothalamic infundibulum. In situ hybridization analysis revealed that the cells containing HDC mRNA were localized to the medial mammillary nucleus (MM) of the hypothalamic infundibulum. We subsequently raised a specific antibody against chick NPGM and examined the localization of NPGM-producing cells by immunohistochemical analysis. NPGM-like immunoreactive cells were distributed across the MM and the infundibular nucleus of the hypothalamus. In order to clarify the relationship between neuronal histamine and NPGM, we compared the localization of histaminergic neurons and NPGM-producing cells. We observed that histamine and NPGM were produced in the same neurons located in the MM. A quantitative PCR analysis showed that mRNA levels of HDC and NPGM in the hypothalamic infundibulum increased during fasting and decreased during post-hatching development. An intracerebroventricular injection of histamine or NPGM in chicks inhibited feeding behavior. These results suggest that histamine and NPGM, which are produced by the same neurons in the chicken brain, exhibit functional complementarity.

Title: Deletion of melanin-concentrating hormone receptor 1 from the accumbens nucleus increases locomotor activity

Authors: *M. J. CHEE, S. E. FLAHERTY, III, P. PISSIOS, N. BRIANCON, J. S. FLIER, E. MARATOS-FLIER;
Endocrinol., BIDMC, Harvard Med. Sch., Boston, MA

Abstract: Melanin-concentrating hormone (MCH) is an orexigenic neuropeptide that is a critical regulator of energy homeostasis. Transgenic deletion of MCH or its receptor MCHR1 results in leanness by increasing energy expenditure and locomotor activity. Since MCHR1 expression is widespread, the function and contribution of different MCH-responsive neurons is poorly understood. We recently showed that a large proportion of MCHR1 cells are GABAergic, including those in the accumbens nucleus. We tested the role of GABAergic neurons for the effects of MCH on body weight, energy expenditure or locomotor activity by selectively deleting

MCHR1 from GABAergic neurons. We next deleted MCHR1 expression in distinct neuroanatomical regions to identify a candidate brain area that supports MCH locomotor actions. We generated the *MCHR1-flox* mouse and crossed it to the *vGAT-cre* mouse; the conditional knockout is designated *vGAT-MCHR1-KO*. In situ hybridization confirmed the absence of MCHR1 from GABAergic regions, most notably in the striatum and arcuate nucleus, but there is no loss of MCHR1 hybridization in glutamatergic regions, including the cerebral cortex, hippocampus and paraventricular hypothalamic nucleus. We next compared differences in body weight and locomotor activity of female *vGAT-MCHR1-KO* mice to their *vGAT-cre* controls. *vGAT-MCHR1-KO* mice were 11% leaner, with 20% less body fat, and had 70% greater total energy expenditure. However the most impressive difference was a 93% increase in total baseline ambulation. Furthermore, consistent with our previous report that increased dopaminergic tone in the accumbens nucleus underlies the hyperactivity of MCH-deficient mice, we found that *vGAT-MCHR1-KO* mice had an enhanced and prolonged response to GBR12909, a dopamine reuptake blocker. GBR12909 produced a two-fold increase in cumulative locomotor activity lasting more than 5 hours. To probe the role of the accumbens nucleus, where more than 95% of neurons are GABAergic, we stereotaxically injected an adeno-associated virus encoding cre recombinase-mCherry into the accumbens of *MCHR1-flox* mice. Deletion of MCHR1 expression from the accumbens nucleus increased total baseline locomotor activity by 82%. These findings show that MCH acts partly via GABAergic neurons to regulate body weight and energy expenditure. Furthermore, MCH signaling in GABAergic cells may inhibit dopamine transmission in the accumbens nucleus to regulate ambulatory activity.

Title: Nicotine and high fat diet differentially modulate body weight, behavior, and neuropeptide expression in female and male C57BL/6J mice

Authors: *C. A. CALARCO, S. LEE, M. R. PICCIOTTO;
Dept. of Mol. Psychiatry, Yale Univ. Sch. of Med., New Haven, CT

Abstract: Obesity is a major health problem in the US with greater than 30% prevalence in the adult population. The high rate of obesity is partially attributable to the popularity of high-fat, high-calorie foods in the Western diet. Despite the negative consequences of obesity such as heart disease and diabetes, many people find losing weight through lifestyle changes difficult. Nicotine exposure through tobacco use has been associated with lower body weight, and subsets of smokers report using nicotine to control appetite, or resisting quitting because of concerns about weight gain. However, many of the mechanisms by which chronic nicotine consumption suppresses weight gain remain unclear. In animal studies, nicotine is associated with reduced weight gain, reduced food consumption, and altered energy expenditure, but these findings vary based on the duration and the route of nicotine administration. Furthermore, sex differences in the effects of nicotine have been reported in rats but remain relatively unexplored. We used high-fat diet (HFD) in tandem with free access to nicotine to mimic the nicotine and food consumption patterns observed in humans, and designed our experiments to test the intake patterns, weight gain, and biochemical changes due to nicotine in male and female mice. Single-housed male and female C57BL/6J mice had *ad lib* access to nicotine via drinking water and either regular chow or 45% HFD for 30 days. As expected, HFD significantly increased body weight over the course of the experiment. However, this body weight gain was attenuated by nicotine in male, but not female, mice. HFD increased caloric intake only in male mice, and nicotine did not affect caloric intake in either diet condition. Male, but not female, mice exhibited less weight gain per calorie consumed when given access to nicotine, suggesting that metabolic and peripheral changes may contribute to the blunted weight gain associated with nicotine treatment and may vary by sex.
To examine the molecular and biochemical changes that accompany the observed changes in weight and feeding behavior, we investigated the expression level changes of multiple genes of interest in the hypothalamus and peripheral tissues. HFD and nicotine differentially regulated hypothalamic feeding peptides in the arcuate nucleus, including AgRP, NPY, and CART. We also examined expression of uncoupling proteins (UCPs) in both brown and white adipose tissue, as a proxy for metabolic function. Based on these data, we can conclude that the weight changes associated with nicotine and HFD consumption differ between male and female animals and that these differences may be due to altered peptide signaling in the hypothalamus.

Title: Neuropeptide-y directly inhibits ventral tegmental area dopamine neurons through g protein-coupled inwardly rectifying potassium channel currents

Authors: *K. STUHRMAN[1], A. G. ROSEBERRY[2];
[1]Neurosci. Inst., [2]Dept. of Biol., Georgia State Univ., Atlanta, GA

Abstract: The mesocorticolimbic dopamine system, the brain's reward system, regulates many different behaviors including food intake, food reward, and feeding related behaviors. There is substantial evidence that hypothalamioc feeding-related neuropeptides alter dopamine neuron activity to affect feeding. For example, neuropeptide Y (NPY), a strong orexigenic hypothalamic neuropeptide, decreases the activity of dopamine neurons in the ventral tegmental area (VTA) of the mesocorticolimbic DA system, and increases motivation for food when injected into the VTA. How NPY decreases the activity of dopamine neurons to mediate these effects is unknown, however. In these studies we have used whole-cell patch clamp electrophysiology in acute brain slices from mice to examine how NPY decreases VTA dopamine neuron activity. NPY activated an outward current in approximately fifty percent of dopamine neurons tested. The NPY current exhibited characteristics of a G protein-coupled inwardly rectifying potassium (GIRK) channel current, as it showed strong inward rectification, a reversal potential near that for potassium ions, and was blocked by extracellular barium. The NPY activated current was also dependent on intracellular calcium levels, as it was significantly smaller with low calcium buffering compared to high calcium buffering, which is similar to GIRK currents activated by dopamine and $GABA_B$ receptor agonists in VTA dopamine neurons. In addition to its direct effects on VTA dopamine neurons, NPY also slightly decreased the amplitude of excitatory glutamatergic post-synaptic currents onto VTA dopamine neurons. Overall we have shown that NPY reduces dopamine neuron activity both by directly activating an inhibitory GIRK current and by decreasing glutamatergic transmission onto VTA dopamine neurons. These studies provide an important advancement in our understanding of dopamine neuron activity and how it is controlled by NPY.

Title: Tectal CRF R1 receptors modulate food intake

Authors: *C. PRATER, B. HARRIS, A. MERRILL, A. ALIYAS, K. ANDERSON, J. CARR; Biol., Texas Tech. Univ., Lubbock, TX

Abstract: The optic tectum (OT) and superior colliculus (SC) rapidly inhibit food intake when a visual threat is present. Previous work from our laboratory indicates that CRF, acting on CRF R1 receptors, may play a role in tectal inhibition of prey capture. Here we test the hypothesis that **tectal CRF neurons modulate food intake in juvenile *Xenopus laevis***. We tested five predictions: 1) Does tectal CRF injection decrease food intake? 2) Does a selective CRF R1 antagonist block CRF effects on feeding? 3) Does a selective CRF R1 antagonist block stressor-induced inhibition of feeding? 4) Does eliminating tectal cells expressing CRF R1 increase feeding? 5) Does food deprivation increase food intake and, if so, can this be reversed with CRF? *X. laevis* were administered oCRF alone or in combination with the selective CRF R1 antagonist NBI27914 or antagonist vehicle. Test agents were bilaterally injected into the tecta of juvenile frogs. CRF conjugated to the ribosomal toxin saporin (CRF-SAP) was administered 2 wk prior to testing to eliminate tectal cells expressing CRF R1. oCRF administered bilaterally into the tecta significantly reduced food intake compared to sham and vehicle injected juveniles. When frogs were injected with oCRF and antagonist vehicle, food intake was significantly reduced. When injected with both NBI27914 and oCRF, food intake was maintained at baseline levels. Frogs ate significantly less when exposed to a reactive stressor (ether vapors) and when pre-treated with antagonist vehicle prior to exposure. NBI27914 reversed stressor-induced inhibition of food intake. Neither CRF-SAP injection nor food deprivation (2 wk) significantly changed food intake. No significant differences in food intake were noted between males and females across all studies. Overall, we found support for questions 1-3 and conclude that activation of the tectal CRF R1 inhibits food intake in frogs. Furthermore, tectal CRF R1 receptors appear to be involved in the reduction of food intake that occurs in response to a reactive stressor. However, elimination of tectal CRF R1 neurons did not increase feeding suggesting that this system may be more important for stress-related vs. baseline feeding. This work was done in partial completion of requirements for the doctoral degree at Texas Tech University (C.P.)

Title: Effects of FGF23/αKlotho on the NPY/AgRPergic system in the hypothalamus

Authors: *T. KOMORI, Y. MORIKAWA;
Dept. of Anat. & Neurobiology, Wakayama Med. Univ., Wakayama, Japan

Abstract: Food intake is regulated via neural circuits located in the hypothalamus. Previously, we have reported that fasting induces αKlotho, a gene associated with longevity, in the hypothalamic arcuate nucleus, especially in the neuropeptide Y (NPY)/agouti-related protein (AgRP)-expressing neurons (44th Annual Meeting of Society for Neuroscience 2014, abstract #11568). To gain insights into the functional roles of αKlotho in the hypothalamus, we analyzed αKlotho-deficient mice. As homozygous αKlotho-deficient mice have a short life span and show severe physical abnormalities like human premature aging, we used heterozygous αKlotho-deficient ($\alpha Klotho^{+/-}$) mice in the present study. The expression of αKlotho gene in the hypothalamus was reduced more than 40% in $\alpha Klotho^{+/-}$ mice compared to wild-type (WT) mice in the fed states. Fasting induced the expression of αKlotho in the hypothalamus of WT mice, but not in $\alpha Klotho^{+/-}$ mice. The body weights in $\alpha Klotho^{+/-}$ mice were similar to those in WT mice in both fed and fasted states. In addition, there was no change in the amount of daily food intake between WT and $\alpha Klotho^{+/-}$ mice. However, the amount of food intake after fasting was reduced in $\alpha Klotho^{+/-}$ mice compared to WT mice. In addition, the expressions of NPY and AgRP after fasting were lower in the hypothalamus of $\alpha Klotho^{+/-}$ mice than those of WT mice, respectively. It has been reported that αKlotho forms the receptor complex with a fibroblast growth factor receptor (FGFR) and acts as the functional receptor for FGF23. To investigate the effects of FGF23 on the expression of NPY and AgRP in the hypothalamus, we injected FGF23 intracerebroventricularly. Intracerebroventricular injection of FGF23 induced the expression of NPY and AgRP in the hypothalamus. These results suggest that FGF23/αKlotho is a novel regulator of the NPY/AgRPergic system in the hypothalamus.

Title: Optogenetic stimulation of MCH axons in the hippocampus: Effects on synaptic plasticity

Authors: *J. J. HARRIS[1], D. BURDAKOV[2];
[1]Imperial Col. London, London, United Kingdom; [2]Francis Crick Inst., London, United Kingdom

Abstract: Hypothalamic neurons containing the peptide, melanin concentrating hormone (MCH), may be important for memory consolidation, particularly during sleep. Studies have shown that disrupting the function of MCH neurons, either by deleting the neurons themselves (Le Bariller et al., 2015) or knocking out MCH receptors (Pachoud et al., 2010), impairs learning and disrupts synaptic plasticity in the hippocampus. Here we address the inverse question: does increasing MCH neuron function facilitate hippocampal plasticity? We injected cre-dependent channelrhodopsin into the lateral hypothalamus of MCH-cre mice. After 5-6 weeks, channelrhodopsin-expressing MCH axons were visible in hippocampal slices. In these slices, we illuminated the hippocampus with blue light (5 ms flashes delivered at 20 Hz for 30 second epochs), whilst electrically stimulating Schaffer collateral axons of CA3 with either a weak potentiating stimulus (100 Hz for 1 sec); a strong potentiating stimulus (100 Hz for 1 sec, four times); or a depressing stimulus (1 Hz for 900 sec). Changes in the slope of the field potential, measured in the stratum radiatum of CA1, were monitored. Optogenetic activation of MCH axons in the hippocampus altered the time-course of plasticity and augmented the effect of a weak potentiating stimulus, compared to a control condition, where blue light stimulation was identical but MCH axons did not express channelrhodopsin. These results align with the idea that MCH neurons, active during REM sleep, play a role in facilitating memory consolidation.

Title: Hyperphagic obesity in adult Dicer CKO mice- the role of hypothalamic AgRP/NPY neurons.

Authors: *K. HAJDUKIEWICZ[1], W. KONOPKA[2];
[1]Neurobio. Ctr., Nencki Inst. of Exptl. Biol., Warsaw, Poland; [2]Nencki Inst. of Exptl. Biol. in Warsaw, Warsaw, Poland

Abstract: Obesity is a worldwide disease of complex etiology. The main appetite regulatory center is located within the brain, in hypothalamus. A putative mechanism responsible for the obesity phenotype involves microRNA interplay between feeding regulatory elements of the hypothalamic AgRP/NPY- and POMC-producing neurons. Dicer is a key enzyme in microRNA processing. In Dicer's absence, there is a pronounced lack of mature microRNAs and a disturbed regulation of translation. We want to observe how massive, spatially and temporally defined, loss of microRNAs impacts metabolism and obesity outcome. To achieve this goal, we injected rAAV-coding Cre recombinase under the AgRP specific promoter into the arcuate nucleus of mice with Cre-dependent Dicer sequence. Our preliminary data show that such administration leads to visible weight gain. This phenotypic effect is thought to be reflected by an imbalance between anorexygenic and orexigenic neuropeptide levels, as measured by the mass spectrometry approach. In addition, reporter constructs coding either mCherry, EYFP or ChR2-EYFP under the AgRP specific promoter were done and stereotacticly injected to arcuate nucleus. In most of the cases we could observe specific expression of reporter genes. This approach is an initial step to explore functional connectivity between AgRP/NPY-producing neurons and other brain structures in Dicer CKO mice.

Title: Dietary macronutrient composition affects the influence of exogenous neuropeptide Y on food intake responses and hypothalamic gene expression in chicks

Authors: *B. MCCONN, E. R. GILBERT, M. A. CLINE;
Virginia Tech., Blacksburg, VA

Abstract: In chicks, central injection of neuropeptide Y (NPY) led to preferential consumption of a high fat diet containing lard as the main source of energy, although molecular mechanisms underlying these effects are unknown and it is unclear whether substituting the lard with a plant-based oil would yield similar effects. Thus the purpose of this study was to evaluate the effects of high protein, fat and carbohydrate diets on food intake responses, and hypothalamic mRNA abundance following intracerebroventricular (ICV) injection of 0, 0.2, or 2.0 nmol NPY at 4 days post hatch. Chicks were fed one of three isoenergetic (3,000 kcal metabolizable energy; ME/kg) and isonitrogenous (22% CP) corn and soybean meal-based diets ad libitum from hatch: 1) high carbohydrate [HC], 2) high protein [HP] (27% CP), or 3) high fat [HF] (30% ME derived from soybean oil). In Experiment 1, consumption of the HF diet led to a non-dose dependent similar magnitude of increased food intake after NPY injection, whereas chicks fed the HC and HP diets increased their food intake dose-dependently. These results, combined with our previous findings, show that a HF diet accentuates the potency of NPY in birds, regardless of the source of fat in the diet. In Experiment 2, total hypothalamic RNA was isolated from samples collected at 1 h post-NPY injection and used for measuring mRNA abundance of appetite-associated factors. There were main effects of diet on mRNA abundance of mesotocin (MT, avian homologue to oxytocin), agouti-related peptide (AgRP), corticotropin releasing factor receptor sub-type 1 (CRFR1), NPY, NPY receptor sub-types 1 and 2 (NPYR1 and 2, respectively), and melanocortin receptors 3 and 4 (MC3R and 4R, respectively). There was also a main effect of NPY treatment on NPY mRNA and also NPY treatment by diet interactions on expression of NPYR1 and MC4R mRNA. In conclusion, the potency of NPY-mediated stimulation of food intake at 4 days post hatch was augmented when chicks consumed a HF diet, and this coincided with changes in hypothalamic mRNA expression of key appetite-associated factors. These results have implications for better understanding the molecular basis of food craving and hording across species.

Title: Des-Tyr DYN, a non opioid DYN peptide regulates physical activity, energy expenditure and hedonic food intake in the paraventricular hypothalamic nucleus.

Authors: *C. E. PEREZ-LEIGHTON[1], L. GAC[1], B. ALVAREZ[1], E. MORSELLI[2], M. HERNANDEZ[2], J. TESKE[3];
[1]Univ. Andres Bello, Santiago, Chile; [2]Facultad de Ciencias Biológicas, Pontificia Univ. Católica de Chile, Santiago, Chile; [3]Dept. of Nutritional Sci., Univ. of Arizona, Tucson, AZ

Abstract: The dynorphin (DYN) peptides are a family of neuropeptides that regulate different behaviors, including food intake and selection. DYN peptides can be opioid or non-opioids, depending on whether they act through opioid receptors. Opioid DYN peptides promote food intake through its actions at the hypothalamic paraventricular nucleus (PVN), an important site in the regulation of feeding behavior and physical activity. Our recent work has focused in the role of non-opioid peptide des-Tyr-DYN (DYN-A_{2-17}) in PVN in mice. We previously showed that injection of DYN-A_{2-17} in PVN simultaneously increases locomotor activity and food intake (Peptides 2016, 76:14-8). Here, we further characterize the effects of DYN-A_{2-17} in food intake and physical activity. DYN-A_{2-17} in PVN at different doses (0, 1, 3 nmol) increases physical activity, overall energy expenditure and physical activity-associated energy expenditure in the absence of food. We also show that a single dose of DYN-A_{2-17} (3 nmol) increases running wheel activity one hour post-injection. Next, we showed that DYN-A_{2-17} increases intracellular calcium in hypothalamic mice cell line, suggesting it acts as an excitatory neuropeptide in the hypothalamus. To further examine the role of DYN-A_{2-17} (0, 1, 3, nmol) in food intake, we evaluated its effects in palatable snack selection and intake compared to the opioid DYN peptide DYN-A_{1-13} (0, 1, 3 nmol) and orexin-A (0 0.2, 0.4 nmol), as the hypothalamic orexin/dynorphin (ox/dyn) neurons release both orexin and dynorphin (DYN) peptides in PVN and other brain sites. Mice were acclimated to short-term access (2 h) to four human palatable snacks and standard rodent chow. After establishing baseline preferences for snacks, mice were injected with each peptide at their different concentrations. Our data suggest only DYN-A_{1-13} increases overall food intake. Analyses of food selection suggest DYN-A_{1-13} and DYN-A_{2-17} increased snack of preferred snacks, but with higher potency of DYN-A_{1-13}, while orexin-A increased chow intake and decreased snack intake. Together, these experiments will improve our

understanding of the mechanisms by which the orexins, opioid and non opioid DYN peptides control energy balance.

Title: Role of enkephalin in dopamine d2-receptor expressing neurons in licking microstructure

Authors: *I. A. MENDEZ[1], H. A. LAM[1], S. N. LEE[1], J. BOULTER[1], S. B. OSTLUND[2], N. P. MURPHY[1], N. T. MAIDMENT[1];
[1]Psychiatry and Biobehavioral Sci., UCLA, Los Angeles, CA; [2]Dept. of Anesthesiol. and Perioperative Care, UCI, Irvine, CA

Abstract: Opioid signaling is implicated in mediating the hedonic and motivational aspects of palatable foods. When licking for palatable solutions, global enkephalin knockout mice emit fewer bouts of licking than wildtypes, but similar bout lengths. Interestingly, the number of times a mouse engages in a new bout of licking is suggested to reflect motivational aspects of feeding behavior, while the length of the bout once engaged is determined primarily by the immediate hedonic impact of the food stimulus. *Objective:* In these studies, we investigated the role of endogenous enkephalin, specifically in neurons expressing dopamine D2 receptors, in licking microstructure. *Design:* D2 specific proenkephalin knockout mice (D2 PENK KO) and their wild-type littermates were trained to lick for 20% sucrose for 5 days in a lickometer. Subsequently, the effects of sucrose concentration (2% versus 20%) and hunger state (4 h versus 18 h food deprivation) were assessed. A second group of D2 PENK KO and wildtype mice were trained to lick for 20% sucrose for 7 days. Following training in these mice, the hypophagic effects of 5mg/kg naltrexone on licking were assessed. *Results:* Compared to wildtype mice, D2 PENK KO mice displayed fewer total licking bouts, but similar mean bout lengths, across sucrose concentrations and hunger states. In the second group of mice, naltrexone decreased total bout number in wildtype mice, but had no effect on mean bout length. No effects of naltrexone were observed in D2 PENK KO licking behavior. *Discussion:* Similar to previous observations in global PENK KO mice, D2 PENK KO mice emitted fewer bouts of licks, but similar licking

bout lengths. Naltrexone hypophagia was driven by decreases in the number of licking bouts, an effect that D2 PENK KO mice were insensitive to. Overall these findings suggests that enkephalin, specifically in D2 expressing neurons, plays an important role in establishing feeding patterns, and may therefore play a role in psychopathological conditions characterized by aberrant feeding behavior.

Title: Investigation of leptin mediated trafficking of K_{ATP} channels in the arcuate nucleus of high fat induced obese mice

Authors: J.-S. RUAN[1], *R.-C. HUANG[2], P.-C. CHEN[1];
[1]Physiol., Natl. Cheng Kung Univ., Tainan, Taiwan; [2]Chang Gung Univ., Tao-Yuan, Taiwan

Abstract: K_{ATP} channels are molecular sensors that couple cell metabolism to membrane excitability. Leptin is a hormone secreted primarily by white adipocytes and is sufficient to regulate body weight, feeding, energy expenditure and glucose metabolism. Within CNS, the hypothalamus is the main site for leptin action and high levels of the leptin receptor (ObRb) are expressed in several hypothalamic nuclei including arcuate nucleus (ARC).There are two populations of neurons in the ARC: neuropeptide Y (NPY) and agouti-related protein (AGRP) containing neurons, and proopiomelancortin (POMC) and cocaine-and amphetamine-regulated transcript (CART)-containing neurons. Neuronal K_{ATP} channels are widely expressed in the brain including POMC and AGRP neurons. Electrophysiological examination has shown that a sub-population, defined as glucose-responsive (GR) neurons. Glucose removal and leptin application hyperpolarize these neurons by activation of K_{ATP} channels in AGRP neurons and inhibition of GR neurons results in decreased transmission output and hence reduced food intake. Most obese patients suffer from a state called leptin resistance which is high circulating leptin concentrations cannot decrease energy intake. The mechanism of this leptin-resistance is still incompletely understood. Interestingly, leptin activates PI3K pathway to hyperpolarize AGRP neurons by opening K_{ATP} channels, but leptin engages PI3K signaling to control firing in POMC neurons.

We hypothesize that the surface K_{ATP} channel is the molecular target regulated by leptin to determine AGRP and POMC neuron activity and dysregulated surface expression of K_{ATP} channel may account for obese induced leptin resistance. Hence, we used hypothalamic N44 cell line and high fat diet induced obese mice to test the hypothesis. *In vitro*, we applied the saturated free fatty acid palmitate and different glucose concentration to mimic the condition of obese induced type II diabetes followed by the analysis of K_{ATP} channel trafficking using surface biotinylation and electrophysiological recording after leptin treatment. *In vivo*, we detected K_{ATP} channel activity in the POMC and NPY neurons of high fat induced obese mice by electrophysiological recording, imaging and biochemical assays. We hope to get a better understanding by how diet induced obese affects effect of leptin on K_{ATP} channel trafficking in arcuate nucleus.

Title: Intrinsic and synaptic plasticity of appetite-promoting MCH neurons during growth, high-fat diet feeding, and food deprivation

Authors: *V. LINEHAN, M. HIRASAWA;
Div. of BioMedical Sciences, Fac. of Med., Mem. Univ. of Newfoundland, St John's, NL, Canada

Abstract: Melanin-concentrating hormone (MCH) neurons are one of the hypothalamic cells groups that promote food intake and weight gain. Therefore, these neurons may be critical for periods of pronounced weight gain such as development, rebound following food restriction, and obesity. To determine whether activation of MCH neurons accompanies these metabolic challenges, whole cell patch clamp recording was performed on MCH neurons from rat hypothalamic slices. Basal electrophysiological properties, miniature excitatory synaptic currents (mEPSCs), and paired pulse ratios were recorded. Two factors were tested: age (juvenile and adult) and dietary condition (high-fat diet (HF), 12-hour fasting, and standard chow fed controls).

We found that MCH neurons experience a decrease in excitability as animals grow. Specifically, compared to 4 week old rats (juvenile), MCH neurons of 7 and 14 week old rats (adult) had a hyperpolarized membrane potential, a lower firing frequency, and a higher firing threshold. Additionally, both the frequency and amplitude of mEPSCs decreased with age, suggesting pre- and postsynaptic changes. This was likely due to a reduction in synapse number and postsynaptic sensitivity as we found no age-dependent change in the paired pulse ratio, a measure of release probability. Activation of MCH neurons also occurs in adult rats that are fed a HF for 4-11 weeks, which induces significant weight gain. MCH neurons of HF fed rats were more excitable, which was due to downregulation of Na^+/K^+-ATPase. Moreover, there was an increase in the frequency of mEPSCs without a change in paired-pulse ratio, suggesting an increased number of excitatory synapses. Finally, activation of MCH neurons can also occur over shorter time scales, such as overnight fasting. However, unlike rats undergoing growth spurts or chronic HF feeding, fasting strengthens existing excitatory synaptic connections to these neurons without increasing their number. This was evident as an increase in mEPSC frequency and a decrease in paired-pulse ratio. Our study suggests that intrinsic and synaptic plasticity occurs in MCH neurons under different physiological states that involve an increased drive for food intake. Activation of MCH neurons through these mechanisms may be important for promoting positive energy balance to meet the physiological demands of growth, development, and weight gain.

Title: Differences between mice lacking neural Pomc enhancers 1 and 2 on food intake and body weight after peripheral leptin treatment.

Authors: *E. NA[1], D. D. LAM[2], E. YOKOSAWA[1], M. LOW[1];
[1]Mol. & Integrative Physiol., Univ. of Michigan, Ann Arbor, MI; [2]Inst. of Neurogenomics, Helmholtz Ctr. Munich, Munich, Germany

Abstract: Past work from our laboratory has demonstrated that expression of the *Pomc* gene is under the regulatory control of two partially redundant enhancers, nPE1 and nPE2. Simultaneous deletion of these neural enhancers results in morbidly obese mice while deletion of either alone produces a mildly obese phenotype (Δ1 knockout) or no overt phenotype (Δ2 knockout). Here we show a dissociable effect of the anorexigenic hormone, leptin on Δ1 knockout and Δ2 knockout mice whereby Δ2 knockout mice are relatively unresponsive to peripheral leptin treatment with food intake being only mildly suppressed by leptin compared to WT and Δ1 knockout mice. We also show that Δ1 knockout mice are more sensitive to the anorectic effects of leptin with a substantial decrease in food intake and body weight after peripheral treatment compared to Δ2 knockout and WT mice, respectively. Interestingly, we do not show an effect of leptin treatment on *Pomc* mRNA expression in the arcuate nucleus of either the Δ1 or Δ2 knockout mice using *in situ* hybridization and qPCR. Collectively, these data suggest that these two neural enhancers have dichotomous effects on food intake and body weight as a result of exogenous leptin treatment and that deletion of nPE2 may render mice less sensitive to the anorectic effects of leptin despite relatively normal levels of *Pomc* mRNA expression.

Title: Genetically anorexic and obese chickens differ in expression of hypothalamic genes involved in appetite and stress response mechanisms

Authors: *J. WANG, J. YI, E. R. GILBERT, P. B. SIEGEL, M. A. CLINE;
Dept. of Animal and Poultry Sci., Virginia Tech., Blacksburg, VA

Abstract: The Virginia lines of chickens were selected for either low (LWS) or high (HWS) body weight and are now comprised of individuals with different severities of anorexia and obesity, respectively. Differences exist between these lines in appetite-associated behaviors and hypothalamic gene expression that are accentuated by previous exposure to environmental stressors. In the current study, we determined the mRNA abundance of appetite-associated

neurotransmitters and receptors within four hypothalamic nuclei: the lateral hypothalamus (LH), paraventricular nucleus (PVN), ventromedial hypothalamus (VMH), and arcuate nucleus (ARC), in stressed and non-stressed chicks. After hatch, chicks were stressed and hypothalamic nuclei were collected 5 days later. Anorexigenic factors were distributed differently between the two lines. The PVN and ARC were the main sites in HWS, whereas in LWS the PVN and LH were the major target nuclei with greater expression of genes that encode anorexigenic neuropeptides and receptors. Compared to HWS, LWS expressed more neuropeptide Y (NPY) in the ARC and NPY receptor 5 (NPYR5) in the PVN, LH and ARC. In both lines, stress increased corticotrophin-releasing factor (CRF) mRNA in the PVN, CRF receptor 2 (CRFR2) and growth hormone secretagogue receptor (GHSR) in the VMH, CRF receptor 2 (CRFR2) and urocortin 3 (UCN 3) in the LH, and leptin, CRF and CRFR2 in the ARC. There were several interactions between line and treatment. Specifically, there was greatest expression of CRF receptor 1 (CRFR1) and UCN 3 in the PVN of stressed LWS chicks then in all other treatment group combinations. These results suggest that hypothalamic gene expression of appetite-associated factors may contribute to differences in feeding behavior and stress responses between HWS and LWS and thus provide insights for understanding the molecular basis for differences in eating disorders.

Title: Galanin neurons in the lateral hypothalamus modulate food reward and locomotor activity

Authors: E. QUALLS-CREEKMORE, S. YU, M. FRANCOIS, C. HUESING, C. MORRISON, H.-R. BERTHOUD, *H. MUNZBERG;
Pennington Biomed Res. Ctr., Baton Rouge, LA

Abstract: The lateral hypothalamus (LHA) is an important integrator of reward and appetitive behavior. Previous work in our lab has shown that LHA galanin neurons which co-express leptin receptors (LepRb) are implicated in food reward. Similarly, activation of LHA GABAergic neurons induces feeding behavior, and molecularly distinct populations of LHA GABA neurons may separately encode the consumption of food and the motivated behavior associated with food reward. Based on overall inhibitory central galanin actions, we hypothesized that LHA galanin neurons represent partially LHA GABAergic neurons. Thus, here we wanted to test if activation of LHA galanin neurons will modulate food reward behavior similarly to LHA GABA neurons. We examined the effect of chemogenetic activation of LHA galanin neurons on feeding behavior and metabolism with a cre-dependent adenoassociated virus for DREADD-Gq expression injected into the LHA of Galanin-cre mice. Our data show that chemogenetic activation of LHA galanin neurons increased food reward behaviors in an operant conditioning progressive ratio schedule. There was no change in consumption of palatable liquid diet (Ensure) in a free-access feeding task. We further verified chemogenetic activation in LHA GABA neurons in vGat-cre mice and successfully recapitulate increased food reward behavior. Also locomotor activity and energy expenditure was increased with activation of both LHA galanin and GABA neurons, suggesting that LHA galanin neurons represent a subset of GABA neurons that drive specifically food reward and locomotor activity. *Supported by R01DK092587, P20GM103629 (HM) P30DK072476 (SY, HM), T32-DK064584 (EQC)*

Sci., Chinese Acad. of Med. Sci. and Peking Union Med. Col., Beijing, China; [4]Southern Med. Univ., Guangzhou, China

Abstract: Hypothalamic Agouti related protein (AgRP) neurons, which are key regulators of energy and glucose homeostasis, receive and integrate neural and humoral signals. The mechanisms by which the hormones insulin and leptin acutely modify the electrical activity of these neurons remains unclear. Here we show that loss of the PI3K catalytic subunits, p110α and p110β, in AgRP neurons abrogates the leptin- and insulin-induced inhibition of AgRP neurons. Moreover, concurrent disruption of p110α and p110β in AgRP neurons results in increased weight gain. The increased adiposity was concomitant with a hypometabolic phenotype: decreased energy expenditure independent of changes in food intake. Deficiency of p110α and p110β in AgRP neurons also impaired glucose homeostasis and insulin sensitivity. In summary, these data highlight the requirement of both p110α and p110β in AgRP neurons for the proper regulation of energy balance and glucose homeostasis.

Title: Lateral hypothalamic neurotensin neurons engage the mesolimbic dopamine system to regulate locomotor and ingestive behavior

Authors: *H. WOODWORTH, G. KURT, H. BATCHELOR, J. BROWN, R. BUGESCU, G. LEINNINGER;
Michigan State Univ., East Lansing, MI

Abstract: The lateral hypothalamic area (LHA) acts in concert with dopamine (DA) neurons in the ventral tegmental area (VTA) to regulate the motivation to feed, drink and move. It remains unclear, however, how specific LHA neuronal populations modify ingestive and locomotor behaviors. We examined how LHA neurons expressing the neuropeptide neurotensin (Nts) engage the DA system to regulate behavior. LHA Nts neurons project to the VTA, where many DA neurons co-express neurotensin receptor 1 (NtsR1). Furthermore, these VTA NtsR1-DA neurons project to ventral striatal brain regions that regulate ingestive behavior and locomotor activity, such as the nucleus accumbens (NA). Activating the LHA Nts neuronal circuit using DREADD technology increases phospho-CREB in the NA, confirming that LHA Nts neurons functionally modulate the mesolimbic DA system. Next we examined the physiologic role of Nts signaling via this circuit, by activating LHA Nts neurons in wild-type (WT) mice and mice that lack NtsR1 (NtsR1KO mice). Activation of LHA Nts neurons increased locomotor activity and energy expenditure in both WT and NtsR1KO mice, which was blunted by a DA receptor 1 (DR1) antagonist. Activation of LHA Nts neurons also increased water intake in WT animals, but not NtsR1KO animals, indicating that NtsR1 is required for LHA Nts-induced drinking behavior. While activation of LHA Nts neurons did not alter chow intake in WT mice, it significantly increased food intake in both NtsR1KO mice and WT mice pre-treated with the selective NtsR1 antagonist, SR48692, indicating that NtsR1 is required to restrain feeding. Since the LHA Nts neuronal circuit increases energy expenditure without concomitant increase in feeding, we asked whether activation of the circuit could promote weight loss in obese mice. Chronic activation of LHA Nts neurons increased energy expenditure in diet-induced obese mice, but similar to mice with disrupted NtsR1 signaling, they also consumed more food and consequently did not lose weight. Together, these data reveal that LHA Nts neurons engage the mesolimbic DA system to modify feeding, drinking, and locomotor behaviors, and that intact signaling via NtsR1 is essential for maintaining appropriate ingestive behavior and body weight.

Title: Neuronal mechanisms involved in thermal tolerance of Antarctic fishes

Authors: *I. I. ISMAILOV[1], J. B. SCHARPING[2], I. E. ANDREEVA[1], M. J. FRIEDLANDER[1];
[1]Virginia Tech. Carilion Res. Inst., Roanoke, VA; [2]Virginia Tech. Carilion Sch. of Med., Roanoke, VA

Abstract: Antarctic teleosts *C. aceratus* (lacks hemoglobin, Hb-) and *N. coriiceps* (expresses hemoglobin, Hb+), both extremely stenothermic, are part of the suborder Notothenioidei that live on the Antarctic shelf at ~0°C. Hb- icefishes are less tolerant to acute increases in temperature (T°) than Hb+ animals, but the mechanisms of this difference are largely unknown. This study investigates for the first time the neural component of Notothenioid thermal tolerance by describing behavioral responses to rises in ambient T° as well as effects of local cerebellar and whole body warming on cerebellar Purkinje cells (PC) and the heart. Both Hb+ and Hb- species, freely swimming in a 700 L tank, responded to warming with a progressive increase in translational movement followed by a decline until loss of equilibrium occurred (average = 13.8±1.0°C in *C. aceratus* and 16.2±0.8°C in *N. coriiceps)*. Opercular beat frequency also exhibited a biphasic pattern, increasing with rises in T as little as 3°C and declining above 9°C in both species. Continuous bilateral pectoral fin movement without translation occurred in both species, at 6.5°C in *C. aceratus* (was also more pronounced) and at 10°C in *N. coriiceps*. Behaviors only characteristic of *N. coriiceps* began at ~6.5°C and included intermittent fin (anal, pelvic, dorsal, and caudal) "jerks", followed by body "jerks". Local step-wise warming of the corpus cerebelli of anesthetized fishes resulted in biphasic changes in spontaneous PC firing (increasing until ~17°C and then decreasing at higher T°, similar in both species) and elicited progressive bradycardia (greater in extent in *C. aceratus* and at lower T°, compared to *N. coriiceps*), reversible with cooling in both species. Irrigation of the gills of anesthetized animals with warmed water (while keeping the cerebellum chilled) led to progressive sinus tachycardia, followed by recurrent episodes of asystole in *N. coriiceps* and by a progressive bradycardia in *C. aceratus*, both leading to cardiac arrest with the onset not significantly different between Hb+ (18.5±2.0°C) and Hb- (19.7±1.8°C) species. In both fishes, tachycardia was accompanied by a decline in PC spiking. We conclude that 1) even slight warming leads to changes in motoric behavior in both species; 2) involuntary spastic activity in *N. coriiceps* at lower T° than in *C. aceratus* suggests that its nervous system is more susceptible to warming; 3) a central chemoreceptor zone may exist in the teleost cerebellum, modulating vagal tone on the heart; 4) the relationship between this zone and peripheral baro- and chemoreceptor modulation of cardiac and respiratory activity is yet to be determined. Title: Trpm8-/- mice have impaired core temperature regulation and altered body composition in response to three-week cold exposure

Authors: *K. J. MOTYL, C. ROSEN;
Maine Med. Ctr. Res. Inst., Scarborough, ME

Abstract: TRPM8 (the transient receptor potential cation channel, subfamily M, member 8) is expressed in sensory neurons and is a detector of environmental cold temperature. TRPM8 activation can induce UCP-1 dependent thermogenesis, which has been shown to be positive for bone health. With age, however, brown adipose tissue function declines concomitantly with loss of bone. We wanted to test how TRPM8 was involved in the co-regulation of these two tissues during aging of both male and female mice. At 52 weeks of age, male C57BL6/J mice with a global deletion of TRPM8 (*Trpm8-/-*) have significantly reduced core temperature, total body mass, fat mass and fat-free mass compared to male *Trpm8*+/+. Although female *Trpm8-/-* mice have reduced body mass and fat mass, they do not have significantly altered lean mass or core temperature compared to *Trpm8*+/+ females. The absence of TRPM8 also significantly reduced total body bone mineral density (BMD) and content (BMC) male, but not female, *Trpm8-/-* mice. When challenged at 18°C and 4°C, male *Trpm8-/-* mouse body temperature decreased significantly compared to *Trpm8*+/+ mice at the same temperatures, while female mice had no genotype-specific alterations in body temperature. Both male and female, +/+ and *Trpm8-/-* mice lost bone after 3 weeks at 4°C, indicating TRPM8 was not required for cold temperature-induced bone loss. In conclusion, male *Trpm8-/-* mice, which have impaired temperature regulation at baseline and in response to cold, also have reduced BMD and growth during the first year of life. These findings are consistent with previous literature suggesting that functional brown adipose tissue promotes bone density.

Title: Dorsal hypothalamic bombesin-like receptor-3 neurons regulate body temperature

Authors: *R. A. PINOL[1], S. H. ZAHLER[2], B. K. TAN[2], C. XIAO[2], O. GAVRILOVA[2], A. KRAVITZ[2], M. J. KRASHES[2], M. L. REITMAN[2];
[1]Natl. Inst. of Diabetes and Digestive and Kidney Dis., Bethesda, MD; [2]NIDDK, NIH, Bethesda, MD

Abstract: Bombesin-like receptor 3 (Brs3) is an orphan G protein-coupled receptor expressed in several brain regions, including the dorsomedial hypothalamic region and paraventricular nucleus of the hypothalamus (PVH). Targeted deletion of Brs3 in mice causes obesity, with reduced energy expenditure and increased food intake. Brs3 agonists suppress food intake and stimulate brown adipose tissue (BAT) through sympathetic activation, increasing energy expenditure. The current aim is to delineate the circuitry through which Brs3 neurons regulate energy expenditure and body temperature (Tb). We measured the effect of local injections of Brs3 agonist MK-5046 on BAT temperature. Small volume, nucleus-targeted, MK-5046 injections in the dorsomedial hypothalamus (DMH), but not the PVH, raised BAT temperature. To assess the effect of acute activation of Brs3 populations in freely moving, conscious mice we expressed the excitatory DREADD hM3D(q) in Brs3-T2A-CreER^{T2} mice. Chemogenetic activation of DMH^{Brs3} neurons increased total energy expenditure and Tb, without an effect on physical activity or food intake. Since projections of dorsal hypothalamic area (DHA)/dorsal DMH (dDMH) neurons to the brain stem raphe pallidus (RPa) have been implicated in the regulation of Tb, we optogenetically probed if the DHA/dDMH^{Brs3} projections to RPa mediate thermogenesis. As expected, fiber terminal stimulation of the DHA/dDMH^{Brs3} projections increased Tb in freely moving, conscious mice. Immunohistochemically detected fos in DHA/dDMH^{Brs3} neurons increased from 4.1 ± 0.35 % in acutely warm-exposed to 24 ± 1.7 % in acutely cold-exposed animals. Accordingly, ablation (with a Cre-dependent diphtheria toxin A virus) of DMH^{Brs3} neurons in adulthood reduced the cold defense response compared to control mice (Cre-dependent GFP virus), but did not alter the stress-induced hyperthermic response. Body weight and food intake (chow or high-fat diet) were not affected by DMH^{Brs3} neuron ablation. These results suggest that the food intake suppression and thermogenic effects of Brs3 activation can be mediated by different subsets of Brs3-expressing neurons. Specifically, DHA/dDMH^{Brs3} neurons are able to increase energy expenditure and BAT temperature through projections to the RPa.

Title: The insulin-like growth factor 1 receptor modulates core body temperature during calorie restriction

Authors: *R. CINTRON-COLON[1], M. SANCHEZ-ALAVEZ[1], W. NGUYEN[1], S. MORI[1], T. BARTFAI[2], M. HOLZENBERGER[3], B. CONTI[1];
[1]Chem. Physiol., The Scripps Res. Inst., La Jolla, CA; [2]Neurochemistry, Univ. of Stockholm, Stockholm, Sweden; [3]Inst. Natl. de la Santé et de la Recherche Médicale, Ctr. de Recherche UMR938, Hôpital Saint-Antoine, Paris, France

Abstract: In homeotherms, including rodents and humans, efficient thermoregulatory mechanisms maintain core body temperature within a narrow range against large differences in ambient temperature. However, when nutrients availability is limited, homeotherms can reduce their core body temperature. This response is regarded as an adaptive mechanism that decreases energy expenditure and it is believed to have evolved to prolong survival until food becomes available. Using genetic and pharmacological approaches in mice, we have found that the insulin-like growth factor 1 signaling pathway participates in the modulation of core body temperature during *ad libitum* feeding and likewise in calorie restriction in a gender-specific manner. Pharmacological blockade of the IGF-1R signaling induced hypothermia in male and female mice. In addition, central but not peripheral administration of recombinant IGF-1 prevented core body temperature reduction during calorie restriction. Similar results were obtained with mice carrying a hemizygous null mutation of the gene encoding the IGF-1 receptor, *Igf1r*$^{+/-}$, previously described to have reduced IGF-1R signaling and increased female lifespan. Compared to wild type littermates, female but not male *Igf1r*$^{+/-}$ mice had transient and circadian robust reduction of core body temperature when fed *ad libitum* and displayed an enhanced hypothermic response to calorie restriction. These findings indicate that IGF-1 receptors play a role in regulating the hypothermic response to calorie restriction and suggest that the mechanisms by which lowering IGF-1 signaling promotes longevity in homeotherms include core body temperature reduction.

Title: Heterotypic signaling by neural HSF-1 specifies thermotolerance and age regulation

Authors: *I. J. GONZALEZ[1], P. M. DOUGLAS[2];
[1]Sch. of Behavioral and Brain Sci., Univ. of Texas At Dallas, San Marcos, TX; [2]Dept. of Mol. Biol., Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Heat Shock transcription Factor (*HSF-1*) orchestrates elaborate responses which enable animals to combat various cellular challenges ranging from acute injury to chronic stresses that can evolve into disease over time. During acute heat stress, *HSF-1* mediated induction of molecular chaperones buffers widespread protein misfolding and helps restore protein homeostasis in cells. Ectopic expression of *HSF-1* exclusively in the nervous system of *C. elegans* protects young worms against heat stress and extends lifespan. Under heat, *HSF-1* in the nervous system bolsters the magnitude of heat-induced chaperone expression and protects young worms. However, no chaperone induction is observed at permissive temperatures in long-lived worms expressing *HSF-1*. Instead, neuronal *HSF-1* signals to intestinal tissues and promotes the activation of the *FOXO* transcription factor, *DAF-16*, which mediates longevity assurance. Previous research has implicated the actin cytoskeleton as being an important target of *HSF-1* mediated increase in lifespan and thermotolerance. We identify a specific intestinal isoform of actin, ACT-5, as being an important target of *HSF-1* which provides an essential barrier to pathogenic invasion and ensures protection against stress and age. Furthermore, we seek to determine whether ectopic expression of *HSF-1* exclusively in the nervous system of *C.*

elegans can induce the protective effects of *HSF-1* in the intestine via bolstering of the actin cytoskeleton.

Title: Activation of TRPV1 receptors in the vagus nerve exacerbates thermal hyperpnea in immature rats

Authors: *K. BARRETT[1], A. ROY[2], R. J. A. WILSON[3], M. H. SCANTLEBURY[4]; [1]Pediatrics, Alberta Children's Hosp. Res. Inst., [2]Physiol. and Pharmacol., [3]Physiol. and Pharmacology, Alberta Children's Hosp. Res. Inst., [4]Pediatrics, Clin. Neuroscience, Alberta Children's Hosp. Res. Inst., Univ. of Calgary, Calgary, AB, Canada

Abstract: Rationale: Thermoregulation in mammals involves a complex interplay of autonomic and behavioral responses, including hyperthermia induced increases in breathing (thermal hyperpnea); immature animals are affected to a greater extent compared to adults. The vagus nerve has also been implicated in the thermal hyperpneic response. The mechanisms underlying this effect are incompletely understood, but may implicate the transient receptor potential vanilloid-1 (TRPV1) receptor which is a heat sensitive ionic channel. In this study we investigated the role of TRPV1 in thermal hyperpnea in immature rats.
Methods: Postnatal day (P) 10 rats were treated with the TRPV1 agonist, piperine, and the respiratory response to hyperthermia was assessed using head-out plethysmography in rats having the vagus nerve sectioned bilaterally or left intact. We also investigated the possibility of using DREADD (Designer Receptors Exclusively Activated by Designer Drugs) technology to specifically target TRPV1 expressing cells in the nodose ganglia of the vagus nerve to confirm their role in thermal hyperpnea. Confocal microscopy and neural recordings were used to assess

expression and functionality of the DREADD, respectively, in P15 rats that were injected with the construct at P1.
Results: Compared to vehicle-treated controls, pups injected i.p. with piperine exhibited an early, rapid and significantly greater increase in respiratory rate ($p<0.024$), tidal volume ($p<0.02$), minute ventilation ($p<0.042$) and rate of expired CO_2 ($p<0.02$). Pre-treatment with AMG-9810 (TRPV1 antagonist) significantly attenuated these effects of piperine ($p<0.019$). The exacerbation in the thermal hyperpneic response noted in rats treated i.p. with piperine was not observed in rats treated i.c.v. Vagotomy also reversed the effects of piperine on breathing in response to hyperthermia; tidal volume ($p=0.002$), minute ventilation ($p<0.01$) and rate of expired CO_2 ($p<0.01$). Regarding the DREADD experiments, we have successfully expressed the DREADD in the P15 rat nodose ganglia of the vagus nerve following injections of the construct at P1.
Conclusion: These results support that activation of TRPV1 receptors localized in the vagus nerve exacerbates the thermal hyperpneic response which may play a key role in thermoregulation. This may have important implications in certain pathophysiological conditions in which the TRPV1 receptor is sensitized, such as during inflammation.

Title: A TRP channel serves as a hypothalamic heat sensor that regulates thermal homeostasis

Authors: *H. WANG[1], K. SONG[2,1], G. KAMM[1], F. DE CASTRO REIS[3], P. HEPPENSTALL[3], H. WENDE[1], J. SIEMENS[1,4];
[1]Inst. of Pharmacol., Univ. of Heidelberg, Heidelberg, Germany; [2]Max Delbrück Ctr. for Mol. Med., Berlin, Germany; [3]Mouse Biol. Unit, European Mol. Biol. Lab. (EMBL), Monterotondo, Italy; [4]Mol. Med. Partnership Unit (MMPU), European Mol. Biol. Lab. (EMBL), Heidelberg, Germany

Abstract: Body temperature homeostasis is critical for survival and well-being of all mammals. The hypothalamus comprises the principal higher-order brain center which regulates thermal homeostasis. The anterior part of hypothalamus, namely the preoptic area (POA), detects and regulates internal temperature via feedback mechanism. Previous electrophysiological recordings have identified a group of neurons, whose firing rates increases with a rise of local temperature. It has been proposed that body temperature is encoded by the firing rate of these warmth-sensitive neurons (WSNs).
Here, we have identified a TRP channel as a primary temperature sensor in WSNs. We demonstrate that the TRP channel mediates temperature-dependent calcium rise in neurons both in dispersed POA cultures and POA slice preparations. The temperature-sensitivity is largely abrogated in neuronal cultures obtained from global channel knockout brains.
To gain in vivo access to this group of neurons, we generated a Cre mouse line which labels the TRP channel-expressing cells with Cre recombinase. We injected cre-dependent DREADD-virus stereotactically into the POA of Cre mice to achieve spatial and temporal control of neuronal activity, specifically in the TRP channel-positive POA neurons.
Interestingly, chemogenetic activation or inhibition of the TRP channel-positive neurons bi-directionally modulates body temperature. To our surprise, chemogentic activation triggers reliable deep hypothermia of the mice, in part by peripheral vasodilation. In addition, this effect could be fully reproduced by only targeting an excitatory subpopulation of the TRP channel-positive neurons, which constitutes only 6% of the TRP+ neurons.
By tracing the outputs of these neurons, we have obtained evidence that neurons in the paraventricular nuclei of the hypothalamus (PVH) receive excitatory input from the TRP-expressing POA neurons and the PVH may potentially relay the hypothermic phenotype to downstream effector organs.
Taken together, we have identified a primary molecular warmth sensor of WSNs and address the importance of thermosensitive TRP channels in temperature interoception. Our work offers an entry point for the genetic dissection of hypothalamic thermoregulatory circuits.

Title: Effects of pharmacologically induced physiological need states on reward processing through intracranial self-stimulation.

Authors: *J. L. SEILER, S. M. CONWAY, M. F. ROITMAN;
Psychology, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Hunger potentiates goal-directed behavior for food and other rewards as well. The mechanisms by which hunger, and other physiological need states, act to motivate behavior remain incompletely understood. Recent work has demonstrated that hunger and thirst may motivate behavior through the generation of a negative affective state for which animals will actively work to alleviate. However, these conclusions are based on results from selective central manipulations to induce the need states and a very specific behavioral paradigm (e.g. real-time place preference). To test whether these results can generalize to other manipulations and behavioral paradigms, here, rats were implanted with stimulating electrodes positioned in the ventral tegmental area and an infusion cannula in the lateral ventricle. We then used intracranial self-stimulation (ICSS) to assess the affective state of rats after different pharmacological manipulations that induce feeding and drinking behavior. Rats were trained to lever press for brain stimulation reward (BSR) on a decreasing logarithmic scale of frequencies (termed 'pass') to determine the threshold at which BSR was no longer reinforcing. Training continued until rats maintained stable BSR threshold values for a minimum of 3 consecutive days. On test days, and after 3 passes, rats received central infusions of feeding- (ghrelin, neuropeptide Y (NPY), and 5-thio-d-glucose (5TG)) or drinking- (angiotensin II) inducing agents into the lateral ventricle followed immediately by an additional 6 passes. Data were then expressed as percent change in threshold relative to the average of the 3 pre-infusion passes. While NPY and 5TG caused increases in threshold (25.39 ± 11.16 and 29.43 ± 6.42 %, respectively), only ghrelin caused a significant increase (44.28 ± 11.9 %; $p<0.05$) relative to saline infusion (-1.34 ± 3.98 %). The direction of the effect is interpreted as an attenuation of BSR and is reminiscent of other pharmacological agents that induce negative affective states. Angiotensin II infusion had no effect on threshold (3.66 ± 6.2 %). These data are consistent with recent work suggesting that need states induce negative affect. However, different behavioral assays likely are differentially sensitive to changes in need states. Moreover, ICSS is sensitive to aspects of hunger but not thirst.

Title: Mu-opioid receptor inhibition decreases voluntary wheel running in a dopamine-dependent manner rats in bred for high voluntary running

Authors: *G. RUEGSEGGER, F. BOOTH;
Univ. of Missouri, Columbia, MO

Abstract: The mesolimbic dopamine and opioid systems are postulated to influence the central control of physical activity motivation. To further understand the inherited neurobiological factors that contribute to physically active and inactive behaviors, we utilized selectively bred rats for high (HVR) or low (LVR) voluntary running behavior to examine: 1) inherent differences in mu-opioid receptor (Oprm1) expression and function in the nucleus accumbens (NAc), a brain region postulated to influence rewarding behaviors, 2) if wheel-running and food intake are differently influenced by intraperitoneal (i.p.) (5, 10, 20mg/kg) injection of the opioid receptor antagonist naltrexone in HVR and LVR rats, and 3) if dopamine is necessary for naltrexone-induced changes in running and feeding behavior in HVR rats. Experiment 1: Oprm1 mRNA and protein expression were increased in the NAc of HVR rats ($p< 0.05$). Application of the Oprm1 agonist D-Ala2, NMe-Phe4, Glyo5-enkephalin (DAMGO) to dissociated NAc neurons produced depolarizing responses in 44% (7/16) of HVR, and 25% (4/16) of LVR neurons. In depolarizing cells, the mean average response to DAMGO was greater in HVR (13.08 ± 2.50mV) than LVR neurons (4.90 ± 1.21mV, $p= 0.04$). Experiment 2: Naltrexone dose-dependently decreased wheel running and food intake in HVR, but not LVR, rats following i.p. ($p< 0.01$) injection. Experiment 3: i.p. naltrexone injection (20mg/kg) during the dark-cycle decreased Th mRNA in the ventral tegmental area (VTA) and Fos, Drd1, and Drd5 ($p< 0.05$) mRNAs in NAc shell of HVR, but not LVR, rats 2h post-injection. Experiment 4: lesion of dopaminergic neurons in the NAc with 6-hydroxydopamine (6-OHDA) ablated the decrease in running, but not food intake, observed in HVR rats following i.p. naltrexone administration. Collectively, these data suggest the higher levels of running observed in HVR rats, compared to LVR rats, are mediated, in part, by increased mesolimbic opioidergic signaling that requires downstream dopaminergic activity to influence voluntary running, but not food intake.

Title: Optogenetic modulation of the subthalamic nucleus impairs the motivation for food in rats.

Authors: *A. TIRAN-CAPPELLO[1], Y. PELLOUX[2], C. MONTANARI[1], M. DEGOULET[1], C. BAUNEZ[1];
[1]CNRS - Inst. De Neurosciences De La Timone, Marseille, France; [2]NIH, Natl. Inst. on Drug Abuse Intramural research program, Baltimore, MD

Abstract: Among the basal ganglia, the subthalamic nucleus (STN) is a well-known structure in the treatment of Parkinson's disease as it represents the major target for application of deep brain stimulation (DBS). Over the past few years, the increasing evidence that STN is critical for limbic and associative processes, lead to investigate its relevance as a potential target for the treatment of addiction and compulsive disorders. It has been established that the inactivation of the STN by various methods (lesion and high-frequency DBS) enhances the motivation for food and reduces the motivation for cocaine (for review Pelloux and Baunez, 2013). These opposite properties regarding natural reward and drugs of abuse appear to be a unique feature of the STN. In order to further characterize its role in the modulation of reward and motivation, we used optogenetic tools to modulate the activity of the rat STN. We injected either a fast kinetic Channelrhodopsin (ChetaTC) or an inhibitory Archaerhodopsin in the STN and tested whether light stimulation could alter food motivation in a similar manner to what was observed with electric DBS. For this purpose, we subjected the rats to FR5 and PR schedules, using sweet food pellets as reinforcer, to monitor their willingness to work despite a low or increasing amount of effort, respectively.
Interestingly, optogenetic stimulation using ChetaTC and electrical stimulation at high frequencies induce opposite behavioral responses, suggesting optogenetic stimulation enhances neuronal activity within the STN in contrast to electrical DBS.

Title: Optogenetic excitation in the ventral tegmental area of glutamatergic or cholinergic inputs from the laterodorsal tegmental area drives reward

Authors: *S. STEIDL[1], H. WANG[2], M. ORDONEZ[1], A. CHAKRABORTI[2], S. ZHANG[2], M. MORALES[2];
[1]Psychology, Loyola Univ. Chicago, Chicago, IL; [2]Neural Networks Section, Integrative Neurosci. Res. Br., Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Converging evidence shows that dopamine neurons of the ventral tegmental area (VTA) receive both cholinergic and glutamatergic inputs from the laterodorsal tegmental nucleus (LDTg). By combining retrograde tract tracing, immunolabeling and in situ hybridization, we found that a higher proportion of LDTg-glutamatergic than LDTg-cholinergic neurons innervate the VTA in rats. We then compared the behavioral effects of VTA light stimulation of fibers from either LDTg-cholinergic or LDTg-glutamatergic neurons, using a 3-chamber place preference apparatus. For these studies, channelrhodopsin-2 (ChR2) was expressed in cholinergic neurons in the LDTg of ChAT::Cre mice (ChAT-ChR2 mice) or in glutamatergic neurons in the LDTg of VGluT2::Cre mice (VGluT2-ChR2 mice). ChAT-ChR2 mice, whose entry into a light-paired chamber resulted in VTA light stimulation of LDTg-cholinergic axons for the duration of their chamber stay, spent more time in this chamber. On a subsequent test day ChAT-ChR2 mice showed a conditioned place preference for the light-paired chamber in the absence of light. VGluT2-ChR2 mice, whose entry into a light-paired chamber resulted in VTA light stimulation of LDTg-glutamatergic axons for the duration of their chamber stay, entered this chamber significantly more times than a light-unpaired chamber, but remained in the light-paired chamber for short time periods and did not show a conditioned place preference. When entry into the light-paired chamber resulted in a single train of VTA light stimulation, VGluT2-ChR2 mice also entered the light-paired chamber significantly more times than the light-unpaired chamber, but spent approximately equal amounts of time in the two chambers. We suggest that excitation of LDTg-glutamatergic inputs to the VTA may be more important for the reinforcement of initial chamber entry while excitation of LDTg-cholinergic inputs to the VTA may be more important for the rewarding effects of chamber stays. We suggest that LDTg-cholinergic and LDTg-glutamatergic inputs to the VTA each contribute to the net rewarding effects of exciting LDTg axons in the VTA.

Title: Persistent conditioned place preference to rewarding aggression experience in male CD-1 mice

Authors: *C. HEINS[1], S. GOLDEN[1], S. RUSSO[2], Y. SHAHAM[1];
[1]Natl. Inst. on Drug Abuse, NIH, Baltimore, MD; [2]Dept. of Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York City, NY

Abstract: We recently developed a conditioned place preference (CPP) procedure, commonly used to study the rewarding effects of abused drugs, to demonstrate that dominant CD-1 male mice form CPP to a context previously associated with defeating subordinate C57 mice. Here we further characterized this aggression reward phenomenon. In Exp. 1, we screened CD-1 mice (10 sessions) that displayed a spectrum of unconditioned aggressive behavior toward younger subordinate C57 intruder mice. We then trained the CD-1 mice in the CPP procedure where one context was intruder-paired while the other context was not. We tested for aggression CPP 1 day after training. In Exp. 2, we used a similar procedure and tested the CD-1 mice for aggression CPP 1 day and 18 days after training. In Exp. 3, we trained the CD-1 mice tested in Exp. 2 to lever-press for palatable food and tested them for footshock punishment-induced suppression of food-reinforced responding. We found robust and persistent aggression CPP in CD-1 mice that either immediately attacked the C57 mice during all screening sessions (aggressive phenotype, ~50% of the sample) or mice that gradually developed the aggressive behavior during the screening phase (variable aggressive phenotype, ~25%). In contrast, CD-1 mice that did not attack the C57 mice during the screening days (non-aggressive phenotype, ~25%) developed conditioned aversion to the context previously paired with the C57 mouse. We also found that the aggressive phenotype did not predict resistance to punishment. Results demonstrate that like experience with abused drugs, aggression experience is highly rewarding and persistent.

Title: Addiction-like aggressive behavior in CD1 mice

Authors: *S. A. GOLDEN, R. C. HEINS, D.-T. LIN, Y. SHAHAM;
Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Background: Two core features of drug addiction are high motivation to seek the drug and high relapse rates during abstinence. These features have been studied for many years using rodent models of drug self-administration and relapse. Based on evidence in humans that some aggressive individuals are highly motivated to seek aggressive encounters, and that violent offenders show high relapse rates, we studied whether these 'addiction-like' features are observed in mouse models of aggression self-administration and relapse.
Methods: In Exp. 1, we trained adult male retired breeder CD-1 mice to lever-press to gain access to attack subordinate male C57BL6/J intruder mice on an ascending 2^{nd} order reinforcement schedule (1^{st} order lever: FR2, FR5, FR10, FR20 for 2 days each; 2^{nd} order lever: FR1) using a 15-block design (3 min ITI), and then tested them on a progressive ratio reinforcement schedule. In Exp. 2, we trained CD-1 mice for aggression self-administration on an FR1 reinforcement schedule for 9 days using a 20-block design. We then tested them for relapse to aggression seeking under extinction conditions (30-min tests) after 1 or 14 abstinence days.
Results: In Exp. 1, CD1 mice readily acquired operant aggression self-administration on the 2^{nd} order schedule and maintained aggression self-administration under the progressive ratio schedule. In Exp. 2, the mice were highly motivated to seek aggression reward in the relapse tests after 1 and 14 abstinence days.
Conclusion: Aggressive CD-1 mice show addiction-like behavior characterized by high motivation to perform an operant response to attack another mouse and persistent relapse vulnerability during abstinence.

Title: Restricted access to palatable food induces neuronal plasticity and behavioral changes similar to addiction

Authors: *G. MUÑOZ ESCOBAR, SR[1], S. D. GRACIA GONZALEZ[2], C. ESCOBAR BRIONES[2];
[1]Anatomía, Facultad de Medicina, Univ. Nacional Autonoma De México, Distrito Federal, Mexico; [2]Dept. de Anatomia, Univ. Nacional Autonoma de México, México, Mexico

Abstract: Restricted access to palatable food (PF) in satiated rats induces anticipatory activity, binge eating and increase of neuronal activity in corticolimbic areas, suggesting an addiction-like behavior. The aim of the present study was to determine whether PF access needs to be restricted in order to generate the addiction-like behavior and to identify behavioral and neuronal changes that provide evidence of an addiction process. To asses this hypothesis we compared: in rats with free access to regular chow and water: 1. Control group (CTRL)-no access to PF, 2. restricted daily access to PF (5 gr chocolate) with a fixed schedule (CH-ENTR), 3. PF (5 gr chocolate) delivered daily with a random schedule (CH-RDA), 4. PF ad libitum (CH-ADLIB): After 4 weeks we found that CH-ENT rats developed anticipatory activity and entrained body temperature, exhibiting a significant decrease of temperature in anticipation to chocolate access, similar to the changes observed in animal models of drug addiction. Such entraining effects were not observed in CH-RDA rats. In a test of effort, all groups of rats were exposed during 5 min to a sealed wire-mesh box containing a piece of chocolate and interaction with the box was monitored, during base line all rats were exposed to an empty box. We observed that both groups under restricted access to PF (CH-ENTR/CH-RDA) showed increased effort behaviors in order to obtain chocolate, indicating that restriction is enough to produce an increase in the motivation and effort to obtain PF. After 21 days of chocolate withdrawal, CH-ENTR and CH-RDA rats exhibited a binge episode, when allowed access to a bar of chocolate. Daily restricted access induced accumulation of αFosB protein and increased GFAP protein in the nucleus Accumbens, Basolateral amygdala and Prefrontal cortex. The magnitude of plastic changes correlated with the intensity of binge eating and effort behaviors to obtain chocolate. We conclude that daily restricted access to PF promotes the development of neuronal plasticity and behavioral changes associated with addiction-like behavior to food. Acknowledgments. Title: Amygdalar, accumbal and ventral tegmental ghrelin and endocannabinoid signaling in alcohol reward

Authors: H. M. BAUMGARTNER, L. J. ZALLAR, S. ABTAHI, E. E. GARLING, *P. J. CURRIE;
Dept. Psychology, Reed Col., Portland, OR

Abstract: Extensive evidence now implicates the gastric peptide ghrelin in the regulation of homoestatic and energetic circuits of the hypothalamus. More recent work has investigated the role of ghrelin in alcohol reward. Indeed we have previously reported that systemic and ventral tegmental (VTA) ghrelin treatment significantly increases alcohol intake whereas hypothalamic injections do not reliably stimulate consumption. In the present report we confirm that both VTA and accumbal ghrelin microinjections increase alcohol intake at 2 and 6 h post-administration. In this paradigm rats were gradually habituated to 8% alcohol, and maintained at 8%, over the course of 12 weeks. In subsequent testing we investigated the effects of ghrelin, in separate groups of rats, with guide cannula aimed at either the central nucleus of the amygdala (CeA), the basolateral amygdala (BLA), the nucleus accumbens (NAcc), or the VTA. These groups of rats had limited prior alcohol exposure of no more than 4 weeks before treatment began. In all treatment groups, ghrelin did not stimulate alcohol consumption whereas food intake was increased in the VTA after ghrelin injection. Further, the CB1 inverse agonist, AM251, alone decreased alcohol and food consumption after injection into the CeA whereas VTA AM251 attenuated ghrelin's action. Overall our findings indicate that ghrelin is most effective in altering alcohol intake in Sprague Dawley rats with chronic prior alcohol exposure, and with stabilized alcohol intakes, whereas the peptide's role in early alcohol exposure does not appear to be robust. Additionally, our work provides some support for CeA endocannabinoid signaling in alcohol consummatory behavior.

Title: Neurochemical phenotype of cannabinoid CB1 receptors in the ventral tegmental area of mice

Authors: *C. ZHAO[1], L. RITERS[1,2], S. GAMMIE[1,2];
[1]Zoology, Univ. of Wisconsin-Madison, Madison, WI; [2]Neurosci. Training Program, Univ. of Wisconsin-Madison, Madison, WI

Abstract: Cannabinoid CB1 receptors modulate motivation, reward, and addiction-related behaviors via interacting with dopaminergic and GABAergic signaling pathways in the ventral tegmental area (VTA). However, neuroanatomical evidence in support of an intimate functional crosstalk between CB1 receptors and dopaminergic as well as GABAergic systems in the VTA remains fairly limited. In trying to define the expression of CB1 receptors and clarify the phenotype of CB1-containing neurons in the VTA of postpartum female mice, we used confocal microscopy and a double immunofluorescence labeling with tyramide signal amplification (TSA). Our results revealed that intensely labeled CB1-immunoreactive neurons were abundantly expressed throughout VTA, with the immunoreactivity predominantly located in the neuronal cell bodies. VTA CB1-immunoreactive neurons co-displayed tyrosine hydroxylase (TH, a marker for dopaminergic neurons) immunoreactivity within single cells and the levels of coexpression of CB1 and TH varied depending on the subdivision examined. Specifically, paranigral nucleus (PN, 70.5%) and parabrachial pigmented nucleus (PBP, 65.5%) displayed high rates of colocalization, while the lowest percentage of colocalization existed in the rostral linear raphe nucleus (RLi, 2.3%). As identified by markers for GABAergic neurons, the vast majority of CB1-expressing cells (82.8-88.4%) were GABA-immunoreactive in the VTA, regardless of the subdivisions tested. Further analysis with calcium-binding proteins as markers for GABAergic interneurons, demonstrated that a portion of CB1-expressing cells were local GABAergic interneurons as they displayed a distinct pattern of coexpression with calbindin D-

28K and calretinin. In conclusion, these data provide a neuroanatomical basis for the functional links for how endocannabinoid signaling interacts with both dopaminergic and GABAergic systems in the modulation of reward-related behaviors in the VTA.

Title: Glutamatergic and GABAergic projections from the Lateral Preoptic Area to the Lateral Habenula differentially drive motivated behavior.

Authors: *D. J. BARKER, J. MIRANDA BARRIENTOS, D. ROOT, H. WANG, S. ZHANG, M. MORALES;
Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: The Lateral Habenula (LHb) has been identified as a brain region that plays important roles in addiction and depression. A primary input to the LHb comes from the Lateral Preoptic Area (LPO). Here, we characterized the anatomical and functional network between the LPO and the LHb. To identify specific LPO neurons targeting the LHb, the retrograde tracer fluorogold was injected into the LHb (1% via iontophoresis). Next, we established the phenotype of the fluorogold-tagged neurons by *in situ* hybridization detection of transcripts encoding either glutamic acid decarboxylase 65/67 mRNA (GAD, a marker of GABAergic neurons) or vesicular glutamate transporter 2 mRNA (VGluT2, a marker of glutamate neurons). Surprisingly, we found that within the total population of fluorogold-positive neurons only 15.9 ± 3.2% expressed GAD mRNA, and as many as 74.7 ± 3.2% expressed VGluT2 mRNA. To establish the functional role of LPO inputs to the LHb, we transfected glutamatergic or GABAergic neurons of the LPO with channelrhodopsin-2 and stimulated terminals in the LHb. *In vitro* stimulation terminals during whole cell recordings support anatomical data, showing weak inhibitory currents and stronger excitatory currents. Ongoing *in vivo* stimulation suggests that glutamatergic and GABAergic neurons both elicit motivated behavior, but of opposing valence. These findings provide evidence for a major excitatory projection and minor inhibitory projection from the lateral preoptic area to the lateral habenula that had been previously uncharacterized. Based on our current understanding of the habenula, this suggests that the LPO-LHb glutamatergic

pathway may be important for numerous psychopathologies including depression or the aversive effects of psychostimulants. Future work will focus on the participation of the LPO-LHb glutamatergic pathway in ongoing behavior in order to specifically investigate its participation in psychiatric illness.

Title: The lateral habenula has vesicles that accumulate either GABA or glutamate

Authors: *S. ZHANG[1], D. H. ROOT[2], D. J. BARKER[2], M. MORALES[2];
[1]Natl. Inst. of Health, Natl. Inst. on Drug Abuse, IRP, Baltimore, MD; [2]Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: The laberal habenula (LHb) is involved in reward, aversion, addiction and depression through descending interactions with several structures, including the ventral tegmental area (VTA). Our recent studies have revealed that within the LHb a single axon terminal from VTA neurons co-transmit glutamate and GABA via a previously unrecognized combinatorial synaptic architecture. In this combinatorial synaptic architecture single axon terminals co-express vesicular glutamate transporter 2 (VGluT2) and vesicular GABA transporter (VGaT), establish both asymmetric and symmetric synapses, express AMPA receptors postsynaptic to asymmetric synapses, and express GABA-A receptors postsynaptic to symmetric synapses (Root et al., 2014). The spatial segregation of asymmetric and symmetric synapses within single mesohabenular axon terminals suggests that glutamate and GABA are released at different synapses and from distinct synaptic vesicles. However, it remains to be untested if dual glutamatergic-GABAergic neurons store glutamate (via VGluT2) and GABA (via VGaT) in the same vesicular populations. To determine whether glutamate and GABA are stored and released from the same or from a different pool of vesicles, we purified synaptic vesicles from the LHb of Sprague-Dawley rats (n = 60). By dual immunolabeling of these isolated synaptic vesicles and their analysis under electron microscopy, we detected two distinct pools of vesicles, a pool of vesicles containing VGluT2-immunolabeling and another pool containing VGaT-

immunolabeling. We found that from a total of 2,815 immunolabeled vesicles 58.92 ± 0.97% expressed VGluT2, 38.92 ± 0.81% expressed VGaT, and a very small proportion (2.15 ± 0.29%) appeared to co-label for VGluT2 and VGaT. The lack of co-existence of VGluT2 and VGaT at the vesicular level was next confirmed by the lack of co-immunoprecipitation of VGluT2 and VGaT from the isolated vesicles. Consistent with our ultrastructural findings, protein preparations of vesicles immunoprecipitated with antibodies to VGluT2 showed vesicular immunodetection of both VGluT2 and the vesicular marker synaptophysin, but not VGaT. Moreover, protein preparations of vesicles immunoprecipitated with antibodies to VGaT showed vesicular immunodetection of both VGaT and synaptophysin, but not VGluT2. Therefore, we conclude that within the LHb, accumulation of glutamate by VGluT2 occurs in vesicles different from those that accumulate GABA by VGaT.

Title: Corticosterone in the ventral hippocampus differentially affects accumbal dopamine release in drug-naive and amphetamine-withdrawn rats

Authors: *B. BRAY, M. A. WEBER, G. FORSTER;
Basic Biomed. Sci., Univ. of South Dakota Sanford Sch. of Med., Vermillion, SD

Abstract: Amphetamine withdrawal is associated with dysphoria and hypersensitivity to stress in humans and rats that can prompt relapse. This effect may be mediated by enhanced stress-induced corticosterone in the ventral hippocampus (vHipp), as is observed in rats. vHipp corticosterone can induce glutamate release and the vHipp sends glutamatergic projections to the nucleus accumbens shell (NAcS) to enhance dopamine output and reward salience. To directly test whether vHipp corticosterone can enhance accumbal dopamine output, a stress-relevant concentration of corticosterone (0.28 ng/µl) was infused into the vHipp of anesthetized adult male Sprague-Dawley drug-naive rats and in rats during amphetamine withdrawal. Resulting NAcS dopamine output was measured by *in vivo* chronoamperometry. In drug-naive rats, vHipp corticosterone *enhances* accumbal dopamine output, peaking 55 min post infusion. This suggests a novel mechanism by which stress exposure could enhance reward value to promote goal-

oriented behavior. Corticosterone activation of glucocorticoid receptors (GRs) is thought to be excitatory in the vHipp. Preliminary findings suggest the dopamine increase can be blocked by the GR antagonist mifepristone, implicating GRs as the underlying mechanism for the corticosterone-induced accumbal dopamine output. In amphetamine withdrawal, vHipp corticosterone immediately *reduces* accumbal dopamine output, peaking 20 min and then 80 min post-infusion. This suggests stress-induced corticosterone in the vHipp could contribute to dysphoric states that prompt drug-seeking and relapse during withdrawal. Furthermore, findings support an opponent-process theory of addiction, in which blunted dopamine reward responses and enhanced corticosterone stress responses contribute to negative reinforcement of drug-taking. GR expression is reduced in the vHipp during amphetamine withdrawal, but vHipp mineralocorticoid receptor (MR) expression is not altered. Thus, corticosterone activation of vHipp MRs may mediate the reduction in accumbal dopamine output during withdrawal, which is currently being tested. Overall, these findings suggest the neural corticosterone system could play an important role in driving positive stress coping mechanisms in healthy conditions, with dysregulation of this system potentially contributing to relapse during amphetamine withdrawal.

Title: Physical effort discounts ACC-VTA moment-by-moment estimates of future reward

Authors: *T. W. ELSTON[1,2], D. K. BILKEY[1,2];
[1]Psychology, Univ. of Otago, Dunedin, New Zealand; [2]Brain Hlth. Res. Ctr., Dunedin, New Zealand

Abstract: A recent value-state theory of dopaminergic signalling suggests that activity in dopaminergic brain areas represents a temporally discounted, moment-by-moment estimate of future reward such that the signal ‘ramps up’ as the temporal distance to an expected reward decreases. We asked if changes in the response requirements to attain a fixed reward would alter the activity in brain areas that may signal this value-state. We hypothesized (i) that an increase in the physical effort required to attain a fixed reward will lead to reduced activity and (ii) that a decrease in the physical effort required to attain a fixed reward will lead to increases in activity.

We examined anterior cingulate cortex (ACC) and ventral tegmental area (VTA) local field potentials in freely-moving rats as they performed a cue-guided effort task in which a visual cue signalled either a non-effortful or an effortful upcoming trial. In the effortful condition, rats had to climb over a 30cm barrier to obtain a fixed reward. VTA theta (4-12 Hz) power decreased immediately prior to the barrier ($p < .005$), potentially indicating a discounting of the instantaneous value of the upcoming reward. In contrast, ACC and VTA theta power increased abruptly ($p = 5.8 \times 10\text{-}5$ and $p < .005$, respectively) when the rat entered the barrier-containing region of the maze on trials when the barrier was absent, potentially indicating an increase in the instantaneous reward value. Additionally, cross-frequency coupling of VTA gamma (30-80 Hz) amplitude to the phase of ACC theta varied consistently between the two task conditions: coupling was weaker when the barrier was present and greater when the barrier was absent ($p < 0.001$). Interestingly, elevations in power and coupling persisted in an extinction condition in which the barrier was never present but condition cues remained ($p < 0.001$). In contrast, neither ACC and VTA theta responses in the reward region were affected by the effort condition suggesting that the appraisal of the reward, as it is consumed, is unaffected by changing response requirements. We found no significant relationship between running speeds and theta modulations. Our results supported both of the hypotheses, which, suggests that ACC and VTA activity reflects an instantaneous value state: the value of the reward as it is perceived at that moment, which is discounted by physical effort.

Title: Effects of memantine administration on progressive ratio schedule performance of rats after binge eating induction

Authors: *W. ZEPEDA-RUIZ[1], D. N. VELAZQUEZ-MARTINEZ[2];
[1]Univ. Nacional Autonoma De Mexico, Mexico, Mexico; [2]Psicofisiología, Univ. Nacional Autónoma de México, Mexico City, Mexico

Abstract: Binge eating is an eating disorder characterized by the overconsumption of food in brief periods, with high motivation to obtain and consume palatable food despite negative consequences. According to the Incentive Motivation Theory subjects with this disorder present alterations in the wanting component, implying they assign a larger incentive value to palatable

food than subjects without the disorder. Since there are similarities of binge eating to addictive behaviors, some drugs employed in the study of addictions reduce the symptoms of the disorder (e.g. induced a decrease in the size or frequency of binges episodes); one of these drugs is memantine (an uncompetitive N-methyl-D-aspartate (NMDA) antagonist). It has been reported that intracranial administration of memantine decreased food seeking behavior, reduced the compulsive-like eating of palatable food and decreased responding for palatable food. Although memantine reduced the consumption of palatable food it is not clear if this decrement was associated to changes in the incentive value of food. The objective was to evaluate the intracranial administration of memantine on the performance of the progressive ratio schedule using the Progressive Ratio Model proposed by Bradshaw et al. (Psychopharmacology, 2012, 222: 549-564); this model provides four parameters; k and T_0 are associated to post-reinforcement pause and δ to the motor component, but α reflects the specific activation (incentive value). When binge eating was inducted, there was an increase in the specific activation parameter with no changes in the motor parameter. After memantine administration, values of the parameter α (associated to incentive value) decreased. Our results are in accordance to those studies that reported alterations in the wanting component.

Title: Examination of the persistence of the anti-craving effects of acute environmental enrichment in rats

Authors: J. HYDE, E. GLUECK, K. NORTH, D. GINDER, O. DEMCHENKO, J. SULC, K. JIGANTI, *J. W. GRIMM;
Dept of Psych and Beh Neurosci, Western Washington Univ., Bellingham, WA

Abstract: Background: Exposure to acute (17h) environmental enrichment (EE) reduces sucrose taking and seeking in rats. Our study examined the persistence of this effect. Following 10 days of sucrose self-administration, male rats responded for either sucrose or a tone + light sucrose-paired cue for one week following acute EE. The first day of testing began either immediately following EE, or one day later after rats had been returned to their regular, single-housed

condition (home cage). This “delayed” condition allowed us to identify whether the anti-craving effect of EE would last beyond the immediate switch from the EE condition to the operant conditioning chamber. Methods: Male Long-Evans rats underwent 10 days (2h/day) of sucrose self-administration before entering acute EE. EE consisted of 3 rats housed in a large, multi-level cage with novel stimuli (toys). After EE (or remaining in the home cage as Controls), rats underwent one week of 1h/day test sessions, responding for either sucrose or the sucrose-paired cue. The persistence of the effects of EE on these measures of sucrose craving was examined by having some rats return to the home cage for one day following EE, prior to the first day of testing (delayed condition). Results: EE-exposed rats responded for significantly less sucrose the two days following EE, compared to Controls. This effect was verified in the delayed condition where responding for sucrose was less than Controls even though EE rats had spent 24h in their home cage prior to testing in the operant conditioning chamber. This persistent effect of EE was not observed in rats responding for the sucrose-paired cue. Specifically, although rats responded significantly less for the sucrose-paired cue compared to Controls immediately following EE, there was no difference between EE and Control rats in the delayed condition. Discussion: Our data indicate that the anti-craving effect of acute EE persists for at least 2 days beyond the immediate transition from EE to the self-administration context. However, this persisting effect only occurs with rats responding for sucrose itself, as opposed to responding for a sucrose-paired cue. We have previously hypothesized that the anti-craving effect of EE is due to rats perceiving the reinforcing effects of sucrose and the sucrose-paired cue as being reduced in the self-administration context following EE. For rats responding for the sucrose-paired cue this negative contrast appears to need to occur immediately prior to testing. Further research is required to evaluate this hypothesis in more detail, as well as to determine how the persisting effect with sucrose self-administration is mediated.

Title: Sex determines effect of exercise on diet preference: role of opioid reward system and microbiome diversity

Authors: *J. R. LEE[1,2], J. MUCKERMAN[1], A. WRIGHT[1], D. DAVIS[3], A. ERICSSON[3], C. HAGAN[3], T. CHILDS[4], F. BOOTH[4], M. WILL[5];
[2]Interdisciplinary Neurosci. Program, [3]Dept. of Vet. Pathobiology, [4]Dept. of Biomed. Sci., [5]Psychological Sci., [1]Univ. of Missouri, Columbia, MO

Abstract: Previous studies suggest an interaction between physical activity and diet preference. However, this relationship has not been well characterized for potential sex differences that may occur. In order to examine the influence of sex on the relationship of physical activity and diet selection, a long-term diet preference test was employed. At 49 days of age, 20 male and 20 female Wistar rats were divided into either sedentary or wheel running conditions for a one week acclimation period. Standard lab chow was then replaced with three unique diets for a four week diet preference test. A high-fat, high-sucrose, and high-corn starch diet were presented simultaneously in the home cage. Sedentary or wheel running conditions remained throughout the duration on the experiment. Body weight, running distance, and intake of each diet were measured daily. At the conclusion of the four week diet diet preference test, animals were sacrificed and microbiome samples and brain tissue from 3 brain regions was collected. Fecal samples were collected before and after the diet preference phase to determine microbiome diversity. Results indicate sex dependent interactions between exercise and both behavioral and physiological measures. Females in both wheel and sedentary conditions preferred the high-fat diet. Males in the sedentary group also preferred the high-fat diet, while the males in the wheel condition consumed significantly less high-fat diet than the other groups and equally preferred all three diets. The influence of physical activity on physiological measurements also revealed sex differences. A significant sex by exercise condition interaction was observed for mRNA expression in both the mu opioid receptor, OPRM1, and preproenkephalin, PENK in the ventral striatum and neuropeptide Y, NPY in the hypothalamus. Characterization of gut microbiota diversity during the pre-diet and post-diet samples for all groups suggest a sex-dependent interaction between physical activity and diet preference. The significant sex differences in response to exercise expressed by both behavioral and physiological measures suggest a potential motivational or metabolic difference between males and females and highlight a necessity for further exploration between male and female response to exercise.

Title: Striosomes may control dopamine activity via disynaptic projections to macaque lateral habenula

Authors: *S. HONG, S. AMEMORI, K.-I. AMEMORI, A. M. GRAYBIEL;
McGovern Inst. for Brain Res., MIT, Cambridge, MA

Abstract: The lateral habenula (LHb) modulates motivation and behavior via its influence on the dopamine (DA) and serotonin (5-HT) systems (e.g., Hong et al., 2011). In non-human primates, the LHb receives a major input from the border neurons in the globus pallidus internal segment (GPb; Hong et al., 2008). A leading hypothesis is that the GPb cells might receive input from neurons in the striosomal compartment of the striatum (Graybiel and Ragsdale, 1978), given evidence in rodents (Rajakumar et al. 1993). Definitive evidence of such a circuit in the primate brain is still missing. To fill this major gap, in two rhesus monkeys, we placed microelectrodes in the striatum for microstimulation and placed a second microelectrode in the LHb to record the responses to striatal microstimulation. We mapped different microstimulation sites in the striatum (to which we applied 3 pulses, 33 μA each, at 300 Hz), and determined whether the microstimulation affected multi-unit activity in the LHb, indicating functional connectivity. We found that, at some sites, stimulation of the striatum induced significant inhibitions or excitations of LHb activity. These effective striatal sites were distributed unevenly along the depth of the stimulating electrode's track; sometimes a brisk excitement or inhibition was induced in the LHb, but at other depths, no LHb response occurred. We made electrolytic marking lesions when we found an effective site, and the brains of the two monkeys were then processed for histological examination using KChIP1 (to demonstrate striosomes), glial fibrillary acidic protein (GFAP, to allow detection of the penetration track) and Prussian blue (to detect iron deposition at marking lesions). Our analyses demonstrated that 9 out of the total of 11 effective sites were in or immediately bordering striosomes, one was in the matrix compartment, and one was in a fiber bundle. The rather long orthodromic latency of ~20 ms for LHb responses suggested disynaptic connectivity, contrasting with the ~5 ms latency for GPb cell stimulation. Our results strongly suggest that neurons in the striosomal compartment of the striatum controls LHb activity via its connection to the GPb. This work, still in progress, has the potential to identify in non-human primates a crucial pathway for the control of mood and motivation.

Title: The striatal striosome compartment encodes the value of sensory stimulus

Authors: *T. YOSHIZAWA, M. ITO, K. DOYA;
Okinawa Inst. of Sci. and Technol., Onna-Son, Okinawa, Japan

Abstract: The striatum consists of the striosome (patch) and matrix compartments. Although the striatum is involved in value-based learning, the specific roles of these compartments has not been clear because the mosaic structure makes it difficult to identify the compartments during electrode recording. We previously hypothesized that the striosome compartment represents the state value, whereas the matrix represents the action value in reinforcement learning (Doya, 2000). In this study, to test whether the striosome neurons represent value information or not, we conducted endoscopic deep-brain *in vivo* calcium imaging (nVistaHD, Inscopix) of transgenic mice with selective GCaMP6s expression in the striosome neurons (Gerfen et al., 2013).
Mice were classically conditioned with four odor cues predicting reward (water 2 or 4 μl), aversive stimuli (air puff), or none. Each trial began with a conditional stimulus (CS; odor, 2 sec.), followed by a delay period (0.5 sec.) and an unconditional stimulus (water/air puff/none). Within the first 7 days (100 trials/day), licking behavior was formed during the CS and delay period for the odor stimuli associated with rewards. This result indicates that mice predicted upcoming reward from odor stimuli. We recorded the activity of the same striosome neurons over 15 days and compared the activities in early learning stage with late learning stage. In the late stage (the odor-reward associations were well learned), some neurons showed activities correlated with the reward amounts during the CS and delay periods, whereas some other neurons showed air-puff predictive activities. To confirm that these activities encode the value information, we applied a regression analysis. The activities of 67% of striosome neurons significantly correlated with the reward values predicted by the different odors. This proportion was significantly larger than in the early stage (39%, $p=0.0145$). The absolute value of regression coefficients was also larger than in the early stage (Median; 0.020 vs. 0.043, $p=0.0073$). While 43% of neurons showed significantly correlated activities with the presentation of the odor associated with air puff in the late stage, there were no significant differences in the proportion and regression coefficients between the early and late stages.
The existence of stirosome neurons coding value information was revealed for the first time using selective optical recording. The result suggests that one of the roles of striosome neurons is

to associate sensory states with predicted reward, in consistence with our hypothesis about value coding in the striosome compartment.

Title: A within-subjects operant model to examine strength theory and ego depletion in rats: effects of glucose administration

Authors: *A. L. LASKE, J. E. MEYERS-MANOR, 55105, E. P. WIERTELAK;
Neurosci. Studies, Macalester Col., Saint Paul, MN

Abstract: Ego depletion research has viewed self-control as a limited mental resource that may be used up. According to proponents of this theory, also referred to as Strength Theory, when this resource is in short supply, self-control may become impaired. The prefrontal cortex is believed to house circuitry that acts as a central executive cognitive system, responsible for organizing the processes that enable self-control. Glucose, as the main source of energy for brain functioning, thus figures strongly in replenishing executive processes. Evidence suggests that replenishing glucose may reverse ego depletion in humans and dogs. The current study was designed to test the possibility of glucose reversal of ego depletion in rats, in order to shed light on the mechanisms of glucose utilization in the brain and investigate further the possibility of ego depletion in modulating self-control.Using an operant conditioning model, eight female Sprague-Dawley rats completed two weeks of baseline training. Baseline training involved shaping the rats to two levers: a long-delay lever and a short-delay lever. Self-control was measured by the percentage of time that subjects chose the long-delay lever over the short-delay lever. A within subject designed was used for testing. White noise bursts were blasted for 10 seconds per minute for 20 minutes in order to establish ego-depletion. Administration of 0.5 mL of glucose was used for depletion reversal.Results indicate that all subjects showed a decrement in their responding compared to baseline following the white noise bursts. This decrement appeared to be reversed by glucose administration following ego depletion. Analysis revealed that subjects in the glucose condition had significantly higher percentages of long-delay reward presses than those rats tested in the water only condition. The current study provides evidence that glucose plays a crucial role in reversing ego depletion as defined here, and improving self-control in rats. This study may help inform research examining the possibility of ego depletion

and glucose in humans, here specifically, the controversy surrounding putative mechanisms of glucose utilization in this effect.

Title: Fos expression after exposure to an effort discounting procedure

Authors: *E. E. HANSON[1], S. H. MITCHELL[2];
[1]Neurosci., [2]Behavorial Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Objective: Apathy is a hallmark of numerous psychiatric disorders, and is thought to impede the development of more healthful behavior patterns. However, our understanding of the processes regulating instances of effort-aversion is incomplete. This project addressed this research gap by measuring markers of neuronal activity to determine the contribution of different brain areas to the decision to work for a food reward. Methods: 48 Long-Evans rats participated. Rats were divided into four groups: a food-restricted experimental group; a food-restricted, yoked-control group; a food-restricted control group; and an unrestricted food control group. Rats in the food-restricted experimental group were trained on an effort-discounting task based upon a modified adjusting amount procedure (Richards et al. 1997, J Exp Anal Behav 67: 353). Rats chose between 150-µL of sucrose solution available following completion of an effortful response, and a smaller sucrose reward available following a negligible-effort response. Rats were tested on five effort levels (0.01, 0.15, 0.35, 0.6, 0.9 Ns), varied daily, where the effort was determined from the force integrated over time. Food-restricted, yoked-control rats were placed in the operant chambers and received sucrose solution on a schedule that was yoked to animals within the food-restricted experimental group. Food-restricted and unrestricted control rats were placed in the operant chambers but did not complete the task. Behavioral data were used to characterize individual differences in the willingness to engage in effortful responding by constructing effort discounting curves and calculating the area under the curve. Prior to being euthanized on their last session, rats experienced 5-10 sessions at the 0.6 Ns effort condition. Brain tissue was then stained for cFos, a habituating marker of neural activation, and FosB, another member of the Fos family of transcription factors. Numbers of Fos-positive cells were

counted visually, and compared between groups for each region. Results: For the trained rats, the subjective value of the 150-μL reward decreased hyperbolically as a function of increasing effort. When rats were tested at a single effort prior to their last session, the subjective value of the 150-μL sucrose was stable across sessions. Preliminary cell-counting suggests an enrichment of cFos-positive cells in the anterior cingulate cortex and accumbens, for food-restricted, experimental animals over controls. Conclusions: These results are consistent with the view that the striatum is involved with the choice to perform effort for a food reward, rather than the value of the reinforcer itself.

Title: Role of the prelimbic prefrontal cortex in operant responding to appetitive, aversive and conflicting cues

Authors: *L. M. HAMEL, B. CAVDAROGLU, R. ITO;
Univ. of Toronto, Toronto, ON, Canada

Abstract: The prelimbic prefrontal cortex (PFC) has been associated with the learning and expression of motivated behaviour elicited by reward and fear-related cues. However, the specific effects of previous manipulations in this region have varied, likely based in part on the nature of the cues, response demands, and outcome contingencies. The current study aimed to elucidate the role of the prelimbic PFC in a set of experiments where analogous tasks of appetitive and aversive cued responding were performed under extinction and non-extinction conditions. The task additionally introduced an opportunity for responding under conditions of conflict where both positively and negatively valenced signals are presented simultaneously. Rats were trained to perform an operant task wherein different discrete auditory and light stimuli were associated with either positively valenced (sucrose pellet reward), negatively valenced (foot-shock) or neutral outcomes (no programmed consequences) upon lever pressing on a variable ratio schedule. Prior to behavioural testing, animals were intracerebrally infused in the prelimbic prefrontal cortex with a combination of the $GABA_A$ and $GABA_B$ receptor agonists muscimol/baclofen or a saline vehicle control in a within-subjects design. During a test under

extinction conditions, the cues were presented in alternating trials signifying either the positive or negative contingencies, or with a superimposition of both the positively and negatively valenced conflicting cues. The same test of cue-induced responding was additionally performed under non-extinction conditions where the animals received either the reward, foot-shock, or a combination thereof. The results indicated that under extinction conditions, inactivated animals performed fewer lever presses in response to the reward cue, as instantiated through a faster rate of extinction. Under non-extinction conditions, no difference was observed between groups in responding for reward; however the inactivated animals pressed more than controls for the negative outcome, and additionally responded more in the conflicting valenced situation, suggesting a diminished aversion. The results reveal contrasting effects of prelimbic PFC inactivation under extinction and non-extinction conditions in cued operant responding, and support a role for this region in the evaluation and integration of cues representing positive and negative valence.

Title: Cocaine pre-exposure enhances negative incentive motivation in a novel mixed-valence approach-avoidance task

Authors: *D. NGUYEN, Y. NESARAJAH, S. ERB, R. ITO;
Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: Approach and avoidance processes are critical components of drug addiction, wherein the addict is compelled by both desire and avoidance for the drug. Evidence suggest that prior exposure to drugs such as cocaine induces long-lasting alterations in brain systems that are fundamentally involved in processing reward and aversion. Indeed, work in our laboratory have previously shown that cocaine pre-exposure dysregulates approach-avoidance conflict resolution in behaving rats tested in paradigms of motivational conflict, biasing decision-making towards appetitive sucrose reward seeking over passive avoidance of foot shock punishment. However, to more completely model the aesthetics of addiction where the addict must actively seek out the drug in order to avoid a negative state of withdrawal, there must be an investigation of avoidance

motivation wherein avoidance of an aversive stimulus requires an active instrumental response. The effects of cocaine pre-exposure on active avoidance processing in animals under a state of motivational conflict is currently unknown. In the present study, male Long Evans rats were subjected to a cocaine sensitization regimen (15-30mg/kg, IP, 7d), prior to beginning of behavioral training. Rats were then trained in a novel modified shuttle box paradigm consisting of two separate but conjoined arms. Rats were trained to lever press for sucrose reward in the presence of a light CS under a specified schedule of reinforcement. Rats were then trained in the other arm to lever press to actively avoid impending foot shock punishment upon presentation of a tone CS. Following successful conditioning, rats were subjected to a forced-choice conflict test in which the reward and avoidance CS were presented simultaneously. Here, over multiple trials, rats could choose to respond on the reward lever for sucrose reinforcement with the consequence of unavoidable and inescapable foot shock, or to respond on the avoidance lever to actively avoid foot shock with the consequence of not receiving sucrose reward. Our preliminary data reveal that cocaine pre-exposed rats prefer the active avoidance response over sucrose reward, suggesting a drug-induced shift in balance of motivational processing.

Title: Differential effects of ventral hippocampal CA1 and CA3 inactivation on learned approach-avoidance decision making in rats

Authors: *A. SCHUMACHER, F. VILLARUEL, R. ITO;
Psychology, Univ. of Toronto, Scarborough, ON, Canada

Abstract: The simultaneous presence of stimuli with opposing valences evokes an approach-avoidance conflict, which can result in the emission of maladaptive responses. The hippocampus is thought to be involved in the resolution of such conflict by exaggerating the value of negative outcomes and increasing the tendency to avoid. Previous work from our laboratory has implicated the ventral, but not dorsal hippocampus in mediating decision making under high approach-avoidance conflict. The present study sought to further investigate the role of different subfields within the ventral hippocampus (vHPC) in learned approach-avoidance conflict. Male

Long Evans rats were trained to associate different non-spatial cues with positive, negative and neutral outcomes in three arms of a radial maze. Following successful cue valence acquisition, rats underwent transient inactivation of the CA1 or CA3 subfields of the vHPC using a cocktail of $GABA_A$ and $GABA_B$ receptor agonists, immediately before a conflict test in which they were presented with a superimposition of positive and negative cues in one arm (conflict cue), and neutral cue in another arm. In addition, all rats underwent tests of anxiety and novelty preference. We found that inactivation of the CA1 subfield led to marked avoidance of the conflict cue, while inactivation of the CA3 subfield resulted in the opposite pattern of behavior, with significant preference for the conflict cue. This was despite the fact that both CA1- and CA3-inactivated rats showed reduced anxiety and impaired novelty preference compared to control rats. Thus, our findings suggest that the CA1 and CA3 region of the vHPC subserve distinct and opposing behaviors in the face of approach-avoidance conflict.

Title: Repeated ketamine exposure impairs the acquisition of negative incentive salience in rats

Authors: *R. ITO, A. SCHUMACHER;
Psychology, Univ. of Toronto, Scarborough, ON, Canada

Abstract: Repeated exposure to sub-anesthetic doses of ketamine in rats has previously been shown to induce cognitive deficits, as well as behavioural changes akin to the positive and negative symptoms of schizophrenia, giving much face validity to the use of ketamine administration as a pharmacological model of schizophrenia. However, close examination of the preclinical literature reveals that there is, at present, no standard dosing regimen for subchronic ketamine administration, throwing into question the translational value of previous findings. Indeed, previous work from our laboratory have shown that two widely used regimens of repeated ketamine administration can induce differential alterations in novelty processing, sucrose preference and working memory, giving rise to the notion that different dosing regimens may elicit differential neural and neurochemical adaptations. This study therefore sought to further characterize the behavioral and neurochemical effects of two different ketamine pre-

treatment regimens, focusing on the acquisition of positive and negative incentive learning. Male Long Evans rats received either 5, or 14 intra-peritoneal injections of 30mg/kg ketamine or saline across 5 or 7 days respectively. After a withdrawal period of 10 days, rats were trained to associate different visuo-tactile cues with different outcomes (positive, negative and neutral) in three arms of a radial maze, and the rate of learning assessed with conditioned cue preference/avoidance tests. Rats then underwent a locomotor test involving the administration of a challenge dose of amphetamine (AMPH). One day after the locomotor test, neurochemical analyses of the striatum were conducted on the brains extracted from a subset of animals from each treatment group. We found that the low-dose (cumulative) ketamine pre-treatment regimen elicited selective impairment in the acquisition of conditioned cue avoidance, but not conditioned cue preference. In contrast, the high-dose ketamine pre-treatment led to a transient enhancement in conditioned cue preference, compared to the saline pre-treated group performance. Furthermore, the low-dose ketamine pre-treated rats showed *enhanced* locomotor activity following an AMPH challenge, indicative of locomotor sensitizaton, while the high-dose ketamine pre-treated rats showed *decreased* locomotor activity, compared to saline rats. These data demonstrate that different regimens of repeated ketamine administration can induce differential effects on incentive learning, which may depend on dissociable adaptations occurring in the midbrain dopamine systems.

Title: Opposing roles of infralimbic and prelimbic cortices in contextual biconditional discrimination memory retrieval

Authors: *S. RIAZ, D. KHAN, P. PUVEENDRAKUMARAN, R. ITO;
Univ. of Toronto, Scarborough, ON, Canada

Abstract: The medial prefrontal cortex (mPFC) has been widely implicated in the contextual control of appetitive and aversive conditioning. Furthermore, the two subdomains within the mPFC, the infralimbic (IL) and prelimbic (PL), have been shown to differentially control context-dependent behaviour. Thus, while activity in the PL cortex has been shown to promote

the expression of conditioned fear and drug seeking behavior, IL activation has been associated with the extinction and inhibition of conditioned fear and drug seeking. However, the potential roles of the PL and IL subregions in contextually driven appetitively motivated behaviours with natural rewards remain underexplored. The present study sought to further examine the functional dichotomy of the mPFC in contextual control over appetitively motivated behaviour, employing a contextual biconditional discrimination (CBD) task in combination with temporary pharmacological inactivation of the PL and IL. To this end, adult male Long Evans rats received CBD training involving the sequential presentation of two distinct auditory stimuli (X and Y) in two different contexts (A and B; differentiated by size and odor). Rats were trained to nose poke in response to the presentation of one stimulus (e.g. X+) for the delivery of sucrose reward, and to withhold a nose poke response to the presentation of the second stimulus (e.g. Y-) in a context-specific manner (e.g. AX+, AY-; BX-, BY+). Following successful acquisition, rats received an intracerebral microinjection of a cocktail of GABAR agonists (Muscimol/Baclofen) or saline into the PL or the IL cortices, prior to undergoing a CBD training session and a CBD extinction test. While PL inactivation resulted in robust impairment in CBD memory retrieval, preliminary data suggest that IL inactivation enhanced discrimination memory. Taken together, these data indicate that the PL and IL have functionally distinct, and potentially opposite roles in the processing of appetitively motivated contextual memories.

Title: Chemogenetic perturbations of the medial prefrontal cortex and the control of consummatory behavior

Authors: *T. K. SWANSON[1], L. M. AMARANTE[2], M. C. CLASEN[2], I. TERWINDT[2], M. I. KONAKLIEVA[2], R. KUSKOVSKY[2], M. LAUBACH[2];
[1]Biol., [2]American Univ., Washington, DC

Abstract: Previous studies from our lab have established that the medial prefrontal cortex (mPFC) contains neurons that vary with the initiation of feeding bouts (Horst and Laubach, 2013) and that reversible inactivations of the rostral part of this region lead to fragmented licking in incentive contrast procedures (Parent et al., 2015). Here, we examined the role of this cortical region with a special focus on its connections with lateral hypothalamic regions known to be involved in feeding and homeostasis. Several experiments were conducted using chemogenetics (using the glutamate targeting CaMKIIa promoter) and pharmacological manipulations of the mPFC. First, bidirectional perturbations using the CNO-based Gq and Salvinorin B-based KOR DREADDs had opposing effects in a progressive ratio licking task, with the Gq DREADD increasing breakpoints and the KOR DREADD decreasing breakpoints. These effects were not observed in control rats that were tested with CNO and Salvinorin-B but without the active chemogenetic AAVs infused into the mPFC. Second, a group of rats was tested with the CNO-based Gi DREADD during a continuous access procedure (5% sucrose or maltodextrin). Some of these animals were implanted with guide cannula to compare effects of CNO and muscimol. Inactivation of the mPFC altered measures of consumption such as the rate of intake and duration of licking bouts. CNO and musicmol were comparable on this simple intake behavior, suggesting that effects of muscimol act on glutamate projection neurons within the mPFC. Analysis of anterograde projections (using antibodies against reporter proteins such as HA and co-infused biotinylated dextrans) from these animals is ongoing and will reveal if variability across rats is associated with different projections from the mPFC to feeding centers in the hypothalamus and reward centers in places such as the nucleus accumbens. Third, retrograde tracing (using cholera toxin subunit B) was done in the area of the lateral hypothalamus, and reveals convergent projections from the mPFC as well as the agranular insular cortex, orbitofrontal cortex, ventral striatum, and ventrolateral periacqueductal gray. Together, these studies suggest that a distributed network of brain area involving the rostral mPFC and the lateral hypothalamus mediates control over consummatory behavior.

Title: Functional interactions among medial, orbital, and motor cortices in the control of consummatory actions

Authors: *L. M. AMARANTE[1], M. S. CAETANO[2], N. K. HORST[3], M. LAUBACH[1]; [1]American Univ., Washington, DC; [2]UFABC, Sao Paolo, Brazil; [3]Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Previous studies from our lab have shown that incentive contrast effects with liquid sucrose rewards are sensitive to both reversible inactivation (Parent et al., 2015a) and modulations of cholinergic and ghrelinergic signaling (Parent et al., 2015b) of the rat rostral medial prefrontal cortex (mPFC), i.e. rostral prelimbic and medial orbital areas. Multi-electrode recordings were made across three cortical areas (orbital, medial, and motor) as rats performed in a licking procedure. Time-frequency analysis (newtimf.m from EEGLab) of field potentials and population spike activity recorded in mPFC, and in the orbitofrontal and oral motor cortices, revealed enhanced event-related spectral power and inter-trial coherence (ITC) of phase angles at the licking frequency were synchronized to individual licks as well as the initiation and termination of licking bouts. ITC was enhanced around individual licks and when rats initiated bouts for the higher value fluid. Circular correlation analysis found no clear effect of bout duration or inter-bout interval on ITC. To probe the role of ongoing phasic activity in the control of licking behavior, electrical and optogenetic (C1V1) stimulation was delivered to sites in the medial frontal and oral motor cortices. Lick-entrained stimulation lead to immediate cessations in licking. These findings suggest that lick-entrained neuronal activity selectively encodes the relative value of ingested solutions and controls ongoing consummatory actions. As our recordings were made across multiple frontal areas, we examined functional interactions among the areas using dimensionality reduction methods (e.g. fastICA, Fourier ICA, milca) as well as an algorithm for calculating mutual information in time-series data (Kraskov et al., 2004). We found consistent evidence for a clustering of recording sites by cortical region. Data from each rat showed three broadly mapped independent components that were strictly partitioned across the cortical areas. Based on these findings, we applied an algorithm for directional coherence analysis (Neurospec 2.1) and found evidence for directional influences of frontal agranular cortex (in a region known to contain the oral motor cortex) driving signals in the medial and orbital cortices at two frequencies (8-12 Hz and ~20 Hz). The 20 Hz component was suppressed during periods of active licking. Orbital fields also exhibited directional influences on the medial fields that were broadly distributed around the licking frequency. Our findings suggest that the oral motor cortex coordinates rhythmic activity in the medial and orbital frontal cortices to enable monitoring of reward value.

Abstract: A major obstacle in the treatment of cocaine addiction is the high propensity of addicts to relapse even after extended drug-free periods (withdrawal). Previous work has implicated the glutamatergic projection from the infralimbic cortex (IL) to the nucleus accumbens (NAc) in drug-seeking following cocaine self-administration and withdrawal. However, it is not clear what information is carried in this projection to support drug-seeking behavior. It is also unknown whether activity in this circuit functions to modulate ongoing behavior, or if it provides feedback to shape future behavior. In order to better understand what information is being encoded by IL→NAc projecting neurons during extinction of cocaine-seeking, we combined cellular resolution calcium imaging with a retrograde Cre virus and a Cre-dependent GCaMP to record projection-defined neurons in awake and behaving rats after 1 (n=125 neurons, 5 rats; E1) or 15 (n=61 neurons, 4 rats; E15) days of cocaine withdrawal. Preliminary analysis indicates that a small portion of IL→NAc neurons (23% E1, 22% E15) display time-locked activity to active lever responding, with most of these neurons increasing firing after the lever press. However, a much larger portion (46% E1, 80% E15) of neurons exhibited significant spatial tuning within the cocaine-associated context. We next used optogenetics to activate the same projection in rats. Channelrhodopsin (n=13) or YFP (n=4) was expressed in the IL under a CaMKII promoter and optical fibers implanted in the NAc, allowing for selective optogentic control of IL→NAc projection neurons. Laser stimulation was delivered on a subset of trials during a single extinction session after cocaine self-administration training and withdrawal. On the stimulation trial, activity in this projection significantly decreased active lever presses (t_{12}=3.3; $p<0.01$) and increased inactive lever presses (t_{12}=3.8; $p<0.01$), while stimulation had no significant effect on behavior on the next trial (t_{12}=1.4; $p>0.05$, active lever; t_{12}=0.90; $p>0.05$, inactive lever). Laser stimulation had no effect on lever pressing in control animals (t_3=0.5; $p>0.05$, active lever; t_3=0.0; $p>0.05$, inactive lever). These data suggest that manipulation of the IL→NAc projection predominantly influences discrimination between the active and inactive lever on the current trial, rather than providing feedback to update subsequent drug-seeking. Taken together with the imaging data, this suggests that the IL→NAc projection

may be responsible for providing spatial information to the NAc that shapes ongoing drug-seeking behavior.

Title: Toward a Greater Moderation and efficient markets: Neuroeconomics-based financial-system regulation may reduce bubble-crash effects of brain risk-seeking and -avoiding networks

Authors: *J. L. HARACZ;
Dept. Psychol. Brain Sci., Indiana Univ., Bloomington, IN

Abstract: Objective: Neuroimaging studies of subjects exposed to lab asset-price bubbles yielded results that were interpreted on the basis of "irrational exuberance" (Smith et al., 2014), "theory of mind" (De Martino et al., 2013), and having a "future time perspective" (Ogawa et al., 2014). However, academic scholars, financial-system regulators, and journalists often have emphasized excessive financial risk taking to explain asset-price bubbles. Clinicians report risky behaviors in association with substance-related or behavioral addictions (e.g., gambling disorder and internet gaming disorder). Therefore, a systematic literature review will focus on the neurobiology of addiction and risky behavior to develop a hypothesis about neural networks potentially involved in asset trading underlying financial-market bubbles.
Methods: The review included neuroimaging studies of risky decision-making tasks (e.g., the Balloon Analog Risk Task [BART] and the Columbia Card Task [CCT]) and substance-related or behavioral addictions.
Results: Healthy subjects' BART decisions were predicted by the balance of fMRI activations in a risk-avoiding cortical-control network and a risk-seeking network (Helfinstein et al., 2014). Resting-state fMRI studies of functional connectivity revealed that, compared to control subjects, individuals with heroin addiction (Xie et al., 2014; Zhai et al., 2015; Zou et al., 2015) or internet gaming disorder (Dong et al., 2015) show greater connectivity between regions in the reward valuation circuit (e.g., nucleus accumbens, ventromedial prefrontal cortex, and amygdala), but less connectivity in the frontoparietal cognitive-control network. Across all subjects, functional connectivity in the valuation and control networks was inversely correlated (Xie et al., 2014;

Dong et al., 2015). Healthy subjects' near-infrared spectroscopy (NIRS)-recorded prefrontal cortical activity was higher in the "cold" deliberative version of the CCT compared to the "hot" affective CCT version (Holper & Murphy, 2014).
Conclusions: If financial risk taking underlies asset-price bubbles, then the above pattern of results is consistent with the hypothesis that asset trading-related lateral neocortical activity is higher during non-bubble periods of markets, so low trade-related lateral neocortical activity may be a NIRS-detectable biomarker of bubbles. Lowered economic volatility of the "Great Moderation" may have ended with the recent global financial crisis (Rudebusch, 2010), but neuroeconomics-based financial-system regulation may become useful for reducing asset-price volatility, thereby enhancing market efficiency.

Title: Disconnection of basolateral amygdala-insular cortex interferes with goal-tracking but not sign-tracking.

Authors: *H. M. NASSER, E. N. LESSER, D. S. LAFFERTY, D. J. CALU;
Univ. of Maryland Dept. of Anat. and N, Baltimore, MD

Abstract: The Pavloivan lever autoshaping procedure reliably distinguishes sign- and goal-tracking behaviors in rats. In this procedure a lever is inserted and retracted, after which a food reward is delivered into a food cup. Rats are not required to press the lever or approach the food cup, but sign-tracking rats approach the lever, while goal-tracking rats approach a food cup. Prior work indicates that sign-trackers show heightened motivation for a food-predictive lever-cue and subsequently show greater cue-induced drug relapse than goal-trackers. Prior work demonstrates that disconnecting basolateral amygdala (BLA) and nucleus accumbens impairs sign- but not goal-tracking. Here we examine the role of reversibly disconnecting BLA from insular cortex (IC) on the expression of sign- and goal-tracking behaviors. We trained rats in lever autoshaping for four days to determine their tracking tendency. On alternating test days we injected vehicle or

GABA agonist cocktail, baclofen and muscimol, unilaterally into the BLA and contralaterally into IC prior to reinforced lever autoshaping sessions. Disconnection of BLA and IC reduced goal- but not sign-tracking behaviors. These findings suggest that the BLA-IC pathway is necessary for supporting food-cup directed behaviors in goal-trackers but not lever-directed behavior of sign-trackers. This finding together with prior work, suggests that sign- and goal-trackers rely on dissociable BLA pathways to drive distinct conditioned responses during lever-autoshaping.

Title: Dynamic causal modeling of human motivation neural circuitry

Authors: *A. KOHLI[1], D. N. BLITZER[2], D. R. WEINBERGER[1], C. F. ZINK[1];
[1]Clin. Div., Lieber Inst. For Brain Develop., Baltimore, MD; [2]Natl. Inst. of Mental Health, NIH, Bethesda, MD

Abstract: Motivation dysfunction is a prevalent and debilitating symptom of several mental disorders; therefore, determining how motivation is represented in the human brain is important to eventually combat motivation deficits. The goal of the current study was to use Dynamic Causal Modeling (DCM) of fMRI data - a method to model effective connectivity between activated brain regions and the impact of task conditions on intrinsic connections - to determine how motivation neural circuitry is connected and how motivation modulates the connectivity pattern. A modified version of the Monetary Incentive Delay task, designed to isolate neural activity of motivation from that of reward, was presented to healthy subjects (n = 105) under fMRI. A whole brain group level ANOVA ($p < 0.05$, FWE-corrected, $k > 50$, n = 105) revealed five significant brain regions, all in which the motivation cues evoked greater activation than neutral cues (Motivation Cues > Neutral Cues): ventral striatum (vStr), midbrain, pre-motor area (PMA), supplementary motor area (SMA), and visual cortex. In order to determine how these regions communicate in the context of motivationally salient stimuli, a DCM analysis was conducted. Average time series were extracted from volumes of interest (VOIs) defined as activated voxels ($p < 0.05$, uncorrected) within a 10 mm sphere centered at the peak voxels in

each of the 5 aforementioned brain regions for each individual. Subjects who did not have activated voxels in all VOIs were excluded from the DCM analysis (final n = 60). An initial DCM was entered into the model space with motivation cues serving as driving input into the model at visual cortex and 15 possible intrinsic connections between brain regions (based on known anatomical circuitry). Connectivity parameters were estimated to determine connection strength. The parameters corresponding to 5 intrinsic connections were significant ($p < 0.05$): visual->midbrain, midbrain->PMA, midbrain->SMA, midbrain->vStr, PMA->SMA. We interrogated the influence of motivation on these specific connections by allowing the cue associated with highest level of motivation to modulate each connection. The resulting estimated modulation parameters showed significant ($p < 0.05$) high motivation modulation of the visual->midbrain, midbrain->vStr, and midbrain->PMA connections. Our results provide a model of how motivation is represented in the human brain not only in terms of which brain regions are involved, but also how they are connected in the context of motivation processes, and how evoked-motivation strengthens the connectivity.

Title: Activation of D1 and D2 expressing neurons in the nucleus accumbens enhances motivation

Authors: *C. SOARES-CUNHA[1,2], B. COIMBRA[2], A. DAVID-PEREIRA[2], S. BORGES[2], L. PINTO[2], P. COSTA[2], N. SOUSA[2], A. J. RODRIGUES[2];

Abstract: The nucleus accumbens (NAc) plays an important role in reward processing and reinforcement. Up to 95% of NAc neurons are GABAergic medium spiny neurons (MSNs) that are typically segregated into two distinct subtypes - those expressing dopamine D1-like receptors and those expressing dopamine D2-like receptors. While striatal D1-MSNs have been classically associated with positive reinforcement and reward, D2-MSNs have been associated with negative reinforcement and aversion.
In this work we demonstrate that activation of both D1- and D2-MSNs in the NAc are positively correlated with behavioural performance in motivation-dependent paradigms, namely the Pavlovian-to-instrumental transfer and progressive ratio schedule of reinforcement. In addition, we show that brief optogenetic activation of NAc D1- and D2-MSNs during reward-predictive cues strongly boosts motivation to work for food in mice, indicating that both neuronal subtypes can contribute in the same direction in the modulation of motivation.
We further extended these results by selectively manipulating D2 neurons in rats: brief optogenetic activation/inhibition of NAc D2-MSNs during reward-predictive cues strongly enhanced/diminished motivation. *In vivo* electrophysiological recordings of downstream regions namely the ventral pallidum and ventral tegmental area showed that the manipulation of D2 neurons was pathway-specific.
Our results suggest that the classic view of D1/D2 functional antagonism in the NAc does not hold true for all dimensions of reward-related behaviours, and that D2-MSNs may play a more prominent *pro-motivation* role than originally anticipated.

Title: Effects of cholinergic receptors blokade in the orbitofrontal cortex on Pavlovian-to-instrumental transfer task

Authors: *Y. CUI[1], A. T. LIU[1], K. WASSUM[2], S. B. OSTLUND[1];
[1]UCI, Irvine, CA; [2]Dept. of Psychology, UCLA, Los Angeles, CA

Abstract: Conditioned stimuli are important guides for behavioral actions. Previous studies have shown that post-training orbitofrontal cortex (OFC) lesions disrupt the use of cue-triggered outcome expectations on action selection, assayed using the outcome-specific Pavlovian-to-instrumental transfer (PIT) task. However, it is not yet known how local neuromodulatory systems in the OFC contribute to this aspect of reward seeking. We were interested in the possibility that OFC acetylcholine signaling might play a role, given recent findings that systemic antagonism of either nicotinic or muscarinic acetylcholine receptors block the expression of specific PIT. Rats were trained to nose-poke to receive two different rewards that were predicted by two different auditory stimuli, which was done to establish a pair of unique stimulus-outcome associations (S1-O1 and S2-O2). Subsequently, the rats were trained to perform two different lever-press actions (left and right), each earning a different reward (A1-O1 and A2-O2). The impact of pavlovian stimuli on instrumental performance was then examined. The two different auditory stimuli were periodically presented while rats were free to choose between the two lever-press actions. Before testing, rats were given bilateral intra-OFC infusions of vehicle, mecamylamine (nicotinic acetylcholine receptor antagonist), or scopolamine (muscarinic acetylcholine receptor antagonist) to temporarily block cholinergic signaling in this region. When rats were tested on vehicle, the stimuli were effective in selectively elevating performance of whichever action was trained with the same outcome as that cue (e.g., S1-A1). We found that blocking cholinergic receptors either with mecamylamine or scopolamine dramatically reduced this effect. Importantly, reinforced lever pressing was not affected either drug treatment, indicating that the disruption of cue-motivated behavior was not the result of gross motor impairment. These results indicate that acetylcholine signaling at both nicotinic and muscarinic receptors in the OFC plays an important role in the use of cue-evoked reward expectations for instrumental action selection.

Title: Time-course expression and locomotor effects of chemogenetic modulation of prelimbic projections to the paraventricular nucleus of the thalamus in the rat

Authors: *S. A. LOPEZ[1], I. R. COVELO[2], M. KOMAIHA[3], S. M. FERGUSON[5], S. B. FLAGEL[4];
[1]Neurosci., [2]Psychiatry, [3]Engin., [4]Neuroscience, Psychiatry, Mol. and Behavioral Neurosci. Inst., Univ. of Michigan, Ann Arbor, MI; [5]Psychiatry and Behavioral Sci., Univ. of Washington, Seattle, WA

Abstract: The paraventricular nucleus of the thalamus (PVT), a midline structure ventral to the third ventricle, is well-positioned to act as an interface between limbic and motor circuits, integrating information about hunger, memory, pain and arousal. Recently, the PVT has been implicated in mediating motivated and emotional behaviors, including food- and drug-seeking. To better understand the role of the PVT in cue-motivated behaviors, we utilize novel chemogenetic technology that allows us to specifically manipulate PVT circuitry in behaving animals. To do this, we use a dual vector approach to selectively express designer receptors exclusively activated by designer drugs (DREADD) in afferents from the prelimbic cortext (PrL) to the PVT in rats. Specifically, a Cre-dependent-flip-excision AAV viral vector expressing silencing (G_i-) or activating (G_q-based) DREADDs is infused into the PrL, while a retrograde CAV-Cre viral vector is infused into the PVT. This technique allows us to transiently modulate (silence/activate) the functional connectivity of the PrL-PVT circuit. However, given that this is a relatively new technology, determining an optimal methodological protocol is needed. The current study aims to identify the appropriate amount of time required from transfection of the DREADD viruses to the time of maximal receptor expression levels, taking into account differences between G_i and G_q- coupled DREADDs. Since DREADD receptor activation relies on the otherwise inert chemical ligand, Clozapine-N-oxide (CNO), those rats that have a longer "incubation" time for DREADD expression, and presumably more receptors, may exhibit different CNO-induced behaviors than those rats with shorter "incubation" times. Thus, the effects of CNO (3 mg/kg) vs. vehicle (6% dimethyl sulfoxide in sterile water) on locomotor activity were tested for both G_q and G_i experimental groups following a 2-, 4- and 6-week "incubation" time. Our results suggest that maximum levels of DREADD expression occur at 6 weeks following transfection. Similarly, CNO effects on locomotor activity become evident after 4 weeks. These data identify the optimal time period for DREADD expression using the dual vector approach, enhancing our ability to examine the role of specific brain circuits in motivated behaviors.

Title: Anterior insular cortex inhibition attenuates optogenetic self-stimulation of the medial prefrontal cortex

Authors: *A. F. PIERCE, S. IKEMOTO;
Behavioral Neurosci., Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: The medial prefrontal cortex (mPFC) is well known to be an integral part of reward circuitry through its connections to the ventral striatum. However, the extent to which the mPFC's connections play a role in reward processes remains unclear. The mPFC and anterior insular cortex have reciprocal connectivity, and the insular cortex has recently been implicated in reward and affective states related to drug abuse. In humans, damage to the insula decreased desire to smoke in previously addicted cigarette smokers. In rats, the blockade of insular D1 receptors resulted in decreased nicotine self-administration. Recently our lab has found that rats will learn to respond vigorously for optogenetic stimulation in the mPFC in an operant task. In addition, this optogenetic stimulation of mPFC in an fMRI machine elicits a phasic BOLD response in the anterior insula. Therefore, we hypothesize that the projection from the mPFC to the anterior insular cortex plays a role in the rewarding effects of mPFC self-stimulation, and inhibition of insula will cause a decrease in mPFC self-stimulation. To test this hypothesis, C57/BL/6j mice received a unilateral injection of AAV encoding for channelrhodopsin with an optic fiber implant in the mPFC and bilateral injections of AAV encoding for inhibitory DREADDs in the insular cortex. Mice learned to lever press for optogenetic stimulation over a 5 day training period and on test days mice received intraperitoneal injections of Clozapine N-oxide or vehicle, before a self-stimulation session. Our initial data suggest that inhibition of insular cortex by DREADDs significantly reduces lever pressing reinforced by mPFC stimulation. Therefore, we tentatively suggest that the anterior insular cortex plays an important role in reward initiated from the mPFC, and the interaction of the anterior insular cortex with the mPFC may be involved in illnesses associated with the mPFC such as drug addiction and depression.

Title: Decoding reward, punishment, and motivation in the primary sensory and motor cortices of non-human primates

Authors: *J. P. HESSBURG[1], A. TARIGOPPULA[1], D. B. MCNIEL[1], J. S. CHOI[1], J. T. FRANCIS[2,1];
[1]Physiol. and Pharmacol., SUNY Downstate Med. Ctr., Brooklyn, NY; [2]Biomed. Engin., Cullen Col. of Engineering, Univ. of Houston, Houston, TX

Abstract: Signals of reward, punishment, and motivation have been recorded in a number of areas in the brain (Bissonnette et al. 2013, Roesch et al. 2004), including a reward signal in the primary motor cortex (M1)(Marsh et al. 2015). This work is continuing this investigation in the hand and arm regions of M1 and the primary sensory cortex (S1). Two non-human primates (NHP) were trained to complete a gripping task on a virtual robotic arm, where the animal gripped and held a given level of force for a specified period of time. Prior to each trial, visual cues were displayed to inform the NHP if the trial would result in a juice reward if completed successfully, a punishment consisting of a five-second timeout if completed unsuccessfully (e.g. if the applied force was too great or released too early), or no reward or punishment, where the task would move immediately to the next trial. Subsets of trials with no cues and with catch trials, where a cue was presented but no reward or punishment given, were included to investigate reward and punishment prediction and error. Neural data were recorded from the hand and arm regions of M1 and S1, and spike sorted to isolate individual units. Time intervals around the cue presentation and reward or punishment delivery were analyzed and used as input into machine learning classifiers to investigate how the value of reward and punishment were represented in these regions, and how the interplay between the two was represented as motivation. We hypothesize that in addition to reward and punishment, motivation is represented in M1 and S1. Investigating the intricacies of these signals in M1 and S1 will allow future brain-machine interfaces (BMI) to capture the breadth of these signals in one or two brain regions that also contain sensorimotor information, rather than requiring multiple implants in multiple regions. These data will be useful in creating algorithms for more robust and nuanced BMI control, taking greater advantage of the range of information available in these regions for better neural control of robotic prostheses.

Title: The supramammillary-septum glutamate pathway modulates affective processes

Authors: *A. KESNER, R. SHIN, S. IKEMOTO;
Natl. Inst. On Drug Abuse, Baltimore, MD

Abstract: The supramammillary nucleus (SuM) is a posterior hypothalamic nucleus that provides dense projections to the septo-hippocampal system. Past research on SuM and septal systems has primarily focused on their role in hippocampal theta rhythm activity, as well as in stress and aversion. However, classically, the septum is implicated in reward as it was the first brain nuclei identified as rewarding when electrically stimulated. Likewise, our lab has shown that pharmacological excitation of SuM neurons induces reward. Thus, we feel these closely linked brain regions are understudied in terms of their roles in reward processes and affect. We first found that rats self-administered the excitatory glutamate agonist, AMPA, into the septal area. Since the SuM provides dense glutamatergic input to the septal area, we designed experiments to investigate whether the SuM mediates reward via its connection to the septal area. We confirmed general cell body stimulation of SuM is rewarding using a *human synapsin-1* mediated *channelrhodopsin-2* (ChR2) in wild-type (C57/BL7) mice. Mice with ChR2 and optic fibers in SuM quickly learned to respond on a lever reinforced by photostimulation and switch responding when lever assignments are reversed. Mice do not reliably self-stimulate when optic fibers are placed in areas adjacent to SuM - the mammillary bodies or ventral tegmental area. Next, using a Cre-dependent ChR2 and vGlut2-Cre, vGat-Cre or Th-Cre mice, we show this rewarding excitation of SuM neurons is likely mediated by glutamatergic neurons, but not dopaminergic or GABAergic neurons. Then using optogenetic terminal-stimulation we dissect which glutamatergic projections from SuM mediate self-stimulation behavior. Mice learned to respond for the stimulation of SuM glutamatergic neurons terminating in the lateral septum, but not terminals in the paraventricular thalamic nucleus, ventral subiculum, or basal forebrain. Currently we are conducting complementary experiments to study the effect of inhibition of SuM-septal glutamate neurons in order to establish a causal role for these neurons in motivation

processes. We conclude that stimulation of septal cell bodies, whether via direct administration of AMPA, or optogenetic elicited release of glutamate from supramammillary neurons, is rewarding. This data speaks to current controversy in the field, as the septum's involvement in reward related processes has recently been called into question. Our results implicate this highly conserved midline system in modulating positive affective processes, warranting future research into its role in psychiatric disorders such as anxiety and addiction.

Title: Depicting the neural architecture constituting human motivational decision making: from single-cell to whole brain activation.

Authors: *T. GAZIT[1], T. GONEN[2], G. GUREVITCH[1,5], H. YAMIN[1], M. NEUFELD[3,5], S. KIPERVASSER[3,5], F. FAHOUM[3], I. FRIED[4,5,6], T. HENDLER[1,5];
[1]Ctr. for Brain Functions, [2]Neurosurg., [3]Neurol., [4]Functional Neurosurg., Tel Aviv Med. Ctr., Tel Aviv-Yafo, Israel; [5]Tel Aviv Univ., Tel Aviv, Israel; [6]UCLA, Los Angeles, CA

Abstract: Motivation is a key aspect in human decision making, shaped by the interaction between environmental reinforcing cues and our specific goals. Reinforcements signal both incentive (reward/punishment) and hedonic (appetitive/aversive) accounts, with their integration often raising a conflict evident in pathological symptoms such as diminished or excessive approach in depression and addiction, and avoidance in eating disorders. Depicting the neural signature of motivational dimensions could advance domain-based brain diagnosis and treatment. **We aimed to illuminate the neural dynamics underlying motivational decision making by deconstructing it into stages; incentive cue, decision (to approach or avoid), action (approach or avoid) and response to outcome (reward or punishment).**
Method: Using an interactive computer game enabled dynamic modelling of high- and low goal-conflict. Intracranial recordings in 7 epilepsy patients provided high-resolution multilevel neural measurements; single-neuron activity (120 neurons) and intracranial EEG (iEEG) in mesio-temporal and medial prefrontal cortex (mPFC). In addition whole brain fMRI activation was

obtained in 50 healthy volunteers.
Results: A cascade of neural activations was observed using intracranial recordings: increased neural firing and gamma power immediately following the incentive cue appearance in the amygdala, hippocampus and mPFC; with increased synchronization among these regions, possibly representing integrative effort to comprehend the stimulus. Subsequently, increased theta in the hippocampus marked the decision phase, more so under high goal conflict; and gamma decreased in the amygdala during the action phase, possibly marking action facilitation. Finally, in response to punishment outcome, amygdala and dorso-mPFC showed higher neural activity (both single cell firing and local iEEG) compared to the hippocampus and ventro-mPFC, and the opposite trend was observed in response to reward outcome. fMRI revealed distributed network activation corresponding to either cues of high or low conflict, or outcome type.
Discussion: This is the first multi-scale neurobehavioral portraying of motivational decision makingin humans. Our findings may guide neural based interventions corresponding to pathological conditions involving specific motivational stages.

Title: How do cortical hubs in the striatum impact on downstream basal ganglia circuitry?

Authors: *S. R. HEILBRONNER[1], M. A. A. MEYER[2], S. N. HABER[2];
[1]Pharmacol. and Physiol., [2]Univ. of Rochester, Rochester, NY

Abstract: The frontal cortico-basal ganglia network plays a central role in action selection, decision-making, associative learning, and motivation. At the level of the cortico-striatal projection, terminal fields from functionally diverse cortical regions overlap in the striatum, allowing for information integration. These areas of convergence ("hubs") are critical to our understanding of the integrative functions of the basal ganglia. Here, our aim was to follow these

converging connections from the frontal cortex through downstream basal ganglia regions, beginning with the striato-pallidal projection, and continuing with the pallidal-thalamic projection.
Our first goal was to understand the overall topography of the striato-pallidal projection based on prefrontal cortical (PFC)-striatal projections. Using these results, we analyzed the data to understand how information from cortico-striatal hubs is conveyed to the pallidum. Specifically, we asked whether the pallidum had cortical hub-like features. Our second goal was to determine whether striatal hubs project particularly broadly within the pallidum. Finally, we wanted to extend our understanding of indirect PFC representations from the pallidum to the thalamus.
We injected anterograde or bidirectional tracers into specific subregions of the striatum in macaques. These subregions were chosen on the basis of their combinations of frontal cortical inputs, which we have mapped previously. We outlined the dense terminal fields in the pallidum, then rendered our injection sites and terminal fields in a 3-D standard macaque brain for comparison and visualization purposes. Finally, we analyzed the striato-pallidal projections according to location and combination of frontal cortical inputs. We performed a similar process for the pallidal-thalamic projection.
Striatal projections to both the GPe/VP and the GPi adhered to a strong topography, such that the location of the striatal injection can explain up to 90% of the variation in resulting pallidal terminal fields. Furthermore, different striatal subregions projected to different regions of the pallidum, with relatively little overlap. However, when examining the (indirect) influence of the cortex on the pallidum, there was substantial overlap, with multiple cortical regions projecting to the same pallidal areas. This could largely be attributed to the impressive convergence of cortical input to the striatum. Finally, we did not find any evidence that those areas of the striatum receiving inputs from a particularly large number of cortical regions (hubs) projected more broadly within the pallidum than other striatal areas.

Title: Extended amygdala neuropeptide circuits for bi-valent hyperarousal states

Authors: *W. J. GIARDINO, D. J. CHRISTOFFEL, L. DE LECEA;
Psychiatry, Stanford Univ., Stanford, CA

Abstract: Appropriate levels of arousal (wakefulness) are necessary for survival, but maladaptive *hyperarousal* is a hallmark of compulsive reward-seeking and pathological anxiety. Hypocretin (Hcrt) neuropeptides are master regulators of arousal that are generated exclusively in the lateral hypothalamus (LH), and LH neurons exhibit major reciprocal connectivity with a region of the extended amygdala known as the bed nucleus of the stria terminalis (BNST). The arousal-related neuropeptides cholecystokinin (CCK) and corticotropin-releasing factor (CRF) are strongly expressed in the BNST, and produce excitatory activity in LH-Hcrt neurons. We expressed AAV-DJ-DIO constructs containing eYFP-tagged ChR2 (or eYFP-only) in the BNST of *CCK*-IRES-Cre and *CRF*-IRES-Cre mice, and implanted fiberoptic cannulae over the BNST. Relative to controls, photostimulation of *CCK*-BNST neurons produced appetitive responding (real-time place preference at 5Hz and 10Hz), and photostimulation of *CRF*-BNST neurons generated avoidance behavior (real-time place aversion at 5Hz and 10Hz). We validated these stimulation parameters with whole-cell patch-clamp recordings in acute BNST slices, using 10ms blue light pulses to evoke single action potentials at frequencies up to 20Hz with high fidelity. Consistent with results from optogenetic studies, bulk chemogenetic excitation of *CCK*- and *CRF*-BNST neurons with hM3Dq designer receptors produced distinct behavioral effects. Specifically, *CCK*-BNST activation enhanced perseverative behavior, while *CRF*-BNST activation strictly generated anxiety-like behavior. Chemogenetic silencing of *CCK*-BNST neurons expressing hM4Di designer receptors revealed a necessary role for this cell group in appropriate approach/avoidance responding toward bi-valent social stimuli. Detailed anatomical characterizations of the BNST identified preferential expression of CCK in dorso*medial* and posterior (principal nucleus) subregions vs. preferential expression of CRF in dorso*lateral* and anterior subregions. Whole-brain mapping of efferents from BNST cell bodies revealed divergent output patterns, namely *CCK*-specific major projections to medial habenula and ventral premammillary nucleus. Similarly, mapping of afferent inputs using cell type-specific rabies retrograde tracing identified signature components of *CCK*- vs. *CRF*-BNST networks. In summary, we generated functional atlases of previously-uncharacterized neurocircuits emanating from distinct cell groups within the extended amygdala, highlighting additional mechanisms for bi-directional emotional control of heightened arousal.

Title: Gustatory responses in macaque monkeys revealed with fMRI

Authors: *P. M. KASKAN[1], A. M. DEAN[1], M. A. NICHOLAS[1], A. R. MITZ[2], L. G. UNGERLEIDER[3], E. A. MURRAY[1];
[1]Section on Neurobio. of Learning and Memory, Lab. of Neuropsychology, [2]Lab. of Neuropsychology, [3]Section on Neurocircuitry, Lab. of Brain and Cognition, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Tastes and their associated values drive food consumption and influence choice behavior. Because macaque monkeys are often used to understand the neural mechanisms underlying reward-guided decision making and value learning, we characterized the gustatory system in macaques with fMRI while measuring licking to control for oral movements, and to assess monkeys' preferences. Though anatomical data indicate that taste information from the ventroposteromedial nucleus of the thalamus (VPMpc) goes to area G (gustatory) in macaques (Pritchard et al., 1986; Ogawa, 1994), physiological responses to taste appear to be more widespread in cortex, including somatosensory cortex (Ito and Ogawa, 1994; Ifuku et al., 2006) and areas within orbitofrontal cortex (Rolls et al., 1990; Lara et al., 2009). To identify taste-responsive cortex in macaques, we delivered small quantities (0.1ml) of sucrose, citric acid, or distilled water in random order without any predictive cues (e.g., visual stimuli) while using event-related fMRI. In addition, we used an MRI-compatible lick sensor to measure monkeys' licking during scans. fMRI signals associated with licking in the absence of fluid delivery were used to mask responses to fluid delivery/receipt and associated licking. Licking in the absence of fluid delivery and fluid receipt times for each tastant were incorporated into a general linear model to analyze fMRI data. By contrasting BOLD responses to either sweet or sour tastes to those from distilled water, and masking with BOLD signals associated with licking in the absence of fluid delivery, we identified taste responses in G, 12o, 13b and somatosensory cortex area 3b in three macaques. Areas activated by fluid delivery in general - as defined by a contrast of all tastes relative to baseline - included area 14, the ventral striatum, the ventral pallidum, the basal nucleus of amygdala, and the perirhinal cortex. Our findings of gustatory responses in G, 12o, 13b and somatosensory cortex area 3b are in agreement with single unit neurophysiological recordings in macaques. Whole brain fMRI in combination with quantification of licking behavior and monkeys' choice preferences for different tastes will be used to identify brain regions that signal value.

Title: Illuminating aggression circuitry in *Drosophila*

Authors: *M. P. WOHL[1,3], K. ASAHINA[2];
[1]MNL-KA, [2]Salk Inst., La Jolla, CA; [3]UCSD, La Jolla, CA

Abstract: The neural circuits underlying the motivation for, or the likelihood of, performing a behavior have been more difficult to dissect than those underlying sensory and motor systems. For instance, aggression encompasses a set of behaviors for which the likelihood of deployment can have serious consequences, and yet little is known about how neural circuits contribute. The relatively simple nervous system of the fruit fly, *Drosophila melanogaster*, is a powerful model for elucidating the neural basis of behavior, especially given the plethora of genetic tools that allow for the dissection of neural circuits at the single-neuron level. A subset of male specific neurons, called aSP-g neurons, were discovered that express the neuropeptide tachykinin, that when activated, significantly increase a male fly's level of aggression only when paired with other males. The neuropeptide tachykinin, as well as one of its receptors, TakR86C, are directly involved with the increased, context dependent, aggression observed during aSP-g stimulation. We hypothesize that a subset of downstream neurons are likely to express TakR86C. We targeted neurons which express the tachykinin receptor TakR86c with the creation of a CRISPr/CAS9 reagent that selectively drives the expression of fluorescent proteins in this population. We found that TakR86C-expressing neurons are numerous and widespread however overlap with aSP-g neurons in some areas. We further refined our search of downstream elements by labeling presynaptic sites of aSP-g neurons using GFP tagged synaptotagmin, which identified a ring-shaped neural arbor in the superior medial protocerebrum. Induction of photoactivateable GFP encircling the "ring structure" revealed TakR86C-expressing neurons in close contact with aSP-g presynaptic zones. Calclium imaging confirmed that TakR86C neurites in this region respond to aSP-g optogenetic activation. We conducted a search of available enhancer trap lines for labeling of processes in the area of interest. Lines that overlap with TakR86C expressing neurons will be tested for functional connection with aSP-g neurons. With these techniques, we hope to identify one or more populations of neurons downstream of aSP-g neurons, the properties of which may aid in our understanding of the transformation from motivation to behavior.

Title: Identification of negative regulators for aggressive behaviors in *Drosophila*

Authors: *K. ISHII, K. ASAHINA;
Mol. Neurobio. Lab., The Salk Inst. For Biol. Studies, La Jolla, CA

Abstract: Aggressive behaviors are generally important for animals to gain social benefits over other individuals. On the other hand, continuous excess excessive aggression is energetically costly and may override sacrifice other behaviors with social and biological advantages. For this reason, animals have evolved sophisticated systems to balance the aggressive state with “accelerators” and “brakes” to modulate the behavioral outcome. Recent studies have focused mainly on the “accelerator” side of neuromodulatory systems that activate aggression, whereas the “brake” systems for suppressing the aggressive state are relatively less understood.
To address this issue, we set up a genome-wide RNAi behavioral screen to identify genes that suppress aggressive behaviors, using *Drosophila melanogastor* as a genetically tractable model. We selected genes with predicted expression in neurons, and expression ofpan-neuronally expressed each UAS-RNAi construct was driven by the pan-neuronal elav-gal4. Among over 1,200 RNAi mutants, we found 11 strains reproducibly showing increased aggression in group-housed males, depending on the presence of the gal4 element. The candidate genes included intracellular signaling enzymes, neuropeptides, gustatory receptors, autophagy-related genes, and others. We further constructedare constructing gene-targeted deletion mutants using the CRISPR/Cas9 system, and confirmedin order to confirm the phenotypes of increased aggression for several candidate genes. We have already confirmed that several genes involved in intracellular signaling cascades are indeed necessary to keep aggression from escalating. We are applying the CRISPR/Cas9 genome -editing technique to create a “knock-in” alleles that allows visualization and manipulation of neurons expressing these genes.
Our study is the first to genetically identify a comprehensive set of negative regulators in aggressive social behaviors. Through further characterization of each candidate gene, regarding the expression patterns and relationship with known positive regulators/neural circuits, Through further characterization of each candidate gene, regarding the expression patterns and relationship with known positive regulators/neural circuits, we expect to gain a systematic understanding of the neuromodulatory systems for animal aggression.

Title: Genetic dissection of aggressive behavior in the BXD recombinant-inbred mouse strains

Authors: *W. E. CRUSIO[1], M.-P. ALGEO[1], B. BONHEUR[1], L. LU[2], R. W. WILLIAMS[2], A. DELPRATO[3,4];

Abstract: Intermale aggression is a complex social behavior that is likely regulated by multiple genes. In this study the BXD recombinant inbred mouse strains (RIS) were used to map quantitative trait loci (QTLs) underlying behaviors associated with intermale aggression. The BXD RIS have been used in a wide range of behavioral and metabolic studies but to the best of our knowledge, this is the first study in which aggressive behavior is tested. Four hundred and fifty-seven males from 55 strains (including the parentals) were observed at an age of 13 +/- 1 week in a resident-intruder test following 10 days of isolation. Attack latency was measured directly within a 10 minute time period and the test was repeated 24 hours later. The variables analyzed were the percentage of attacking males in a given strain (on days 1 and 2, and both days combined), as well as the attack latency on days 1 and 2. On day 1, 29% of the mice attacked, which increased to 37% on day 2. Strain differences were highly significant for all variables measured, indicating significant heritability. From these data, we identified suggestive QTLs on mouse chromosomes 7, 11, 12, and 13 for both attack and latency variables. Additional strains will need to be tested to obtain significant results and increased resolution for interval mapping. mRNA expression data and phenotype correlation analyses show significant relationships with the amygdala and striatum, and with fear and anxiety. Given the fact that only a relatively small proportion of animals attacked and that most strains showed very low proportions of attacking males, the BXDs may not be very well suited to localize QTLs involved in the regulation of aggression.

Title: Social dominance status predicts vicarious fear learning from conspecifics in male laboratory rats

Authors: *C. E. JONES[1,2], M.-H. MONFILS[1];
[1]Psychology, Univ. of Texas at Austin Dept. of Psychology, Austin, TX; [2]Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Acquiring information about stimuli that predict danger, through either direct experience or inference from a social context, is crucial for individuals' ability to generate appropriate behaviors in response to threats. Utilizing a modified demonstrator-observer paradigm (fear conditioning by proxy) that allows for free interaction between subjects, we show that social dominance hierarchy, and the interactive social behaviors of caged rats, is predictive of the potency of social fear transmission, with subordinate rats displaying increased fear responses after interacting with a fear conditioned dominant rat during fear retrieval. We found that 1) the majority of standard laboratory cages had an easily identifiable social hierarchy, 2) subordinate rats learned to freeze more when observing and interacting with a more dominant animal, and 3) play fighting indices of the social relationship correlated with the occurrence of ultrasonic vocalizations during social transmission sessions, freezing displayed after exposure to a fearful conspecific, and the neuroendocrine (corticosterone) response to a vicariously conditioned stimulus.

Title: Involvement of ventral pallidal vasopressin in the sex-specific regulation of opposite-sex preference in rats

Authors: *B. DIBENEDICTIS, C. J. SMITH, H. K. CHEUNG, E. R. NUSSBAUM, A. H. VEENEMA;
Psychology Dept., Boston Col., Chestnut Hill, MA

Abstract: The ventral pallidum (VP) is a critical node of the mesocorticolimbic 'reward' circuit, and is a component of the 'social decision-making network.' Arginine vasopressin (AVP) is a neuropeptide implicated in the regulation of many social behaviors, and AVP signaling via the V1A receptor (V1AR) within the VP is necessary for the expression of socially motivated affiliative behaviors in male prairie voles. Here, we aimed to characterize the AVP system in the VP and subsequently tested the functional significance of the VP-AVP system in sociosexual motivation in male and female rats. We found that male and female rats expressed equivalent levels of V1AR binding in the VP. However, males had nearly twice the density of AVP fibers in the VP compared to females. These findings suggest that males may experience enhanced AVP signaling in the VP. Given this sex difference, we next blocked AVP signaling in the VP by antagonizing VP-V1ARs in male and female rats and tested subjects' preference to investigate an unfamiliar male or unfamiliar estrous female confined to corrals located on opposite ends of a three-chamber apparatus. Under vehicle conditions, males showed a robust preference to investigate an opposite-sex over same-sex conspecific. However, VP-V1AR antagonism significantly reduced males' innate preference to investigate the estrous female. Compared to males, vehicle-treated estrous female subjects displayed only a modest preference for the opposite-sex. Interestingly, VP-V1AR antagonism resulted in a significant increase in females' preference to investigate the opposite sex. Importantly, all subjects could reliably discriminate between male and female stimulus rats regardless of drug treatment, suggesting a change in motivational state rather than a perceptual impairment. These results provide a novel functional link between a sex difference in ventral pallidal AVP fiber density and the sex-specific regulation of a sexually motivated behavior necessary for reproductive success.

Title: Lateral septum vasopressin system interacts with nucleus accumbens and prefrontal cortex to regulate social play in sex-specific ways

Authors: *N. NASCIMENTO, G. S. RO, C. J. REPPUCCI, R. BREDEWOLD, A. H. VEENEMA;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Social play is a highly rewarding and motivated behavior, which peaks at the juvenile period and facilitates the development of social skills needed throughout the lifespan. We recently showed that the AVP system in the lateral septum (LS) modulates social play behavior in juvenile rats in sex-specific ways. Specifically, blockade of the AVP V1a receptor (V1aR) in the LS increased social play in males but decreased social play in females. Here, we aimed to determine the neural pathway by which the LS-AVP system modulates social play behavior in sex-specific ways. To study this, single-housed juvenile male and female rats were exposed in their home cage to an age- and sex-matched unfamiliar juvenile for 10 min ("play") or placed similarly without the introduction of a play partner ("no play"). In addition, all rats were given either a vehicle or a V1aR antagonist injection into the LS 20 min prior to the play or no play session. Rats were killed 80 min after the play test, and brain tissue was processed using immunohistochemistry to detect the expression of c-Fos, an early marker of neuronal activation. Preliminary results show a higher number of c-Fos positive cells in vehicle-treated females exposed to play compared to their male counterparts in the anterior shell of the nucleus accumbens (NAcc) and in the anterior prelimbic and infralimbic divisions of the prefrontal cortex (PFC). Interestingly, V1a receptor antagonist-treated rats did not show this sex difference. Together, this suggests that social play is associated with sex differences in neuronal activation in NAcc and PFC subregions and that these sex differences are eliminated by LS-V1aR blockade. Because the LS projects directly to the NAcc, future studies will investigate the causal involvement of the anterior shell of the NAcc in the sex-specific regulation of social play by the LS-AVP system.

Title: Involvement of dopamine and noradrenaline in he sex-specific regulation of social play by vasopressin

Authors: *R. BREDEWOLD[1], N. F. NASCIMENTO[2], A. H. VEENEMA[2];
[1]Dept. of Psychology, [2]Pychology, Boston Col., Chestnut Hill, MA

Abstract: Social play is an affiliative and rewarding behavior displayed by nearly all mammals and peaks during the juvenile period. We recently showed that arginine vasopressin (AVP) acting via the V1a receptor (V1aR) within the lateral septum (LS) regulates social play in opposite directions in male and female juvenile rats. The LS receives dopaminergic input from the ventral tegmental area and adrenergic input from the locus coeruleus. Therefore, we sought to determine whether AVP interacts with dopamine (DA) and/or noradrenaline (NE) to regulate social play behavior in sex-specific ways. Using retrodialysis combined with microdialysis in awake and freely moving juvenile rats, we found that exposure to social play increased DA release in the LS of females, but not of males. Interestingly, V1aR blockade in the LS abolished this sex difference in DA release during social play. In contrast to DA release, exposure to social play did not alter NE release in the LS of either sex. However, V1aR blockade in the LS caused an increase in NE release in the LS of females but not of males. These findings suggest that the sex-specific regulation of social play by the LS-AVP system involves differential monoaminergic neurotransmission in the LS of male and female juvenile rats. Using pharmacological manipulations, we currently determine the causal involvement of DA and NE released in the LS in the sex-specific regulation of social play by AVP.

Title: Role of arginine-vasopressin (AVP), serotonin (5-HT) and galanin (GAL) within the anterior hypothalamus (AH) on aggression and social communication in male and female hamsters

Authors: *N. HARDCASTLE, T. E. LARKIN, J. I. TERRANOVA, Z. SONG, A. NORVELLE, H. E. ALBERS;
Neurosci., Georgia State Univ., Atlanta, GA

Abstract: Aggression and social communication are necessary to establish and maintain social heirarchies. In hamsters, AVP, 5-HT and GAL are involved in the regulation of aggression and a form of social communication called flank marking. In male hamsters, AVP injected into the AH stimulates aggression and flanking marking. In females, AVP injected into the AH inhibits aggression and stimulates flank marking. The aim of this study was to determine if there is a sex difference in the effects of GAL on aggression and whether GAL or 5-HT influence AVP-induced flank marking. Socially isolated hamsters implanted with a guide cannula aimed at the AH were handled daily and estrous cycles were monitored in females. Hamsters were injected with 9.0 µM AVP alone or in combination with 1 mM of the 5-HT1a agonist 8-OH-DPAT (DPAT) or 100 µM GAL. The number of flank marks were recorded during a 5 min test. There was a sex by drug interaction ($p < 0.01$). GAL and DPAT reduced AVP-induced flank marking in males (AVP: 55.3 ± 3.0; AVP/DPAT: 26.44 ± 5.81; AVP/GAL 8.0 ± 3.87) and females (AVP: 51.7 ± 7.3; AVP/DPAT: 31.2 ± 5.8; AVP/GAL 34.7 ± 6.1). Males injected with GAL/AVP flank marked significantly less than females injected with GAL/AVP. The effect of GAL on aggression was recorded in a resident-intruder test after microinjections of 0, 10, 100, or 1000 µM GAL. Although there was a significant main effect of sex (Male: 47.6 ± 9.6; Female: 94.6 ± 14.8) GAL was not found to alter the expression of aggression in either males or females. These data suggest that GAL does not modulate the expression of aggression but that both GAL and 5-HT influence the expression of AVP-induced social communication by their actions in the AH.

Title: Socially rewarding behavior recruits orexin/hypocretin neurons in juvenile male and female rats

Authors: *C. J. REPPUCCI, C. K. GERGELY, N. F. NASCIMENTO, G. S. RO, R. BREDEWOLD, A. H. VEENEMA;
Psychology, Boston Col., Chestnut Hill, MA

Abstract: Orexins/hypocretins (ORX) are neuropeptides whose central synthesis is restricted to neurons in the lateral hypothalamic area (LHA) and adjacent dorsomedial and posterior hypothalamic nuclei. The ORX system has been shown to modulate many reward-driven and motivated behaviors, but its role in socially rewarding behavior is largely unknown. Social play is a highly rewarding motivated behavior predominately displayed by juveniles, and expressed by nearly all mammalian species. Here we examined whether social play recruits ORX neurons in juvenile male and female rats. Single-housed juveniles were exposed, in their home cage, to an age- and sex-matched unfamiliar juvenile for 10 min ("Play" condition) or received similar handling but no partner ("No Play" condition). Rats were sacrificed 80 min after the test, and brain tissue was later processed using fluorescent immunohistochemistry methods for combined detection of the immediate early gene product Fos and identification of ORX-positive neurons in the LHA. Preliminary analysis showed that social play increased recruitment of ORX neurons in the juxtadorsomedial LHA (LHAjd); a greater percentage of ORX neurons were double-labeled for Fos in the Play compared to the No Play condition. Interestingly, this effect was stronger in males compared to females. These findings suggest a novel role for LHAjd ORX neurons in socially rewarding behavior at the juvenile age. The LHAjd is interconnected with regions that comprise the social behavior and mesocorticolimbic reward networks, and ORX fibers innervate many of these regions. Thus, this neuronal population is well-positioned to coordinate the expression of socially rewarding behavior. Future work will examine recruitment of specific ORX-dependent pathways during social play, and assess whether pharmacological manipulations of the ORX system alter expression of social play in males and females.

Title: Novel behavioral test for social motivation in syrian hamsters

Authors: *J. BORLAND, E. SONG, K. GRANTHAM, L. AIANI, A. NORVELLE, K. FRANTZ, H. E. ALBERS;
Neurosci. Inst., Georgia State Univ. Neurosci. Inst., Atlanta, GA

Abstract: Social interaction is a powerful motivator that is observed in every animal species. A well-validated behavioral test that investigates the rewarding properties of social interaction in rodents is the conditioned social preference (CSP) test. Yet the validity of CSP as a pure measure of social reward is limited because CSP has a significant memory component. In this study we developed an approach that allows animals to choose either to engage or not engage in social interaction and is independent of social memory. A three-chamber arena (two small, one large) with a one-way, entry-only door separating the two small chambers from the main chamber was constructed. Hamsters were placed into the main chamber, and then allowed to choose to enter a small chamber with a conspecific, an empty chamber, or neither. 20 seconds after choice, hamsters were placed immediately back in the main chamber by an experimenter. Social motivation was operationally defined as the number of door entries into a chamber containing a conspecific during a 10-minute test. The amount of force required to open the door was varied with weights to provide an additional measure of social motivation. Male and female Syrian hamsters had significantly ($p=0.009$) more entries into the social chamber (14.7 +/-4.58 entries) than the non-social chamber (7.5 +/-0.58 entries), with impact of door weights remaining to be determined. These data demonstrate that male and female Syrian hamsters are motivated to engage in same-sex conspecific social interaction. Supported by NSF IOS-0923301

Title: Dissecting prefrontal circuitry that supports social investigation.

Authors: *M. MURUGAN[1], J. P. TALIAFERRO[1], M. PARK[2], H. JANG[2], I. B. WITTEN[1]; [1]Princeton Neurosci. Inst., [2]Princeton Univ., Princeton, NJ

Abstract: Although appropriate social interactions are crucial for the survival and well-being of all mammals (including humans), very little is known about the neural substrates that support such behaviors. A major obstacle that has prevented more progress in this area is the intricacy of the underlying neural circuitry, as a large number of interconnected brain regions are involved in mammalian social interactions. Several lines of evidence implicate the prelimbic cortex (PL) as important to social behavior. However, the PL projects to a number of downstream regions and it remains unclear as to which, if any, of these projections are essential for regulating social behavior. In this study we focused our attention on three anatomical subpopulations of PL neurons: PL projections to the nucleus accumbens (NAc), the basolateral amygdala (BLA) and the ventral tegmental area (VTA. First, to measure how much overlap existed between these three subpopulations of PL neurons we used dual color retrograde tracing with cholera-B-toxins (488, 555, 647nm). We found that these three subpopulations were largely distinct with little overlap (< than 10%; % overlap - PL→NAc vs PL→BLA : 8.14, PL→NAc vs PL→VTA : 3.98, PL→BLA vs PL→VTA : 0.26). To test if manipulating the activity of these different subpopulations had an effect on social investigation, we injected ChR2 bilaterally into PL and stimulated PL afferents in the NAc, BLA or VTA bilaterally while animals were engaged in a social assay. We found that optogenetic activation of PL→NAc neurons (ChR2 n=10; YFP n=8, p =0.00386) but not the PL→BLA (ChR2 n=9, YFP n=8, p = 0.8873) or the PL→VTA (ChR2 n=11, YFP n=8, p=0.9215) neurons disrupted social investigation. Additionally, no effect was observed on the investigation of the novel objects. Furthermore, to characterize the neural dynamics of this population during social interactions we monitored the activity of the PL→ NAc using cellular-resolution imaging in freely moving mice in a modified version of the three chamber social assay. Interestingly, we observed that a significant subset of these neurons (16/131 neurons) responded in the location of the social target mouse even when the location of the social target was altered. By combining cellular resolution imaging, viral intersectional strategies and optogenetics, this study provides insight into the neural circuits that underlie social behavior, pointing to an important role for the prelimbic cortical projection to the nucleus accumbens in mediating social investigation.

Title: Involvement of mu opioid receptors in the regulation of juvenile social novelty seeking behavior: Brain region specific effects and modulation by social separation

Authors: *C. J. SMITH, A. M. RATNASEELAN, S. LI, A. H. VEENEMA;
Boston Col., Chestnut Hill, MA

Abstract: The drive to approach and explore novel conspecifics is inherent to social animals and may promote optimal social functioning. Juvenile animals seek out interactions with novel peers more frequently and find these interactions to be more rewarding than their adult counterparts. We have previously shown that juvenile rats spend more time interacting with a novel conspecific than a cage mate (sex and age matched). However, the underlying neural mechanisms have yet to be determined. Given their role in the regulation of rewarding juvenile social behaviors, we hypothesized that μ-opioid receptors (MORs) might play an important role in the facilitation of juvenile social novelty-seeking behavior. Using the MOR antagonist CTAP, we show that central (intracerebroventricular) MOR blockade reduces social novelty-seeking behavior in juvenile male rats. This effect appears to be specific to the opioid system as oxytocin, vasopressin V1a, or dopamine D2 receptor blockade had no effect. Moreover, this effect appears to be brain region-specific as local MOR antagonism in the anterior nucleus accumbens, but not the basolateral amygdala, reduces social novelty-seeking, despite the fact that both brain regions display dense MOR binding in juvenile rats. Finally, an acute period of social separation (3 hours) reduces juvenile social novelty-seeking behavior, an effect that can be rescued by central MOR agonism (using DAMGO). Taken together, these results demonstrate that MOR activation facilitates juvenile social novelty-seeking behavior by acting on the nucleus accumbens and restores juvenile social novelty-seeking behavior following social separation. This research was supported by NSF GRFP 2012138127 to CJS and NSF IOS1253386 to AHV.

Title: Role of opioids and endocannabinoids on the expression and motivational properties of social play behaviour in rats

Authors: *M. ACHTERBERG[1], M. M. H. VAN SWIETEN[2], D. J. HOUWING[2], M. AALDERINK[2], N. V. DRIEL[1], V. TREZZA[3], L. J. M. J. VANDERSCHUREN[2];

Abstract: Social play behaviour a characteristic form social behaviour displayed by the young of many mammalian species, including rats and humans, which is thought to be important for social and cognitive development. Being a rewarding activity, the performance of social play depends on its pleasurable and motivational properties. Opioids and endocannabinoids have an important role in social play behaviour, perhaps through modulation of reward processes. However, it is unknown whether opioids and endocannabinoids are also involved in the motivation for social play behavior. Therefore, we assessed the effects of opioid and cannabinoid (ant)agonists in an operant conditioning setup in which rats responded for social play under a progressive ratio schedule of reinforcement. This setup allowed for the parallel measurement of the performance of social play.
Treatment with the opioid receptor agonist morphine increased the performance of play behavior but did not affect operant responding. Blocking opioid receptors with naloxone reduced both responding for play and its performance. Enhancing endocannabinoid levels with the anandamide-hydrolysis inhibitor URB597 modestly reduced operant responding, without affecting social play performance. Treatment with the cannabinoid-1 receptor antagonist rimonabant non-specifically reduced operant responding, due to its pruritic effect, without affecting social play performance.

Consistent with previous work implicating opioid neurotransmission in social play behaviour, these data demonstrate also have an important role for opioids in the motivational properties of social play. However, although endocannabinoids are known to be involved in social play behaviour, they have only a minor role in the motivation for social play.

Title: Social representations in the mouse prefrontal cortex

Authors: ***D. R. LEVY**, A. WEISSBROD, O. YIZHAR;
Neurobio., Weizmann Inst. of Sci., Rehovot, Israel

Abstract: The prefrontal cortex (PFC) is crucial for modulation of complex social functions in the mammalian brain. In autism spectrum disorders, functional and morphological abnormalities in this region are thought to be associated with diverse social deficits. Yet to date, it is unclear how the PFC encodes social information, and how such social representations might drive complex behavioral responses in health and disease. To address these questions, we utilized a novel apparatus to record unit activity in the medial prefrontal cortex (mPFC) of behaving male mice presented with rapid and precisely timed social and non-social olfactory cues. We found that a large fraction of all recorded mPFC units (117/278) responded exclusively to social over non-social odors. Many of these units were stimulus-specific, such that 33% responded solely to male cues, while 24% responded exclusively to female odors. We also observed distinct temporal response patterns to male and female cues. While presentation of male odors elicited a robust neuronal response within 150 ms of cue delivery, female-evoked responses developed more slowly, peaking within 1450 ms after stimulus onset. High-resolution analysis of behavior

revealed that activation of both female-specific and male-specific units, but not non-social units, was significantly correlated with the initiation of approach behavior. These patterns of social coding were significantly altered in capsr2 knockout mice, a well-established genetic model of autism. mPFC units in these mice showed decreased specificity for social odors, and blunted stimulus-evoked neuronal dynamics. Furthermore, while response magnitude was significantly larger for social over non-social odors in wild-type mice, units in caspr2 knockout mice responded with similar magnitude to all presented cues. Taken together, our results identify specific representation for salient social stimuli in the mPFC and reveal changes in mPFC information processing in a genetic model of autism.

Title: Post-weaning social isolation of female mice delays maturation of parvalbumin-positive interneurons in the orbitofrontal cortex

Authors: *D. JEONG[1], E. KANG[1], D. JO[1,2], M. KIM[1,2], Y. KIM[1,2], S. KIM[1,3], S.-H. LEE[1]; [1]KAIST, Daejeon, Korea, Republic of; [2]Daejeon Sci. High Sch. for the Gifted, Daejeon, Korea, Republic of; [3]Univ. of California, Berkely, CA

Abstract: Social perception is important for animal survival and matures slowly after the birth. However, we still do not understand the brain mechanism of circuit maturation during the development of social behavior. Here, we adapt a mouse model of post-weaning social isolation (PWSI) to identify circuits matured during the social critical period. We found that the prolonged social isolation during the juvenile period significantly enhanced the sociability in female mice. Furthermore, the maturation of parvalbumin-positive (PV+) interneurons in the orbitofrontal cortex significantly delayed in the female PWSI mice. Interestingly, we did not observe any

impairment of PV+ neurons in male PWSI mice, even though they showed significant reduction in the social memory. Our results demonstrate that gender-specific PV+ circuit maturation in the prefrontal cortex is important for normal development of social behavior during the social critical period in mice.

Title: Single neuronal correlates of social bias

Authors: *R. BÁEZ-MENDOZA, F. BOUNNI, Z. M. WILLIAMS;
Neurosurg., Massachusetts Gen. Hospital-Harvard Med. Sch., Boston, MA

Abstract: Social groups can have a profound influence on their member's decisions, and can often bias an individual's behavior in both, positive and negative ways. Here, we explore the neuronal mechanisms through which social groups influence an individual's behavior. By using small groups of mice in a foraging task and covertly introducing biased participants, we discovered specific cells in the anterior cingulate cortex (ACC) that uniquely encoded social biases introduced by their group's decisions. This information was complemented by a second ensemble of cells that reflected conformity or opposition to the group. Neuronal responses to social bias were surprisingly insensitive to reward success and were most strongly modulated by group consensus, even when decisions were wrong. These effects were strongest when foraging in less reliable patches and were weakest when foraging democratically or when guided by non-social cues. Interestingly, electrical disruption of normal activity in ACC reduced the influence of the group on individual's behavior. These findings reveal a subgroup of cells in ACC that specifically encoded social biases introduced by group decisions while disrupting their normal activity reduced social biases. Overall, our results suggest an early phylogenetic process that may have allowed social animals to make decisions collectively as a group.

Title: Differential effects of oxytocin on maternal attachment in Sprague-Dawley and Fisher 344 preweanling rats.

Authors: D. E. HUMPHREY, A. TERAN, E. M. ALDERSON, Z. R. HARMONY, *C. A. CRAWFORD;
Dept. of Psychology, California State Univ., San Bernardino, CA

Abstract: Fischer 344 (F344) rats exhibit reduced play behavior when compared to various other rat strains, including Sprague-Dawley (SD) rats. This finding suggests that F344 rats may be useful for studying social interaction deficits that are common in developmental psychiatric disorders. The purpose of the present study was to determine whether F344 and SD rats differ in their ability to form maternal attachment bonds during the preweanling period. In addition, we assessed whether the prosocial hormone oxytocin would alter attachment behavior in either rat strain. We measured attachment in F344 and SD rat pups on postnatal day (PD) 12 by using a maternal odor-induced conditioned place preference (CPP) procedure. The CPP procedure consisted of a habituation day, a conditioning day, and a test day, and was conducted in a Plexiglas three-compartment chamber. On the habituation day (PD 10), rats were given free access to the testing chamber for 1 min. On the conditioning day (PD 11), rats were given three 30-min conditioning sessions separated by 3 h of maternal deprivation. Sessions consisted of either placing the pups in a holding cage with a lemon-scented dam (maternal group) or in an identical cage with lemon-scented cotton balls (neutral group). On the test day (PD 12), all rat pups were given 5 min free access to the testing chamber, in which one side contained lemon scent and the other side was unscented. In Experiment 2, the identical procedures were used, with the exception that rat pups were injected with saline or oxytocin (250, 500, or 1000 ng, IC) prior to the first conditioning trial. In both experiments, time spent in the two compartments and the number of compartment entries were measured. As expected, rat pups in the maternal group spent more time in the lemon-scented compartment than rats in the neutral group. The maternal group also had more compartment entries. The latter effect was only evident in SD rats. In the second experiment, SD rats were unaffected by oxytocin treatment, while F344 rats were

impacted by oxytocin in a sex-dependent manner. Specifically, 250 ng oxytocin increased the odor preference of male F344 pups, while 1000 ng oxytocin increased odor preference in female F344 pups. The lower dose of oxytocin also caused a general increase in locomotor activity (i.e., increased entries into both compartments), but only in female F344 rats. In sum, these data indicate that SD and F344 rat pups exhibit a similar preference for dam-associated odors, but the preference shown by F344 rats could be enhanced by an exogenous application of oxytocin.

Title: Female mice social preference - interaction with the reproductive cycle

Authors: *L. F. MOREIRA, S. Q. LIMA;
Champalimaud Fndn., Lisboa, Portugal

Abstract: Cyclic changes in circulating sex hormones are known to guide females into sexual receptivity. On the other hand, in rodents, the midbrain dopaminergic circuit has been implicated in the appetitive aspects of sexual behavior with relevance to the pursuit of sexual cues.
We are interested in understanding how different hormonal states influence midbrain dopaminergic activity during social interactions, with either socially or sexually relevant stimuli (female vs male, respectively), as well as socially or sexually relevant stimulus predicting cues (pure tones that are associated with the different stimuli), sustaining a sexually receptive state.
To do so, we developed an operant task where female mice are rewarded with social interactions (each corresponding to 5 seconds of restricted nose-nose contact, odors and vocalizations) with either a male or a female conspecific, during 1 hour. In this task, trial initiation causes the delivery of a tone that indicates which of the two possible outcomes (male or female) is available for the female to cash. Vaginal smears are collected after every session to classify the physiological receptivity of each female. Therefore, we are able to investigate how hormone fluctuations influence female performance on the task.
Preliminary data indicates that sex hormones affect several behavioral parameters in female performance (such as reaction times and time spent with each stimulus). Using fiber photometry to record calcium transients in dopaminergic neurons of the ventral tegmental area, we are now

starting to investigate if the representation of reward predicting cues and social rewards are modulated by sex hormones.

Program, Brown Univ., Providence, RI; [8]Univ. of California, San Francisco, San Francisco, CA

Abstract: While strong evidence supports the effects social bonds have on numerous aspects of human health, efforts to understand the neural basis of bonding have left many open questions. This is in part due to the relative shortage of appropriate animal models; biomedical research relies heavily on rats and mice, but these animals do not form strong, selective bonds with other adult conspecifics. However, laboratory-amenable prairie voles offer further opportunities to understand how social bonds are formed and maintained because, as a monogamous species, they form highly selective affiliative bonds between mated partners. Multiple lines of converging evidence suggest that the nucleus accumbens (NAc) plays a critical role in pair bonding. Monogamous prairie voles exhibit high levels of oxytocin receptors in the NAc. Local antagonists or reduction of oxytocin receptors in the NAc inhibits bond formation, while increasing levels of these receptors can enhance bond formation. Moreover, neuroplastic changes within this region may underlie the patterns of bond maintenance. While the NAc has clear importance for pair bonding, very little is known about the neural circuit within the NAc that mediates this behavior, the degree of sexual dimorphism in patterns of circuit activity, and how this circuit changes upon bond formation and over time. In order to understand the neural circuits that underlie these social bonds, we have used miniaturized microscopes to perform freely-

moving calcium imaging in vivo to monitor activity of large populations of NAc neurons in male and female prairie voles during epochs of social interaction. This allowed us to observe population activity in response to interactions with their mate, a novel conspecific, and other non-social stimuli both before and at several time points following bond formation. We have found that NAc neurons are robustly activated in response to social interaction. Our ongoing efforts are aimed at further deciphering how the population code within the NAc is related to interactions with a bonded partner versus a novel conspecific, changes with time after bonding, and the extent to which population dynamics may differ between males and females.

Title: Neural correlates of socio-emotional states in macaques

Authors: *M. JAZAYERI, S. WIRTH, J.-R. DUHAMEL;
Inst. of cognitive neuroscience, CNRS, Lyon, France

Abstract: Most non-human primates live in social environments, where appropriate decisions are believed to contribute to group fitness and seem to be crucial for survival and reproduction. Recent work in non-human primates shows that several brain regions, including prefrontal cortical, limbic and basal ganglia structures are implicated in the processing of motivational and emotional domains, extending to and integrating the social dimension of subjective experiences (1, 2, 3, 4). In our study we used a decision-making task akin to an iterated dictator game where, based on the monkeys' choices, positive or negative reinforcements could be delivered to self, another monkey or to nobody. Our previous behavioral results showed that, in terms of both pro-social decision rates and associated measures of social interaction like mutual gaze and eye blink rates, macaques take into account the welfare of their peers even when this has no impact on their own welfare (5). While monkeys were performing this task we investigated neuronal activity in orbitofrontal cortex (OFC), amygdala (AMY) and anterior insula (AI) by using

multiple contact electrodes. We recorded from one monkey at a time or from both simultaneously, as well as from one brain region or from two areas in parallel, as monkeys alternated in making social decisions. Preliminary neuronal findings show distinct populations of neurons responding differentially to outcomes for self and other, and to appetitive and aversive outcomes. Interestingly, information carried by neurons in the amygdala was highly specific and predicted not only outcome recipients and valences but also differentiated between self and other as the agent of social decisions. Together these results suggest that evaluating the social context of decisions about reward and punishment involves different, distributed subsets of neuronal specialization.

Title: Neural mechanisms of communication via facial expression

Authors: *S. V. SHEPHERD, W. A. FREIWALD;
Rockefeller Univ., New York, NY

Abstract: Human communication abilities are unique, but build upon a common foundation we share with our primate kin. Primates live in complex social groups with which they must coordinate their behavior, exchanging signals comprising postures, movements, and vocalizations. Scientists have made progress in understanding how facial signals are decoded in primate brains, but know almost nothing about how these signals are produced. We recorded brain activity in monkeys seeing and responding to communicative signals in an MRI scanner. Stimuli were made from video recordings of six monkeys producing a variety of facial expressions. Stimulus videos were simultaneously recorded from multiple angles; a half-silvered mirror was used when recording direct gaze to facilitate naturalistic eye contact. Two 10-second clips were gathered from each monkey, synchronously from three viewpoints. Phase scrambled versions of each video were used as low-level visual controls, and were generated by randomly rotating each Fourier component a consistent amount across each frame. To reduce habituation, we limited exposure to each video. Long (14 second) gaps were placed between videos. Within each run, only one video per subject was shown. Within each session, each video (i.e. subject, event, perspective and scramble) was shown exactly once.
Monkeys produced an affiliative gesture, called a 'lipsmack', in response to brief video of subject-directed monkey expressions. Facial movements were recorded by MR-safe video camera and later analyzed both digitally and by manually scoring behavior while blind to stimulus condition. IRON-fMRI imaging was used to track changes in cerebral blood volume associated with neural activity. By comparing both perceived and produced facial behavior to these simultaneously-recorded brain images, we identified key regions involved in processing social interactions and translating perceived signals into appropriate expressive responses. We find that perception of social stimuli activated the extended face patch system, and that production of the macaque 'lipsmack' signal correlated with activation of facial motor regions. Finally, we examine functional correlations between perceptual and motor face patches to determine candidate pathways by which these socially-driven facial expression may arise.

Title: Neural encoding of dynamic social interactions

Authors: ***M. AINSWORTH**[1,3], D. KYRIAZIS[2], M. G. KELLY[2], O. JOLY[2], A. H. BELL[2,3]; [2]Dept. of Exptl. psychology, [1]Oxford Univ., Oxford, United Kingdom; [3]MRC Cognition and Brain Sci. Unit, Cambridge, United Kingdom

Abstract: Over the past decade, numerous studies have identified regions within the primate brain that seem to be necessary for the representation of social information. These include, but are not limited to face-responsive regions, such as the fusiform face area, as well as regions responsive to body parts and species-specific vocalisations. These studies have predominantly, although not exclusively, utilised static images. However, social information in natural environments evolves continuously based on interactions within a group. Therefore, not only is using static images not representative of our daily experience. But more critically - it limits our ability to understand the neural mechanisms by which these regions facilitate our processing of social situations.

In the present study, we collected functional neuroimaging (fMRI) data from awake, behaving macaques presented with video clips. These clips contained a variety of social interactions between macaques. Interactions were classified as "positive" (e.g., grooming), "neutral" (e.g., indifference), or "negative" (e.g., fighting). Three macaques were trained to fixate on a cue and were rewarded while they maintained their gaze within the frame area of the video clip (approx 10º wide). We obtained fMRI data from all subjects (at 3T, 1.5 mm isotropic voxels, TR=2s, TE=19ms; 1320-1760 volumes per session, 12 sessions per macaque). Video clips were presented in 220s runs and consisted of four "ON" blocks (40s) in which clips 5-20s long, were randomly interleaved and three "OFF" blocks (20s) in which only a fixation cue was presented. To identify regions putatively involved in encoding social context and interactions, we contrasted the nature of the interaction (positive, negative) with neutral interactions as well as scenes featuring only one macaque. We included several additional regressors (e.g., number of macaques), as well as nuisance regressors (e.g., luminance changes, overall motion, etc.). Timeseries data were subjected to a general linear model. Consistent with previous studies changes in the number of macaques activated visual and temporal cortex including documented face and body part selective regions. Of note, we found regions that were significantly activated for proximal positive and negative interactions (over neutral). Specifically, ventral prefrontal cortex, inferior and superior banks of the superior temporal sulcus as well as subcortical activations (amygdala and basal ganglia). These data suggest the existence of a network of regions in the macaque brain extending beyond the face-selective patches of the temporal lobe that is responsible for encoding social interactions.

Title: Effects of varying social interaction parameters to optimize acquisition of a socially transmitted food preference

Authors: *L. AGEE, L. K. CORMACK, M.-H. MONFILS;
Psychology, Univ. of Texas At Austin, Austin, TX

Abstract: Learning through observation of conspecifics is an important form of information gathering in many species. The social transmission of food preference (STFP) paradigm is a common model for studying social learning in rodents, and involves pairing of an observer animal with a demonstrator that has recently eaten food containing a novel flavor (Galef, 2012 for review). Given the choice between two novel flavors, observers are found to show a preference for the flavor that was eaten by their demonstrator. As part of a larger study we will be running using the STFP paradigm, we compared the ability of observer rats to learn a food preference from a demonstrator when learned under two different conditions of either high or low social interaction with their demonstrator. The rats in the low social interaction condition were socially isolated during the demonstrators' food deprivation period and were then given only 15 minutes of social interaction after demonstrators were exposed to the novel food. In the high social interaction condition, rats were kept in the same cage separated by a cage barrier during the food deprivation period, given 30 minutes of social interaction, and the demonstrators' noses were powdered with the appropriate flavor after they ate. In both conditions, rats acquired preference for the demonstrated behavior. However, the effect size for the high social interaction condition, was higher than for the low social interaction condition, and this difference was statistically significant (10,000 bootstrap replications). We conclude that the higher social interaction condition yielded much better learning of the socially transmitted taste preference. This finding hints at the profound importance of the degree of social interaction in transmitting important behaviors amongst conspecifics.

Title: Aggressive arousal and escalated aggression are dissociated by CRF-amine VTA-DRN-LH microcircuits in mice: targets for alcohol

Authors: H. E. COVINGTON[1], D. STEIN[1], M. LEONARD[1], E. NEWMAN[1], L. M. DARNIEDER[2], M. DAWES[1], K. GOBROGGE[1], J. F. DEBOLD[1], *K. A. MICZEK[3]; [1]Psychology, Tufts Univ., Medford, MA; [2]Neurosci., Tufts Univ., Boston, MA; [3]Moses Hunt Professor of Psychology, Tufts Univ., Medford, MA

Abstract: More than half of violent acts are associated with the consumption of alcohol. However, types of aggression vary widely when considering impulsive vs. premeditated and calculated offenses towards another. Here, aggression and the motivation to commence aggressive acts were quantitatively examined in mice under the following conditions. First, access to the opportunity to engage in fighting behavior was permitted in separate groups of outbred (CFW) and inbred (C57 Bl/6J) mice, using a fixed-interval ten-minute (FI 10) schedule for aggression as reinforcement. Second, the role of corticotrophin releasing hormone (CRH) receptors was examined on aggressive arousal and performance of aggressive acts. Third, mice were trained to self-administer alcohol and then gain access to fighting by their successful completion of behavioral demands. Both inbred and outbred mice were highly motivated by the opportunity to fight and schedule-controlled aggression was significantly escalated (Fish et al. 2004, 2008). Increasing doses of the selective CRH receptor subtype 1 antagonist CP 376395 completely abolish motivational aspects of aggressive behavior without influencing the escalation of attack behaviors during confrontations with an intruder. As expected, self-administered alcohol dose-dependently modulates both the motivation to engage in aggression and fighting performance. Experiments using optogenetics further examine the particular role of CRH neuronal populations on alcohol-escalated aggressive behaviors. Both the dorsal raphe nucleus and hypothalamus modulate aggressive behavior, but CRH projections from these areas to the posterior ventral tegmental area appear to contribute uniquely towards aggressive arousal or the escalation of aggressive acts. In sum, these experiments are aimed at identifying the motivational components of premeditated violence and the neural elements that control reactive “hot” acts of aggression commonly associated with sympathetic activation.

Title: Post-retrieval midazolam inhibits ethanol memory reconsolidation in adolescent rats

Authors: *K. BYRKET, J. HICKEY, A. SIBERT, E. SMALLEY, J. J. QUINN;
Miami Univ., Oxford, OH

Abstract: Memory retrieval often induces a time-dependent period of destabilization followed by reconsolidation. Destabilization of the memory occurs upon retrieval. Together these processes allow long-term memories to be updated with new information. Both aversive and appetitive memories have been shown to undergo reconsolidation. The ability to update appetitive memories, in particular, has relevance to the treatment of substance abuse disorders. The present experiment addressed whether ethanol conditioned place preference (CPP) memories undergo reconsolidation following a non-reinforced retrieval session in male and female adolescent rats. On day 1, rats underwent baseline preference testing during which they were allowed unrestricted access to all three compartments of the conditioning chamber for 15 minutes. On days 2-9, rats were trained using alternating daily exposures to the ethanol-paired and control-paired compartments (four exposures to each). On ethanol days, rats were allowed access to 10g of ethanol gelatin while restricted to the ethanol-paired compartment for 30 minutes. On control days, rats received access to the control gelatin in the control-paired compartment for 30 minutes. On day 10, rats were placed into the ethanol-paired compartment for 10 minutes with no access to gelatin. Immediately following this reactivation session, rats received an injection of midazolam (MDZ; 3mg/kg) or vehicle. The next day, rats were tested for 15 minutes with access to all three compartments (identical to the baseline test). The number of entries into and time spent in each compartment were assessed. Vehicle-injected control rats did not appear to acquire a preference for either compartment. However, MDZ-injected rats spent significantly less time in the ethanol-paired chamber, compared to controls. These data suggest that the rats had acquired a memory for each compartment, and this memory was susceptible to reconsolidation upon retrieval. No sex differences were apparent. We are currently assessing

whether extended training will yield a strong preference for either chamber and whether this stronger memory will be susceptible to reconsolidation. Together, these investigations will provide valuable information regarding appetitive memory reconsolidation in adolescence, with relevance to the heightened susceptibility to substance abuse behaviors observed during this developmental period.

Title: The role of NMDA receptors in the retrieval and reconsolidation of context fear discrimination memory

Authors: *D. E. KOCHLI, A. F. POSTLE, R. S. LAB, E. W. HOLLINGSWORTH, T. L. CAMPBELL, V. C. MORDZINSKI, J. J. QUINN;
Psychology, Miami Univ., Oxford, OH

Abstract: Mounting evidence suggests that, under certain conditions, retrieved memories become destabilized and must be re-stabilized via a process termed reconsolidation. However, boundary conditions on the induction of the process are not well understood. In addition, the evidence for the role of NMDA receptors in reconsolidation is somewhat inconsistent; some studies suggest that NMDAr antagonism is sufficient to disrupt reconsolidation *per se*, while others suggest NMDArs play a role in memory destabilization but not reconsolidation. Further, there is mixed evidence as to whether or not NMDArs are necessary for the retrieval of a previously learned memory. The present work displays strong evidence that NMDArs are necessary for the retrieval of a context fear discrimination memory. While previous work from our lab demonstrates that well-learned context discrimination memories undergo protein-synthesis-dependent reconsolidation, the present work suggests that less well-learned discriminations do not. This points to a clear role for prediction error as a boundary condition of discrimination memory reconsolidation; if there is no clear prediction to violate, then there is no error present to initiate the reconsolidation process. Alternatively, it is possible that the memory for the shock-reinforced context may be overtrained. As animals reach asymptotic levels of

freezing to the reinforced context by approximately day four of training but do not reach appropriate levels of discrimination (i.e. low freezing in the non-reinforced context) until day 10, it is possible that the CTX+ association is being overtrained. It is well-documented that strong memories are resistant to reconsolidation. Current efforts are exploring this question with an alternative training approach aimed at minimizing overtraining by including a greater number of exposures to CTX- compared to CTX+ over the course of training. Demonstration of a reconsolidation deficit with this approach will provide further evidence supporting memory strength as a boundary condition, and will allow us to better assess the contributions of NMDArs to memory destabilization and reconsolidation.

Title: The effect of extinction on the destabilization of an overtrained memory

Authors: *M. MCDANIEL, M. DUNN, M. MYERS, V. DIANA;
Psychology, Miami Univ., Oxford, OH

Abstract: Reconsolidation is a process by which memories are destabilized, updated, and then restabilized. Strong memories are resistant to undergoing reconsolidation. Therapeutically, this resistance has proven difficult since behavioral and pharmacological interventions that interfere with memory reconsolidation in the laboratory often are of little efficacy in treating strong emotional memories in the clinic. In the present experiment, we addressed whether an overtrained fear memory could be made susceptible to reconsolidation by first extinguishing, and then renewing, the memory. Rats were trained with ten tone-shock pairings, followed by eight days of tone extinction in the same context. The next day, rats were placed into a second context and memory for the tone was reactivated/renewed with a single tone presentation. Immediately following reactivation, rats received an injection of Midazolam or vehicle. Midazolam has previously been shown to disrupt the reconsolidation of fear memories. Rats were then tested for freezing to the tone in a third context. Results indicate that Midazolam had no effect in rats that did not undergo tone extinction. This is consistent with previous finding suggesting that strong

memories do not undergo reconsolidation upon retrieval. Rats that underwent tone extinction froze less than those that received no extinction. This is consistent with findings showing that renewal of an extinguished memory tends to be less that the original, non-extinguished, memory. Importantly, Midazolam significantly attenuated freezing to the tone in extinguished rats. This suggests that those rats that received tone extinction underwent tone memory reconsolidation following its renewal. These data suggest that strong emotional memories may, in fact, be capable of updating following weakening of memory expression through extinction. This could prove invaluable for therapeutic approaches that attempt to weaken the impact of debilitating memories.

Title: The role of the ventral tegmental area in the reconsolidation of context fear discrimination memory

Authors: M. M. PERRY, J. L. GENARO, H. E. LINDNER, C. N. DYE, D. E. KOCHLI, R. J. FLOYD, *J. J. QUINN;
Psychology, Miami Univ. Dept. of Psychology, Oxford, OH

Abstract: Under certain conditions, retrieved memories become destabilized and must be re-stabilized via the reconsolidation process. However, conditions necessary for the induction of the process are not well understood. A body of research suggests that a prediction error must occur to initiate memory destabilization. It has been suggested that dopamine signaling may critically support the signaling of a prediction error. Inactivation of the VTA, the principal source of dopaminergic input to forebrain and limbic structures, prevents destabilization of appetitive memories. However, much less is known regarding dopamine-mediated destabilization of aversive memories. The present work explored whether VTA inactivation with a muscimol/baclofen cocktail would prevent memory destabilization and subsequent disruption of reconsolidation via systemic administration of the $GABA_A$ agonist, midazolam. While earlier work from our lab shows that well-learned context discrimination memories are destabilized following a non-reinforced reactivation trial in CTX+, the present study suggests that less well-

learned discriminations are not. This pattern suggests that a prediction error is requisite for the initiation of the reconsolidation process. With no clear prediction to violate, omission of the US does not initiate reconsolidation. It is also possible that the memory for CTX+ was overtrained. Because animals reach asymptotic levels of freezing to CTX+ after five days of training but do not display robust discrimination (i.e. low freezing in CTX-) until days 10-12, it is possible that appreciable overtraining occurrs. It has been demonstrated that strong memories are resistant to reconsolidation. We are currently exploring this possibility with an alternative training approach designed to eliminate overtraining. This approach includes more exposures to CTX- relative to CTX+ during discrimination training. Demonstrating a reconsolidation deficit using this approach would provide further evidence that memory strength can serve as a boundary condition. Additionally, this would allow us to assess the role of dopaminergic signaling in memory destabilization.

Title: Effects of the swimming exercise on the consolidation and persistence of auditory and contextual fear memory

Authors: *G. T. REIS[1], A. B. BERETA[2], L. S. GUTIERRES[2], F. F. C. SOBRINHO[2], I. D. MIRANDA[2], J. DOS REIS[2], E. V. DIAS[2], C. R. SARTORI[3], R. S. DE FARIA[2], D. A. R. MOREIRA[2];
[1]Faculdade De Medicina De Itajubá, Passos, Brazil; [2]Fac. of Med. of Itajubá, Itajubá, Brazil; [3]Unicamp, Campinas, Brazil

Abstract: Exposure to negative environmental events triggers defensive behavior and leads to the formation of aversive associative memory. Cellular and molecular changes in the central nervous system underlie this memory formation, as well as the associated behavioral changes. In

general, memory process is established in distinct phases such as acquisition, consolidation, evocation, persistence, and extinction of the acquired information. After exposure to a particular event, early changes in involved neural circuits support the memory consolidation, which corresponds to the short-term memory. Re-exposure to previously memorized events evokes the original memory, a process that is considered essential for the reactivation and consequent persistence of memory, ensuring that long-term memory is established. Different environmental stimuli may modulate the memory formation process, as well as their distinct phases. Among the different environmental stimuli able of modulating memory formation is the physical exercise which is a potent modulator of neuronal activity. There are many studies showing that physical exercise modulates learning and memory processes, mainly in the consolidation phase of the explicit memory. However, there are few reports in the literature regarding the role of physical exercise in implicit aversive associative memory, especially at the persistence phase. Thus, the present study aimed to investigate the relationship between swimming exercise and the consolidation and persistence of contextual and auditory cued fear memory. Male Wistar rats were submitted to sessions of swimming exercise five times a week, over six weeks. After that, the rats were submitted to classical aversive conditioning training by a pairing tone/foot shock paradigm. Finally, rats were evaluated for consolidation and persistence of fear memory to both auditory and contextual cues. Our results demonstrate that classical aversive conditioning with tone/foot shock pairing induced consolidation as well as persistence of conditioned fear memory. In addition, rats submitted to swimming exercise over six weeks showed an improved performance in the test of auditory cued fear memory persistence, but not in the test of contextual fear memory persistence. Moreover, no significant effect from swimming exercise was observed on consolidation of both contextual and auditory fear memory. So, our study, revealing the effect of the swimming exercise on different stages of implicit memory of tone/foot shock conditioning, contributes to and complements the current knowledge about the environmental modulation of memory process.

Abstract: OBJECTIVE:The present study aimed to investigate the relationship between swimming exercise and the extinction memory. METHODS: Male Wistar rats were submitted to sessions of swimming exercise five times a week, over six weeks. After that, the rats were submitted to aversive conditioning training. After 28 days rats were evaluated for exctintion of fear memory to contextual cues. The following groups were formed: Sedentary NAIVE: Not exercised rats, unconditioned;Trained NAIVE: Exercised swimming rats , unconditioned; Sedentary COND: Not exercised rats, submitted to fear conditioning and evaluated 28 days after the conditioning training, Trained COND: Exercised swimming rats, submitted to fear conditioning and evaluated 28 days after the conditioning training. RESULTS: It was observed that on day one of extinction test the rats of the groups conditioned to aversive training: Sedentary Conditioned, Trained and Conditioned showed no statistical differences between them ($p > 0.05$; $F3.31 = 1.71$; $P = 0.4901$). The analysis post hoc Tukey's multiple comparison tests indicated that the mice Sedentary Naive groups and trained Naive differ significantly from Sedentary Conditioned groups. Trained and Conditioned ($p < 0.0001$). It was observed that the fifth day of extinction test, unlike the first day, the rats of Group Trained Conditioned demonstrated lower freezing value when compared to the group of rats Sedentary Conditioned ($F3.31 = 71.38$; $p < 0.001$; one-way ANOVA followed by Tukey-Kramer test for multiple comparisons). Additionally, it was observed that member groups that did not go through aversive conditioning training (Sedentary Naive, Trained Naive) had a lower percentage of freezing when compared to mice conditioned Sedentary groups Conditioned, Trained Conditioned ($F3.31 = 71.38$; $p < 0.001$; one-way ANOVA followed by Tukey-Kramer test for multiple comparisons). CONCLUSION: Our results showed that exercised rats had the extinction of the context memory first than the sedentary ones. Demonstrate that swimming exercise induced a positive effect in the reconsolidation memory. So, our study, revealing the effect of the swimming exercise on different stages of implicit aversive memory, contributes to and complements the current knowledge about the environmental modulation of memory process.

Title: Saliency and distributed conditioning contribute to making context fear memory independent of the hippocampus

Authors: S. KISHUN, K. JUNGKUNZ, C. CARTER, *H. LEHMANN;
Psychology, Trent Univ., Peterborough, ON, Canada

Abstract: Damage to the hippocampus (HPC) following contextual fear conditioning in rats typically causes retrograde amnesia, but distributing/repeating the conditioning over several sessions can mitigate the retrograde amnesic effects. Hence, context fear memory can rapidly become independent of the HPC over repeated learning episodes. It is unclear, however, whether repetition of the learning episodes alone is sufficient or whether a combination of repetition and high conditioning saliency is necessary to make the context fear memory become HPC independent. To examine this possibility, rats were trained under a distributed contextual fear conditioning protocol (10 single shock sessions; two per day for five days) using either a 0.4, 0.7, or 1.0 mA shock intensity, which respectively corresponded to low, intermediate, and high saliency. Three to five days after the last conditioning session, the rats received sham surgery or neurotoxic lesions of the HPC and 12-14 days later were tested for memory of the context fear. During the retention test, the rats with HPC damage from the low saliency condition (0.4 mA) froze significantly less than their respective sham control group, suggesting that the damage caused retrograde amnesia despite the distributed conditioning. The same pattern was observed with the rats in the intermediate saliency condition (0.7 mA). In contrast, the rats with complete HPC damage in the high saliency condition (1.0 mA) did not freeze significantly less than their respective sham control group, suggesting that the lesions failed to cause retrograde amnesia in this instance. Thus, repeated contextual fear conditioning episodes can cause context fear memory to become independent of the HPC, but only when the saliency of the event is high and causes strong conditioning.

Title: Persistence of long-term contextual fear memory in the absence of the hippocampus.

Authors: *D. C. GIDYK, R. J. MCDONALD, R. J. SUTHERLAND;
Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: Contextual fear memory is among the most robust long-term memories (LTM). During one conditioning session, intact rats rapidly form a memory that is maintained for very long intervals (for example, 180 days, Lehmann et al. 2007). The pattern of results with complete HPC damage includes: 1) if HPC damage follows the learning episode, there is profound retrograde amnesia, regardless of how long after the conditioning session the damage takes place (Broadbent & Clark, 2013; Sutherland et al., 2010); 2) if HPC damage precedes the learning episode, there is little if any evidence of anterograde amnesia (Maren et al. 1997, Wiltgen et al. 2006). Thus, LTM for contextual fear can be supported by the HPC and non-HPC networks. However, it is likely that that some properties of HPC and non-HPC long-term memories differ. One recent study measured whether non-HPC contextual fear memory in rats decays more rapidly over time (Zelikowsky et al., 2012). Briefly, prior to contextual fear conditioning, rats received either neurotoxic lesions to the dorsal hippocampus (dHPC), or sham lesions. Rats were then tested for retention of learned fear 1, 3, 10, or 30 days later. Intact rats displayed high levels of freezing at all time points. Rats with dHPC damage displayed memory of the experience one day, but not 30 days later, indicating accelerated decay of the contextual fear memory. These data were interpreted as evidence for the dHPC being necessary for consolidation of contextual fear memory in non-HPC regions. Given that the vHPC was intact, it is unclear if the reported pattern of memory decay was due to a non-HPC memory being less resilient to decay, or whether a dysfunctional memory was acquired by the partially compromised HPC and was more prone to decay. The present study is an attempt to replicate Zelikowsky et al (2012), with the addition of a 16 site complete HPC lesion group. Neither lesion group exhibited rapid decay of a context fear memory. Our results suggest that non-HPC systems create a long-lasting context fear memory in the absence of HPC.

Title: Glucocorticoid receptor phosphorylation in the amygdala and hippocampus after acquisition of contextual fear conditioning

Authors: R. PONCE-LINA, M. CARRANZA, N. SERAFIN, R. A. PRADO-ALCALÁ, *G. L. QUIRARTE;
Inst. de Neurobiologia, UNAM Juriquilla, Queretaro, Mexico

Abstract: Glucocorticoid release during the acquisition process facilitates memory consolidation, especially of highly emotional or stressful experiences. This effect depends on several factors, among them is glucocorticoid receptor (GR) activation. The GR is a transcriptional factor whose transcriptional activity and cellular localization depends on its phosphorylated state. The present work aimed to investigate the effect of contextual fear conditioning training on the phosphorylation of GR at serine 211(Ser 211) and serine 226 (Ser 226) in the amygdala and the hippocampus. Male Wistar rats (250-350 g) were trained in contextual fear conditioning in a single session (11 min) under different foot-shock intensities (0.0, 0.5, or 1.5 mA). There were two groups for each intensity, in the first one the subjects were tested for memory retention at 48 h and the other group was sacrificed 1 h after training, and the amygdala and the hippocampus were extracted. Total GR and GR phosphorylated at Ser 211 and Ser 226 levels were measured by SDS-PAGE/WB. Rats trained with 0.5 and 1.5 mA learned the task. The optical density of total GR was the same for all the intensities in the amygdala and the hippocampus, with higher levels in the hippocampus. Density of GR phosphorylated at Ser 211 was higher than Ser 226 in the two brain areas and there were no differences among intensities. Phosphorylation at Ser 211 was higher in dorsal hippocampus and amygdala, whereas phosphorylation at Ser 226 was higher in ventral hippocampus. Phosphorylation ratio Ser 211/Ser226 showed that dorsal hippocampus and amygdala had the highest levels. These results indicate that in the acquisition phase of the contextual fear conditioning task, GR phosphorylation is not a process that depends on the stressor intensity during training, and that those areas involved in context-footshock association (dorsal hippocampus and amygdala) have the highest levels of GR phosphorylated at Ser 211, which probably could be related to an increase of transcription of molecules involved in plasticity. Title: Maternal seperation exaggerates spontaneous recovery of extinguished contextual fear in adult female rats

Authors: *W. LIPING[1], G. XIONG[2], L. XU[2];
[1]Kunming Inst. of Zoology, Yunnan Province, China; [2]Kunming Inst. of Zoology, CAS, Kunming, China

Abstract: Early life stress increases the risk ofposttraumatic stress disorders (PTSD). Patients with PTSD show impaired extinction of traumatic memory, and in women, this occurs more often when PTSD is preceded by child trauma. However, it is still unclear how early life stress accounts for extinction impairment.Here, we studied the effects of maternal separation (MS, postnatal day 2 to 14)on contextual fear extinction in adult female rats. Additionally,to examinechangesin synaptic functionaffected by MS, we measured long-term potentiation (LTP) in prefrontal cortex and hippocampus in vitro, both of which have been implicated in fear extinction. We found that adult female rats had been subjected to MS exhibited significantspontaneous recovery of fearto the extinguished context.Furthermore, MS exposure resulted in LTP impairment in both infralimbic prefrontal cortex layer 2/3-layer 5 and hippocampal SC-CA1 pathways. Interestingly, no obvious effectsof MS on contextual fearconditioning, fear recall as well as extinction training and recall were observed. Innate fear in the elevated plus maze or open fieldtest remained nearly unaffected. These findings provided the first evidence that MSmayexaggerate spontaneous recovery after contextual fear extinction, forwhich LTP impairmentin the medial prefrontal cortex and hippocampus may be responsible, thereby possibly leading to impaired extinction associated with PTSD.

Title: Effects of stress and corticosterone on spatial memory consolidation and Arc protein expression in hippocampal dentate gyrus in rats

Authors: *J. M. CERÓN GONZÁLEZ, M. LAMPREA;
Psychology, Natl. Univ. of Colombia, Bogota, Colombia

Abstract: Memory consolidation is the process of gradual stabilization of long-term memory after learning has occurred. This process requires activation of intraneuronal molecular cascades that regulate patterns of gene expression and protein synthesis in specific brain regions. Previous work has shown that memory consolidation can be modulated by different post-training interventions, either impairing or facilitating long-term retention of recently acquired information. The current work shows that exposure to a mild stressor or the exogenous administration of the glucocorticoid corticosterone immediately after training in the Barnes maze, enhances long-term retention in this task. Thus, during the memory retention test, stress and corticosterone-treated animals exhibited decreases in exploration errors and escape latency as well as an enhancement of spatial preference compared to their respective control groups. Additionally, it was found that exposure to a stressor or corticosterone administration alone did not modify the basal levels of the activity-regulated cytoskeletal-associated protein (Arc) in the hippocampal dentate gyrus. Nevertheless, the eight-trial training session in the Barnes maze led to a significant increase in Arc protein expression in this brain region predominantly observed in the dorsal blade and measured two hours after training had finished. Importantly, this induction was not significantly modified by post-training stress or corticosterone. The present findings suggest that post-training exposure to stress and glucocorticoids enhance spatial memory consolidation and this effect does not seem to involve a modulation in the expression pattern of Arc protein in the dentate gyrus of the hippocampus in the time point evaluated.

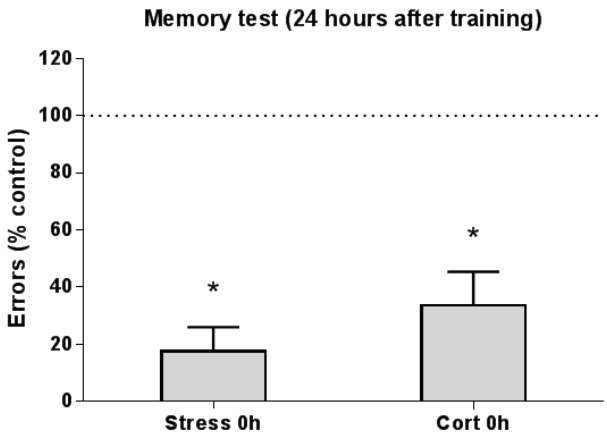

Figure 1. Non-goal hole explorations during the memory test (number of times the animal pokes its nose into a hole that did not contain the escape box during training). Data are expressed as normalized to the respective control group performance during the test (*): p<0.05 (n=8 each group). Abbreviations: Cort: corticosterone injection; 0h: treatment immediately after training.

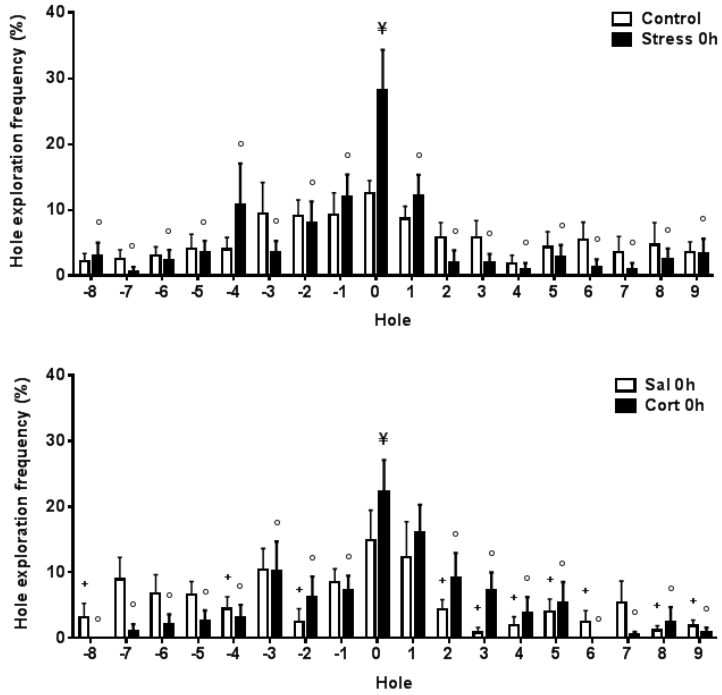

Figure 2. Hole exploration frequency (escape-hole is numbered as hole 0 and the remaining holes are numbered 1 to 9 clockwise, and −1 to −8 counterclockwise). (+): p <0.05 compared to escape-hole exploration frequency within the control group. (°): p <0.05 compared to escape-hole exploration frequency within the experimental group. (¥): p <0.05 compared to escape-hole exploration frequency in the respective control group.

Title: The dynamic nature of systems consolidation stress during learning as a switch guiding the rate of the hippocampal dependency and memory quality

Authors: *L. K. PEDRAZA CORREA[1], R. SIERRA[2], F. BOOS[2], J. HAUBRICH[2], J. QUILLFELDT[2], L. ALVARES[2];
[1]Biophysics Dept., Federal Univ. of Rio Grande Do Sul, Porto Alegre, Brazil; [2]Federal Univ. of Rio Grande do Sul, porto alegre, Brazil

Abstract: Memories fade after a time point, becoming more schematic or abstract. The loss of contextual detail in memory may reflect a time-dependent change in the brain structures supporting memory. It is well established that contextual fear memory relies on the hippocampus for expression shortly after learning, but becomes hippocampus-independent at later time point, a process called systems consolidation. This time-dependent process correlates with the loss of memory precision. Here, we investigated whether the training intensity predicts the gradual decay of the hippocampal dependency to retrieve memory and the quality of the contextual memory representation overtime. We found that learning intensity modulates the progressive decay of the hippocampal dependency and memory precision. Strong training intensity accelerates systems consolidation and memory generalization in a remarkable timeframe match. The mechanisms underpinning such process are triggered by the glucocorticoid and noradrenaline released during training. These results suggest that the stress/arousal levels during emotional learning act as a switch, guiding the fate of memory quality. A moderate stress will create a detailed memory, whereas a highly stressful training will develop a generic gist-like memory.

Abstract: The reconsolidation hypothesis posits that after reactivation,memory goes from an inactive to an active,labile state, and it needs a re-stabilization-storage process as during consolidation. Persistence is an attribute of long-term memories (LTM) that has recently caught researcher´s attention in search for mechanisms triggered by experience that assure memory perdurability. However, up-to-date, scarce evidence of relationship between reconsolidation and persistence has been described. We have recently shown that reconsolidation-induced cytosolic ERK activation can be modulated in mice hippocampi to regulate memory strength using a pharmacological approach on the inhibitory avoidance task (Krawczyk et al. 2015). Here, we broadened our studies by further characterizing ERK participation in long-term memory stabilization for longer periods. Although intra-dorsal-hippocampal (dHIP) administration of an ERK inhibitor (PD098059, PD) 3 h after retrieval did not affect reconsolidation, when tested at 24 h, it impaired performance when animals were tested 7 days after memory reactivation, regardless of the training´s strength; and being specific to memory reactivation. To the best of

our knowledge, this is the first report showing that persistence might be triggered after memory reactivation involving an ERK/MAPK-dependent process.

Title: Role of NMDA receptors in the storage of conditioned fear memory

Authors: *S. YAN, F. WINDELS, P. SAH;
Queensland Brain Inst., Brisbane, Australia

Abstract: The N-methyl-D-aspartate (NMDA) receptor is a ligand-gated ion channel that plays important roles in synaptic plasticity and learning. Studies have shown that activation of NMDA receptors during fear conditioning is essential for the acquisition of conditioned fear memory. However, whether NMDA receptors are activated after fear conditioning is unclear. To address this question, we injected NMDA receptor competitive antagonist 3-[(+)-2-carboxypiperazin-4-yl]-propyl-l-phosphonic acid (CPP) intraperitoneally (10mg/kg) into adult male Sprague-Dawley rats immediately after discriminative auditory fear conditioning. Conditioned memory was tested 24 h after conditioning, and freezing measured during the presentations of danger (CS+) and safety (CS-) cues. The results showed that post-conditioning blockage of NMDA receptors partially disrupt storage of discriminative memory: animals showed less freezing to CS+, while freezing was not affected during CS-. We then investigated the effect of local NMDA receptor inactivation in a series of brain regions that have been proposed to be involved in the storage of fear memory. Guide cannulas were bilaterally implanted into the basolateral amygdala (BLA), the medial division of medial geniculate nucleus (mMGN), or the perirhinal cortex (PRh) in different groups of rats. Either 0.5 μL or 1 μL CPP solution (60ng/μL) was injected into the target areas (0.5 μL/min) immediately after discriminative fear conditioning. Animals receiving post-conditioning CPP infusion into the PRh showed reduced fear response to CS+ and unaffected freezing during CS-, similar to the result observed after post-conditioning CPP

intraperitoneal injection, suggesting that the amnesiac effect of systemic CPP injection was partly due to inactivation of NMDA receptor in the PRh. In contrast, post-conditioning CPP infusions into the BLA or MGN did not significantly affect the retention of discriminative memory. Our data suggest a post-learning consolidation phase that is NMDA receptor dependent, and the activation of NMDA receptors in the PRh is involved in the processing of fear memory after learning.

Title: Assessment of memory mechanisms in rat brain by administration of the NMDA receptor antagonist AP5 using *In vivo*, *In vitro* and behavioral methods.

Authors: *C. W. SPANIS[1], R. R. BEYER[2];
[1]Neurosci., Univ. San Diego, San Diego, CA; [2]Neurosci., Univ. of San Diego, San Diego, CA

Abstract: The first set of experiments were designed to evaluate memory by observing an emotionally learned task and how and when the task was impaired, using AP5, considered causative of impairing NMDA receptors in the basolateral amygdala. Our work adds to past studies on impairment to the hippocampus. Pre-training infusion of AP5 did not affect the training acquisition but blocked the retention performance, given adequate training trials. Posttraining administration of AP5 also impaired retention performance in a staggered time frame, which lessened from significant impairment at five minutes post administration to no impairment at administration of drug given at 30 minutes post administration time. The second study involved in vivo injections of AP5 into the hippocampus in regions between CA1 and CA3. We noted a comparable result to study one, with impairment of LTP formations following injections of the drug. In the third series of experiments involving use of in vitro methods, we noted total loss of LTPs formed at loci between CA1 and CA3 following injections of AP5. The employment of AP5 in three different experimental procedures has allowed us to offer additional information on how memory works; in this case, at the level of activation or inhibition of NMDA receptors either in the BLA or the hippocampus using behavioral and/or in vivo and in vitro methods.

Title: Observational learning of a spatial discrimination task in the rat

Authors: *P. MEYRAND[1], B. JURA, Jr[2], B. BONTEMPI[1], T. BEM, s[2];
[1]Inst. des Maladies Neurodégénératives, CNRS UMR5293 Univ. de Bordeaux, Pessac Cedex, France; [2]Lab. of Physiol. and Modelling of Neural Networks, Nalecz Inst. of Biocybernetics and Biomed. Engin. Polish Acad. of Sci., Warsaw, Poland

Abstract: Learning by observing others has long been acknowledged as a powerful learning strategy. In several species, it has been reported that prior observation of fear conditioning or other operational procedures can improve subsequent acquisition. However, what an animal may gain by simply observing a conspecific performing a spatial discrimination task remains to be further explored. To this end, we have developed an original procedure in which Long Evans adult rats are submitted to spatial memory testing in an 8-arm radial maze. Inexperienced food-deprived observer rats (rats observing a demonstrator, RODs) were placed in a mesh cage positioned above the maze while a demonstrator rat was trained to locate the spatial position of three constantly baited arms of the maze. Each trial was terminated after the demonstrator retrieved the third food pellet and had returned to the central platform of the maze. During the observational period, each ROD was assigned a set of two naive demonstrators performing 6 trials per day during 9 days. The control group consisted of rats placed in the observation cage and looking at the empty maze (rats observing the maze, ROMs) for the same amount of time as RODs. After 9 days of observation, RODs and ROMs were placed in the maze and tested according to the same protocol as the demonstrators (9 daily sessions of 6 trials). Our findings reveal that RODs were capable of integrating relevant spatial information during the observational period and of using it efficiently when later submitted to spatial discrimination testing in the maze. Whereas both ROMs and demonstrator rats needed 9 days of learning to achieve mastery of the task with a low level of reference memory errors (less than 1.5 per trial), RODs needed only 4 days of testing to reach a similar level of performance. This beneficial effect of observation relied primarily on observing errors made by demonstrator rats. Indeed, RODs did not express any gain of observation when able to observe previously trained

demonstrators performing the task perfectly since the very first day of demonstration. These data challenge previously reported results using operant conditioning and suggesting that the improvement in performance of observers is related to the absence of any mistake during demonstration.

Title: Past experience with complexity enables strategy formation and rapid learning by rats in novel environments, without affecting synapse counts.

Authors: *C. D. COX, L. C. PALMER, D. T. PHAM, B. H. TRIEU, J. HUI, K. NGUYEN, I. MANFREDO, C. M. GALL, G. LYNCH;
Anat. and Neurobio., Univ. of California Irvine, Irvine, CA

Abstract: Most learning in nature occurs in complex environments with minimal obvious reward or punishment. Whether animals transfer information and strategies gained from past experience with complexity to novel, challenging environments, as is routine with humans, is a fundamental question that has received little attention. In the present study, we used a free exploration task that was too complex to be learned in a 30 minute session by rats given extensive handling or several days of free exercise. In contrast, rats that had spent an equivalent period in a social, multilevel complex environment prior to exploration rapidly encoded both short- and long-term memory in the apparatus. The three groups were not detectably different on various measures of arousal and anxiety. Markov Sequence Analysis showed that rats with prior exposure to the enriched environment (EE) were less predictable with regard to future locations after long movement sequences than the handled or exercise groups. Consistent with this, the EE animals also repeated long sequences to a greater degree. Both the predictability and sequence effects

were markedly greater in a second 30-minute long session conducted 24 hours later. We propose that the results reflect a shift from local to global processing of information due to the transfer of search strategies formed during prior experience with a different complex environment. We tested if the extensive, experience based learning that occurred during EE exposure was accompanied by an increase in synapse numbers in hippocampus, as assayed by quantifying PSD95 immunoreactive elements. The results were negative across 14 hippocampal sampling fields; there was, however, a detectable shift towards larger synaptic volumes in the dentate gyrus molecular layer of EE rats. In sum, these findings demonstrate that rats transfer past experience-based learning to new circumstances resulting in the rapid formation of information processing strategies and rapid learning. The material acquired during past interactions was not encoded by increased numbers of synapses.

Title: Novel object recognition: importance of counterbalancing and retention intervals

Authors: *M. CANEN, A. M. BABCOCK;
Psychology, Montana State Univ., Bozeman, MT

Abstract: Murine novel object recognition paradigms have presented challenges to researchers for many years. Previous studies have used a variety of techniques that have yielded inconsistent results in the novel object recognition paradigm. The present study evaluated the importance of counterbalancing in murine models of object recognition. Using a one-trial test in Balb-C mice, counterbalancing was evaluated using tasks that manipulated object location, object color and size, and unique side preference of the individual mice. Five studies were conducted to test the significance of each individual technique, all three variations combined, and a model with no counterbalancing. Mice spent significantly more time with the novel object compared to the familiar object when counterbalancing was present. No preference was observed when no counterbalancing was present. The current study demonstrates the importance of counterbalancing in studies of object recognition in mice.

Title: The mechanism of rimonabant's facilitatory effect on cocaine-associated memory consolidation in mice: A sex difference study

Authors: *S.-J. HU, H.-A. CHANG, W. DAI;
Dept of Psychology, Natl. Cheng Kung Univ., Tainan, Taiwan

Abstract: Cannabinoid CB_1 receptors are implicated in various forms of learning and memory, including cocaine-associated memory. We previously found that systemic or intra-medial prefrontal administration of the CB_1 receptor antagonist/inverse agonist rimonabant facilitates the consolidation of conditioned place preference (CPP) induced by a low dose (2.5, 5, or 10 mg/kg) of cocaine in male wild-type mice. The current study aimed to investigate the receptor and hormone mechanisms underlying the facilitatory effect of rimonabant on cocaine-induced CPP. We first examined whether CB_1 receptors mediates rimonabant's effect by using CB_1 knockout mice. We found that rimonabant did not facilitate memory consolidation of a low-dose (10 mg/kg) cocaine-induced CPP in both genders of the CB_1 knockout mice. Moreover, rimonabant did not enhance the low-dose cocaine-induced CPP in female wild-type mice. Intriguingly, the facilitatory effect of rimonabant on cocaine-induced CPP was found to be mediated by the increased level of plasma corticosterone in male wild-type mice. Next, to test whether the sex hormone estrogen is involved in the sex difference effect, we examined rimonabant's effects on the low-dose cocaine-induced CPP in vehicle-treated *vs.* estrogen-treated ovariectomized (OVX) female wild-type mice and found two interesting results. First, estrogen replacement in the OVX mice *per se* enhanced the low-dose cocaine-induced CPP memory. Second, rimonabant facilitated cocaine-induced CPP memory in the OVX mice supplied with sesame oil, while impaired the same memory in the OVX mice supplied with estrogen. Taken together, our results indicate: 1) The facilitatory effect of rimonabant on cocaine-induced CPP is mediated by CB_1 receptors and corticosterone in male wild-type mice; 2) Estrogen is involved in a sex difference in the facilitatory effect of rimonabant on cocaine-associated memory.

Title: Novel function of histone demethylase of JHDM in spatial learning and memory

Authors: *H.-J. KIM[1], S.-Y. KIM[1], M.-H. KIM[1], J. PARK[2], S. KIM[1], Y.-S. CHUN[1];
[1]Dept. of Biomed. Sci., Seoul Natl. Univ. Col. of Med., Seoul, Korea, Republic of; [2]Ctr. for Cognition and Sociality, Inst. for Basic Sci. (IBS), Daejeon, Korea, Republic of

Abstract: Dynamic changes in histone modification play a role in regulating the gene expression program linked to the memory formation. Among them, however, very little is known about the role of Jumonji-containing histone demethylases which erase the methyl group of H3K4, H3K9, H3K27, H3K36 and H4K20 that are associated with memory formation. Here, we documented the physiological role of JHDM (H3K9 demethylase) in both learning and memory at the adult stage of mice. It is of interest that the expression of JHDM is shown to be significantly increased in the hippocampus. In agreement, we found out that the JHDM overexpressed transgenic mice displayed enhancement in both spatial-memory formation and contextual fear conditioning compared to the wild-type mice. On the other hand, JHDM-deficient mice derived by Lenti-viral vector in the hippocampus showed impairment in the hippocampus-dependent memory function. Therefore, our results suggest that JHDM has an important role in memory formation in the hippocampus.

Title: Synthesis of a memory blocker during *Aplysia* sleep prevents maladaptive long-term memory formation

Authors: *R. LEVY[1], A. SUSSWEIN[2];
[1]Goodman Fac. Of Life Sci., Bar Ilan Univ., Ramat Gan, Israel; [2]Bar |ilan Univ., Ramat Gan, Israel

Abstract: Training *Aplysia* with inedible food during the active phase of their daily cycle, but not during the sleep phase, produces long-term memory. During the active phase, inhibiting protein synthesis before training with a short-acting dose of anisomycin prevents memory formation. However, during the sleep phase this treatment allows memory to be formed, indicating that memory formation after training during the sleep is blocked by a protein synthesis-dependent process. Even a brief training that is ineffective at other times in forming long-term memory is effective during the sleep phase, after treatment with the anisomycin. Proteins already present before the anisomycin treatment are required for memory formation, and elimination of these proteins prevents long-term memory formation. After an effective training during the sleep phase, subsequent long-term memory formation requires transcription and a later stage of translation, as shown by blocking memory formation with the transcription blocker DRB, or with a longer-lasting dose of anisomycin. C/EBP transcription in the buccal ganglia was increased both after treatments leading to long term memory, and after treatments not leading to long term memory, indicating that increased C/EBP transcription could not account for memory formation. By contrast, increased CREB1 transcription was seen only after training that led to long-term memory. Increased CREB2 transcription was not seen after either effective or ineffective training. These findings suggest that molecular processes during sleep that underlie consolidation of experiences from the previous active phase enhance the ability of new experiences to form new memories. However, new memories formed at this time may not be adaptive. To prevent the formation of new, maladaptive memories, and to prevent new experiences from interfering with the ongoing consolidation, the formation of new long term memories during sleep is actively blocked by a protein synthesis-dependent process.

Title: New learning while consolidating memory during sleep is actively blocked by a protein synthesis dependent process

Authors: *A. J. SUSSWEIN[1], I. HURWITZ[2], R. LEVY[2];
[1]Bar-Ilan Univ., Ramat-Gan, Israel; [2]Bar Ilan Univ., Ramat Gan, Israel

Abstract: The effects of a new experience while a memory of a previous experience is being consolidated have provided insight into the nature of the consolidation process: 1) an transitory experience that would generally not be consolidated may capture the ongoing consolidation, producing long-term memory (a process known as synaptic or behavioral tagging and capture); 2) a new experience may interfere with the consolidation (the original observation showing that a memory requires consolidation). However, interactions between consolidation and a new experience may cause problems: 1) it may not be adaptive for a weak experience that captures a consolidating process to create a long-term memory; 2) it may not be adaptive to interrupt the consolidation by a new experience. It is well known that after a period of consolidation immediately following an experience, an additional stage of consolidation occurs while animals sleep. Why divide consolidation to different stages? Why defer aspects of consolation for many hours? We propose that partially deferring consolidation to sleep, when animals are relatively inactive, is a mechanism to minimize new experiences that might interact with the molecular processes underlying consolidation. However, when animals are awakened from sleep, these molecular processes are unlikely to be terminated immediately. At this time, even fleeting experiences could produce unwanted long-term memory, because of the ongoing consolidation. New data from our lab indicate that potential maladaptive memory formation from experiences when animals are awakened from sleep is prevented because new experiences at this time initiate an active protein synthesis dependent block of long-term memory. Removing the block allows even fleeting experiences to capture molecular processes underlying sleep phase consolidation, thereby leading to maladaptive long-term memory.

Title: Retuning memory valence: novel reconsolidation-mediated updating procedure to disrupt fear memories

Authors: *J. HAUBRICH[1], A. CRESTANI[2], L. CASSINI[2], F. SANTANA[2], R. ORDONEZ SIERRA[2], L. DE OLIVEIRA ALVARES[2], J. QUILLFELDT[2];
[1]Federal Univ. of Rio Grande Do Sul, Porto Alegre, Brazil; [2]Federal Univ. of Rio Grande do Sul, Porto Alegre, Brazil

Abstract: When a consolidated memory is retrieved, it can return to a labile state and undergo reconsolidation, becoming sensitive to pharmacological and psychological interferences. This process can lead to memory updating through the integration of new information into a previously consolidated memory background. Thus reconsolidation provides the opportunity to modify an undesired fear memory by updating its emotional valence to a less aversive level. Here we evaluated whether a fear memory can be reinterpreted by the presentation of appetitive stimuli during its reactivation. We found that this procedure resulted in the suppression of a fear response that was not amenable to reinstatement, spontaneous recovery and rapid reacquisition. This effect was prevented by systemic injections of the L-type voltage-gated calcium channels blocker nimodipine or intra-hippocampal infusion of the GluN2B antagonist ifenprodil, what suggests that memory updating was mediated by the reconsolidation process and hippocampal neuronal plasticity. Taken together, this study shows that reconsolidation allows for a re-signification of unwanted aversive memories through the incorporation of information of opposing valence. It brings a new promising cognitive approach to treat fear-related disorders.

Title: Potential interplay between the lysine acetyltransferase PCAF and estrogen receptors in the rat hippocampus for short-term object-in-place memory

Authors: *K. A. MITCHNICK[1], S. D. CREIGHTON[1], R. JAMIESON-WILLIAMS[2], A. LACOUSIERE[1], J. M. CLOKE[1], S. CASTELLANO[4], C. MILITE[4], G. SBARDELLA[4], B. E. KALISCH[3], E. CHOLERIS[1], B. D. WINTERS[1];
[1]Psychology, [2]Cell. and Mol. Biol., [3]Biomed. Sci., Univ. of Guelph, Guelph, ON, Canada; [4]Med. Chem., Univ. of Salerno, Salerno, Italy

Abstract: The actions of lysine acetyltransferases (KATs), which include chromatin remodeling via histone acetylation as well as modifications to non-histone proteins, are increasingly implicated in mnemonic processes. We have previously found that antagonism of the KAT p300/CBP-associated factor (PCAF) by embelin impairs long-term (24h) object-in-place (OiP) memory in rats when administered to either the perirhinal cortex or hippocampus (HPC). However, intra-HPC embelin also impairs short-term (20min) OiP memory, and PCAF knockout mice display short-term spatial and object memory deficits. As PCAF has been shown to activate nuclear hormone receptors, and nuclear estrogen receptors (ERs) are known to be involved in short-term memory processes, the present study explored the potential interaction of PCAF and ERs in the rapid regulation of OiP memory in the HPC of rats. Behavioural results were consistent with this interpretation, as intra-HPC administration of the non-selective ER antagonist, fulvestrant, impaired short-term OiP memory, the PCAF activator, SPV-106, enhanced short-term memory in a sub-optimal learning version of the task, and co-administration of an otherwise ineffective concentration of fulvestrant blocked the enhancing effects of SPV-106. Although intra-HPC SPV-106 also facilitated long-term OiP memory, no evidence was found for ER involvement in this effect. Finally, intra-HPC administration of ERα agonist PPT enhanced short-term OiP memory, whereas the ERβ agonist DPN did not. Ongoing molecular analyses are examining the potential interaction between PCAF and ERα following learning. Thus, PCAF appears to regulate short-term and long-term memory via dissociable mechanisms. The present data are consistent with the notion that PCAF can influence short-term memory through a non-epigenetic process related to the stimulation of ERα, which has been shown to induce relatively rapid effects on hippocampus-dependent learning and dendritic spine density.

Title: Examining sex-based differences in unconditioned and conditioned fear

Authors: *M. VOULO, R. G. PARSONS;
Psychology, Stony Brook Univ., Stony Brook, NY

Abstract: Fear conditioning is one of the dominant models of learning and memory, and one that may help shed light on fear-based psychopathology, yet it's been estimated that less than 2% of research related to fear conditioning has been conducted in females (Lebron-Milad & Milad, 2012). Furthermore, the limited studies that have investigated sex-based differences in fear have produced mixed results. The current study investigated sex-based differences in both unconditioned and conditioned fear in male and female Sprague-Dawley rats. In the first experiment, animals were tested in a light-enhanced startle paradigm (LES) in which acoustic startle responses were measured in the dark and in the presence of a bright light, which has been shown to be anxiogenic in rodents (Walker & Davis, 1997). During Phase 1 rats received 30 startle trials in a darkened chamber. Five minutes later this procedure was repeated in the presence of a bright light (experimental) or in the dark (control), and percent potentiation was calculated for each animal and compared across sessions (control vs. experimental) to investigate the degree of LES. The results showed that while both sexes showed significant light-enhanced startle, there was no difference in the magnitude between males and females. In the second set of experiments, animals were fear conditioned with 2 pairings of a tone and foot shock. The next day they were exposed to 20 presentations of the tone alone to undergo fear extinction. They were tested for extinction retention 24 hours later with 8 presentations of the tone alone, and on the final day they were tested for contextual fear. Freezing behavior was recorded and fear acquisition, extinction training, extinction testing, and context testing data were compared between males and females. Our findings show that males and females acquire fear to a similar degree, but females showed significantly greater extinction during the extinction training session. In addition, females showed a trend for greater retention of extinction learning during the following testing session, although the difference between males and females did not reach

statistical significance. Consistent with prior studies, males exhibited higher levels of freezing during the contextual fear test. Current studies are investigating fear conditioning and extinction in both sexes using a fear-potentiated startle paradigm to determine if a similar pattern of data emerges using another measure of fear.

Title: Acoustic startle response as a predictive index of a PTSD-like phenotype in rats

Authors: *A. S. RUSSO, R. G. PARSONS;
Psychology, Stony Brook Univ., Stony Brook, NY

Abstract: Although a large portion of the population is exposed to a traumatic event at some point, only a small percentage of the population develops post-traumatic stress disorder (PTSD). Identification of factors that make some individuals more likely to develop PTSD than others is crucial to the further understanding of the mechanisms underlying the development of PTSD, but prospective models that aim to identify susceptible populations prior to trauma exposure are limited. Abnormal acoustic startle response (ASR) has been shown to be associated with PTSD, so it is of interest to investigate this reflex as a potential predictor of the development of PTSD-like symptoms. Since poor extinction and retention of extinction learning are characteristic of PTSD patients, it is of interest to determine if abnormal ASR is predictive of development of such deficits. To determine whether baseline ASR has utility in predicting the development of PTSD-like symptoms, the relationship between baseline ASR and extinction of fear response was analyzed in 45 adult, male Sprague-Dawley rats. Baseline ASR was measured for each rat as the average startle amplitude across 30 trials of a 50 msec, 95 dB white noise burst. The rats were then exposed to a Pavlovian fear conditioning paradigm consisting of training with 2 pairings of a 30 sec, 4 kHz tone and a 1 sec, 1 mA footshock. Following conditioning, the rats received extinction training and testing sessions, consisting of 20 and 8 additional presentations of the tone, respectively. Freezing behavior was measured throughout the experiment as an indicator of fear, and was used to calculate values for magnitude of extinction learning and retention of extinction learning for each rat. Analysis of the relationships between baseline ASR and measures of extinction and retention revealed that low baseline ASR was associated with poor within-session extinction learning and poor retention of extinction learning. Furthermore,

the rats were ranked based on their baseline ASR and assigned to “low,” “medium,” or “high” startle groups. The “low” startle rats had poorer retention of extinction learning than the “high” startle rats, but the groups did not differ in retention of the conditioning memory or rate and magnitude of extinction learning. The results show that low baseline ASR is associated with poor retention of extinction learning following fear conditioning. Since impaired ability to recall extinction learning is characteristic of patients with PTSD, these results suggest that the ASR may have value as a predictive index of the development of a PTSD-like phenotype.

Title: Good made better: L-DOPA reduces return of fear after successful within-session extinction

Authors: *R. KALISCH, A. M. V. GERLICHER, O. TÜSCHER;
Deutsches Resilienz-Zentrum (DRZ), Johannes Gutenberg Univ. Med. Ctr., Mainz, Germany

Abstract: Background
Relapse, or return of fear (ROF), is a frequent problem after exposure-based fear therapy. One promising counter-strategy is adjunctive treatment with a pharmacological enhancer of the extinction memory formation presumed to occur during and after exposure. Accumulating evidence suggests that the effects of enhancers may depend on successful fear reduction during exposure. However, there is currently no controlled laboratory study systematically investigating a potential dependency of pharmacological ROF prevention on extinction success using objective physiological measures. We employed the dopamine precursor L-DOPA, which is stable, safe and well-tolerable and powerful in preventing ROF when given after extinction training in rodents. First data indicate it may also work in humans.
Methods
In a three-day paradigm including fear conditioning (day 1), extinction (day 2) and spontaneous recovery of fear (day 3, ROF test), N=79 (experiment 1) and N=32 (experiment 2) healthy male participants were pseudo-randomly assigned to a post-extinction administration of 150 mg L-DOPA or placebo. We tested whether end-fear after short (10 trials, experiment 1) and long (25

trials, experiment 2) extinction moderated the effect of L-DOPA on ROF. Skin conductance responses were used as primary outcome.
Results
In both experiments, L-DOPA, but not placebo, participants showed low ROF when extinction end-fear was low, but high ROF when end-fear was high.
Conclusions
These results point towards a common boundary condition for pharmacological interventions targeting extinction memory consolidation and emphasize the importance of limiting their clinical use to successful exposure sessions. They also confirm the potential of L-DOPA as an adjunct to exposure treatment.

Title: Propranolol as a potential adjunct to exposure therapy in the treatment of pathological fear memory: an animal model

Authors: *A. M. SCHNEIDER[1], P. E. SIMSON[3], Z. FRANK[1], N. PALADUGU[1], V. GOMES[1], R. ABISHEK[1], J. KANG[1], C. H. WONG[1], C. EVERBACH[2], L. G. KIRBY[4]; [1]Dept Psychol, [2]Dept Engin., Swarthmore Col., Swarthmore, PA; [3]Dept Psychology and Ctr. for Neurosci., Miami Univ., Oxford, OH; [4]Ctr. for Substance Abuse Res. and Dept. Anat. and Cell Biol., Lewis Katz Sch. of Med. at Temple Univ., Philadelphia, PA

Abstract: Clinical studies have shown that exposure therapy is effective in reducing abnormal fear memory such as in post-traumatic stress disorder (PTSD). The treatment, however, is limited and abnormal fear memory often recovers. Using an analogue of exposure therapy in rats—hereafter referred to as the brief exposure procedure—we investigated the extent to which the effectiveness of the brief exposure procedure in reducing retention of fear could be enhanced or impaired by the ß-adrenergic blocker propranolol, a drug used to treat PTSD. Male Long Evans rats underwent contextual fear conditioning followed 24 hr later by the brief exposure procedure; the next day the animals received a retention test. Contextual fear conditioning consisted of placing rats in a dark compartment for 120 sec followed by a single footshock; the brief exposure

procedure, in contrast to the standard extinction procedure, consisted of confining the animals to the dark compartment for 30 sec in the absence of shock and removing them before an opportunity to recall fear developed to a significant degree; the retention test consisted of returning the animals to the dark compartment for 180 sec. Freezing behavior provided a measure of fear during the brief exposure and the subsequent retention test. Propranolol (4 mg/kg or 10 mg/kg) or saline was injected 20 min prior to the brief exposure procedure or was injected in the absence of the brief exposure procedure yielding a total of 6 groups. The doses of propranolol chosen were based on electrophysiological evidence from a previous study indicating that propranolol has opposing dose-dependent effects on amygdala (central nucleus, CeA) activity: a relatively high dose (10 mg/kg) increases CeA activity; a relatively low dose (4 mg/kg) suppresses spontaneous CeA activity. The results were as follows: 1) Neither the brief exposure procedure administered in the absence of propranolol nor propranolol (4 mg/kg or 10 mg/kg) administered in the absence of the brief exposure procedure affected retention of the fear memory. 2) Propranolol administered prior to the brief exposure affected freezing behavior in a dose-dependent manner: the CeA activity-suppressing dose (4 mg/kg) did not affect freezing behavior either during the brief exposure or during the retention test 24 hrs later; the CeA activity-increasing dose (10 mg/kg) increased freezing behavior and did so during both the brief exposure and the retention test 24 hrs later. In conclusion, the present results indicate that the efficacy of propranolol as an adjunct to exposure therapy may be dose-dependent and suggest the importance of minimizing amygdala activation and resulting fear during exposure therapy.

Title: Neurogenesis regulates fear recovery after extinction by recruiting hippocampal and prefrontal activity

Authors: *A. MARTINEZ-CANABAL[1], G. LOPEZ-OROPEZA[1], A. GAONA-GAMBOA[1], P. BALLESTEROS-ZEBADUA[2], O. GALVAN DE LA CRUZ[2], S. MORENO-JIMENEZ[2], F. SOTRES-BAYON[1];

[2]Neurol. and Neurosurg. Natl. Inst. - Radioneurosurgery Dept., Mexico City, Mexico

Abstract: Learning to extinguish a defensive response to a threat (fear) associated to a context, leads to the formation of a new memory that inhibits a previously acquired fear memory to the context. This fear inhibition, however, is temporary as fear responses often return spontaneously with the passage of time. It is not clear what brain mechanisms underlie this recovery of fear. Given that contextual fear and extinction memories are hippocampus-dependent and adult-born hippocampal neurons (neurogenesis) have been reported to modify preexisting fear memories, we hypothesized that neurogenesis-mediated modification of a preexisting extinction memory modifies fear recovery levels. To test this, rats previously trained to press a bar to obtain food underwent contextual fear conditioning (day 1), extinction training (day 2) and an extinction memory retrieval test in the same context (day 3). Next, we manipulated hippocampal neurogenesis levels by exposing rats to an enriched environment (EE) to enhance neurogenesis or by X-ray focal irradiation (IRR) to ablate neurogenesis. One month after these manipulations, rats were tested to evaluate spontaneous fear recovery with respect to the previous retrieval test, and their brains collected for immunostaining. We found that EE after extinction prevented fear recovery, as indicated by low freezing and high bar pressing levels as compared to controls during memory retrieval test. In contrast, we found that IRR after extinction promoted fear recovery, as indicated by high freezing and low bar pressing levels as compared to controls during memory retrieval test. These effects on fear levels were not present when EE or IRR occurred before or without extinction learning, suggesting that the observed effects are extinction-dependent. By using the expression of doublecortin as a neurogenesis marker, we show that neurogenesis levels increased with EE, decreased with IRR and were correlated with freezing and bar-pressing at test. Importantly, by using the expression of c-Fos as neuronal activity marker, we found that low fear recovery mediated by increased neurogenesis recruited CA3 hippocampal region and decreased prelimbic prefrontal cortex activity, whereas high fear recovery mediated by ablated neurogenesis decreased CA3 and infralimbic prefrontal cortex activity. Together, our findings suggest that manipulation of hippocampal neurogenesis levels after extinction learning modifies the strength of the extinction memory by modifying hippocampal-prefrontal activity, and thereby altering fear recovery levels.

Abstract: DNA methylation, once considered static and restricted to directing cellular lineage specificity during early development, is now recognized to be highly dynamic and reversible across the lifespan. Although it is known that there are more than 20 DNA modifications, nearly all research aimed at elucidating the role of these chemical modifications in the brain has focused on either 5-methylcytosine (5mC) or the recently rediscovered 5-hydroxymethycytosine (5hmC), which is a functionally distinct oxidative derivative of 5mC. 5mC and 5hmC are highly prevalent in neurons relative to other cell types and both modifications are regulated in response to learning. Despite these exciting threads, a complete understanding of how DNA methylation controls neuronal gene expression to facilitate memory formation is severely lacking. Here we report that the novel eukaryotic DNA modification N6-methyl-2'-deoxyadenosine (m6dA), which is beyond cytosine methylation, drives activity-induced gene expression and is associated with fear extinction memory in the infralimbic prefrontal cortex (ILPFC) of adult C57/Bl6 mice. In primary cortical neurons, m6dA accumulates within the P4 promoter of the gene encoding brain-derived neurotrophic factor (bdnf) via a putative m6dA-specific methyltransferase, N6amt1. An N6amt1-dependent increase in the deposition of m6dA is associated with an active chromatin state, as well as the recruitment of the activating transcription factor Yin-Yang 1 and RNA polymerase II, which promote bdnf exon IV mRNA expression. The same process regulates learning-induced bdnf exon IV mRNA expression in the adult brain. Viral-mediated knockdown of N6amt1 in the ILPFC blocks the effect of extinction learning on m6dA deposition and related chromatin and transcriptional activity, resulting in a significant impairment in extinction memory.

Title: ADAR1 dual function as RNA editing and potential DNA binding enzyme in the activity-dependent regulation of adaptive behaviour in the mouse

Authors: *P. MARSHALL[1,2], X. LI[2], L. WEARICK[3], T. VIOLA[3], T. BREDY[2];
[1]Neurobio. and Behavior, [2]Univ. of California Irvine, Irvine, CA; [3]Pontifícia Univ. Católica do Rio Grande do Sul, Porto Alegre, Brazil

Abstract: RNA editing enzymes have been known for some time to affect the qualitative and quantitative nature of RNA products. RNA editing has also been correlatively linked to the mediation of behaviour of organisms ranging from flies to humans, with the highest levels of these enzymes in humans. Mechanistically, this has been suggested to occur by their ability to bind to RNA and participate in deamination of: cytosine in the case of APOBECs', or adenosine in the case of ADARs'. However, two caveats arise in the proposed relationship. One is that not all variants of these enzymes appear to operate solely by this mechanism; they can also bind to DNA. And two, that much of the mechanistic work for this latter point has been divorced from a behaviourlly relevant context. Therefore, in order to assess the function of these domains in the context of behavioural adaptation, genome-wide DNA sequencing for ADAR1 was performed both with cultured primary cortical neurons (PCN's) and 6-8 week old C57 mice subjected to fear conditioning and extinction. An shRNA was also designed against ADAR1 and transfected with PCN's and into the infralimbic cortex of the trained mice. It has been observed that ADAR1 appears to bind a number of targets on DNA. Additionally and surprisingly, it was observed that although mRNA and protein levels appeared elevated specifically to extinction behaviour, following knockdown of ADAR1 in the infralimbic cortex the expression of fear was enhanced, while fear extinction remained unaffected. It remains to be seen whether this effect is mediated primarily by ADAR1's RNA editing activity or the binding capacity to DNA.

Title: Infralimbic projections to the basolateral amygdala, but not the nucleus accumbens, are required for the extinction of fear memories

Authors: *D. W. BLOODGOOD[1], J. A. SUGAM[1], H.-J. JO[1], M. TORRUELLA SUAREZ[1], T. L. KASH[2];
[2]Bowles Ctr. for Alcohol Studies, [1]UNC-Chapel Hill, Chapel Hill, NC

Abstract: The prefrontal cortex (PFC) has been shown to be involved in the inhibition of learned emotional responses. Deficits in emotional learning are a key feature of Post-Traumatic Stress Disorder and are thought to be characterized by a loss of top-down control over subcortical regions. Importantly, distinct outputs control different domains of behavior whereby outputs to the nucleus accumbens (NAc) act in the appetitive domain to reduced cued drug seeking while outputs to the basolateral amygdala (BLA) act in the aversive domain to reduce cued fear responses. There is also a dorsal-ventral of distribution of function in the PFC whereby the prelimbic cortex (PLC) is required for the expression of fear behavior while infralimbic cortex (ILC) is required for the extinction of fear behavior. Previously it has been shown that pharmacologic and optogenetic inhibition of ILC impairs fear extinction. However these studies have not examined the role of PFC neurons with respect to output region. To functionally assess this, we preformed retrograde anatomic tract tracing experiments and found that BLA and NAc outputs are discrete non-overlapping populations in both the PLC and ILC. We next used patch clamp electrophysiology with fluorescent retrobeads to assess changes in excitability following fear acquisition and extinction. We found increased excitability following extinction specifically in BLA projecting neurons. This change was subregion dependent and increased excitability was found only in ILC but not PLC. Finally we used a multiplexed chemogenetic technique to inhibit

PFC neurons based on output and found that projections to BLA are required for extinction of conditioned fear responses while NAc projections are not. Our findings are consistent with previous results and highlight that behavioral responses are controlled by the specificity of output.

Abstract: Small conductance Ca2+-activated K+ channels (SK channels) are widely expressed in the central nervous system and regulate neuronal functions at all levels, including synaptic plasticity, neuronal excitability, sensory, behavior, emotion and cognition. We previously demonstrated that pharmacological blockade of SK channels with apamin enhanced learning and memory, while activation of SK channels with EBIO produced the opposite effect. Further, SK2 channels expressed on dendritic spines of pyramidal neurons in the hippocampus and amygdala shape glutamatergic EPSPs and modulate the induction of long-term potentiation. Excessive fear

is a hallmark of several emotional and mental disorders such as phobias and panic disorders. Considerable effort has been given to defining the neurobiological mechanisms of the extinction of conditioned fear memory as such mechanisms may hold clinical significance for remediating aberrant fear memory. Fear memories require protein synthesis in the amygdala for reconsolidation after retrieval. We theorized that fear memory extinction is associated with a dynamic alternation in SK channel expression and/or functioning. Male C57BL/6J mice received trace fear conditioning (8 CS-US pairings with a stimulus-free gap between the onset of each stimulus of the pair) followed by extinction (8 CS). 24 h after extinction, mice that experienced fear conditioning and extinction exhibited a significantly greater sensitivity to the locomotor suppressing effect of systemic EBIO treatment during an open field test. Western blot results revealed that mice that experienced fear conditioning and extinction presented a higher expression of SK2 channel protein in synaptosome fractions, but not the cytosolic fractions prepared from amygdala samples. Voltage clamp recordings from amygdala neurons in slices prepared from mice after conditioning, revealed that fear conditioning was associated with an increase in the amplitude of slow and medium components of the AHP current (sIAHP, mIAHP). Together, these data suggest that fear extinction is associated an upregulation of SK2 channels in amygdala synapses, which may hold a significant influence on the behaviorally-triggered synaptic plasticity required for fear memory extinction.

Title: Mechanisms underlying the structural, functional and epigenetic responses in the primary sensory system of adult mice accompanying olfactory fear learning

Authors: *F. G. MORRISON[1,2], B. G. DIAS[2], K. J. RESSLER[1,2];
[1]Psychiatry, McLean Hosp., Belmont, MA; [2]Psychiatry and Behavioral Sci., Emory Univ., Atlanta, GA

Abstract: Olfactory sensory neurons (OSNs) within the main olfactory epithelium (MOE) provide a rich model to study the perception of external cues and the underlying mechanisms regulating structural plasticity within the olfactory system. Using the M71-LacZ mouse line, we have previously demonstrated an increased number of M71+ OSNs in the olfactory epithelium and increased M71+ glomerular area in the olfactory bulb (OB) following cue-specific olfactory fear conditioning to acetophenone, an odorant shown to specifically activate the M71 receptor. Functionally, mice exhibit enhanced freezing to the conditioned odor stimulus following olfactory fear conditioning. We sought to determine whether the behavioral and structural changes observed after olfactory fear conditioning may be reversed with extinction training. Using native chromatin immunoprecipitation (N-ChIP) protocols on the MOE, we investigate the dynamic alterations in histone marks around the M71 gene locus following both olfactory fear acquisition and extinction. Additionally, to understand cell dynamics as a function of fear learning, we used 5-Ethynyl-2'-deoxyuridine, 5-Du Alkyne (EdU) labeling to investigate cell birth and turnover. To understand rates of cell death and survival, we used cell death assays such as terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL). With these parallel assays, we sought to determine the role of cell turnover dynamics in the structural plasticity accompanying olfactory learning. Male mice were trained to associate mild footshocks with acetophenone. Three weeks after the last conditioning session, animals were handled only or exposed to an extinction session and 3 weeks after the last extinction session, animals were sacrificed. Extinction training specific to the conditioned odorant cue reversed the conditioning-associated increases in freezing and M71-specific OSN number and glomerular area. We also demonstrated a dynamic regulation of histone marks around the M71 locus associated with both cue-specific fear learning acquisition and extinction. Our observations shed light on how the olfactory sensory system responds dynamically to extinction learning after fear conditioning.

Title: The role of cholinergic input from the medial septum in cued and contextual fear extinction memory

Authors: *J. M. STAIB[1], D. KNOX[2];
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Psychological and Brain Sci., Univ. of Delaware, Newark, DE

Abstract: In classical fear conditioning, a neutral stimulus (CS) is paired with an aversive stimulus (US), causing the animal to associate the US with CS, and display a fear response to the CS. Fear extinction occurs when the CS is presented without the US and the animals learn that the CS no longer predicts the US, thus learning to no longer show fear with CS presentation. Ventral medial prefrontal cortex inhibition of neural activity in basolateral and central amygdala nuclei is critical for extinction memory formation. Recently, we observed that cholinergic lesions in the Medial Septum and Diagonal Bands of Broca (MS/DBB), induced with 192-IgG saporin results in fear extinction memory deficits and contextual fear memory generalization between the conditioning and extinction contexts. While this suggests that MS/DBB cholinergic neurons may be a component of the fear extinction circuit, these neurons project to many brain regions. As a result, the MS/DBB cholinergic efferents that are critical for mediating extinction memory and contextual fear memory discrimination are unknown. The goal of the present study is to isolate the exact MS/DBB efferents that mediate extinction memory and contextual fear memory discrimination. While the study is in progress, some results have been collected. Cholinergic lesions in the dorsal hippocampus, ventral hippocampus, and medial prefrontal cortex have no effects on fear extinction memory or contextual fear memory discrimination. This is surprising because all of these regions are components of the fear extinction circuit and the dorsal hippocampus is critical for contextual learning during acquisition of fear and extinction memory. The MS/DBB also projects to habenula nuclei, and there are cholinergic interneurons in the MS/DBB as well. For the remainder of the study, we explore the potential role of MS/DBB cholinergic input to the habenula and MS/DBB cholinergic interneurons in mediating extinction memory and contextual fear memory discrimination. Isolating a region that has a direct role in mediating extinction memory could help focus future research in fear memory disorders like post traumatic stress disorder.

Title: Fear conditioning and extinction alter ventral hippocampus activation of nmdar currents in infralimbic neurons

Authors: O. SOLER-CEDENO[1], O. TORRES-RODRIGUEZ[3], L. MALDONADO-LABOY[4], A. HERNANDEZ-LOPEZ[2], *J. T. PORTER[5];
[1]Basic Sci., [2]Ponce Hlth. Sci. Univ., Ponce, PR; [3]Interamerican Univ. of Puerto Rico, Ponce, PR; [4]Pontifical Catholic Univ. of Puerto Rico, Ponce, PR; [5]Ponce Sch. Med., Ponce, PR

Abstract: After exposure therapy, some patients with posttraumatic stress disorder (PTSD) relapse when trauma-associated cues are experienced outside of the therapeutic context. Similar to humans, fear extinction in rodents, which mimics human exposure therapy, is context-dependent such that extinguished fear of a cue renews when the cue is presented in a context different from where the extinction occurred. Recent evidence suggests that synaptic plasticity between the ventral hippocampus (vHPC) and the medial prefrontal cortex (mPFC) could be mediating the context-specificity of fear extinction memory. Therefore, we investigated whether extinction in the conditioning context causes different synaptic changes in vHPC synapses in the mPFC than extinction in a different context. To address this, we assigned male Sprague Dawley rats to one of the following experimental groups: pseudo-conditioning, fear conditioning, same context extinction, and different context extinction. We did whole-cell patch-clamp recordings of prelimbic (PL) and infralimbic (IL) pyramidal neurons in the mPFC to assess AMPA and NMDA receptor-mediated excitatory postsynaptic currents (EPSCs) evoked by optical stimulation of channelrhodopsin expressing vHPC axons. Surprisingly, we found in IL that NMDA to AMPA ratios were significantly reduced after fear conditioning due to a reduction in NMDA EPSCs. Moreover, extinction in the conditioning context caused a larger reversal of changes induced by fear conditioning than extinction in the different context. Interestingly, animals that failed to recall same context extinction had smaller NMDA to AMPA ratios and NMDA EPSCs than animals with successful extinction recall. These synaptic alterations were not observed in vHPC connections to PL. Taken together, our data suggest that fear conditioning weakens NMDA receptor-mediated excitation of IL neurons by vHPC synapses, and that extinction in the conditioning context strengthens the weakened vHPC synapses. The inability of different context extinction to inducing similar strengthening of vHPC synapses in IL might account for fear renewal, which could explain relapse in certain patients with PTSD.

Title: Early life stress does not result in impaired generalized extinction in adult rats

Authors: *N. ELLIOTT, R. RICHARDSON;
Univ. of New South Wales, UNSW Sydney, Australia

Abstract: Anxiety disorders have a severe and long-lasting impact on an individual's quality of life and overall functioning. A growing body of research suggests that alterations in fear generalization processes are involved in the emergence of psychopathology. Indeed, human studies have found that individuals diagnosed with anxiety show increased generalization of fear after conditioning. Although fear generalization is a well-researched phenomenon in the animal literature, few studies have examined how generalization contributes to the development of anxiety using animal models. Further, no research to date has examined how the generalization of extinction learning influences the emergence of psychopathology. Given that anxiety disorders are thought to stem from both increased fear learning, as well as impaired fear inhibition, it is expected that rats prone to anxiety will show decreased generalized extinction. In this study, we examined generalized extinction after early life stress, which has been shown to be associated with anxiety. Rats were exposed to maternal separation from postnatal day 2-14 (MS; a rodent model of early life stress) or reared as normal. In adulthood, rats received fear conditioning to two distinct tone conditioned stimuli (i.e., CS1 and CS2). The following day, rats received extinction training to one CS (i.e., CS1). Standard reared rats tested the next day showed generalized extinction, such that they demonstrated low levels of fear to both the extinguished CS (i.e., CS1) and the non-extinguished CS (i.e., CS2). It was predicted that MS rats would exhibit less generalized extinction, but they performed similarly to the standard-reared animals. That is, the MS rats also exhibited generalized extinction, showing low levels of fear to both the extinguished and non-extinguished CS. Both MS and SR rats that received extinction training showed lower levels of fear to both CS1 and CS2 compared with non-extinguished controls. That is, contrary to expectations, animals prone to the development of anxiety were not impaired at generalized extinction. These findings contribute to the current body of research on the role of generalization in anxiety disorders, but suggest that perhaps altered generalization of fear inhibition does not influence to the development of psychopathology. **Support:** ARC grant DP150104835 and NHMRC grant and APP1031688.

Title: Systemic administration of 5-HT receptor agonist m-chlorophenylpiperazine (mCPP) modulates fear extinction

Authors: *A. E. REIMER[1,2,3], A. R. DE OLIVEIRA[4,2], M. R. MILAD[3], M. L. BRANDÃO[1,2]; [1]Dept. de Psicologia, Univ. de Sao Paulo, Ribeirao Preto, Brazil; [2]Inst. de Neurociências e Comportamento, Ribeirão Preto, Brazil; [3]3Department of Psychiatry, MGH – Harvard Med. Sch., Boston, MA; [4]Dept. de Psicologia, Univ. Federal de São Carlos, São Carlos, Brazil

Abstract: Although much is now known about the serotonergic (5-HT) mechanisms involved in fear conditioning, less is known about 5-HT mechanisms underlying fear inhibition. The neurocircuitry involved in fear inhibition is impaired in anxiety and mood disorders. Considering that the leading treatments to diverse mental disorders include the use of pharmacological compounds aimed at the 5-HT neurotransmission, understanding how the modulatory 5-HT mechanisms influence fear inhibition can contribute to the developing of better approaches to treatment. The aim of this study is to evaluate fear extinction of rats acutely treated with the 5-HT agonist m-chlorophenylpiperazine (mCPP). Male Wistar rats underwent a 3-day fear conditioning and extinction protocol. On day 1, rats received tone-footshock pairings (conditioning). On day 2, rats received either mCPP (0.5 or 1.0 mg/kg) or vehicle prior to extinction learning. On day 3, extinction memory was assessed. Locomotor activity and exploratory behavior were also assessed using the open-field test. mCPP did not affect extinction learning, compared to vehicle. However, mCPP decreased freezing response during extinction recall, suggesting enhanced extinction memory consolidation. Both mCPP doses decreased ambulation in the open-field test, while only the higher dose increased immobility. Given the widespread of 5-HT1A, 5-HT2A and 5-HT2C receptors expression through brain areas involved in both fear expression and inhibition, it is challenging to specify the exact target responsible for the facilitation of fear extinction in the present study. However, given the presence of these receptors in both medial pre-frontal cortex (mPFC) and amygdala, we hypothesize that mCPP

enhanced fear extinction memory via influence of the 5-HT receptors within the mPFC-BLA circuit.

Title: Impaired fear extinction retention in adolescent rats: Pharmacological evidence for a failure to recruit NMDA receptors during extinction

Authors: *K. D. BAKER, R. RICHARDSON;
UNSW Australia, Sydney, Australia

Abstract: Adolescents, both humans and rodents, exhibit a marked impairment in extinction of learned fear relative to both younger (e.g., juvenile) and older (e.g., adult) groups. This impaired fear inhibition could be caused by NMDA receptors not being recruited efficiently during fear extinction in adolescents as these receptors are critical for the acquisition and consolidation of fear extinction. It is well-established that systemic administration of NMDA receptor antagonists (e.g., MK801) before fear extinction training impairs the retention of extinction in adult and juvenile rodents but it is unknown whether this is also the case for adolescents. In the present experiments we investigated the effect of pharmacologically manipulating the NMDA receptor on fear extinction retention in adolescent rats. In Experiment 1, rats were only given one day of extinction training (which typically results in impaired extinction retention) while in Experiment 2 animals were given two days of extinction training (which usually results in good extinction retention). In Experiment 1, animals were given either saline, D-cycloserine (DCS; a partial NMDA receptor agonist), or MK-801 (an uncompetitive antagonist) while in Experiment 2 animals were given either saline or MK-801 (only on the second day of extinction training). In Experiment 1 saline-treated rats showed the typical impairment of retention of extinction after one day of extinction training whereas DCS-treated rats showed enhanced extinction retention. In contrast, MK801-treated rats showed a similar level of freezing at test as saline-treated rats,

indicating there was no further impairment of extinction retention induced by NMDA receptor blockade. However, when adolescent rats were given twice the amount of extinction training in Experiment 2 so that saline-treated rats showed good retention of extinction at test, MK801 given before the second day of extinction training caused impaired extinction retention to a level comparable to that of rats given only one day of extinction training. The findings of these experiments suggest that extinction in adolescence does not initially involve NMDA receptors and this is a likely mechanism that contributes to the impaired fear inhibition observed at this age. However, NMDA receptors appear to be recruited with extended extinction training which leads to effective extinction retention.

Title: The neural correlates of fear extinction in adults and adolescents: an fMRI study

Authors: *D. E. GANELLA[1], E. P. GANELLA[2], J. H. KIM[1], S. L. WHITTLE[2]; [1]Florey Inst. of Neurosci. and Mental Hlth., Melbourne University, Australia; [2]Dept. of Psychiatry, Melbourne Neuropsychiatry Centre, The Univ. of Melbourne, Melbourne, Australia

Abstract: Anxiety disorders are the most common of all mental disorders worldwide, with 75% of those suffering from an anxiety disorder being diagnosed during childhood or adolescence. Fear extinction deficits have been suggested to be a fundamental mechanism underlying anxiety disorders. While rodent research suggests that deficits in adolescent fear extinction may be caused by abnormal ventromedial prefrontal cortical (vmPFC) function, no similar work has been done in human adolescents. Using a novel paradigm, we investigated the neural correlates of fear extinction learning and recall using functional magnetic resonance imaging (fMRI) in adolescent and adult humans. Given that females are twice more likely to suffer from an anxiety disorder than males, we also investigated gender differences within the adolescent group. Healthy adults (15, aged 25-35) and healthy adolescents (9, aged 14-16), underwent fMRI using a novel fear learning paradigm involving the pairing of a neutral face (CS) with a fear face plus

scream (US). The paradigm involved four phases: (A) Trace conditioning, where one of two neutral faces (CS+) was paired with an aversive sound (female scream, US) on 100% of trials. The other neutral face was a control stimulus (CS-) that was never paired with the US, (B) Extinction, CSs were presented without the US, (C) Reinstatement, two presentations of the US, and (D) Extinction recall, where both CSs were again presented without the US.
Analyses using SPM12 revealed that adults demonstrated the expected vmPFC activation during extinction (cs+ > cs-); however adolescents showed decreased vmPFC and increased rostral/dorsal anterior cingulate cortex activity during both extinction learning and recall, as compared to adults. We found that male adolescents showed reduced vmPFC activity during extinction learning compared with females. When tested for fear recall, however, the pattern reversed, such that female adolescents showed reduced vmPFC activity compared to males. These findings suggest that vmPFC deficits may not appear until after the initial extinction learning phase in female adolescents. These findings have implications for understanding risk factors and treatments for adolescent anxiety. They highlight the importance of investigating extinction learning and recall both across development and gender in order to elucidate the mechanisms of anxiety disorders.

Title: Characterizing adolescent fear extinction learning in a rodent model of youth anxiety

Authors: *I. ZBUKVIC[1,2], J. PARK[1,2], D. GANELLA[1], A. J. LAWRENCE[1,2], J. H. KIM[1]; [1]Florey Inst. of Neurosci. & Mental Hlth., Melbourne, Australia; [2]Univ. of Melbourne, Melbourne, Australia

Abstract: Treatment for anxiety disorders frequently involves cue exposure therapy (CET), based on the principle of extinction. Extinction learning involves dopamine signaling in the prefrontal cortex (PFC), a system undergoing dramatic alterations during adolescence. Developmental changes in the infralimbic cortex (IL) of the PFC are implicated in adolescent extinction deficits, which model youth resistance to CET in the clinical setting. Importantly, resistance to CET due to extinction impairments may help explain adolescent vulnerability to anxiety disorders. The present study aimed to elucidate the role of prefrontal dopamine in extinction learning across adolescent development. Using a fear conditioning paradigm, adolescent (postnatal[P]35 and P53) and adult (P70 and P88) rats were conditioned using 3 tone-footshock pairings. The next day, rats underwent a single extinction session consisting of 30 tone presentations in absence of the footshock, designed to model CET. On testing the next day, long-term extinction was most effective in P88 rats and least effective in P35 rats. In separate subjects, changes in PFC dopamine 1 receptor (D1R) and dopamine 2 receptor (D2R) gene expression were measured following cue extinction. At age P35, PFC D1R/D2R ratio was lower for rats that received cue extinction ($p<0.05$), while at age P88 PFC D1R/D2R ratio was higher for rats that received cue extinction compared to handled controls ($p<0.05$). In a second study, age P35 and P88 rats underwent conditioning then received a bilateral intra-IL infusion of vehicle, the D1R agonist SKF-81297 (0.1ug/hemisphere), or the D2R agonist quinpirole (1.0ug/hemisphere) immediately before extinction. Acutely enhancing D1R signaling in the IL at the time of extinction had no effect on extinction learning in either age group. In contrast, acutely enhancing IL D2R signaling impaired extinction learning in adults, whereas it significantly enhanced long term extinction in adolescents ($p<0.05$). Results highlight a differential role for PFC D2R signaling in extinction learning across development, and offer important insights into the molecular mechanisms of fear extinction deficits during adolescence.

Title: The role of heritable phenotype and social environment on fear extinction learning in rats

Authors: *K. E. PRATER[1,2], E. L. AURBACH[2], H. K. LARCINESE[2], P. BLANDINO, Jr.[2], S. J. WATSON[2], S. MAREN[3], H. AKIL[2];
[1]Neurosci. Grad. Program, [2]Mol. and Behavioral Neurosci. Inst., Univ. of Michigan, Ann Arbor, MI; [3]Psychology Dept., Texas A&M Univ., College Station, TX

Abstract: Heritable propensities, such as temperament, that promote vulnerability or resilience in certain individuals are likely to interact with environmental factors (like trauma) to predict the development of PTSD. However, we know little about these interactions in humans or in animal models. The social buffering hypothesis posits that social support can mediate the effects of stress on an individual. We manipulated the social environment of rats to examine whether this variable would affect extinction behavior in male outbred and selectively bred animals. We compared outbred Sprague Dawley rats to rats selectively bred for high (bHR) or low (bLR) locomotor response to a novel environment. We demonstrated that the heritable phenotype of selectively bred animals leads to stable differences in fear extinction behavior across generations, indicating that these differences are similar to "genetic" propensities. We also observed that social environment significantly influenced the extinction learning of both outbred and selectively bred rats. We then manipulated the locomotor phenotype of the selectively bred animals through selective breeding and observed the interaction of this change in their heritable phenotype with the social environment. We found evidence that manipulating both the heritable locomotor phenotype and the social environment of selectively bred rats leads to additive effects, demonstrating a possible gene-by-environment interaction between novelty-seeking phenotype and social environment during extinction learning. Our work provides strong evidence that social environment significantly affects the extinction of learned fear in outbred and selectively bred rats, and has implications for both experimental design considerations and developing further understanding of gene-by-environment interactions in animal models.

Abstract: While the spiking activity of hippocampal place cells is well known to be modulated by spatial position, it is also simultaneously modulated by other factors including speed (McNaughton et al., 1983) and internal cellular dynamic processes such as refractory period, bursting, and theta oscillations. Furthermore, it has been traditionally believed that head direction does not influence hippocampal single units during 2D random foraging, but our group has recently demonstrated significant head direction modulation in this task (Acharya et al., 2016).These studies did not estimate the independent contribution of running speed on place cells. Such estimation is crucial since many theories of hippocampal function require the existence of robust speed modulation of place cells firing rates.
Importantly, the *independent and relative* contributions of each of these factors has not yet been disentangled. Such independent estimation is crucial yet difficult due to correlations amongst these factors which bias traditional method of calculating rate maps, such as binning. For example, a cell with a place field at the edge of a table may show a spurious negative speed correlation due to lower running speeds there. Furthermore, due to different methods of estimating rate maps from different factors, assessment of their relative importance is difficult. Here we develop a unified framework for identifying and quantifying the independent influence of these features on hippocampal place cells using generalized linear models (GLMs) along with basis expansions. The method yielded not only the independent contribution of position, head direction and running speed to neural spiking, but also provided an estimate of their relative magnitudes.
This framework was used on hippocampal neurons recorded from freely behaving rats during a 2D random foraging task with various types of visual cues. Surprisingly, we found that only a small fraction of neurons showed significant speed modulation. Further, speed modulation of place cells was weaker than both positional and head directional modulation. These results thus provide novel insights about the mechanisms governing place cells, and have important implications for theories of hippocampal function.

Title: Emergence of hippocampal half-theta in virtual reality.

Authors: K. SAFARYAN[1], Y. SHEN[1], *M. R. MEHTA[1,2,3,4];
[1]Departments of: Physics & Astronomy, Neurology, Neurobio., Univ. of California at Los Angeles (UCLA), Los Angeles, CA; [2]W. M. Keck Ctr. for Neurophysics, [3]Integrative Ctr. for Learning and Memory, [4]Brain Res. Inst., UCLA, Los Angeles, CA

Abstract: The rodent hippocampus shows robust theta rhythm (Green & Arduini 1954, Buzsaki & Vanderwolf 1983), which plays a crucial role in synaptic plasticity, learning and memory, and hippocampal information processing. Prominent theories of hippocampal function critically depend on the precise frequency of theta rhythm. Hence, it is important to understand the mechanisms governing theta rhythm. While theta rhythm is generated internally, it is also influenced by other variables including behavior. For example, during immobility, hippocampus shows Type 2 theta that has low frequency (~6Hz), that is quite irregular and has low amplitude. During spatial exploration, Type 2 theta is replaced by Type 1 theta with higher frequency (~8Hz) that has much larger amplitude and regularity. Further, the amplitude and frequency of Type 1 theta rhythm increases with running speed. In addition to locomotion, several other variables, such as vestibular and sensory cues, change between immobility and spatial exploration. To disentangle these different contributions, we compared the nature of hippocampal theta rhythm when rats were running either in the real world or in visually similar virtual reality (Cushman et al. 2013). Consistent with our recent findings (Ravassard et al. 2013) we found that the frequency of Type 1 theta was slightly smaller in virtual reality than in the real

world. Surprisingly, in the local field potential (LFP) on many electrodes we also discovered a novel theta rhythm, whose frequency (~4Hz) is nearly half of the Type 1 theta (~8Hz). Hence, we called this Half-Theta. Unlike Type 2 theta which only appears during immobility and does not coexist with Type 1 theta, Half-Theta was present during locomotion and coexisted with Type 1 theta. Half-Theta was only found in virtual reality and not in the real world. Unlike both Type 1 and Type 2 theta that are found on all electrodes in the hippocampus, significant Half-Theta was found on only about a third of electrodes. Both Type 1 theta and Half-Theta amplitudes increased with running speed in virtual reality. These results thus reveal a novel, behavior- and environment-dependent rhythm in hippocampal LFP, which would help elucidate the mechanisms of hippocampal theta rhythm. The Half-Theta in rodents in virtual reality has similar frequency and amplitude characteristics as that seen in primates and humans in virtual reality, thus bridging the gap in theta properties across species.

Abstract: The Morris Water Maze is a classic, widely-used behavioral test of spatial memory and navigation, as it tries to minimize non-specific local cues such that only distal visual cues can guide navigation. But this elimination of local cues is often not complete, and the neural basis of this behavior is not well-characterized. Hence, we have previously described a virtual

reality (VR) apparatus where only distal visual cues define spatial location[1,2]. Rats readily learn to successfully navigate in the virtual (water) maze task[2], displaying different trajectories based on the start position in the virtual environment. Here we characterized the responses of dorsal hippocampal CA1 single units while rats performed the virtual navigation task.

Surprisingly, pyramidal cells, the traditional "place cells" thought to underlie the cognitive map, do not exhibit allocentric spatial selectivity during virtual navigation. This is similar to the lack of an allocentric map during virtual random foraging tasks[3]. Instead, many cells are selective to the distance travelled from the start point of a trial, termed the episodic distance. However, episodic distance alone is not enough to uniquely define the position of the goal location in the virtual water maze when the rat starts from different positions. Hence we compared the episodic distance coding from different start locations. Episodic distance coding neurons exhibited three different patterns: I. Tuning for the same distance with the same peak firing rate regardless of start position; II. Tuning for the same episodic distance with differential firing rates based on start position (i.e. rate remapping); and III. Tuning for different episodic distances based on start position (i.e. global remapping). This modulation of rate by start position could be influenced by the distal visual cues defining head angle within the virtual space[4]. Additionally, this may be influenced by prospective coding based on the planned future path; it is unlikely to represent retrospective coding based on the previous path, because start positions were randomized across trials, and did not follow a reliable pattern. These results demonstrate that hippocampal single unit responses during virtual (water) maze navigation contain episodic information both about the distance along a trajectory as well as the position from which a trajectory started. This information could allow rats to successfully navigate in this task, even in the absence of an allocentric cognitive map.

Title: Comparative influence of visual versus other multisensory cues on hippocampal spatial and directional tuning

Authors: *S. DHINGRA[1,2,3,4,5], R. SANDLER[1,2,3,4,5], C. VUONG[1,2,3,4], L. ACHARYA[6], M. MEHTA[1,2,3,4,5];

Abstract: Hippocampal neurons show robust spatial selectivity during free behavior, i.e. during two dimensional (2D) random foraging. It has been commonly believed that place cells in rodents do not show any directional tuning (*McNaughton et al. 1983*), despite the inclusion of polarizing visual cues (*Muller et al. 1994*). However, methodological issues in experiments (e.g. presence of uncontrolled, nonspecific, multisensory cues) and analysis (e.g. interaction between spatial and directional variables) can strongly impact spatial and directional selectivity estimates. We recently developed a virtual reality system that eliminates spatially informative nonspecific multisensory cues, and generalized linear model (GLM) techniques which provide independent estimate of spatial and directional selectivity (*Aghajan et al., 2014; Acharya et al., 2016*). Using these we discovered that nearly a third of hippocampal neurons show significant directional selectivity in both real world and virtual reality, and visual cues alone are sufficient to generate directional tuning, in a causal manner, in the virtual world.
However, during natural behavior in the real world, both visual and other cues (e.g. vestibular, olfactory etc.) are present. In this case, it is important to understand if directional selectivity could exist even without visual cues, e.g. supported by vestibular cues, as is the case in the head direction system.
We conducted rodent experiments with different distal visual cues conditions. These conditions ranged from having no visual stimuli, to abundant visual stimuli but without any directional information and, to having varying amounts of directional visual information. We then estimated the independent contribution of position, head-direction and speed using a GLM framework (*Sandler et al., SfN Poster, 2016*).
We find that distal visual cues are not necessary for spatial selectivity in the hippocampus, though the spatial modulation seems to be significantly reduced under conditions with minimal distal visual stimuli, consistent with previous works (*Quirk et al., 1990*). We also find that even though spatial modulation might exist with non-distinct distal visual cues, they are significantly less coherent than with distinct cues. Importantly, we found a profound decrease in directional tuning in the absence of directionally informative visual cues. This shows that vestibular cues alone are insufficient for hippocampal directional selectivity. These results thus elucidate the relative contribution of visual versus other sensory cues in governing hippocampal spatial and directional selectivity, and constrain theories of hippocampal function.

Title: Hippocampal place cells differentially integrate visual and locomotor inputs

Authors: *O. V. HAAS[1,2,3], J. HENKE[1,2,3], C. LEIBOLD[1,2], K. THURLEY[1,2];
[1]Biol. II, Ludwig-Maximilians-Universität München, Planegg, Germany; [2]Bernstein Ctr. for Computat. Neurosci., München, Germany; [3]Grad. Sch. of Systemic Neurosciences, München, Germany

Abstract: Hippocampal place cells provide a neural representation of an animal's location within its environment. To accomplish this, the hippocampus integrates signals from multiple modalities. However, it is unclear how these different inputs are combined into place fields. We investigated how visual spatial cues and an animal's locomotion are integrated by place cells. We recorded from the hippocampus of Mongolian gerbils (Meriones unguiculatus), while animals moved on a virtual linear track by rotating an air-suspended sphere. In virtual reality, we could decouple locomotion from visually perceived movement by changing the gear ratio between movement of the sphere and the visual projection. Place cells both in CA1 and CA3 responded differentially to this manipulation. We find that a subset of cells mostly encodes visual information, as it keeps their place fields in accord with the virtual environment. Whereas in another subset of cells, place fields remain at the same running distance. An in-depth analysis revealed that visual fields predominantly occur at locations at which visual textures change and that place field width decreases with prominent visual landmarks. For locomotion-induced place fields, we find that their width increases with running distance. Some place cells even exhibited two place fields, each driven by one of the two different modalities. A small fraction of cells changed their field's position in a way that could not be attributed to changes in gear ratio (remapping). All place cells adjusted their firing field according to the gear ratio on a single run basis; no adaptation over multiple runs was necessary, arguing for a mechanism that acts on a (milli-)second time scale. Altogether our results show that hippocampal place cells retain strong sensory influence from multiple modalities suggesting a role of the hippocampus as a multisensory associator.

Title: The Honeycomb Maze: a new behavioral apparatus for testing spatial navigation

Authors: *J. M. O'KEEFE, M. BAUZA, M. BERTELLI, S. BURTON, A. DELEKATE, A. HASTINGS, D. HOWETT, J. KRUPIC, R. WOOD;
Univ. Col. London, London, United Kingdom

Abstract: The Morris Water Maze has been the workhorse for testing hippocampal-dependent allocentric spatial learning in rodents for over 30 years. It has the advantage that animals are started from different locations on each trial and therefore must approach the goal from different directions, ruling out directional and cue-approach strategies. Animals with damage to the hippocampus are deficient in learning the task. Its drawbacks are that it does not offer a series of discrete choices on the path to the goal making it difficult to score performance, it does not easily lend itself to varying the level of task difficulty, successive choices along the path to the goal are not independent, and it is not compatible with chronic single unit recording. We have devised a new behavioral test which retains the advantages of the water maze and overcomes these disadvantages. The Honeycomb Maze consists of 37 platforms organized in an overall hexagonal shape. Each platform is situated on top of a pneumatic tube which can be raised or lowered independently of the others. In the standard allocentric spatial navigation task one platform is designated as the goal and the animal is started from different platforms on each trial. Each trial consists of the food-deprived rat being placed on a raised start platform and after a short period 2 adjacent platforms raised to offer it a binary choice. Selection of one of these results in the start platform and the non-chosen platform being lowered and two new choice-platforms being raised. This continues until the animal has reached the goal where it is fed or after five minutes has elapsed. The animal's knowledge of goal direction can be assessed at each choice, and results from trials in which neither choice-platform points in the goal direction support the idea that animals can perform vector computations. Test difficulty can be varied by varying the angle between the two choice-platforms. Control animals and animals with ibotenic acid lesions of the hippocampus were given four trials per day for 17 days. Controls learned rapidly, on average reaching a criterion of 90% correct choices in 18.5 trials while lesioned animals were significantly impaired, with 4/8 of animals not reaching this criterion within 68 trials. While

primarily designed to test allocentric spatial navigation to a goal location, the Honeycomb Maze is easily adapted to test other forms of spatial and non-spatial learning.

Title: Structural determinants of granule cell activity in the dentate gyrus of freely-moving rats

Authors: *M. DIAMANTAKI[1,2], M. FREY[1], P. PRESTON-FERRER[1], A. BURGALOSSI[1]; [1]Werner-Reichardt Ctr. For Integrative Neurosci., Tuebingen, Germany; [2]Grad. Training Ctr. of Neurosci. - IMPRS, 72074 Tübingen, Germany

Abstract: To understand how neural circuits contribute to behavior, it is crucial to relate in-vivo activity patterns to the underlying neuronal elements. In the dentate gyrus – a key component of the spatial memory circuits – granule cells (GCs) are known to be morphologically diverse and to display heterogeneous activity profiles during behavior. To resolve structure-function relationships, we juxtacellularly recorded and labeled single GCs in freely-moving rats. We found that, in line with previous observations, the large majority of neurons were silent during exploration (196 out of 228). Active GCs displayed a unique spike waveform, which could be used for assigning unidentified recordings to the GC population with high accuracy. Most identified and classified GCs fired at low rates and showed spatial activity. Compared to silent neurons, identified active GCs displayed a higher degree of dendritic complexity, and contributed ~2 times more high-order dendrites within the molecular layer. Spine densities were not different between active and silent GCs, but increased as a function of dendritic branch order; as a consequence, active neurons displayed significantly more spines than silent ones. Average firing rates strongly correlated with dendritic complexity ($r=0.68$; $p= 0.01$) and the total number of spines ($r=0.62$; $p= 0.02$). Our data thus provide the structural basis for functional heterogeneity among the GC population. We propose that the in-vivo activity of GCs is determined by their dendritic organization, which quantitatively constrains the total amount of postsynaptic sites available to excitatory entorhinal inputs.

Title: Degenerate mechanisms mediate decorrelation and pattern separation in the dentate gyrus

Authors: *P. MISHRA, R. NARAYANAN;
MOLECULAR BIOPHYSICS UNIT, INDIAN INSTITUTE OF SCIENCE, BANGALORE, India

Abstract: A prominent hypothesis regarding the physiological significance of neurogenesis is its role in pattern separation, a process by which similar afferent inputs impinging on a network result in distinct (decorrelated) population responses. In this computational study involving heterogeneous conductance-based models of dentate granule (GC) and basket cells (BC), we quantitatively delineated the specific contributions of different forms of neuronal diversity to response decorrelation. We first employed a random-sampling procedure to build physiologically and biophysically constrained populations of BCs and GCs that exhibited significant parametric variability and weak pair-wise correlations. We constructed a dentate gyrus (DG) network of these models (500 GCs and 75 BCs) with connectivity defined by anatomical data. Based on a virtual animal's traversal in a square arena (1 m × 1 m) at rodent speeds, this DG network received external inputs from the medial (grid-like) and lateral (contextual) entorhinal cortices. In one set of experiments, we fed identical external inputs to the network, and assessed response decorrelation in networks built with different combinations of intrinsic, synaptic and neurogenesis-induced variability. We demonstrate that the mere presence of experimentally constrained intrinsic biophysical variability was sufficient to introduce significant decorrelation of GC responses to identical inputs. Additionally, correlations between population responses decreased when the strengths of excitatory or inhibitory synapses were increased. Next, we incorporated synaptic and neurogenesis-induced diversity (in addition to intrinsic diversity) into

the network, and found that population correlations achieved with either form of diversity were comparable to those attained solely with intrinsic variability. In a second set of experiments, we designed two distinct arenas and gradually morphed one to the other, fed spatial information from these morphed arenas to the network and computed response correlations of the same cells across different arenas. Here, we show that efficient pattern separation could be achieved by the presence of intrinsic and synaptic variability, with non-significant contributions from an additional layer of variability introduced by neurogenesis. Our results suggest that degenerate mechanisms (1), involving disparate combinations of intrinsic, synaptic, connectivity and neurogenesis-induced forms of variability, contribute to pattern separation/decorrelation in the DG.

Title: Measuring the topological dimensions of hippocampal place cell firing rate space generalizes to all classes of neurons

Authors: *S. E. FOX, J. B. RANCK, Jr;
Dept Physiol & Pharmacol, State Univ. of New York Downstate Med. Ctr., Brooklyn, NY

Abstract: The firing of a class of neurons can be represented as a manifold embedded in a larger dimensional space. For N neurons, the space has N dimensions, each point a vector whose components represent the persisting effect of each action potential (a generalized rate space). We know that there is typically a small dimensional embedded space, because the activity of most neural classes can be described in a few words.
The inductive method to measure the topological dimension, which is always an integer, exploits the property that a boundary of a subspace with unknown topological dimension n, in an N-dimensional space has n-1 dimensionality. A randomly selected point in the rate space becomes the center of an n-sphere with a diameter small enough to fit inside that N-space. A point on its boundary is then selected as the center of a new (n-1)-sphere. The number of times this process must be applied in order to be left with only 2 points is the inductive dimension of the embedded

manifold.
This can be appreciated intuitively in a 3D space that is uniformly populated with points. The 1st step produces a 2D surface of a sphere, the 2nd, a 1D curve (a circle) and the 3rd, 2 points: 3 steps = inductive dimensionality of 3. The firing rate space of N neurons during behavior is a sparsely populated N-space having an embedded manifold with an inductive dimensionality ($n \leq N$, usually $n<<N$) that represents the number of terms necessary to describe the firing in the subspace. To deal with the sparsity, the inductive method was modified to use a thick shell for the boundary, rather than a surface.
We measured the inductive dimension of an 89D space describing the firing rate vectors for 89 place cells (courtesy of Dr. Eva Pastalkova) recorded simultaneously for 1 hr while the rat foraged for food pellets scattered on a 1 m square open field. Initially, we expected the dimensionality of the embedded manifold to be 2, representing the coordinates of the open field, but the modal result was 3, which is, upon further consideration, the right answer.
Whereas the conclusion was predictable for place cells during foraging because the sensory-behavioral correlates are well known, there are many neuronal populations and conditions for which there are an unknown number of parameters necessary to account for the firing rate vectors over time, e.g. firing with no change in behavior, as in sleep. The topological dimension of the manifold is useful because: 1) it allows more extensive mathematical analyses to be used, e.g. maps between manifolds, combining manifolds, and 2) it allows us to define circumstances in which the experiential curve intersects itself, i.e. in which something is the "same", as is required in learning and recognition.

Title: Asymmetry of temporal and rate codes for space by hippocampal place cells

Authors: *A. B. TORT, B. C. SOUZA;
Brain Institute, UFRN, Natal, Brazil

Abstract: The rodent hippocampus plays a role in spatial memory and navigation. Some hippocampal neurons, called place cells, increase their firing rate when the animal is at a specific location of the environment, known as the 'place field' of the cell. As the animal crosses place fields, place cells form spike sequences coordinated by the hippocampal theta rhythm - a prominent field potential oscillation at 5-12 Hz - by firing action potentials coupled to earlier phases of the theta cycle, a phenomenon known as 'phase precession'. Place fields and phase precession are considered canonical examples of rate and temporal codes, respectively, in which the firing rate of the neuron and the exact spike timing relative to the theta cycle provide information about space. Whether temporal and rate coding are governed by independent or related mechanisms is currently unknown and the subject of wide debate. Here we show that the spike timing of place cells couples to theta phase before major increases in firing rate (i.e., before the animal enters the classical, rate-based place field). In contrast, theta-phase coupling rapidly ceases as the animal leaves the place field and firing rate decreases, revealing that temporal coding has strong asymmetry around the place field centre. Interestingly, place cells are not coupled to theta phase at positions distant from the place field centre; therefore, the dynamics of place cell activity can be separated into three stages: phase coupling, phase precession and phase decoupling. These results suggest independent mechanisms of temporal and rate coding by hippocampal place cells.

Title: A nonlinear unsupervised-learning method extracts spatial information and more from hippocampal population activity of freely-moving rats

Authors: *M. ITO, K. DOYA;
Okinawa Inst. of Sci. and Technol. (OIST), Okinawa, Japan

Abstract: How to extract information coded in large population of neuronal activities has become an important issue, with the recent progress in neural recording technology, especially in

calcium imaging. Currently, a decoding method is one of the most common techniques to analyze a large population data. This supervised-learning method uses a data set of population activity X and a target variable Y, for example, a parameter of stimulus animal is receiving, to construct a decoder (mapping from X to Y). Information of Y coded in X can be quantified from the accuracy of estimation Y for new X. However, in this analysis, Y should be selected as a candidate of coded information in advance. Thus, it is impossible to find out unknown information that researchers don't think of.
In this study, we propose that unsupervised-learning methods can extract information purely from X without Y. We focused on the population activity of hippocampal pyramidal cells, because they are well known to convey spatial information. We recorded activities of 338 CA1 pyramidal neurons expressing calcium indicator (GCaMP6f) simultaneously with a miniature fluorescence microscope (inscopix) while a rat was exploring in an open space (45 cm x 45 cm). We applied a nonlinear unsupervised-learning method, called t-SNE (t-distributed stochastic neighbor embedding) to the population activity X. t-SNE extracted three-dimensional structure from X in 338-dimensional space spanned by each neuron's activity. Then, we added a new coordinate system for the three-dimensional structure by a principal component analysis.
We found that 1st and 2nd components represented the position of the rat in the environment. The mean-squared error from the actual x-y trajectories was significantly lower than the chance level (7.2 cm < 22.5 cm) after the adequate transformation (mirror, rotate, and scale). Surprisingly, the error was significantly smaller than that of a supervised-learning method (a grid-based Bayesian method) when the data size was smaller than 300. Furthermore, we found that the remaining 3rd component significantly correlated with the moving speed of the rat. When the 3rd component was a lower value, the tendency of staying at the same position was stronger.
These results demonstrated that an unsupervised-learning method can be a strong tool to extract unknown information from the population activity. By this method, we newly found that the moving speed was also represented in the hippocampus as well as spatial information.

Title: Dynamical properties of hippocampal reactivation of two-dimensional spatial representations

Authors: *F. STELLA, P. BARACSKAY, J. CSICSVARI;
IST Austria, Klosterneuburg, Austria

Abstract: Sharp wave/ripples (SWR) are high-frequency oscillatory events that dominate periods of slow wave sleep in the CA1 region of the hippocampus. Importantly, the bursts of highly synchronized neuronal activity that accompany these events are thought to promote the consolidation of memory patterns across multiple areas. Indeed activity observed during SWRs is highly structured and often corresponds to the firing patterns of place cells expressed during previous environment exploration. More specifically, it has been shown that the reactivation of spatially-modulated hippocampal cells is organized into sequences that replay previous experience by reproducing the order of place fields in the environment.
A wide breath of studies have characterized reactivation and replay of hippocampus place cells, yet the link between this information-rich activity and the neural mechanisms regulating its expression over the course of a SWR is still missing. As a consequence it is still unclear how the findings of sequential activation, mostly studied in one-dimensional environments (e.g. linear track), may be extended to two-dimensional environments with fewer geometrical constraints (e.g. open field).
To address this question, we analysed activity of CA1 neurons during sleep following the exposure to a large open field environment. By using Bayesian decoding techniques we are able to track the evolution of space-related activity during each reactivation event and to reconstruct the set of environment locations expressed during each SWR. We find that reactivation events properties distribute on a spectrum ranging from the expression of a single-location to the sequential activation of distant, unrelated sets of positions. The statistical properties of these events appear to reflect those characterizing stochastic processes like random walks, suggesting that such a heterogeneous phenomenology might actually emerge from a common, shared process.

Title: Hippocampal neuron firing during a cue preparation period for trajectory planning

Authors: *H. IGATA, T. SASAKI, Y. IKEGAYA;
Lab. of Chem. Pharmacology, Grad. Sch. of Pharmaceut. Sci., The Univ. of Tokyo, Tokyo, Japan

Abstract: Animals adaptively navigate to remembered goals according to instantaneous demands of external environments. To attain such online navigation, the brain circuit needs to plan future possible routes based on current environmental/idiothetic cues. Recent studies have demonstrated that hippocampal circuits not only encode present locations (so-called place fields) but also generate organized firing patterns corresponding with future behavior. However, the detailed spatio-temporal characteristics of such prospective activity are not fully understood. In this study, we designed a spatial task in which rats learned to traverse specific locations in a two-dimensional open field. The rats began a trial with their active nose poke in a small box where guidance cues with or without a light cue were presented for five seconds. A start door was then opened to allow the rats to enter into the field. If the rats could travel along a correct trajectory toward a goal door corresponding with the cue pattern, the goal door was opened so that they obtained a reward. During the task, we performed multiunit recordings from hippocampal CA1 neurons. A certain population of cells exhibited trajectory-dependent place-selective firing in the open arena. In addition, during the 5-s cue presentation period, we observed cue-specific firing sequences of neuronal ensembles, including cells that would be both active and silent during the subsequent spatial running. We will further analyze the detailed characteristics of the cue-driven firing sequences, such as which types of cells are involved in the sequence, whether the sequences are associated with task performance, and how the sequences are modulated by local field oscillations of the hippocampus. The results will help understand the contribution of internal activity patterns stored in the hippocampal network to online planning of upcoming behavior in response to continuously changing situations.

Title: The role of hippocampal replay in a computational model of path learning

Authors: *M. J. RAGONE[1], S. GIANELLI[2], D. SCHWARTZ[3], L. SU[5], O. O. KOYLUOGLU[4], J.-M. FELLOUS[2];
[2]Dept. of Psychology, [3]Electrical and Computer Engin., [4]Dept. of Electrical and Computer Engin., [1]Univ. of Arizona, Tucson, AZ; [5]Dept. of Computer Sci., Zhejiang Univ., Hangzhou, China

Abstract: Hippocampal place cells play an important role in spatial navigation in rodents, but the exact mechanism by which networks of place cells store and process spatial information is poorly understood. “Replay” events, in which behaviorally relevant place cells are reactivated offline during sharp-wave ripples (SPWs), are likely critical to spatial information storage. However, the mechanisms by which cells are selected to fire within SPWs are unknown.
In this study, we use a mobile robot and a biophysically realistic network model of place cells and interneurons with spike timing-dependent plasticity (STDP) to simulate hippocampal activity during spatial navigation. The robot is comparable in size to a rat and generates paths that are approximations of typical rat trajectories in spatial noise and velocity. These paths are used as inputs to the model and cause specific patterns of activation in the network, which, coupled with the STDP rule, generate a synaptic matrix that contains path-specific information. When SPWs are simulated in a trained network, its synaptic matrix lays constraints on which cells are reactivated, and may explain why some cells are selected for replay firing and others are not. The firing patterns of these cells during path traversal are then decoded in an ideal observer framework to estimate the path taken by the robot. We hypothesize that place cells that participate in trajectory replay events will convey more information about the path than non-replaying cells. We use the mean squared error (MSE) of the estimated location to test this hypothesis by comparing the MSE of decoding between different ensembles of place cells—all cells, replaying cells, and non-replaying cells.
Recent work suggests that grid cells and place cells are spatially coherent during replay events. In a separate set of simulations, we investigate the effects of including modular or non-modular grid cell information to path decoding with the aforementioned place cell ensembles. We test the robustness of different code ensembles with nominal paths and paths that contain significant perturbations. Our study shows the extent to which replay is governed by the synaptic weights of the network as learning occurs across trials, and how replay may affect the encoding of a learned path in the face of perturbations.

Title: Real-time identification and closed-loop control of hippocampal replay content in freely behaving rats

Authors: *D. CILIBERTI[1,2], F. MICHON[1,2], F. KLOOSTERMAN[1,2,3];
[1]NERF, Leuven, Belgium; [2]Biol. Psychology, KU Leuven, Leuven, Belgium; [3]VIB, Leuven, Belgium

Abstract: The formation and retrieval of new memories is thought to be supported by a complex dialogue among different brain structures coordinated by the hippocampus. In the rodent hippocampus, signatures of memory processing at the cellular and network level can be found in the experience-modulated firing of principal cells and in the accelerated replay of firing patterns that occur during characteristic sharp-wave ripple (SWR) events. Previous work has shown that non-specific interruption of SWR events in both awake and rest state impairs the acquisition of spatial tasks. However, no direct evidence exists yet that causally links specific spike patterns (replay content) to the ability to learn and execute a memory-guided behavioral task. In order to bridge this gap, we developed a brain-computer interface (BCI) that performs real-time identification of replay content and enables content-specific manipulation of replay events in freely behaving rats.

Our BCI deploys an efficient spike-sorting-free neural decoding algorithm and a simple but effective strategy to estimate replay content using the initial portion of a replayed spike sequence. Both algorithms are implemented in a custom-made, general purpose multi-threaded software. This software executes a user-defined signal processing graph in soft real-time and provides the critical advantage of computing parallelization. The software framework only adds a small millisecond-scale latency to the computation time required by the decoding and replay content identification algorithms, which is negligible for our purposes.

For online replay content identification, we continuously searched in a short sliding window of decoded positions for fragments of target trajectories in a multi-segment track (y-maze or radial-arm maze). In order to reduce spurious detections of non-SWR associated sequences, the content identification is complemented with concurrent detection of a multi-unit burst and a SWR event. In tests on pre-recorded datasets, the replay content algorithm positively identifies target replay content within less than 50 ms after SWR start with >80% sensitivity and specificity.

Finally, we demonstrate real-time identification of replay content in live streaming neural data recorded in a freely behaving rat.

Title: Hippocampal representations of spatial information of self and other

Authors: *T. DANJO, S. FUJISAWA;
Lab. for Systems Neurophysiol., Riken Brain Sci. Inst., Wako, Japan

Abstract: When animals explore an open field, how do they recognize their own place and other positional information in the field? Amounts of studies have shown that such spatial memory is founded on the hippocampal place cells, activated specifically when the one is located in their place fields. The assemblies of the place cells are hypothesized to establish the cognitive map, by which animals are able to find a place and navigate to go there, same as we find a place by referring a map. In this map-based navigation, spatial representations are allocentric, and thus place cells should represent not only the self's position, but also the positions of external cues which the animals pay attention to. However, neurons with such a feature have never been identified yet. Moreover, the mechanisms for the representation of a place where the animal is not located remain to be elucidated.
The main purpose of this study is to identify the mechanisms of how spatial information of other animals is represented in the brain. To this end, we record electrophysiological activities from the hippocampus while the rat is required to observe the position of the other rat, and then isolate neuronal activities that contribute to represent the position of the other. We show that the spatial information of self and other is jointly represented in the hippocampus.

Title: Spatial non-grid cells in the primate entorhinal cortex

Authors: *M. L. MEISTER, E. A. BUFFALO;
Physiol. and Biophysics, Washington Natl. Primate Res. Ctr., Seattle, WA

Abstract: In primates, vision is the primary modality used to gather information from the environment, and cells representing visual space and eye position are found in many brain areas. Previous work identified neurons in the entorhinal cortex (EC) which exhibit grid-like visuospatial representations reflecting fixation locations across image space (Killian et al., 2012). To further examine the extent of spatial representation and to identify the spatial reference frame for the primate EC, we determined whether spatial activity was locked to the bounds of a visual image or instead locked to body position.

The spiking activity of 349 EC neurons from two rhesus macaque monkeys was recorded as they viewed complex images (30° x 25° or 30° x 15°) on a monitor. In alternating trial blocks, the images appeared in one of two locations that were laterally offset from each other by 4°. Firing rate maps for each neuron were computed for each of the two image positions, and the spatial correlation between the maps was computed for a range of incremental spatial offsets between 0 and 100% lateral shift. A high correlation at 0% implies no shift (egocentric reference frame), whereas one at 100% implies a complete shift of spatial activity with the image bounds (allocentric reference frame). Spatial stability was assessed within each image location. Spatial correlations were considered significant if they surpassed the 95th percentile of bootstrapped values (shuffling the spike train relative to eye position).

A large proportion of the neurons (138/349, 40%) demonstrated stable spatial activity, and this proportion was similar across animals. Both monkeys showed an even distribution of cells with an allocentric (49%) and egocentric (51%) reference frame, and reference frames were not always identical for simultaneously recorded cells. An analysis of reference frame that included the full population of cells (i.e., cells that were not pre-selected for spatial activity) revealed that

most had maximum correlation values at either 0% or 100% lateral shifts rather than at intermediate spatial offsets.
These results indicate that a large proportion of entorhinal neurons represent eye position. While some cells represent eye position relative to the bounds of an examined image, other cells simultaneously represent eye position relative to body position (or other elements that were invariable in our experiment like the room itself). These findings show that visuospatial representation is a fundamental property of entorhinal neurons and suggest these neurons may support relational memory and motor planning by coding attentional locus in distinct, behaviorally relevant frames of reference.

Title: View cells in the primate hippocampus during visual exploration and directed saccades.

Authors: *S. D. KOENIG[1,2], E. A. BUFFALO[3,4];
[2]Grad. Program in Neurosci., [3]Physiol. and Biol., [1]Univ. of Washington, Seattle, WA;
[4]Washington Natl. Primate Res. Ctr., Seattle, WA

Abstract: Decades of studies in humans, non-human primates, and rodents have demonstrated that the hippocampus and surrounding cortex are important for memory formation. Single unit recordings in rodents have revealed place cells in the hippocampus and grid cells in the entorhinal cortex that are hypothesized to support the spatial aspects of episodic memories. However, spatial representations in the primate hippocampus are not fully understood. Notably, Rolls and colleagues (1997) identified neurons in the primate hippocampus that fired selectively

when a monkey viewed portions of the environment, independent of the monkey's physical position. Recent work in our lab identified visual grid cells in the primate entorhinal cortex which fired in a grid-like pattern reflecting fixation location during the free-viewing of complex images presented on a computer monitor (Killian, Jutras, and Buffalo, 2012). To further explore visuospatial representations in primates, we recorded the spiking activity of 282 hippocampal neurons from two monkeys as they freely viewed complex images. We found that 82 (29%) of these neurons were spatially stable and had significant (all p's < 0.05) spatial information scores (Skaggs et al., 1993). These spatial view cells were more prevalent in the posterior 2/3^{rds} of the hippocampus (36% of cells compared with 19% in the anterior 1/3rd). In between free-viewing trials, monkeys performed a directed saccade task in which they received reward for fixating a sequence of 4 items presented in different spatial locations against a black background. Unique sequences were used for each recording session. Of the 70 view cells that contained at least 1 of these sequence items in their view field, 58 (83%) showed significantly higher firing rates for items placed inside versus outside their view field (t-test, $p < 0.05$). These data suggest that spatial view responses are not driven selectively by free exploration compared to directed saccades. However, many view cells additionally demonstrated contextual modulation, with significant differences in firing rates during free-viewing as compared to the directed saccade task. Taken together, these data suggest that neurons in the primate hippocampus are modulated by viewing location. These neurons are found most prominently in the posterior 2/3^{rds} of the hippocampus, and many of these neurons are additionally modulated by behavioral context. Further, these results suggest that visual exploration in primates and physical exploration in rodents may engage similar neural mechanisms in the hippocampus.

Title: Spatial representations in the monkey hippocampus during free-foraging in virtual reality

Authors: *Y. BROWNING[1,2,3], M. J. JUTRAS[4,5], K. L. MORRISROE[5], C. LEWIS[6], E. FIEDLER[7], T. STIEGLITZ[7], P. FRIES[6], A. L. FAIRHALL[4,2], E. A. BUFFALO[4,2,5]; [2]Washington Res. Fndn. Abstract: A long history of research has identified exquisite spatial representations in the rodent hippocampus. However, the extent to which similar representations can be demonstrated in the primate hippocampus is not fully understood. In order to address this, we trained rhesus monkeys to perform a virtual reality task analogous to the rodent free-foraging task. Here, head-fixed monkeys were trained to use a joystick to navigate a first-person avatar towards targets (bananas) that were randomly scattered around a courtyard in virtual space. Bananas appeared in sets of ten, with new bananas appearing only after the previous set had been collected. The monkeys received food reward for each collected banana. For neural recordings, one monkey was prepared with chronically implanted, flexible, polyimide arrays which enabled recordings from 36 electrode contacts positioned throughout the anterior-posterior axis of the hippocampus. These arrays enabled stable recordings from single cells across multiple virtual environments and across days. Within a given recording session, in alternating blocks of trials, the monkey foraged in either a square or circular virtual arena. In initial analyses of 21 isolated neurons, we were unable to identify clear spatially selective responses related to the location of the monkey in virtual space. Instead, we identified 9 cells (42%) that were selective for the maneuver made by the monkey in the virtual world. Two types of maneuver cells were identified: “turning cells” and “speed cells”. Each of the turning cells fired preferentially for either left or right turns, irrespective of the monkey’s position within the virtual arena. Speed cells had firing rates that correlated significantly with the speed of the monkey’s avatar. For individual cells, these response preferences were consistent across environments (square or circle) and across multiple recording days, suggesting stable representations of maneuvers independent of context. Importantly, attention to spatial features and distal landmarks in the virtual environment was not required for successful performance in this virtual foraging task. Indeed, behavioral analyses suggest that monkeys complete this task using a set of stereotyped maneuvers, rather than explicit route planning. Taken together, these data suggest that in this task, hippocampal responses reflect parameters necessary for successful task performance, even though these parameters are not explicitly spatial. Future work will focus on the use of spatial memory-dependent tasks to further elucidate the role of the monkey hippocampus in encoding representations of space and memory.

Title: Logical representation of space in monkey hippocampus

Authors: P. BARADUC[1], J.-R. DUHAMEL[1], A. PLANTÉ[1], S. PINÈDE[1], *S. C. WIRTH[2];
[1]Ctr. de Neurosci. Cognitive, Bron, France; [2]Ctr. De Neurosci. Cognitive, Bron, France

Abstract: Two macaque monkeys were trained to navigate with a joystick a virtual reality maze, in search of a hidden liquid reward. The reward was obtained at the end of one of the 5 identical arms of the star maze, and could only be located with respect to the 5 distinct landmarks that were placed at a distance between the arms. Animals started their search at an arm end, and after reaching another arm end, they were passively translocated to a new start in a straight path outside the maze arms, preventing them from retracing their steps to the reward. Each training session comprised two periods; in the first, the animals learned a novel maze layout, in the second period they navigated a previously learned, familiar maze. These periods were run in counterbalanced order. The activity of 270 neurons in the hippocampus was recorded concurrently with the animals' gaze and joystick motions.
The monkeys' oculomotor behavior was consistent with a perception of the 3-dimensional environment and an anticipation of their subjective motion. Animals quickly found the reward and performed above chance in 12.3 ± 2 trials (monkey S) or 14.8 ± 2.4 trials (monkey K). They also successfully generalized from an incomplete exploration of the maze, suggesting a correct internal representation of the environment.
A great majority of hippocampal cells were sensitive to place, but these also responded to one or more variables like head direction, point of gaze, or task context. Many cells fired at the sight of a single landmark in a viewpoint- or task-dependent manner, simultaneously encoding the animal's logical situation within a set of actions leading to the goal. Overall, hippocampal activity was best fit by a logical state-space comprising current position, view and action contexts: 44% of the task-active recorded cells contained significant information in that space, and this information content was statistically higher than in positional, viewpoint or point-of-

gaze space. Some cells even distinguished the same position, orientation, and next action depending on the action context. Furthermore, correlation between the activity maps in the familiar and novel environments was highest in the reward-referenced logical state space. In this space, 24% of the cells were significantly correlated between the familiar and the environment, some of them coding novel and familiar mazes in a strikingly similar way, although the two mazes had no common landmark. This shows that while animals forage for food, hippocampal cells can represent space in a task-situated, goal-referenced, logical manner.

Title: A novel shortcut task for analyzing hippocampal sequences

Authors: *E. M. IRVINE, M. A. VAN DER MEER;
Psychological and Brain Sciences,Dartmouth Col., Hanover, NH

Abstract: The ability to take novel shortcuts towards a goal location is a signature behavior of the hippocampal “cognitive map,” and model-based behavior more generally. Despite a long history of behavioral work, there is currently little known of the neural processes that underlie successful shortcut-taking. Previous work examining neural activity in the hippocampus has focused on changes in place fields following experience with the shortcut, leaving open how the shortcut was chosen in the first place. It has been widely noted that internally generated sequences in the hippocampus, such as those associated with sharp wave-ripple complexes (SWRs) have properties suitable for model-based behavior, and therefore may be associated with successful shortcut behavior. Testing this idea requires a task in which (1) neural activity can be measured before rats take a session-unique shortcut, and (2) neural representations of the shortcut trajectory can be compared with those of trajectories that are novel but not shortcuts. To this end, we developed a three-phase shortcut task using a modular, flexibly reconfigurable track system. In Phase 1, subjects traversed a variant of a roughly U-shaped track, receiving food reward at both ends. In Phase 2, two novel segments were added to the maze. These segments were blocked with clear barriers, making them visible but not physically accessible. One of the

segments was a shortcut between the two reward sites; the other segment led to a "dead-end" away from the rewards. In Phase 3, the barriers were lifted and subjects could traverse the novel segments. The modular nature of the maze allowed for session-unique configurations of both shortcut and “dead-end” novel segments. Crucially, the rats need to choose both novel segments a certain number of times so that place fields on both track segments can be estimated; we then retrospectively use these place fields to determine to what extent these novel segments were represented in hippocampal sequences prior to taking them. In Phase 3, rats (n = 4), implanted with 16-tetrode arrays recording from CA1, explored both novel segments. They showed a preference for the shortcut over both the U-shaped and “dead-end” tracks, demonstrating the shortcut is behaviorally relevant. Cells with place fields on both novel trajectories participated in SWR events prior to Phase 3, suggesting that animals represented both trajectories prior to direct experience, enabling further statistical comparison of the relative frequencies and temporal dynamics of shortcut vs. non-shortcut novel paths.

Title: Intra-hippocampal cell synapse learning may support pre-exposure based latent learning by means of improved replay events

Authors: *M. LLOFRIU ALONSO[1], P. SCLEIDOROVICH[2], T. PELC[3], N. CAZIN[4], P. F. DOMINEY[4], J.-M. FELLOUS[3], A. WEITZENFELD[2];
[1]Computer Sci. and Engin., [2]Univ. of South Florida, Tampa, FL; [3]Univ. of Arizona, Tucson, AZ; [4]INSERM, Bron, France

Abstract: Early on, Small (1901) recognized the importance of unrewarded pre-exposure of animals to the environment to facilitate learning. Tolman (1948) analyzed Blodgett’s (1929) experiments on a multiple-T maze, which showed how unrewarded pre-exposure of a rat to the environment can increase the learning speed once rewarded trials begin, a latent learning phenomenon. In Blodgett’s experiment, 2 groups of rats were trained to find food on a multiple-T labyrinth, one with pre-exposure and one without. He observed that after the exploration

period, the rate at which the pre-exposed group of rats learnt the path to the food was much higher than control. We hypothesize that this higher learning rate could be explained by an improved quality of replay events due to a better “cognitive map” built during the unrewarded pre-exposure trials. Building a cognitive or experience map with greater coverage would allow the rat to generate longer replay events, which could improve offline learning. To test this hypothesis we implement a model of navigation based on the three main characteristics stated in Johnson & Redish (2005): the learning of intra-hippocampal synaptic weights, the generation of replay events based on this connectivity and the application of reinforcement learning to the replay trajectories. We apply this model to Blodgett’s experiments and assess whether the model is able to explain the observed difference in learning rates. We predict that the modulation of intra-hippocampal synapses and replay could constitute a concrete plausible biological mechanism for the latent learning phenomenon observed by Tolman in Blodgett’s experiments. We also predict that pre- exposure animals would present replay events that cover longer distances. Title: A hippocampal-entorhinal microcircuit model for dynamic communication in a memory-based navigation task.

Authors: *T. KURIKAWA, T. FUKAI;
RIKEN, Brain Sci. Inst., Wako City, Saitama, Japan

Abstract: Neural rhythm plays an important role in communication between different cortical areas. Such a communication is not constant in time, but dynamically changed depending on demands of memory-consolidation, memory recall, and so forth. Gamma and theta rhythms in hippocampus and entorhinal cortex are critical for memory-based navigation task. A recent study

(Yamamoto, et al., 2014, Neuron) has shown that coherence of these rhythms is dynamically changed during a T-maze task in which a rat is required to choose one of arms depending on the previous choice. They have found that neural activities locked with theta rhythm is selectively higher in a test trial than in sample trial and also found that gamma synchrony between hippocampus and entorhinal cortex which only occurs around a decision point is necessary for the correct choice. Blocking this connection reduces success rate to chance level. This study implies that information of previous choice is transported through the gamma synchrony. What mechanism, however, underlies such a dynamic and flexible communications remains unclear. For understanding this mechanism in microcircuit level, in this study, we model a local neural circuit including pyramidal neurons and some types of inhibitory neurons. This model network has three sub networks corresponding to CA1 and entorhinal cortices (EC3 and EC5) with input from CA3 to CA1 and that from a thalamus nucleus (reuniens). We assume that working memory of the previous choice is stored in EC3 and/or EC5 neurons as persistent activities and the decision is triggered by medial PFC via reuniens. By this model, we analyze the functional role of theta and gamma rhythms and conditions of each type of neurons under which the synchronization occurs in appropriate timing.We found that persistent activity with locked to theta rhythm is triggered by non-linear interactions of inputs from CA3 and EC3 to CA1 through CA1-EC5-EC3 loop. Because CA3 input encodes spatial information, this theta rhythm is generated in specific location on the maze. We also found that gamma synchronization that transfers the information stored in entorhinal cortices to CA1 is generated by interaction between feed-back and feed-forward inhibitions with triggered by reuniens. These results implies different roles of theta and gamma rhythm: theta-locked activity stores information in longer time scale (during a trial) and gamma synchronization triggered by the thalamus input controls more detailed timing to transfer the stored information.

Title: Hippocampal place cell remapping encodes alterations in task contingencies rather than valence in an aversive decision making task

Authors: *J. ORMOND, J. P. JOHANSEN;
Lab. for Neural Circuitry of Memory, RIKEN Brain Sci. Inst., Saitama, Japan

Abstract: Aversive experiences produce fear of contexts in which they occur and avoidance of those contexts when other options are available. In humans, contextual fear creates an expectation of potential future danger that characterizes anxiety, suggesting its study in rodents may provide important information about the neural mechanisms which underlie anxiety disorders. Contextual fear requires an intact hippocampus, likely due to the hippocampus's central role in spatial memory. Both physical and contextual changes in an environment can lead to changes in the properties of hippocampal place fields, a phenomenon termed remapping. A number of studies have demonstrated that aversive experiences cause remapping in hippocampal subregion CA1, but it not known whether remapping also occurs in hippocampal area CA3, which is distinguishable from CA1 based on its partially distinct anatomical connectivity. Furthermore, it is not clear if this remapping encodes a general change in the valence of the context from neutral to aversive, or whether it reflects changes in task contingencies and/or behavioral decisions. To address these questions, we developed a behavioral paradigm in which food-deprived rats chose one of three routes leading to food reward; two routes were paired with aversive eye-lid shock, and rats learned to avoid these routes in favor of a "safe" route. Notably, rats voluntarily ran along "shock" routes during forced-choice trials (i.e. when the "safe" route was blocked), allowing for an assessment of remapping on all routes after changes in the locations of the aversive stimuli. We show that introducing aversive stimuli to a subset of routes after first allowing the animals to run all routes in the complete absence of aversive stimuli induces remapping. We also observed remapping in subsequent sessions when the locations of "safe" and "shock" arms were switched but the overall aversiveness of the task environment was kept constant; this did not occur when the shock contingencies were left unchanged, demonstrating that place fields do not simply become unstable in an aversive context. These data suggest that place field remapping reflects changes in environmental/behavioral contingencies during decision making and not simply changes in the overall valence of the environment. This remapping was apparent in both areas CA1 and CA3, constraining hypotheses on the underlying afferent circuits which produce this reorganization of place cell coding in response to aversive experiences.

Title: Role of dopamine in spatial acquisition and reversal learning

Authors: *L. ZHANG[1], A. GARTHE[1,2], C. WINTER[3], G. KEMPERMANN[1,2];
[1]Dfg-Center For Regenerative Therapies (CRTD), Dresden, Germany; [2]German Ctr. for Neurodegenerative Dis. (DZNE), Dresden, Germany; [3]Med. Fac. Carl Gustav Carus, Technische Univ. Dresden, Dresden, Germany

Abstract: Background: Dopamine is a key neurotransmitter in the brain. Distinct dopamine systems play different roles, either in reward-motivated behavior or in motor control and other hormones release. Dopamine's effects on higher cognitive function have also been studied in monkeys and rodents. But the mechanisms are still unclear. Methods: Three months old C57BL6/J mice were trained to perform a flexibility-involved water maze task. At some key time points of learning, mice brains were dissected immediately and the certain dopamine content levels in ROIs were measured by punch tissue and HPLC method. Results: Significantly decreased path lengths and escape latency show that all mice can learn the spatial learning task. For the HPLC analysis results, dopamine and its metabolites levels in nucleus accumbens increased when the mice were at the beginning of reversal learning. Conclusion: The results suggested that when the goal position was switched, a mismatch between expectation and outcome occurred. The new goal position worked as a novel stimulus and lead to elevated dopamine content.

Title: A subset of CA1 and subiculum neurons selectively encode rewarded locations

Authors: *J. L. GAUTHIER[1,2,3], D. W. TANK[1,2,3];
[1]Mol. Biol., [2]Princeton Neurosci. Inst., [3]Bezos Ctr. for Neural Circuit Dynamics, Princeton Univ., Princeton, NJ

Abstract: The hippocampus is known to be critical for the retention of spatial memories, but it remains unclear which features of hippocampal physiology encode memories of known locations, or how that information is transmitted to other brain areas. Previous studies have shown that when rewards are presented at fixed locations, firing fields in CA1 form at an increased density near the rewards. We set out to distinguish whether the "excess" firing fields encode place per se, or whether they are instead associated with the reward. Mice were trained to run on a virtual linear track with a reward at a fixed location, and simultaneous optical recordings were made from two major hippocampal output structures, CA1 and the subiculum. Consistent with previous studies, an increased density of fields was found near the rewarded location. When the reward was moved to a new location, some of the reward-associated fields also shifted to the new location, suggesting they encoded the reward itself rather than a specific region of space. These fields continued to be reward-associated even when the mouse was trained to run on a different linear track and most CA1 fields underwent global remapping. These observations reveal a previously undescribed feature of hippocampal remapping: a distinct neural population that shifts its firing fields to consistently predict a rewarded location, despite unrelated restructuring of simultaneously recorded place fields. Population activity was also tracked across several weeks as animals became familiar with the new reward location. A preliminary analysis suggested that development of reward-associated activity tracked behavioral learning, and reward-associated fields developed in CA1 earlier than subiculum. A further trial-by-trial analysis revealed that activity of reward-associated cells correlated with behavioral anticipation of reward, raising the possibility that these cells transmit memory of the rewarded location to other brain areas.

Title: Micro-organization of grid cells in layer II of medial entorhinal cortex

Authors: *Y. GU[1], A. A. KINKHABWALA[2], D. W. TANK[1];
[1]Neurosci. Inst., Princeton Univ., Princeton, NJ; [2]Dept. of physiology, Northwestern Univ., Chicago, IL

Abstract: The medial entorhinal cortex (MEC) is important for spatial representation and episodic memory. Grid cells are abundant in the superficial layers (II and III) of MEC and exhibit firing fields on the vertices of a triangular lattice as rodents navigate in open arenas (Moser et al., 2014). Previous studies using tetrode recordings showed that grid cells form discrete functional modules. Grid cells within a module share similar scale, orientation, asymmetry and theta-frequency modulation. Anatomically, although modules with larger scale generally distribute more ventrally in MEC than modules with smaller scales, most modules show significant overlap (Stensola et al., 2012). Since the resolution of tetrode recordings prevents identification of the anatomical location of individual cells, it is unknown how cells in different modules are organized at microstructural level. In addition, layer II of MEC contains two excitatory cell types: pyramidal cells and stellate cells (Kitamura et al., 2014; Ray et al., 2014). The contribution of the two cell types to the grid cell population is still unclear. Here, we addressed these two questions by cellular resolution two-photon imaging of calcium dynamics in neurons in layer II of MEC while mice navigated on virtual linear tracks. The same population of grid cells was imaged in two behavior sessions (the two sessions could be on the same track or different tracks). Grid cells were then assigned to different modules based on their field spacings and widths, which were calculated from their activity patterns in the two sessions. Stellate and pyramidal neurons were simultaneously imaged and identified *in vivo* based on the diameters of their cell bodies. We found that co-modular grid cells generally clustered and separated from cells in other modules, although some degree of intermingling existed at the boundaries between modules. Most grid cells were stellate cells (~80%). More specifically, 43% of stellate cells were identified as grid cells, whereas only 17% of pyramidal cells were grid cells. Stellate cells showed significantly more speed-modulated activity than pyramidal cells. In summary, the anatomical clustering of cells within grid modules raises the possibility that co-modular cells form strong functional connectivity and receive common inputs during navigation. Our results

also support the idea that the stellate cell population encodes more position information than the pyramidal cell population.

Title: Representation of an abstract non-spatial coordinate by firing fields in the hippocampal/entorhinal circuit

Authors: *D. ARONOV, R. NEVERS, D. W. TANK;
Princeton Univ., Princeton, NJ

Abstract: Neurons in the hippocampus and the medial entorhinal cortex (MEC) fire in discrete fields within a spatial environment. However, these areas are critical not only for spatial navigation, but for a variety of memory-guided behaviors. How does hippocampal/entorhinal activity implement the more general function of these brain regions? One possibility is that the activity of neurons like place and grid cells is not fundamentally a framework for representing location; rather, such activity patterns may generally serve to represent the values of behaviorally-relevant variables.
To test this idea, we performed tetrode recordings in CA1 and MEC of rats trained in an acoustic virtual reality apparatus to “navigate” along a non-spatial “linear track” defined by sound frequency. Animals deflected a joystick to increase the frequency of a pure tone and were required to release it in a target zone between two frequency values. The scaling factor between joystick deflection and the rate of change of sound frequency was varied across trials to uncouple sound frequency from elapsed time.
About 40% of the CA1 cells fired in discrete fields that, across the population, spanned all phases of the behavioral task – including individual “locations” within the frequency space, as well as periods before and after joystick deflection. Neurons active during the joystick deflection fired in the same ranges of frequencies across trials of different durations, indicating that they did

not simply represent elapsed time. Cells engaged by the acoustic task partially overlapped with place cells, identified by recording during random foraging in a separate spatial behavioral arena. MEC neurons, including grid, border, and head direction cells, also formed firing fields in the acoustic navigation task, indicating that a variety of known cell types in the hippocampal/entorhinal circuit may be repurposed between spatial and non-spatial tasks.
Our results show that an abstract, non-spatial axis may be represented by hippocampal and entorhinal activity in a fashion similar to the known representations of location. They suggest a model in which discrete firing fields are flexibly used by the hippocampal/entorhinal circuit to represent arbitrary abstract spaces, supporting not only spatial navigation, but cognition in general.

Title: Learning on multiple timescales with metaplasticity

Authors: *P. KHORSAND[1], S. FARASHAHI[2], A. SOLTANI[2];
[2]Dept. of Psychological and Brain Sci., [1]Dartmouth Col., Hanover, NH

Abstract: Adaptive decision making not only requires learning from reward feedback but also necessitates adjusting this learning based on how often reward contingencies change (i.e. reward uncertainty) in a given environment. In the context of reinforcement learning, the latter is accomplished by adjusting the learning rate according to reward uncertainty in the environment. Generally, finding the proper learning rate requires optimization but neural mechanisms underlying computations necessary for finding the optimal learning rates are unknown. Alternatively, Bayesian models that incorporate uncertainty into learning can achieve optimal behavior, but they require knowledge of the environment. Recently, we have extended a cascade model of synaptic plasticity for memory (Fusi et al., 2005) to a reward-dependent domain, and showed that the ensuing model provides a plausible solution for choice during a probabilistic reversal learning (PRL) task. In this task, the subject chooses between two options with assigned reward probabilities, but these probabilities change between blocks of trials. Importantly, the difference in reward probabilities and the block length determine reward uncertainty in a given environment. Here, we examined alternative models of reward-dependent metaplasticity (RDMP) to further study how such models can achieve robust and near-optimal performance, in

the absence of any explicit optimization or knowledge of the environment. To this end, we considered three general models based on cascades of meta-states with monotonically decreasing transition probabilities. Using mean-field approaches and Monte Carlo simulations, we found a generalized cascade model of RDMP that provides a near-optimal and robust solution during the PRL task. In this model, synapses mostly occupy meta-states with transition probabilities that match the timescale of changes in a given environment (i.e. block length) and moreover, fractions of synapses in different meta-states are influenced by reward probabilities. Overall, our results show the ability of the cascade architecture to solve very different problems faced by the brain, such as preserving memories over long timescales and integrating reward under uncertainty.

Title: Taming synaptic heterogeneity for adaptive learning

Authors: *M. MORADI SPITMAAN[1], P. KHORSAND[2], A. SOLTANI[2];
[1]Psychology and Brain Sci., [2]Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Most of our knowledge of the world is acquired through learning from reward feedback. However, because reward contingencies can change unpredictably, this learning should be adjusted depending on the frequency of those changes (i.e. reward uncertainty) in a given environment. In the context of reinforcement learning (RL), this adjustment could happen via optimization to fine-tune the learning rate according to the reward uncertainty. Alternatively, considering the heterogeneity in reward-dependent plasticity (which underlies learning from reward feedback) throughout the brain, one could assume that adaptive learning could be achieved by combining the output of a population of synapses each with a different learning rate. In the absence of any additional mechanisms, however, signals generated by synapses with disparate learning rates might cancel each other out. Therefore, we hypothesized that specific neural mechanisms should be in place so that reward uncertainty in the environment could structure heterogeneity to make it beneficial for adaptive behavior. We have recently proposed that reward-dependent metaplasticity (RDMP) can enable synapses to adapt to reward statistics in a given environment. Therefore, here we aimed to test whether RDMP can provide a neural

substrate for structuring heterogeneity for adaptive choice. To do so, we used a heterogeneous population of metaplastic synapses with a wide range of transition probabilities and simulated a generalized probabilistic reversal learning task which allows us to control the level of uncertainty in the environment. Furthermore, we compared the results with those using a heterogeneous population of RL models. Specifically, we applied a combination of decoding (linear support vector machine, SVM) and encoding (mutual information, MI) methods to estimate the information content of these populations in different environments. Results based on the SVM classifier showed a superior performance and higher dimensionality for RDMP over RL populations. Moreover, we found a larger width of SVM weights for RDMP than RL, indicating that a larger number of synapses were used for discrimination in the former model. Critically, the increase in the width of SVM weights between RL and RDMP was predictive of the improvement in performance from RL to RDMP. The MI analysis revealed that information content of pairs of RDMP synapses overlaps less than that of RL synapses, further expanding upon the findings based on the SVM classifier. Overall, our results show that metaplasticity can provide a plausible mechanism for structuring synaptic heterogeneity in order to make it beneficial for adaptive learning.

Abstract: Theory of aging is based on increased oxidative/nitrosative stress that occurs over time and can cause neurodegenerative diseases and cognitive impairment. Taurine has neuroprotective and antioxidant effect in the central nervous system. This study aimed to

evaluate the effect of taurine chronic administration from day E15 to 8 months of age on oxidative/nitrosative stress, learning process and memory. Pregnant Sprague-Dawley rats were separated into two groups: (1) control rats without treatment; (2) rats with taurine chronic administration (50 ppm in the drinking water). Four brain regions (cortex, brainstem, cerebellum and subcortical nuclei) were dissected out to measure lipid peroxidation by Gerard-Monnier and nitrites by Griess method at different ages: 15 day old, 1 and 8 months old. Reference spatial learning in Morris water maze was trained daily during 5 days and the long-term memory was evaluated 7 days after learning. In addition, novel objects recognition (NOR) was evaluated at 2 months old; habituation was made in the first day, familiarization in the second day; retention was evaluated 3 h and 24 h later. Our results showed an increase in lipid peroxidation and nitrite production dependent on age in the control group. Chronic administration of taurine caused damage only in the cerebral cortex-hippocampus in male rats, comprising of 300% increase in lipid peroxidation at 15 day old, 100% at 1 month old and 231% at 8 months old, as compared with the control group. Nitrite production was also increased by 70% at 15 days old, 81% at 1 month old and 137% at 8 months old, when compared with the control values. Interestingly, no significant changes were determined in female rats. Memory in treated infant rats was not different from the controls when evaluated by the Morris water maze, but NOR test performed at 2 months of age showed a decrease by 60% in the acquisition, by 53% in short-term retention and by 39% in long-term retention in male. We can conclude that the chronic administration of taurine from gestational day E15 caused damage of the cerebral cortex-hippocampus with consequent alterations of cognitive processes, such as learning and memory, in male rats, but not in female rats. These results show for the first time that exists a sexual dimorphism to the susceptibility to taurine supplementation in the cerebral cortex of the rat.

Autonoma de Puebla, Puebla, Mexico; [3]Inst. De Seguridad Y Servicios Sociales De Los Trabajadores Del Estado, Ciudad de Mexico, Mexico; [4]Ctr. de Investigación y de Estudios Avanzados del Inst. Politécnico Nacional, Ciudad de Mexico, Mexico

Abstract: Zinc is the second most abundant metal in the human body and is crucial for life. Zinc availability in neonatal and early postnatal period is required for adequate growth, normal birth weight, low morbidity, mental development and effective behavior. Zinc is highly regulated in the body, so its deficiency leads to multiple pathological conditions, whereas its excess can cause toxicity in the brain. Zinc is also known to exert a dual effect; cytotoxicity, increasing oxidative/nitrosative stress, lysosomal dysfunction, cell death and autophagy, or cytoprotection as a neuromodulator in excitatory synapses, stress response and neuronal functionality. Recent reports show that zinc subacute administration prevents the loss of long-term memory in male adult rats. However, the effect of zinc chronic administration on nitrosative stress and long-term memory is still unknown during the pubertal period of male and female rats. Male and female Sprague-Dawley rats (P30) were treated with different doses of $ZnCl_2$ (0, 0.1, 0.5 and 1 mg/Kg), every 24 h, during 14 days. Learning (P45) was evaluated by a daily training for 5 days in a Morris water maze. The long-term memory was evaluated on day 7 after learning (P57). The cerebral cortex and hippocampus were dissected out (P57) to evaluate levels of nitrites by Griess method and lipoperoxidation by Gerard-Monnier assay. Our results showed that repetitive zinc doses of 0.1 mg/kg improved learning and did not trigger nitrosative stress. Loss of memory and increase in nitrosative stress occurred in male rats treated with repetitive zinc doses of 0.5 mg/kg. Interestingly, female rats showed tolerability to all repetitive zinc doses; even the dose as high as 1 mg/Kg was unable to activate nitrosative stress although could improve long-term spatial memory. These results show for the first time that exists a sexual dimorphism to requirements of zinc in pubertal rats. The molecular and cell mechanisms remain to be elucidated.

Title: Coadministration of 5-HT7 receptor antagonist and agonist on forgetting

Authors: *R. SOLÍS GUILLÉN[1], A. MENESES[2];
[1]Farmacobiología, Ctr. De Investigación Y De Estudios Avanzados De, Ciudad DE Mexico, Mexico; [2]Farmacobiología, CINVESTAV, Mexico, Mexico

Abstract: Evidence indicates that 5-HT_7 receptor antagonist have antiamnesic effects (Gasbarri et al, 2008), while its stimulation improves spatial memory and attention (Ruocco et al 2014). It is unclear the reasons the paradoxical effects; hence we are asking if these drugs have effects on forgetting, which has been little explored as therapeutic target for dysfunctional memory. Certainly forgetting and amnesia differ in neuroanatomical and pharmacological terms. In this work, SB-269970 (SB, 5-HT_7 receptor antagonist) & LP-211 (LP, 5-HT_7 agonist) are examine during short- (STM) & long-term memory (MLP), as well as forgetting protocol (Tellez et al, 2012) in an autoshaping learning task. Initial results show that SB (1 amd 10 mg/kg) and LP (0.5 and 1.0 mg/kg) have no effect on forgetting; however, LP211 (at 2.5 and 5 mg/kg) partially inhibits forgetting. Importantly, coadministration of SB 1 mg/kg plus LP 0.5 mg/kg and SB 10 mg/kg plus 2.5 mg/kg eliminated forgetting; indicating that 5-HT_7 receptor might be a useful target for altered memory.

Title: Effect of environmental enrichment as adjunctive therapy to administration of EMD386088 5-HT_6 receptor agonist on memory formation & amnesia

Authors: *F. APARICIO NAVA;
Ctr. De Investigación Y Estudios Avanzados Del I, México, Distrito Federal, Mexico

Abstract: Environmental enrichment (EE) may potentiate the promnesic effect of 5-HT_6 receptor drugs; hence, we are examining the combined effect of EE and 5-HT_6 receptor agonist EMD 386088 (EMD, 0.5 mg /kg, i.p. sub-effective dose) during authoshaping short- (STM1.5 h) and long-term memory (LTM 24 &48 h) or dizocilpine-induced (0.2 mg / kg, i.p) amnesia. EMD had no effect and dizocilpine reduces conditioned responses (CR%) in the STM and EE reverses

it. EE and EMD (sub-effective dose) combination significantly increases CR% and eliminated dizocilpine-effect. Conclusions: EE reversed memory impairment induced by a deficit in glutamatergic associative learning. Importantly, EE in combination with a sub-effective dose of EMD produce a synergistic effect on memory. These results support the therapeutic potential of environmental enrichment as adjunctive therapy and 5-HT_6 receptor on memory and its dysfunctions

Title: Preclinical characterization of SUVN-I4035- a novel and selective muscarinic m1 positive allosteric modulator

Authors: *R. ABRAHAM[1], R. MEDAPATI[2], R. BADANGE[3], V. REBALLI[3], A. SHINDE[3], V. GOYAL[4], S. PANDEY[4], S. YATHAVAKILLA[2], V. GOURA[2], S. EDULA[5], R. SUBRAMANIAN[5], V. MEKALA[5], N. MUDDANA[6], V. UTHUKAM[6], S. DARIPELLI[6], B. DEVARAPALLI[6], R. EEDA[6], R. NIROGI[7];
[2]In-vivo Pharmacol., [3]Medicinal Chem., [4]Toxicology, [5]In-vitro biology, [6]ADME, [7]Discovery Res., [1]Suven Life Sci., Hyderabad, India

Abstract: Memory decline in the elderly due to dementia and Alzheimer's disease (AD) are widely known causes. Currently, there are only symptomatic treatments available for these conditions. Though muscarinic acetylcholine subtype 1 (M_1) receptor agonists showed cognitive improvement, their clinical utility was limited by insufficient selectivity leading to cholinergic side effects. The conservative nature of the orthosteric site makes it difficult to identify selective M_1 receptor agonists. As allosteric receptor modulation leads to high selectivity and minimal side effects, the positive allosteric modulators (PAM) of the M_1 receptor were designed and explored. SUVN-I4035 is one of our lead M_1 positive allosteric modulator. It was evaluated for its binding potential at the orthosteric site of muscarinic receptors and its ability to potentiate the effect of acetylcholine in the reporter gene assay. The pharmacokinetics and brain penetration of SUVN-I4035 was evaluated in rodents. The efficacy of SUVN-I4035 was evaluated in animal models of cognition. Cardiovascular safety was assessed using the patch clamp technique. General safety was assessed in rodents and mutagenicity was assessed using the bacterial reverse mutation assay. The physiochemical properties were studied as well. The results indicate that SUVN-

I4035 did not bind to the orthosteric site up to the tested concentration of 10μM. It significantly potentiated the effect of acetylcholine. It also showed good selectivity against M_2 - M_5 receptors. It has adequate water solubility, and was found to be orally bioavailable (76 ± 7%) in rats with adequate brain penetration and free fractions (fu, 17%). SUVN-I4035 reversed memory deficit in object recognition task and T-maze task. SUVN-I4035 potentiated the pro-cognitive effect of donepezil and promotes non-amyloidogenic APP processing in rats. SUVN-I4035 also enhanced the cerebral blood flow in rats. In rats SUVN-I4035 did not increase salivation induced by acetylcholine esterase inhibitors. SUVN-I4035 was found to be safe when tested in hERG patch clamp assay and in early stage animal toxicity studies. SUVN-I4035 is non-mutagenic in the bacterial reverse mutation assay. Hence, SUVN-I4035 was characterized as a M_1-PAM demonstrating robust efficacy in animal models of cognition.

Title: Esculetin attenuates sleep deprivation-induced cognitive dysfunction by modulating neuroinflammation and TrkB-BDNF signaling pathway in mice

Authors: *K. SULAKHIYA[1], C. C. BARUA[2], V. PARAMANIK[3];
[1]Ctr. for Excellence for Indigenous Knowledge, Indira Gandhi Natl. Tribal Univ., Amarkantak, India; [2]Dept. of Pharmacol. & Toxicology, Col. of Vet. Sciences, Assam Agricultur Univ., Guwahati, India; [3]Fac. of Science, Zoology, Fac. of Science, Indira Gandhi Natl. Tribal Univ. (IGNTU), Amarkantak, India

Abstract: Converging line of evidences suggest that insomnia is a predisposing factor for the cognitive dysfunction and about 45% of Alzheimer's disease (AD) patients show sleep disturbances. Neuroinflammatory and TrkB-Brain derived neurotrophic factor (BDNF) signaling pathway involved in the pathogenesis of AD and associated cognitive impairments. BDNF plays an important role in the synaptic plasticity and memory function. Total sleep deprivation is an inflammatory process which further leads to neurobehavioural changes and alteration of TrkB-BDNF signaling process. Esculetin (ESC), a coumarin derived potent antioxidant, also possessing anti-inflammatory and neuroprotective activity. The present study investigated the effect of ESC pre-treatment on SD-induced cognitive impairment and neuroinflammattory as well as TrkB-BDNF signaling pathway in mice. Mice (N=8) were pre-treated with ESC (50 mg/kg BW, p.o) for 14 days and subjected for 5 days of sleep deprivation protocol. After SD protocol animals were subjected to Morris water maze (MWM) and novel object recognition test to evaluate cognition and memory. Hippocampal cytokines, TrkB, BDNF, MDA and GSH level were analyzed. Results showed that 5 days sleep deprivation (SD) significantly increased the escape latency in MWM ($P<0.001$) and decreased recognition index ($P<0.001$) in mice which was significantly ($P<0.01$) attenuated by 14 days pre-treatment of ESC. Moreover, pro-inflammatory cytokines (IL-1β, IL-6 & TNF-α), MDA & GSH level increased significantly ($P<0.001$) after SD in mice which was reversed by the ESC pre-treatment. Furthermore, hippocampal TrkB & BDNF level were decreased after SD protocol which was attenuated by chronic pre-treatment of ESC. In conclusion, results suggested that ESC provided protective effect against SD-induced cognitive dysfunction by modulating neuroinflammation and TrkB-BDNF signaling pathway. Thus, ESC may be potential therapeutic agent for the treatment of insomnia and cognitive impairments associated with Alzheimer's disease.

Title: Positive effect of biflorin: memory amelioration in cholinergic blockade-induced memory deficit in mice

Authors: *Y. GWON;
Col. of Pharm., Kyunghee Univ., Seoul, Korea, Republic of

Abstract: To examine the effect of biflorin, a component of *Syzygium aromaticum,* on memory deficit, we introduced a scopolamine-induced cognitive deficit mouse model. A single administration of biflorin increased latency time in the passive avoidance task, ameliorated alternation behavior in the Y-maze, and increased exploration time in the Morris water maze task, indicating the improvement of cognitive behaviors against cholinergic dysfunction. The biflorin-induced reverse of latency in the scopolamine-treated group was attenuated by MK-801, an NMDA receptor antagonist. Biflorin also enhanced cognitive function in a naïve mouse model. To understand the mechanism of biflorin for memory amelioration, we performed Western blot. Biflorin increased the activation of protein kinase C-ζ and its downstream signaling molecules in the hippocampus. These results suggest that biflorin ameliorates drug-induced memory impairment by modulation of protein kinase C-ζ signaling in mice, implying that biflorin could function as a possible therapeutic agent for the treatment of cognitive problems.

Title: Sex differences in ventral hippocampal muscarinic acetylcholine antagonist scopolamine effects on spatial memory in rats

Authors: *B. J. HALL[1], Y. ABREU-VILLAÇA[2], M. CAULEY[2], A. KIANY[2], S. JUNIAD[2], H. WHITE[2], E. D. LEVIN[2];

Abstract: Sex differences in cognitive function have been previously documented in experimental animal studies. One key difference that has been shown is that male rats tend to perform more accurately than females during spatial working memory tasks. The neural sources for these sex-related differences in cognition are not well understood. In the current study, we examined the roles of muscarinic and nicotinic acetylcholine receptors in the hippocampus and frontal cortex on spatial working memory in rats performing the radial-arm maze task. It was hypothesized that cholinergic projections to these areas played roles in sex differences in spatial memory performance. Young adult male and female Sprague-Dawley rats were trained for 18 sessions on a 16-arm radial maze. Twelve arms of the maze were baited at the beginning of each session to assess working memory, and the remaining four arms were left unbaited to assess reference memory. After training, the rats were implanted with bilateral cannulae for local infusions of muscarinic (scopolamine, 0, 1, 3 and 10 µg/side) and nicotinic (mecamylamine, 0, 1, 3 and 10 µg/side) antagonists into the ventral hippocampus or medial frontal cortex. Scopolamine infusions into the ventral hippocampus showed a differential effect on male and female rats. Females showed significant spatial working memory impairments in the task, whereas males did not show impairments under this dose range of scopolamine. In the frontal cortex, the highest test dose of scopolamine caused spatial working memory impairment regardless of sex. No differential effects of mecamylamine were observed in the task when infused in the hippocampus or frontal cortex of male and female rats. These studies show that muscarinic acetylcholine receptors in the ventral hippocampus are differentially vulnerable to cause spatial memory impairments in females. Ventral hippocampal muscarinic acetylcholine receptors may play a key role in male-female differences in spatial memory.

Title: Prolonged exposure to varenicline did not altered the memory of male rats

Authors: *J. Z. MAGALHÃES[1], D. P. FIGUEIREDO[2], G. R. ABREU[2], E. L. RICCI[2], M. S. B. UDO[3], H. S. SPINOSA[4];
[1]Dept. of Pathology, Sch. of Vet. Med. and Animal Sci. U, São Paulo, Brazil; [2]Mackenzie Presbiterian Univ., São Paulo, Brazil; [3]Sch. of Pharmaceut. Sci. - Univ. of São Paulo, São Paulo, Brazil; [4]Dept. of Pathology, Sch. of Vet. Med. and Animal Sci. - Univ. of São Paulo, São Paulo, Brazil

Abstract: Varenicline is a synthetic chemical used for the treatment of smoking. Its mechanism of action is by binding to nicotinic cholinergic receptors as a partial agonist of the receptors α4β2 and α3β4 and a full agonist of the receptor α7. Varenicline has some effects on memory and cognition. Pre-clinical trials show that this substance can improve attention and labor memory in patients with only three days with absence of nicotine. This mechanism is still not clear, but the hypothesis is that these effects are related with the pre-synaptic neurotransmitters released, including gamma-aminobutyric acid (GABA). Considering that there is a tendency to expand the clinical use of varenicline and that are few studies related to behavioral, cognitive and motor effects, become necessary more studies on their pharmacological effects. The aim of this study is to evaluate the behavior of male rats exposed to different doses of varenicline for 28 days in the open field, Barnes maze and passive avoidance. Forty male rats received different doses of varenicline or tap water by gavage for 28 days: control group (A) - 1mL/kg of water; group B - 0.03 mg/kg of varenicline (therapeutic human dose); group C - 0.1 mg/kg of varenicline; group D - 0.3 mg/kg of varenicline. n=10 male rats/group. Varenicline was obtained from the commercial product Champix® - Pfizer, diluted on tap water. It was evaluated the general activity of these animals in the open field and the memory using the Barnes maze and passive avoidance. The parameters evaluated on the open field were: frequency of locomotion, rearing, grooming and defecation, and time of grooming and immobility. The parameters evaluated on the Barnes maze were the number of errors and the latency to find the escape box. The parameter evaluated on the passive avoidance was the latency to enter on the black box. The analysis of the behavior of male rats in the open field showed alterations on only two parameters, when compared to the control group: the rats from group B had an increase of the locomotion frequency on the 14º day of treatment ($p<0,01$) and a decreased of the time of immobility on the same day of treatment ($p<0,05$). Regard the Barnes maze and the passive avoidance, the statistical analysis did not showed significant differences between the groups. The results indicate that although there were some alterations on the open field parameters, the exposure to different doses of varenicline did not altered the general activity and the exploratory behavior of male rats. This exposure also did not alter the space and the short term memory of male rats.

Title: The t-type calcium channel blocker, z944, reduces conditioned fear in genetic absence epilepsy rats from strasbourg and the non-epileptic control.

Authors: *W. N. MARKS[1], N. K. ZABDER[1], Q. GREBA[1], S. M. CAIN[2], T. P. SNUTCH[2], J. G. HOWLAND[1];
[1]Physiol., Univ. of Saskatchewan, Saskatoon, SK, Canada; [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: T-type calcium channels exhibit unique biophysical properties implicated in the generation of low-threshold spikes that can lead not only to the oscillatory behavior in the brain observed during sleep, but also the burst-firing observed during pathological events such as absence seizures. Although the electrophysiological properties of T-type calcium channels have been studied extensively, less is known about the contribution of T-type calcium channels to cognition and behaviour. Genetic Absence Epilepsy Rats from Strasbourg (GAERS) are a well-described rodent model of childhood absence epilepsy that display a gain-of-function missense mutation in the *Cacna1h* gene encoding the Cav3.2 T-type calcium channel. GAERS have previously been demonstrated to have heightened learning and delayed extinction of Pavlovian fear conditioning. Our objective was to examine the effects of the highly potent and selective pan-T-type calcium channel blocker, Z944, on conditioned fear behaviour in GAERS and the Non-Epileptic Control (NEC) strain. Z944 (10 mg/kg; ip) was administered 15 min prior to either the conditioning or recall (24 hrs later) of delay-conditioned fear. Extinction of conditioned fear was examined 48 hrs after conditioning. Z944 treatment prior to conditioning enhanced freezing during conditioning, but reduced freezing to tone cues during recall in both strains. In GAERS, Z944 treatment prior to conditioning reduced freezing during initial exposure to context cues during recall and reduced freezing to both tone and context cues during extinction. Z944 treatment prior to recall produced similar behaviour to vehicle treated animals during recall of tone cues, but increased freezing during initial exposure to context cues during recall in both strains. Z944 treatment prior to recall had no effect on extinction. Regardless of treatment, GAERS showed increased freezing during conditioning, recall, and extinction of conditioned fear relative to NEC animals. Overall, Z944 treatment prior to conditioning normalized fear behaviour in GAERS whereas treatment in NEC animals impaired recall of

conditioned fear. The effects of Z944 on Wistar rats is currently in progress. These results demonstrate that T-type calcium channels contribute to the neural systems that mediate the learning and memory of conditioned fear. Continued research into the therapeutic potential of T-type calcium channel regulation may be particularly fruitful for the treatment of disorders characterized by enhanced memory of negative experiences.

Title: Impact of short-term fructose ingestion on brain plasticity and function

Authors: *A. JIMENEZ MALDONADO[1], Z. YING[1], H. BYUN[1], F. GOMEZ-PINILLA[1,2,3]; [1]Dept. of Integrative Biol. and Physiol., [2]Dept. of Neurosurg., UCLA, Los Angeles, CA; [3]Brain Injury Res. Ctr., UCLA, Los angeles, CA

Abstract: The monosaccharide fructose is abundant in the Western diet and it is becoming a major cause of metabolic syndrome (MetS), diabetes, and obesity. Even more recently, clinical evidence has started to accumulate pointing to the pervasive effects of fructose for a range of neurological and psychiatric disorders. Previous studies have found that long-term high fructose ingestion associated with MetS induces lower cognitive performance and protracted brain plasticity in rodents (Agrawal et al, J. Physiol., 2012). The aim of this study is to evaluate the effect of short-term fructose ingestion on the brain before establishment of the MetS condition. Male Sprague-Dawley rats were supplemented with fructose in water (8% w/v) or pure water (control) for one (1W) or three weeks (3W), under standard chow feeding. Results of the glucose tolerance (GTT) and insulin tolerance (ITT) tests showed no disruption in glucose homeostasis or insulin tolerance, respectively. There was a reduction in the hippocampal dry weight in the 1W, which was accompanied by a reduction in the neuronal marker NeuN and Myelin Protein Basic (MBP). The same 1W time point showed an increase in the fructose transporter Glut5 in the hippocampal region. Levels of the peroxisome proliferator activated-receptor gamma,

coactivator 1 alpha (PGC-1α) and Cytochrome c oxidase subunit II (COX2) were lower for 1W group, suggesting a reduction in mitochondrial function in the hippocampus. There also was a trend to reduce the spatial memory in the1W group. The liver weight and the PGC-1α levels were higher in the 3W group. The data suggest that short-term fructose ingestion affects the brain directly before the metabolic syndrome condition is established. The results of these studies are particularly significant on the light of recent studies showing the pervasive effects of fructose on many genes associated with important neurological and psychiatric disorders (Meng et al., eBiomedicine, 2016)

Title: Antidepressant reactivates the plasticity of vestibular-dependent navigation in the adult

Authors: *Q. JIANG, D. MA, D. SHUM, Y. CHAN;
The Univ. of Hong Kong, Hong Kong, China

Abstract: Antidepressant is known to reactivate the critical period for ocular dominance in adult rats. In the vestibular system, we have previously revealed an early critical period during which neuronal activities in the vestibular nucleus (VN) shaped adult navigation behavior. It is known that one key factor that determines the critical period is the ratio of excitation to inhibition (E/I ratio), which declines from birth to adulthood. We therefore hypothesize that antidepressant can restore the plasticity of navigation behavior by switching E/I ratio of the adult VN to a neonatal state. In the present study, we treated juvenile rats with antidepressant for one week, and found that perturbation of neurotransmission in the VN even after the postnatal critical period could lead to deficits in spatial navigation at adult stage. To determine whether the observed restoration of navigation plasticity is accompanied by an increase in E/I ratio within the VN after antidepressant treatment, we used *in vitro* whole-cell patch-clamp technique to measure excitatory postsynaptic current (EPSC) and inhibitory postsynaptic current (IPSC) of VN neurons. We found that the E/I ratio was increased to a level comparable to that observed within the postnatal critical period. Notably, a decrease in the frequency of mIPSC but not mEPSC was

observed in the VN of juvenile rats treated with antidepressant for one week, suggesting that reduction of inhibitory neurotransmission is the major cause of the increase in E/I ratio. In addition, immunohistochemical results from these juvenile rats revealed a significant increase in the number of proliferating GABAergic VN interneurons following antidepressant treatment. This suggests that antidepressant accelerates neurogenesis of interneurons within the VN. Taken together, our findings suggest that antidepressant restores navigation plasticity in adulthood by increasing E/I ratio in the VN. The mechanism by which antidepressant-induced neurogenesis of interneurons influences the excitation-inhibition balance of the VN circuitry awaits further investigations.

Title: In quest for finding the key regulators of the molecular mechanisms of long-term memory

Authors: *I. MICHAELEVSKI[1], N. BOROVOK[1], E. NESHER[2], A. SHEININ[1], M. REICHENSTEIN[1], A. PINHASOV[2];

Abstract: Contemporary understanding of memory formation relies on the concept of long-term synaptic plasticity, for which protein synthesis is a vital requirement. Activity-dependent changes occurring in synapses upon memory acquisition initiate multiple signal transductions enhancing protein turnover, facilitating *de novo* synthesis of plasticity related proteins, crucial factors of memory engram. The best understanding of the synaptic plasticity comes from the studies of hippocampus, playing the central role in memory formation. Deterioration of hippocampal activity is associated with multiple forms of cognitive impairments and neurodegeneration. Despite extensive studies to elucidate molecular mechanisms of memory traces formation and the role of their impact on cognitive impairment, identity of the involved molecular factors is still elusive. Using the advantage of radial arm maze long-term spatial memory paradigm, we investigated protein turnover in mouse hippocampus during the learning process. Utilizing quantitative proteomics, we identified 1592 proteins, exhibiting a complex picture of expression changes during spatial memory formation. Variable linear decomposition

enriched factors responsible for memory-related protein levels' variance at: the initial phase (167 proteins), during the steep learning improvement (150 proteins) and final phase (123 proteins). Gene ontology and signaling pathways analysis revealed correlation between memory improvement and learning phase-curbed expression profiles of proteins belonging to specific functional categories. We found differential enrichment of: a) neurotrophic factors signaling pathways, proteins regulating synaptic transmission, microfilament assembly during the first day of learning curve; b) transcription and translation machinery, protein trafficking, metabolic activity and Wnt pathway during the steep phase of learning; c) cytoskeleton organization proteins at the final step. Network analysis of protein expression profiles revealed candidate key regulators of memory formation. Further the role of two selected candidates was confirmed in synaptic plasticity. Summarizing, identification of the key regulators opens new horizons in understanding of memory formation molecular mechanisms, as well as in therapeutic targeting of specific protein-protein interaction networks to shut down pathogenetic pathways of memory impairment.

Title: Attentional gating of learning in monkey visual cortex

Authors: *U. H. SCHNABEL, X. CHEN, P. R. ROELFSEMA;
Netherlands Inst. of Neurosci., Amsterdam Zuidoost, Netherlands

Abstract: Theories have proposed that attentional feedback is important for the gating of synaptic plasticity so that attended items are learnt and non-attended items are not (Roelfsema et al., 2010). To examine the influence of attention on learning, we used a redundant cue paradigm (Wagner et al. 1968) in which one item is attended during learning and another item is not, although both items are equally informative about the required behavioral response. A macaque monkey learned to choose between two responses while he saw an attended shape and an equally

informative, but unattended, second shape. We then used a morphing strategy in which familiar shapes were gradually morphed into new shapes, until the new shapes bore no resemblance to the originals. Shapes were presented on top of a moving texture pattern, allowing us to examine neuronal activity in area V1 that was elicited by texture elements, throughout the learning process. The monkey consistently selected one of the to-be-attended shapes (the "special" shape) and selected the behavioral response based on the presence or absence of this shape. The special shape elicited stronger multi-unit activity in area V1 than any other shape, in accordance with the hypothesis that it was attended. As the special shape morphed into a novel shape, the morphed shape continued to elicit an increased neural response, whereas the other shapes elicited weaker responses. After this morphing procedure, the monkey learned to map the attended shape onto the correct response but he failed to correctly map the unattended shape, although it had been consistently paired with the attended shape and was equally informative about the required response. Our results demonstrate that attention gates the learning of new shapes in the visual cortex.

Title: Conditioned inhibition and extinction of conditioned excitation in Hermissenda: similarity of cellular and intracellular signaling mechanisms.

Authors: *J. FARLEY;
Indiana Univ. Bloomington, Bloomington, IN

Abstract: Exposure of *Hermissenda (H.c.)* to explicitly-unpaired (EU) presentations of light (L) and rotation (R), separated by many mins, results in persistent enhancement of phototaxis and complementary changes in photoresponses and excitability of Type B and A photoreceptors (conditioned inhibition learning and memory, CI). EU-produced decreases in photoresponses and

excitability of B cells (and increased photoresponses and spiking of A cells) reflect intrinsic somatic ionic conductance changes. Voltage clamp analysis of B cells revealed increases in I_A and $I_{K\text{-}Ca}$ K^+ currents for days after CI training. Elimination of $I_{K\text{-}Ca}$ abolished CI-produced difference in photoresponses; 4-AP block of I_A abolished differences in spiking. Computational models of B cells incorporating the EU-changes in I_A and $I_{K\text{-}Ca}$ reproduced the physiological results in photoresponses and spiking. Protein phosphatase 1 (PP1) and the 12-lipoxygenase (12-LOX) metabolite, 12(S)-HPETE, are implicated in EU-increases in B cell K^+ currents and decreases in spiking (Walker et al. 2010). Using *in vitro* conditioning protocols and pharmacology, we've found these same signaling pathways to underlie both CI learning as well as extinction of conditioned-excitation (CE) associative memory (i.e., effects of L-R pairings; Cavallo et al. 2012). After intact *H.c.* received either L-R pairings (Paired), or control training (Random or Untrained preparations), B cells were recorded from during *in vitro* extinction stimulation (two series of 15 consecutive light-steps, LSs). When extinction was administered shortly after Paired training, B cells showed robust declines in spiking while control cells did not. Selective inhibitors of PP1 (Calyculin A), PP2B (cyclosporine A), and 12(S)-HPETE (baicalein, a 12-LOX inhibitor) indicated that all three molecules contributed to the spiking decreases produced by extinction training. Conversely, injection of catalytically-active PP1 (caPP1) or PP2B (caPP2B) into Untrained B cells partially mimicked the spike frequency declines observed in Paired cells, as did bath-applied arachadonic acid (AA), and occluded additional LS-produced reductions in spiking in Paired cells. Similar results have now been observed for the decreased spiking and hyperpolarization produced by *in vitro* CI stimulation.

Title: NSI-189, a neurogenic compound enhances short-term and long-term potentiation in C57BL/6 mice and reverses LTP impairment in a mouse model of Angelman Syndrome.

Authors: *Y. LIU[1], M. P. HEFFERAN[2], K. JOHE[2], X. BI[1], M. BAUDRY[1];
[1]Western Univ. of Hlth. Sci., Pomona, CA; [2]Neuralstem, Inc., Germantown, MD

Abstract: Previous studies have examined the tolerability and efficacy of NSI-189, a benzylpiperizine-aminopyridine neurogenic compound for treating major depressive disorder (MDD). NSI-189 has shown significant potential as a treatment for MDD, with concurrent improvement of cognition in a small double-blind, placebo-controlled study. NSI-189 is a novel chemical entity, which enhances neurogenesis from human hippocampus-derived neural stem cells in vitro, stimulates neurogenesis in normal young adult mouse hippocampus, and increases hippocampal volume of normal young adult mice. However, the precise mechanism of NSI-189 action is still unknown. To directly test the effect of NSI-189 on hippocampal synaptic plasticity, we incubated hippocampal slices from wild-type adult mice with various concentrations of NSI-189 (100 nM to 10 μM) for various periods of times, from 1 h to 3.5 h, before applying theta burst stimulation (TBS) to elicit long-term potentiation (LTP) in field CA1. NSI-189 had no effect on baseline synaptic transmission or on paired-pulse facilitation. On the other hand, NSI-189 produced a time- and concentration-dependent enhancement of LTP magnitude. It also produced a time- and concentration-dependent enhancement of short-term potentiation (STP), and the concentration dependency for STP was shifted to the left as compared to LTP. NSI-189 had no effect on burst responses, indicating that it does not affect NMDA receptor properties. In addition, NSI-189 restored normal LTP in hippocampal slices from a mouse model of Angelman Syndrome, $Ube3a^{m-/p+}$ mice, which exhibit a deficit in LTP and learning and memory. Further studies will delineate the mechanisms underlying the enhancement of both STP and LTP, as well as the possibility of using NSI-189 for reversing learning and memory impairment in AS mice.

Title: Social isolation decreases social memory persistence and induces a depressive-like phenotype in Swiss mice via distinct mechanism.

Authors: *L. D. GUARNIERI[1], A. R. PEREIRA-CAIXETA[1], N. S. S. AQUINO[2], R. E. SZAWKA[2], M. F. D. MORAES[1], G. S. PEREIRA[1];
[1]Dept. de Ciências Fisiologicas, Univ. Federal De Minas Gerais - Núcleo De N, Belo Horizonte, Brazil; [2]Dept. de Ciências Fisiologicas, Univ. Federal De Minas Gerais, Belo Horizonte, Brazil

Abstract: Memories tasks involving perceived connection between response and reinforce are affected by mood fluctuations. However, there are few data regarding the influence of depressive states in non-conditioned memories. Social recognition memory task relies in the olfactory ability of mice to recognize co-specifics and is based on their natural interest for novelty. We showed previously that seven days of social isolation (SI) limits to few hours the persistence of social recognition memory (SRM), while enriched environment (EE) rescued that deficit. Here we tested the hypothesis that SI is affecting animal's mood, which in turn impairs SRM persistence. Adult male Swiss mice were maintained in groups of 5 (Standard Grouped, SG) or alone (Isolated, IS) for seven days (7d). After, mice were submitted to different behavioral tests to measure mood alterations. We also verify whether EE would block SI effect on mood behaviors, as did with social memory. SI mice presented a depressive-like state measured in tail suspension, forced swimming (FST) and sucrose preference test. Furthermore, food and water intake, as well as weight gain were decreased along the 7d of SI. EE prevented all the behavioral and metabolic deleterious effects of SI. We also verified if animals under SI would present morphological and biochemical features related with depression. SI mice showed a smaller olfactory bulb (OB) as well as lower levels of norepinefrine, dopamine and serotonin in the dorsal hippocampus and OB, with no changes in BDNF expression. Afterward, we treated animals with Fluoxetin (30 mg/kg) or Desipramine (30 mg/kg) i.p., 30 minutes before FST (acute) or once a day during 7d of social isolation (chronic). Both drugs, similar to EE, were effective in recover depressive-behavior caused by SI. Finally, we predicted that if SI animal's mood is limiting SRM duration, antidepressant drugs should also recover the SRM deficit. Only chronic fluoxetin was effective. Our group already showed that EE rescued SRM of SI mice via a neurogenesis-dependent mechanism. Therefore, our next step is to evaluate neurogenesis levels in the SI mice treated with antidepressants. Altogether, our results show that 7d of SI prone Swiss mice to mood disorders; at the same time it impairs SRM. As only chronic treatments with fluoxetin or EE were able to rescue SRM deficit, it is possible that the social memory deficit observed in SI mice are at least partially unrelated to mood disorder.

Title: Topographical memory impairments in the Hamlet Test

Authors: *T. MAURICE, D. GILABERT, L. CROUZIER;
INSERM U 1198, Montpellier, France

Abstract: An alert sign for aged people suspected of developing Alzheimer's type dementia is spatio-temporal disorientation, particularly in a familiar environment. No behavioral procedure in animal studies addresses currently this alert sign of the pathology. We developed a learning task allowing mice to familiarize with a complex environment mimicking a small village, by decidedly adopting an anthropomorphic approach, named The Hamlet Test®. The apparatus comprises a central agora and 20 streets expanding from it in a 5-branch shape leading to functionalized houses. The agora served as a gathering area and as a start box for training and test trials. The functionalized houses contained food (physiological function encoded: Eat), water (Drink), an assortment of toys (Play), a running whell (Run) or a stranger/unknown mouse (Interact). Animals were trained in groups by spending 4 h/day during 2 weeks in the Hamlet Test and their ability to orientate can be tested after short or long time periods, in normal or pathological conditions. Topographical memory was tested in a probe trial after a 20 h water deprivation. Animals were placed in the agora and their latency and number of errors spent to reach the Drink house measured. Water-deprived animals showed significantly decreased latencies and numbers of errors or increased entries into the Drink house, showing that topographical memory is activated in the test. Animals administered with scopolamine 5 mg/kg SC, but not 0.5 mg/kg SC, before the probe test showed a significant impairment of topographical memory. In order to address the topographical disorientation in Alzheimer's disease, animals were trained during 2 weeks and then intracerebroventricularly injected with oligomeric Amyloid-$ß_{25-35}$ peptide (9 nmol) or a scrambled control peptide 3 days after training. When retested in the Hamlet Test after 7 days, $Aß_{25-35}$-treated animals showed a significant memory impairment to find the Drink house. Analyses are in progress with senescence-accelerated mice and several transgenic mouse lines, but the Hamlet Test appears as a novel test that can address specifically topographical disorientation, an alert sign in Alzheimer's disease.

Title: Adolescent cannabinoid exposure and novelty-seeking: Effects on spatial memory and hippocampal neurogenesis in female Long-Evans rats

Authors: K. L. STANSAK[1], A. L. RIGDON[1], F. E. GRIFFEY[1], *P. A. JACKSON[2], D. M. HAYES[1];
[1]Psychology, [2]Radford Univ., Radford, VA

Abstract: In a national survey on drug use, about 7.4% of persons aged 12-17 years reported using marijuana in the past month. Additionally, use is on the rise despite knowledge that chronic adolescent marijuana exposure leads to a host of neurobiological and behavioral alterations in adulthood. Thus, the current study examined the effects of chronic adolescent cannabinoid exposure in rats on behavior and hippocampal neurogenesis in adulthood. Neurogenesis is the 4-stage process of proliferation, differentiation, maturation, and survival in the brain through which new cells are born and ultimately integrated into existing circuitry. One of the regions in which this occurs is the hippocampus. Abboussi et al. (2013) found that chronic adolescent exposure to cannabinoids significantly decreased hippocampal neurogenesis and impaired spatial memory in adulthood. However, Jiang et al. (2005) showed that chronic cannabinoid exposure in adult rats actually promoted cell proliferation. Other research has suggested that adolescent cannabinoid exposure has no effect on neurogenesis in females (Lee et al., 2013) resulting in discrepancies amongst cannabinoid studies. Due to the variability in results for cannabinoid studies, novelty-seeking phenotype was investigated as a potential mediating variable. Novelty seeking defines an animal's tendency to explore novel environments; high responders (HR) appear less anxious and have greater activity while low responders (LR) have more anxiety and less activity. Dellu et al. (1996) has also shown that HR animals have a prolonged increase in corticosterone levels after exposure to novelty, and chronic high levels of stress have also been shown to suppress neurogenesis in rats (Brummelte & Galea, 2010). In the current study, adolescent female Long-Evans rats were injected with CP 55,940 (0.35 mg/kg) or saline for 14 days during adolescence and then tested on a spatial memory task during adulthood. All rats were screened for phenotype before the injection period and were classified as HR or LR using a median split for the time spent with a novel object. Results from an object location task (recognition of spatial placement in an open-field) revealed that LR drug-exposed animals performed better than control animals. At the end of behavioral data collection, rats were perfused and the brains collected for analysis of cell proliferation. Sections of brain revealing ki67-positive cells were counted in hippocampal tissue using an Olympus BX-43 microscope.

Neurogenesis analyses are ongoing but the behavior suggests that the LR drug animals may show increased levels of cell proliferation in the hippocampus.

Title: Genetic deletion of neurexin-1 in rats impairs learning and memory.

Authors: *L. VER DONCK[1], S. EMBRECHTS[2], M. MAHIEU[2], H. VAN CRAENENDONCK[2], H. DUYTSCHAEVER[2], P. DE HAES[2], R. WILLEMS[2]; [1]Janssen Res. & Development, A Div. of Jans, Beerse, Belgium; [2]Neurosci., Janssen Res. & Development, A Div. of Janssen Pharmaceutica NV, Beerse, Belgium

Abstract: Neurexins (NRXNs) are presynaptic proteins that help to connect neurons at the synapse by interaction with postsynaptic neuroligins. They mediate signaling across the synapse, and influence the properties of neural networks by synapse specificity. In humans, alterations in genes encoding NRXNs are implicated in cognitive disabilities and neurological disorders such as autism. The objective was to evaluate behavioral and cognitive performance of rats with homozygous knock-out of NRXN1. Adult male and female NRXN1-KO rats and wild type (WT) littermates (n=7-10/group; Horizon, Cambridge MA) for evaluation in a battery of behavioral tests involving motor activity, sensory processing and learning and memory. Prepulse inhibition and acoustic startle response were not different between genotypes, but a gender effect was observed in PPI and a trend effect in startle (2w-ANOVA). Spontaneous locomotor activity was not different between male and female WT and male NRXN1-KO, but was significantly higher in female KO ($p<0.001$), indicating a hyperactive phenotype. Working memory was assessed in a 2-arm V-shaped maze as the preference to spend more time in exploring the novel arm vs the alternate familiar arm that was explored just before. Female, but not male NRXN1-KO showed trend for reduced preference for the novel arm compared to WT. Spatial learning and memory was evaluated in the Morris water maze test. Rats did 3 training sessions of maximally 60 sec each per day for 4 days to learn the location of an escape platform hidden under the water surface. Latency to find the platform decreased over the training days in WT to 18±3 sec (female) and 13±2 sec (male) on day 4 vs 53±3 (female) and 59±1 (male) sec in KO, indicating that NRXN1-KO did not learn the location of the platform ($p<0.001$). During a probe trial 3 days

after the last training day, the platform was removed to evaluate memory consolidation. WT rats showed a strong preference for the quadrant where the platform was located during the training sessions, while NRXN1-KO rats did not. Further testing in other paradigms is in progress. It is concluded that deletion of NRXN1 results in a hyperactive phenotype and impaired working memory in female rats, while spatial learning was impaired in both sexes.

Title: Learning and memory of sweet taste in rats with bilateral transection of chorda tympani nerves

Authors: *J. JAHNG, S. CHUNG, J.-H. LEE;
Seoul Natl. Univ. Sch. Dent., Seoul, Korea, Republic of

Abstract: Some patients in dental clinics appeal not only altered taste perception but also negative emotion after lingual nerve damages. We have previously reported that bilateral transections of the lingual and chorda tympani nerves (Nx) lead to the development of depression-like behaviors in rats. Furthermore, the retrieval of hedonic taste memory was blunted in Nx rats. In this study, we have examined if the disrupted sweet taste memory is mainly due to the loss of chorda tympani nerves rather than the loss of lingual nerves. In the experiment 1, male SD rats underwent 7 days of drinking training with 3-bottles (one sucrose bottle with visual cue, two water bottles without visual cues) and then received bilateral transections of chorda tympani nerves (CTx) or sham surgery. CTx and sham rats were subjected to drinking test with three water bottles (one with visual cue, two without visual cues) after a week of post-operational recovery. Water consumption from cued bottle was significantly increased in sham rats, but not in CTx, compared to non-cued bottles. In the experiment 2, drinking training was performed for 9 consecutive days after a week of recovery from CTx or sham surgery, and then the drinking test was done on the following day. Sham rats consistently drank more sucrose than water during

the whole training period. However, sucrose consumption of CTx rats did not differ from water during the first two days of training and thereafter it was increased for the rest of period. On the test day, water consumption from the cued bottle was increased in sham rats compared to both the non-cued bottles, but in CTx only to one of them. Results suggest that taste sensory loss from the anterior 2/3 of tongue may affect both the acquisition and retention of hedonic taste memory.

Title: Stimulus viewing duration prompts divergent learning trajectories in a same-different visual discrimination task

Authors: *M. AYLWIN[1], M. S. M. QUIÑONES[1], D. M. GOMEZ[2];
[1]Univ. de Talca, Talca, Chile; [2]Ctr. Investigacion Avanzada en Educacion, Univ. de Chile, Santiago, Chile

Abstract: ”Sameness” and “difference” judgments (SDJ) are basic cognitive processes that underlie perceptual discrimination. SDJ have been characterized with simple visual stimuli in same-different tasks (SDT) and asymmetries in performance for same and different stimuli have been observed. We studied whether the time to view the stimuli modified the performance asymmetries in a SDT with a complex stimuli category. Performance was obtained in six daily sessions of SDT with checker-like stimuli (30 exemplars). Two groups of participants, performed a SDT (360 trials/session, 4 blocks, 90 trials each) stimuli presented sequentially with short (SSE, 100 ms, n = 16) or long (LSE) 1000 ms, n=17) stimulus exposures and obtained d’, criterion, percentage of correct responses (PCR) for same and different responses. Statistical significance was evaluated by ANOVA and paired comparisons with Bonferroni correction. SDT practice increased d’ across sessions with SSE (2.2$\pm$.8 to 4.1$\pm$.5) and LSE (3.1$\pm$.6 to 5.4$\pm$.8). In contrast, LSE produced a greater increase in the criterion (1.6$\pm$.3-2.5$\pm$.5) compared to SSE (1.3$\pm$.4-1.8$\pm$.4; $p<0.01$). These results are consistent with a similar practice dependent improvement on discrimination with both stimuli durations, although there is a smaller performance across sessions and a smaller reduction in the probability of false alarms for same stimuli with SSE. PCRs increased with same (.72$\pm$.10 to .91$\pm$.06) and different (.85$\pm$.09 to

.97±.02) stimuli pairs with LSEs, and there was no interaction between session and duration. Similarly, PCRs increased with same (.63±.14 to .78±.09) and different (.72±.14 to .94±.03) pairs with SSEs, but there was an interaction between session and pair (p=0.05), suggesting a different effect of sessions in same and different performance. Pairwise comparisons showed similar performance in sessions 1 and 2, but greater difference detection in sessions 3 to 6. Overall, performance with same pairs was consistently smaller than with different pairs, with both stimulus exposures. Moreover, there was a similar improvement in performance with same pairs across sessions, but an overall greater performance with LSEs. On the contrary, there was a greater performance improvement with different pairs with SSEs. Taken together, these results indicate that SDJs with a complex stimulus category are determined by the time subjects have to view the stimuli. Specifically, with LSEs both, sameness and differences, detections are easier compared to SSEs, and with SSEs it is easier to detect the differences compared to sameness. Finally, irrespective of stimulus exposure, there was an advantage of difference over sameness detection.

Title: Feature-unspecific repetitive sensory stimulation induces visual perceptual learning

Authors: *A. MARZOLL[1], H. R. DINSE[1,2];
[1]Inst. für Neuroinformatik - Neural Plasticity Lab., Ruhr-Universität Bochum, Bochum, Germany; [2]Neurologische Klinik am Berufsgenossenschaftlichen Universitätsklinikum Bergmannsheil, Ruhr-Universität Bochum, Bochum, Germany

Abstract: Past studies showed that repetitive sensory stimulation could induce improvements or impairments of perceptual abilities in touch (e.g. Pleger et al., 2003; Ragert et al., 2008) and in vision (Beste et al., 2011) which depended on stimulation frequency. Here, we investigated whether intermittent high-frequency stimulation is able to improve orientation discrimination

(OD) ability in human observers. In a pre-post design, subjects performed a fine-OD task (Schoups et al., 1995), where a central circular grating pattern's orientation had to be judged to either deviate clockwise or counter-clockwise from an oblique target orientation. Between sessions, subjects randomly received one of four possible treatments: stimulation with a phase-alternating sinusoidal grating (SG) of either the same or the orthogonal target orientation used during the OD task, stimulation with an orientation-alternating bar or sham stimulation with only a static fixation cross present on the screen. In each case, stimulation lasted for about 42 minutes, was presented centrally and flickered intermittently at 20 Hz (on/off for 5 sec/5 sec). There was a significant between-subject effect of treatment on performance (repeated-measures ANOVA: $p = .004$), with Bonferroni-corrected post-hoc analysis revealing a significant lowering of OD thresholds post-stimulation for same-orientation SG (threshold-change: -6.4%, paired-samples t-test: $p = .001$), orthogonal-orientation SG (-3.4%, $p = .002$), orientation-alternating bar (-3.8%, $p = .0002$) but not for sham stimulation (-2.6%, $p = .22$). These results show that fine-OD ability can be improved by peripheral high-frequency stimulation. Unlike previous studies in the visual modality, which investigated the influence of stimulation on attentional processes (Beste et al., 2011), here we could show improved discrimination ability for a low-level visual feature. Furthermore, this effect does not require the stimulation features to be congruent to those of the behavioral task (orientation, shape), which suggests a different degree of specificity than that of classical perceptual learning, which is usually highly specific to stimulus features.

Title: Refocusing mental fixation and visual one-shot learning

Authors: *T. ISHIKAWA[1,2], M. TOSHIMA[3], K. MOGI[2];
[1]Tokyo Inst. Technol., Yokohama, Japan; [2]Sony Computer Sci. Labs., Tokyo, Japan; [3]Dept. of Informatics, Grad. Univ. for Advanced Studies, Tokyo, Japan

Abstract: The fixating and defixating (or focusing and defocusing) of salient features are one of the important functions in our visual systems. The same is also true of the cognitive counterpart, i.e., mental fixation. Mental fixation refers to an inability to complete certain types of cognitive operations (e.g., remembering, problem solving, and creative idea thinking) as the result of interference from inappropriate knowledge and experience (Smith, 2003). In the context of

creative problem solving, the mental fixation is thought to be a nuisance, which prevents us from getting the right solution. For instance, in the verbal domain, inappropriate associate prior cues generate additional mental fixation (Storm, 2011), resulting in distracted and impaired remote associate task performance (Smith and Blankenship, 1991). In the visual domain, the ease of perceiving alternative interpretations of multistable ambiguous figure (e.g., Duck-Rabbit figure), indicating the degree of freedom from mental fixation, predicts creative divergent thinking task performance (Wiseman, et al. 2011). As a special case of the ambiguous figure, two-tone black and white hidden figures such as "the Cow" (Dallenbach, 1951) and "the Dalmatian" (Gregory, 1970) are difficult to interpret properly for naïve viewers. The only perception in the state of mental fixation or impasse, is meaningless blob pattern (Ishizu, 2013) or "false alarm", i.e., spurious perception (Ludmer, et al. 2011). Once holistic perception is acquired appropriately for these hidden figures, however, it seems almost impossible to return to the previous ignorant state (mental fixation): one-shot learning (Giovannelli, et al. 2010; Ishikawa and Mogi, 2011) sometimes accompanying positive emotional reaction, or "aha!" experience (Gick and Lockhart 1995; Topolinski and Reber 2010). Although the mentally fixated state before creative insight may be an inevitable waypoint, the role of mental fixation in the visual one-shot learning and "aha!" experience is not yet well known. Here we employ the dynamic hidden figure presentation method using morphing paradigm (Ishikawa and Mogi, 2011) to investigate variation, irresistibility ("attractiveness"), and duration of mental fixation in the hidden figure perception and its association with total reaction time and positive surprise measured by subjective "aha!" rating. We discuss and shed light on the sunny side of the mental fixation preceding one-shot learning: that is, it may not be merely a certain kind of cognitive failure viewed in the short-term standpoint, but "desirable undesirable state" (Jarman, 2016) leading to long-term cognitive benefit.

Title: Anodal but not cathodal stimulation (tDCS) over the human right occipital cortex modulates visual cognition

Authors: *D. RIVOLTA[1], M. BARBIERI[1], M. NEGRINI[2], M. A. NITSCHE[3];
[1]Univ. of East London, London, United Kingdom; [2]Maastricht Univ., Maastricht, Netherlands;
[3]Leibniz Res. Ctr. for Working Envrn. and Human Factors (IfADo), Dortmund, Germany

Abstract: Non-invasive techniques that affect neural plasticity, such as Transcranial direct current stimulation (tDCS), have been successfully adopted to modulate human cognition. It is typically believed that "depolarization" (which induces performance improvement) is induced by an anodal stimulation (a-tDCS), whereas "hyperpolarization" (which induces performance decrease) is induced by a cathodal stimulation (c-tDCS). A cognitive domain that has, so far, received little attention is "face processing". This is surprising given that effective neuromodulation protocols may be applied in clinical conditions characterised by face processing aberrations (e.g., autism, schizophrenia and prosopagnosia). Thus, we here examined whether the administration of anodal-tDCS (a-tDCS) and cathodal-tDCS (c-tDCS) over the right occipital cortex modulates the performance on four tasks tapping memory and perception for faces and non-face stimuli. In this single-blind, sham-controlled study, tDCS has been delivered at 1.5 mA via a pair of surface sponge electrodes (25 cm^2) soaked in a saline solution (0.9% NaCl). Subjects received tDCS stimulation for 20 minutes before task execution. The sites of stimulation were identified using the Electroencephalography 10-20 system, with the active electrode (i.e., anodal/cathodal) over PO8 (i.e., right occipito-temporal cortex) and the reference electrode over FP1 (left prefrontal cortex). A total of sixty healthy adult volunteers (i.e., twenty in each of the three conditions) took part in the experiment. Results showed that, compared to the sham condition, offline a-tDCS causally enhanced the perception and memory performance of both faces and objects. There was no effect of c-tDCS on behaviour. Overall, our findings showed a polarity-specific effect of tDCS on visual cognition. In particular, we showed that a-tDCS causally enhances cognitive skills, whereas c-tDCS has no effect. Our results add relevant information about the breadth of cognitive processes that can be modulated by tDCS, and about the design of effective neuromodulation protocols, which have implications for advancing theories in cognitive neuroscience and clinical applications.

Title: Orienting to probable stimuli affects early perception: Modulating the 'C1' visual evoked potential in an orientation estimation task

Authors: *S. JABAR[1], A. FILIPOWICZ[1], B. ANDERSON[1,2];
[1]Dept. of Psychology, [2]Ctr. for Theoretical Neurosci., Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Probable stimuli are detected faster and more accurately. What is the source of this perceptual benefit? Electrophysiological studies of stimulus probability find modulation of the P3, a relatively late component thought to reflect fronto-parietal activity and suggesting that probability effects are top-down and attentional. However, there is also evidence for effects earlier in visual processing. For example, single-unit recordings in macaques have found that orientation training changes the widths and preferences of V1 neurons. Behaviorally, we find precision differences that are strongest for cardinal orientations and an interaction with obliquity, effects thought to be V1 mediated. We have therefore hypothesized that the probability-driven changes in perceptual processing are mediated early, possibly at the level of V1, with P3 changes reflecting secondary, follow-on effects.
To test this hypothesis we recorded EEG while participants performed a modified orientation estimation task in which probable orientations were location-contingent. While we did find probability effects on the magnitude of 'P3' potentials, we also demonstrated robust earlier modulations. Probability modulations at parieto-occipital electrodes were detectable within the first 100 ms. The polarity of the potentials at this time depended on whether the stimuli were presented in the upper or lower visual fields suggesting that they were an early, 'C1' visual response.
At the level of the individual participant the size of the probability-based C1 modulation correlated with the size of the probability-based precision difference measured behaviorally. C1 magnitude also correlated with the probability-based P3 modulation. On a trial-by-trial basis, the magnitude of the C1 amplitude predicted the magnitude of the later P3 amplitude. However the magnitude of the P3 potential did not predict the subsequent, next trial, C1 amplitude.
The results of this study support our hypothesis that probability effects are at least partially mediated by changes local to V1. This suggests that, like orientation training, probability 'learning' is the consequence of acquired local changes in neuronal tuning that are driven by stimulus frequency and that do not require expectation or top-down 'attentional' influences.

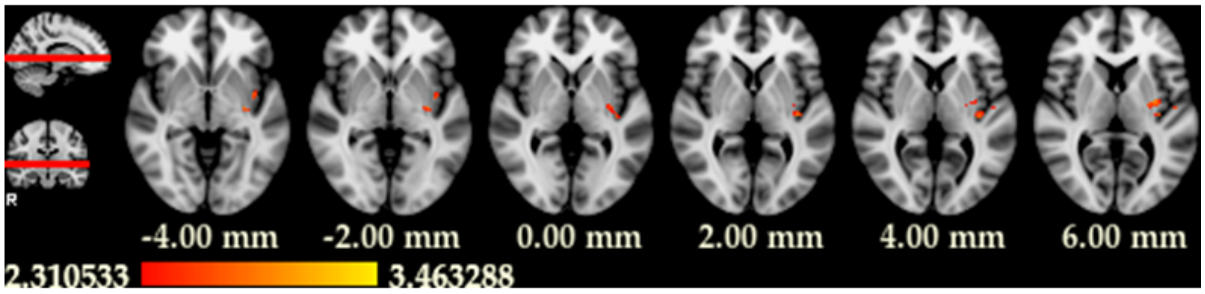
Title: FMRI evidence for an intrinsic positive prediction error signal in the putamen for memory guided visual search

Authors: *S. POLLMANN, S. SOMMER;
Univ. Magdeburg, Magdeburg, Germany

Abstract: We investigated fMRI responses to visual search targets appearing at locations that were predicted by the search context. Based on previous work in visual category learning (Daniel and Pollmann, *NeuroImage*, 59, 3457-3467, 2012) we expected an intrinsic reward prediction error signal in the putamen whenever the target appeared at a location that was predicted with some degree of uncertainty.
We ran an event-related fMRI-experiment (Siemens Trio 3T, 8-channel head coil, T2*-weighted EPI, TE = 30ms, TR = 2000ms, slice thickness = 3mm, slice gap thickness = 0.3 mm, FOV = 192mm, matrix size = 64 x 64, flip angle = 80°, 34 AC-PC oriented slices) with 18 participants (age: mean=25.7, sd=3.93; 8 female). Participants searched for a T among L-shaped distractors. During learning, 16 displays were repeated across 16 blocks, along with 8 novel displays with randomly arranged - non-predictive - distractor configurations. In the subsequent fMRI session containing 16 blocks, part of the repeated displays remained the same as during training. In another part, the target occured in the learnt or a novel location in 50% of repetitions, respectively. In this way, part of the repeated contexts predicted the target location with probability p=1, respectively p=0.5.
Comparing target appearance at locations predicted with probability p=0.5 to either locations predicted with p=1 or unpredicted locations, increased activation was observed in left posterior putamen and adjacent left posterior insula. Thus, our hypothesis of an intrinsic prediction error-like signal was confirmed. This extends the observation of intrinsic prediction error-like signals, driven by intrinsic rather than extrinsic reward, to memory-driven visual search.



The figure shows the overlap of activation obtained in the following contrasts: (1) target occurence at the expected location with p=0.5 - target occurence with p=1 respectively (2) target occurence with p=0.5 - target occurence at an unpredicted location.

Title: Timing of the lateralized readiness potential is consistent with analyses of behavioral reaction times: Application to perceptual learning

Authors: *M. J. WENGER[1], S. E. RHOTEN[2];
[1]Ctr. for Applied Social Res., [2]Psychology, The Univ. of Oklahoma, Norman, OK

Abstract: The present effort tests the hypothesis that improvements in perceptual performance as a function of practice with multi-element stimuli may lead to the subjective organization of the stimulus information into a meaningful perceptual object. This has been referred to as ``unitization," “holism,” or the learning of a Gestalt. The goal of this study was to determine whether timings on a feature of electroencephalography (EEG)---specifically, the lateralized readiness potential (LRP)---could provide neural evidence consistent with the behavioral evidence. Specifically, we investigated the extent to which analysis of timings on this EEG feature would be consistent with analysis of behavioral reaction times (RTs). The LRP is a negative-going waveform, measured in central electrodes contralateral to the motor response that it precedes. Our concern was with the start time for the LRP, here operationalized as the earliest time at which the LRP became reliably less than 0. Four undergraduate students (three females, ages 19-21 years) were paid to participate in 12-15 sessions of practice. All participants were all right-handed and reported having normal to corrected-normal vision. Stimuli consisted of either 0, 1, or 2 contrast-defined target pattern features at varying contrast levels. Stimuli were constructed at levels of contrast (Michaelson ratio) running from 0.1% to 60.0%, in steps of 0.1%. Analyses were performed on RTs and start times for LRPs for correct responses. Examination of the RTs and the start times for the LRPs revealed a modest but reliable correlation. Analysis of the RTs supported the conclusions that observers began practice by processing the stimulus features in a serial exhaustive manner and that, after practice, observers processed the stimulus features in a parallel self-terminating manner. Critically, when the start time for the LRPs were analyzed in the same way, the same conclusions were supported. These results suggest that timings on brain dynamics have the potential to support the timings on behavioral responses as a source of converging evidence.

Title: The neural bases of interoceptive recall.

Authors: D. C. DEVILLE, K. BURROWS, K. L. KERR, J. A. AVERY, C. MULLINS, J. BODURKA, M. PAULUS, *W. K. SIMMONS;
Laureate Inst. For Brain Res., Tulsa, OK

Abstract: Recent theories have proposed that the brain's interoceptive network continuously monitors the state of the body, associating external stimuli with their interoceptive consequences, thereby allowing later recall of these associations to guide behavior. While previous studies have identified the neural circuitry involved in interoceptive stimulation, it is unknown whether these brain regions are involved in the recall of interoceptive sensations. We thus examined the neural basis of interoceptive recall using a paired associates learning task. Fifteen right-handed healthy adults (9 female; mean age = 26 years) completed the Interoceptive Encoding and Recall (IER) task. During the IER task, subjects were intermittently exposed to an inspiratory breathing load (loads ranging from 10 to 50 cmH2O/L/sec), an unconditioned aversive interoceptive stimulus, while viewing one of 3 abstract geometric symbols. As an exteroceptive control, subjects viewed 3 different geometric symbols while an aversive auditory scream played at varying volumes through headphones. Geometric symbols were counterbalanced across conditions and subjects. Later, while undergoing fMRI scanning, subjects performed an incidental (i.e., unexpected) recall task, in which they were presented with the geometric symbols they saw during the encoding phase and were instructed to focus on the intensity of the stimulus (i.e., load or scream) associated with each shape. Recall of breathing loads, relative to recall of auditory screams, resulted in activation within a broad network of regions previously implicated in visceral interoception, including the dorsal mid-insula, anterior cingulate, and thalamic nuclei known to relay afferent visceral interoceptive signals from the body. Thus, simply recalling stimuli associated with a previous interoceptive challenge was sufficient to activate the brain's interoceptive network; at the time of the fMRI scan, subjects were no longer experiencing actual interoceptive stimulation. By providing a better understanding of how the brain constructs and retrieves interoceptive associations, these findings may eventually help to shed light on the interoceptive dysfunctions reported in multiple psychiatric disorders and inform the development of novel psychiatric treatments.

Title: You look like an expert: eye movement dynamics and performance in cognitive tasks

Authors: *J. PERRICONE[1], B. HELFER[2], D. FORD[3], T. QUATIERI[2];
[1]Bioengineering Systems and Technologies, [2]MIT Lincoln Lab., Lexington, MA; [3]NCSU, Raleigh, NC

Abstract: Previous studies have shown that experts and novices have distinctive eye movement dynamics; however, the nature of these characteristics and how they are learned remain poorly understood. This study provides evidence that there exist favorable eye movement dynamics which may be learned and applied to novel tasks resulting in superior performance.
Ten healthy subjects (4 female, 6 male) performed two novel visual tasks (120 trials/task) that test pattern recognition and spatial reasoning. In the first task, subjects were presented three cards with objects of varying shape, number, color, and shading. They were then asked to determine if the cards adhered to a pattern defined by the rules of the game SET. In the second task, subjects were presented a shape and a clockwise rotated version, where the rotation angle was drawn randomly from 45°, 90°, 180°, or 270°. They were then asked to identify if the presented angle of rotation was set to 90°. In both tasks, subjects gave time-constrained responses via keypad and received immediate feedback after each trial (correct/incorrect). Saccades, blinks, fixations, position of gaze, and pupil diameter were measured using eye-tracking glasses (SMI, Boston, MA). Both accuracy and mean response time were strongly correlated for subjects between the two tasks ($R = 0.8$, $R = 0.95$). Features derived from fixations and saccades proved to have strong predictive power of subjects' accuracies for both tasks. In particular, the average number of fixations per trial showed a strong negative correlation ($R = -0.6$) with accuracy, while the average duration of fixations showed a strong positive correlation ($R = 0.6$). Furthermore, the standard deviation of number of fixations across trials produced even stronger negative correlations with accuracy ($R = -0.7$). Together these results suggest that top-performing subjects tend to produce fewer fixations of longer duration in each trial, efficiently extracting task-relevant information, as has been shown in other eye-tracking studies. Additionally, subjects who perform well show less variability in the number of

fixations/saccades from one trial to the next.The presented results suggest that eye dynamics can be used as an indicator of relative expertise. Future work will build upon these findings to identify if these features can be used to predict proficiency and learning in untested visual tasks. Title: Human EEG exhibits task related changes in fractal scaling and dimensionality, congruent with a soft-assembled system

Authors: *T. L. MCKINNEY[1], T. J. WILTSHIRE[2], M. J. EULER[2], J. E. BUTNER[2]; [1]Psychology, Univ. of Utah, Salt Lake City, UT; [2]Psychology, Universioty of Utah, Salt Lake City, UT

Abstract: Soft-assembled dynamical systems are comprised of components that are temporarily formed and have flexible dynamics where the system self-organizes to functionally, and often efficiently, meet the demands of a task or situation. In prior work, the primary evidence that a system is softly-assembled has taken the form of fractal scaling relations, though we argue this case can be strengthened by changes in fractal scaling, as well as dimensionality. We conducted a priming experiment in which we recorded electroencephalography (EEG) for 14 participants as they made an arbitrary semantic decision about visually depicted objects that were each seen six times. Event related potentials were calculated for each of the six stimulus presentations and we used a multi-level modeling approach to compare changes in fractal scaling and the correlation dimension from pre to post stimulus and as a function of familiarity. Overall, we found that the dimensionality decreased from pre-to-post stimulus and the fractal scaling exponent increased from pre-to-post stimulus. The correlation dimension was also sensitive to the repetition of stimuli, although increased as a function of familiarity. The change in dimensionality suggests that following the stimulus, cortical activity overall is more coordinated, given that it required a lower dimensional structure to respond to the stimuli. The increase in fractal scaling following stimulus onset interacted with the effect of familiarity, which was associated with a decrease in

fractal scaling. This suggests the task induced transition to a non-stationary state with more long range temporal correlations was mitigated with increasing familiarity. Taken together, these task-related changes in both the fractal scaling exponents and the correlation dimension provide a more nuanced account of human EEG reflecting a softly-assembled dynamical system.

Sch. of Med., Durham, NC

Abstract: There is a tight interplay between perception and action. Interacting with a dynamic world requires rapid integration of information from the environment that leads to the generation of movement. A prime example of perception-action coordination is the performance in a marksmanship paradigm, and our goal was to study the sensorimotor processes driving the acquisition of skill in this visually-guided task. Moving beyond conventional laboratory experimentation, we implemented a novel marksmanship simulation task, modeled after Olympic Trap Shooting standards in the Duke immersive Virtual Environment. During the task, a subject is surrounded on all sides by an interactive, dynamic, 3-dimensional virtual reality. We examined the movement dynamics and end-point performance during marksmanship training in twenty naïve human subjects. The task was to point and “shoot” a ray at a flying target that simulated the physics of an arcing clay pigeon. The population showed consistent improvements in shot accuracy during a training session that consisted of 7 repeated blocks of 50 trials. Through precise tracking of hand movement patterns that were split into ballistic and refinement phases

based on velocity, we observed systematic changes in dynamics that correlated with the improvement of performance. In particular, while reaction times and shot response times did not change over the course of practice, individuals exhibited longer and slower movements during the ballistic phase. At the end of the ballistic phase, the angular error between the ray direction and target direction decreased with training, indicating a more precise and directed initial phase of movement. The changes in rotational movements of the head mimicked those observed with the hand in that peak velocities decreased through training. The total angular rotation of the head decreased, as well. In order to evaluate the relative contribution of task parameters, head and hand movement dynamics, and trial history on the shot accuracy, we used regularized regression analysis. In addition to task parameters such as trial number and target trajectory that were consistently informative, the inclusion of movement related parameters significantly improved the model fit. On a trial-by-trial basis, movement reaction times, peak ballistic velocities, velocities at the time the shots were taken, and shot times were highly predictive of success. The results provide novel insight into the behavioral changes that accompany full-body skill learning, demonstrating the potential for studying the interplay of human perception and action in a naturalistic, yet tightly quantifiable, virtual reality environment.

Title: Sensorimotor orienting in immersive virtual reality: EEG correlates of skill learning

Authors: *L. G. APPELBAUM[1,2], J. CLEMENTS[3], Y. LU[2], H. M. RAO[4], R. KHANNA[2], D. J. ZIELINSKI[5], K. VITTETOE[2], N. D. POTTER[6], R. KOPPER[5], M. A. SOMMER[4]; [2]Psychiatry and Behavioral Sci., [3]Electrical and Computer Engin., [4]Biomed. Engin., [5]Duke Immersive Virtual Envrn., [6]Athletic Dept., [1]Duke Univ., Durham, NC

Abstract: Sensorimotor learning refers to improvements that occur through practice in the performance of sensory-guided motor behaviors. Psychophysiological studies, in which

performance is measured through quantitative biometric analysis, have revealed regularities at the neural, biomechanical, and behavioral level suggesting organizational principles for learning. Despite this growing body of research, there is still a very incomplete picture of the full cascade of component neuro-behavioral processes that underlie complex visual-motor coordination and a growing demand to utilize comprehensive technologies to implement this knowledge in applied setting. In order to gain a more complete picture of the processes and mechanisms that underlie skill learning and to improve scientific translation to real-world applications, we developed a novel marksmanship simulation performed in an immersive virtual reality environment (see accompanying abstract by Rao et al.). During this training simulation, modeled after Olympic Trap Shooting standards, eleven participants performed 7 blocks of 50 trials each, with the goal of shooting (using a pistol grip) a flying target that simulated the physics of an arcing clay pigeon. During this task, 16-channel electroencephalography (EEG) was recorded while end-point precision and head/hand movement dynamics were monitored with 3D tracking. From these data we observe systematic changes in movement dynamics that underlie improved shot accuracy over the training protocol. In particular, while reaction times and shot response times did not change over the course of practice, individuals exhibited longer, slower and more precise ballistic hand movements, leading to less need for refinement and better shooting accuracy. Analysis of head tracking and horizontal EOG suggests a tradeoff wherein head movements reduce in magnitude (peak velocity and total degrees) while eye movement increase in magnitude over the course of practice. EEG analyses reveal visual evoked potentials over the occipital cortex that index sensory processing for the different launch conditions prior to the onset of eye, head, and hand movements, while shot-related ERPs exhibit central distributions peaking around 400 ms that distinguish hits from misses in the shooting task. These findings illustrate the capacity to perform precision monitoring of movement dynamics and neural activity while individuals perform end-point full body orienting in virtual environments. Future work will explore the possibility that these biomarkers may predict performance accuracy in our simulation and may be utilized to provide real-time feedback for skill training.

Title: Novel representations that support rule-based categorization are acquired on-the-fly during category learning

Authors: *F. A. SOTO[1], F. G. ASHBY[2];
[1]Dept. of Psychology, Florida Intl. Univ., Miami, FL; [2]Dept. of Psychological and Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: A body of evidence suggests that some stimulus dimensions have a "preferred" status: they are represented independently and can be selectively attended. In the cognitive psychology literature, these are usually called "separable" dimensions. Humans learn categorization rules that are aligned with separable dimensions through a rule-based learning system implemented in prefrontal cortex, hippocampus, and basal ganglia. Behaviorally, such categorization rules are learned faster and they generalize more easily than categorization rules that require integration of information from different dimensions. Recent research suggests that learning to categorize objects along a new dimension changes the perceptual representation of such dimension, making it more separable and discriminable. In this study, we asked whether such newly learned dimensions could support rule-based category learning. One group received extensive categorization training and a second group did not receive such training. Later, both groups were trained in a task that made use of the category-relevant dimension, and then tested in an analogical transfer task (Experiment 1, testing generalization to new stimuli sharing the relevant dimension) and a button-switch interference task (Experiment 2, testing whether the category-response assignments could be easily switched under verbal instructions). Based on the previous literature, we expected that only the group with extensive pre-training (with well-learned dimensional representations) would perform well in these tasks, showing evidence of rule-based behavior. Surprisingly, both groups performed as expected from rule-based learning. A third experiment tested whether a single session (less than one hour) of training in a categorization task would facilitate learning in a task requiring executive function. There was a substantial learning advantage for a group with brief pre-training with the relevant dimension. We hypothesize that extensive experience with separable dimensions is not required for rule-based category learning. Instead, the rule-based system seems to learn representations "on the fly" that allow rule application. We discuss what kind of neurocomputational model might explain these data best, given the speed of acquisition of novel representations and their immediate pronounced effect on rule-based behavior.

Title: The role of frontal polar cortex in category learning: rule integration or switching?

Authors: *D. PANIUKOV, T. DAVIS;
Psychological Sci., Texas Tech. Univ., Lubbock, TX

Abstract: Category learning is a critical neurobiological function that allows organisms to simplify a complex world. Recent research on the neurobiology of category learning has focused on the role that different learning systems, such as the striatum and medial temporal lobes, play in acquiring new categories. However, there are a number of additional underexplored brain regions that are critical for categorization. One underexplored brain region that is often active in neurobiological studies of category learning is the frontal polar cortex (FPC). A number of functions have been ascribed to the FPC including theories that emphasize its role in switching between representations and theories that emphasize its role in representational integration. The goal of the present study was to clarify the role of FPC in category learning by developing a task in which representational switching and integration could be dissociated. To this end, we utilized two common types of category learning tasks, matching and classification. The matching task involved matching a multidimensional reference stimulus to target stimuli that matched the reference image on a single dimension. Participants would learn a rule about how to match the reference stimulus to a particular target via trial and error. After a number of correct trials, the rule would switch. In the classification task, participants were shown a single stimulus and learned to classify it into one or two categories based on trial and error. Like in the matching task, the rule that determined category membership was unidimensional and was switched after participants completed a number of correct trials. Although nearly identical, matching and classification place differential demands on switching and integration. In matching, a rule can be known with certainty after a single correct answer. In classification, participants may need to integrate evidence for a rule even after an initial correct response. This critical difference allows isolation of integrative functions from switching functions by comparing activation during asymptotic performance in matching and categorization. If the FPC is primarily involved in switching between representations, it should cease to be active once participants settle on a given rule in both tasks. If the FPC is involved in integration, its activation should persist in the classification task, but not matching, as additional evidence in support of a rule is integrated. The results revealed that FPC activation persisted into correct trials in classification, but not matching, suggesting that it continues to integrate information even after a rule has been settled upon.

Title: Lengthening of circuit memory via mechanisms of synaptic plasticity

Authors: *K. HIMBERGER, A. FINN, C. J. HONEY;
Psychology, Univ. of Toronto, Toronto, ON, Canada

Abstract: How do neural circuits integrate past information with input that may arrive seconds later? The ability to integrate information over time is fundamental to cognition. For example, we need to be able to understand the words at the end of a sentence in terms of the words that came before. Currently popular models (e.g. liquid and echo state machines) suggest that reverberating activity enables information to persist over seconds of time in local circuits. But why does information about some stimuli (e.g. meaningful sequences) persist for longer than others (e.g. random sequences)?
Inspired by models of birdsong learning, we hypothesized that a combination of spike-timing dependent plasticity (STDP) and heterosynaptic plasticity (HP) mechanisms can reshape circuit reverberations, lengthening the circuit memory of common input patterns. We tested this idea computationally by implementing a spiking model of a localized cortical circuit, incorporating both STDP and HP. Consistent with our hypothesis, we observed that circuit memory was lengthened specifically for stimuli that were repeatedly pre-exposed to the network, and only when timing dependent plasticity was in operation. In ongoing work, we are (i) analyzing the topology of synaptic changes that support the lengthening circuit memory, and (ii) behaviorally testing predictions of this model for visual and auditory statistical learning.

Title: Can adaptive cognitive training improve efficiency of attentional control in the aging brain?

Authors: *J. KENT[1], H. LEE[4], E. SCHULTZ[1], E. FOSTER[2], F. WOLINSKY[1], M. MERZENICH[4], M. VOSS[3];
[2]Biostatistics, [3]Psychology, [1]Univ. of Iowa, Iowa City, IA; [4]Brain Plasticity Inst., San Francisco, CA

Abstract: Evidence supporting the efficacy of cognitive training programs in older adults is mixed. We tested a rigorous and novel cognitive training program to provide clearer evidence for potential outcomes. The Plasticity-based Adaptive Cognitive Remediation (PACR) is a computerized adaptive training program designed to improve cognition by challenging participants with a variety of tasks that require attention and inhibitory control. Here, participants were randomized to either the PACR or a control program of non-adaptive games (e.g. checkers). Both groups completed five cognitive training sessions weekly for ten weeks. We asked whether the PACR training improves performance on the Flanker task which was not a part of the training program. The flanker task tests higher order cognitive functioning such as response competition and attentional focus. We measured performance using reaction time and functional neuroimaging before and after training. Sixteen participants have completed the trial thus far (Age=69.38, 56% female). Behaviorally, PACR (N=8) and control (N=8) groups significantly decreased their reaction time ($p < .05$) from pre-training to post-training, but there was no group-by-time interaction ($p = .912, .147$). However, the functional neuroimaging did reveal a significant group-by-time interaction selective to the flanker condition requiring the most attentional control in the Superior Parietal Lobule ($p < 0.05$, cluster corrected, max MNI coord: -36 -50 48). This area is important for attentional control and response competition suggesting that adaptive training may lead to more efficient stimulus processing relative to non-adaptive training.

Title: Perceptual and motor contributions to spatial neglect following parietal damage

Authors: *T. D. PUNT[1], G. W. HUMPHREYS[2];
[1]Univ. of Birmingham, Birmingham, United Kingdom; [2]Univ. of Oxford, Oxford, United Kingdom

Abstract: Patients with spatial neglect following stroke typically fail to respond to stimuli presented on the side of space contralateral to their lesion. This complex syndrome may be generated by a number of different deficits, including some that are perceptual in nature (e.g. poor uptake of information on the affected side of space) and others that are more motoric in nature (e.g. a failure to programme movement to the affected side). In order to disentangle perceptual from motoric aspects of the syndrome, Mattingley et al. (1998) had patients make directional responses to targets on either the left or right of fixation and found that response times to contralesional targets were only slowed when the response required a contralesional movement. Using a similar procedure, we too found an interaction between perceptual and motor processing in parietal patients, though the perceptual deficits were more pronounced and eliminated effects of movement direction to contralesional targets. For some patients, these deficits were only evident when a directional response was programmed. We discuss implications for understanding the role of the parietal lobe as a sensorimotor interface, and the relations to prior studies.

Title: Attention changes connectivity strength in a hierarchical manner across the visual network

Authors: *S. KWON[1,2,3], A. BARTELS[1,2,3];
[1]Max Planck Inst. for Biol. Cybernetics, Tuebingen, Germany; [2]Vision and Cognition Lab, Ctr. for Integrative Neurosci., Tuebingen, Germany; [3]Dept. of Psychology, Univ. of Tuebingen, Tuebingen, Germany

Abstract: Attention improves behavioral performance by selectively enhancing neural responses to attended task-relevant stimuli. Several models have been suggested that explain modulation of neural responses by attention. These models are typically limited to effects of attention on single regions, and do not take into account the hierarchical organization of regions involved in processing. Here, we introduce a model that quantifies the connectivity changes across the visual hierarchy encompassing regions V1, V2, V3, up to hV4 and V5/MT+. We measured fMRI activity in humans performing a demanding visual attention task during ultra-long blocks lasting 2 minutes, alternating with passive viewing blocks involving the same stimuli. This paradigm allowed for high-quality functional connectivity measurements free of confounds related to on- and offset effects of stimulus blocks. Functional connectivity was measured between regions of the dorsal attention network (DAN) and visual regions, as well as between default mode network (DMN) regions and visual regions. We then quantified the slope and baseline of connectivity strength of a given DAN or DMN region with the visual hierarchy, as a function of attention. The results revealed that each of the DAN regions had a gradient in its connectivity strength along the visual processing hierarchy: the DAN regions showed stronger connectivity with high-level areas that decreased towards low-level areas, revealing a descending gradient from V5/MT+ and V4 towards V1. Attention enhanced this baseline connectivity pattern in additive manner for IPS, whereas right FEF additionally increased the slope, thus showing also multiplicative effects along the visual hierarchy. DMN regions had an inversed gradient of connectivity with the visual hierarchy. Attention tended to have multiplicative effects for all regions, but (negative) additive effects only in left lateral parietal cortex. The current study provides a first quantitative model of attention induced changes in connectivity between attention and default mode networks and the hierarchy of early visual areas.

Title: Effects of top-down attention to a polygon on N2pc in a visual search task

Authors: *A. KITAMI[1], T. URAKAWA[2], H. AZETAKA[2], A. SAYAMA[2], O. ARAKI[2];
[1]Dept. of Applied Physics, [2]Tokyo Univ. of Sci., Tokyo, Japan

Abstract: In a visual search task, N2pc (Negative 2nd peak Posterior Contralateral), an ERP component, is thought to reflect the attentional capture when we search a specific target. The N2pc has been reported to appear when participants search not only a specific target but also targets defined by a category (category target) such as letters or digits. (Nako et al., 2014a; Wu et al., 2013) Since it is easy to detect familiar letters and digits, they would be special cases as the category targets in the searching tasks. In a similar experiment that used pictures of clothing and kitchen items as category targets, N2pc was also observed (Nako et al., 2014b). Although they showed the attentional capture by the categorical top-down process, it remains unclear whether N2pc is observed when we search more unfamiliar and abstract category target. Here, using the N2pc component, we attempted to clarify whether or not the attentional capture would occur when plane figures with physical features such as number of vertices were category targets in a visual search task. The figures were not so familiar as letters and digits. Moreover, the category target was distinguished from a specific target by changing orientation and length of sides. After the target cue was presented, six figures arranged in a circle were presented. Subjects were asked to answer whether the target was present in the left or right side, or absent in the search array. First, one of three kinds of targets is indicated: (1) exactly the same figure as the target cue (item-based task), (2) a figure belongs to the indicated category, e.g. triangle and rectangle (category-based task), (3) the form singleton (control task). The mean reaction time was as follows: item (586ms), category (771ms), and control (932ms). This shows that the item and category based searching are promoted by the top-down attention, and item-based attention is more effective than that of category-based one. ERP analysis exhibited that there was clear N2pc in the item-based task ($p<0.001$). On the other hand, in the category-based and control tasks, no N2pc was observed. These results suggest that the attentional capture does not occur because of the vague attentional template when we search a category of polygon, which is more abstract than letters and kitchen items.

Title: Theta and alpha oscillations play dissociable roles in goal-directed attention

Authors: *A. M. HARRIS[1], P. E. DUX[2], C. N. JONES[1], J. B. MATTINGLEY[1,2]; [1]Queensland Brain Inst., [2]Sch. of Psychology, The Univ. of Queensland, St Lucia, Australia

Abstract: Recent studies have characterized distinct oscillatory frequencies associated with feedforward and feedback visual information flow. Theta and gamma oscillations have been associated with feedforward signaling, while alpha/beta oscillations have been associated with feedback processes. It remains unclear, however, whether such oscillatory activity is recruited for task-based processing. Here we investigated the roles of theta (4-8 Hz) and alpha (8-14 Hz) oscillations in human goal-directed visual attention. We had participants respond to a brief target of a particular color among heterogeneously colored distractors. Prior to target onset, we cued one location with a lateralized, non-predictive cue that was either target- or non-target-colored. During the behavioral task, we recorded brain activity using electroencephalography (EEG), with the aim of analyzing cue-elicited oscillatory activity. We found that theta oscillations lateralized early and in response to all cues, and this lateralization was stronger if the cue matched the target color, consistent with a feedforward signal enhanced by feature-based prioritization. Alpha oscillations lateralized later, and only in response to target-colored cues, consistent with a feedback signal involved in the allocation of spatial attention. Our findings suggest that changes in theta and alpha amplitude reflect the task-based modulation of feedforward and feedback signaling, respectively.

Title: Mental fatigue in a prolonged multiple object tracking task

Authors: *Y. MOHSENZADEH[1], K. MICHMIZOS[2], D. METAXAS[2], D. PANTAZIS[1]; [1]McGovern Inst. for Brain Res., MIT, Cambridge, MA; [2]Computer Sci., Rutgers Univ., Piscataway, NJ

Abstract: Prolonged cognitive activities associated with considerable mental fatigue are becoming increasingly common in modern life. Mental fatigue can lead to lack of attention and hence difficulties in performing tasks that require concentration and sustained effort. Yet the psychophysiological, behavioral aspects, and neural signatures of this phenomenon are not well understood.

To study the mechanisms of mental fatigue, we performed a MEG experiment using an attention paradigm that demands sustained spatial attention. The multiple object tracking (MOT) task involved tracking several objects (target dots) moving on a screen while ignoring other distractor dots. The number of target dots varied randomly in trials, enabling us to investigate the relationship between task difficulty, attention, and mental fatigue. We further collected data from an eye tracker and a high speed camera, aiming to develop a computational model predictive of neuro-motor representations of fatigue. The task duration was 3 hours and there were no rest periods. Every 30 minutes the subjects were prompted to report their resistance in continuing the task, which is a self-report measure previously shown to highly correlate with mental fatigue. Analysis of MEG data showed a progressive increment in alpha band power over the duration of the task, which signifies lack of attention towards the end of the experiment. Alpha power was overall inversely related to task difficulty. The eye-tracker data revealed the pupil diameter increased with task difficulty, corroborating previous studies on pupil size as a measure of individual's attentional efforts (Alnaes et al. 2014). Moreover, our data demonstrated that pupil diameter consistently increased over time, indicating the task required increased mental efforts to maintain performance towards the end of the experiment.

Title: Flow: The application of psychophysiology to understand user experience in video games

Authors: M. ROSAZZA, *M. M. NIEDZIELA, B. THAU;
HCD Res., Flemington, NJ

Abstract: Usability research involves understanding human limits of perception, attention, and memory in ease of use and learnability of human-made objects such as websites or video games. Cognitive modeling involves creating a computational model to estimate usability based on psychological principles and experimental studies. Cognitive models can be used to improve user interfaces or predict problems, errors, and pitfalls during the design process. Flow is the mental state of operation in which a person performing an activity is fully immersed in a feeling of energized focus, full involvement, and enjoyment in the process of the activity, a theory pioneered by psychologist Csikszentmihalyi. The aim of our study was to use electrophysiology (fEMG, HRV, GSR) and eye tracking to identify flow events in physiological responses linked to in-game events. Twelve male participants (18-35 yrs) were measured with electrophysiology (fEMG, HRV, GSR), eye tracking while playing a novel video game, Darksiders 2, and given a post-game survey. Flow was calculated by amount greater than average arousal (GSR) generated and attention/motivation experienced (HRV) and then compared with performance in video game play at that time interval. On average, we found gamers entered a flow state 20.3% of the time coinciding with intense moments during the game with 24.6% of this time being a positive experience. Our study revealed that it is possible to predict the occurrence of flow during video game play. The ability to model flow using physiological measures may help game designers create better games and help researchers better understand game play.

Title: Rhythmic sampling of visual objects is mediated by inhibitory alpha activity

Authors: *J. JIA[1,2,3], F. FANG[1,2,3], H. LUO[2,3];
[1]Ctr. For Life Sci. At Peking Univ., [2]Dept. of Psychology, [3]IDG/McGovern Inst. for Brain Res., Peking Univ., Beijing, China

Abstract: To deal with a crowded visual scene, it is important that attention is allocated over time and space efficiently. Previous studies suggest that attention acts as a moving spot light dwelling on each location serially, whereas other studies reveal that attention can stay on multiple locations simultaneously. Interestingly, recent behavioral findings demonstrate rapid temporal fluctuations in attentional behavior, suggesting that attention shifts between two spatial locations rhythmically. However, the neural mechanism underlying the space-time distribution of attention remain largely unexplored. In the present study, we combined covert attentional paradigm and temporal response function techniques (TRF) to address the issue. EEG was recorded from fifteen human subjects as they were presented with 5-sec dynamic sequences at two spatial locations and were asked to attend to one of them. Notably, the visual sequences at the two locations were randomly modulated in luminance and independently manipulated, so that we can estimate the TRFs for attended and unattended visual sequences separately (Att vs. Unatt) from the same EEG response. First, compared to Unatt condition, TRFs for Att condition showed an alpha-band (~10 Hz) power inhibition around 100ms, commensurate with previous findings that alpha activities represent inhibitory processes during attention. Second, the alpha inhibition did not display spatial specificity as found before (e.g., decrease on contralateral side and increase on ipsilateral side), suggesting that it may represent an object-level attention independent of space. We further examined TRFs when both visual sequences are in motion and revealed similar alpha inhibition, confirming its nature of object-based attention. Finally, the alpha inhibition was followed by a subsequent alpha enhancement, indicating attentional switching from attended to unattended object. Interestingly, this alpha switching pattern was modulated by task context. Specifically, the Att-Unatt alpha switching pattern became stronger with the decrease in attentional cuing validity (from 100% to 75% and 50%). Our findings suggest that attention efficiently and flexibly distributes over space and time to accommodate changing task demands. We propose that attention samples multiple visual objects in a rhythmic manner, by modulating and coordinating inhibitory alpha-band neuronal activities.

Title: Neurophysiological signatures of proactive versus reactive control in young adults

Authors: *V. EXPOSITO, T. HAGEN, J. HALVORSEN, S. AMINIHAJIBASHI, M. STAVRINOU, M. FOLDAL, T. ESPESETH;
Psykologi, Univ. of Oslo, Oslo, Norway

Abstract: During the execution of a cognitive task, processing and maintaining context information is necessary for guiding behavior and achieving desired goals. The AX-Continuous Performance Task (AXCPT) has been developed to study cognitive control and has proven successful to demonstrate differences in context processing between young vs. old people or healthy adults vs. patients with schizophrenia. The task requires to provide a specific response (eg pressing on right key) to the target trials in which the valid cue (A) is followed by the valid probe (X) . All other cue-probe pairs are considered as non-target trials and require a non-target response (eg pressing the left key). While in some non-target trials, the invalid cue (all non-A letters) has a predictive value to trigger the correct response, in others, attending to the invalid probes (all non-X letters) is determining for accuracy. Here we used pupillometry to study the temporal dynamics of attention during the delay period between the presentation of the cue and the probe, and also after the presentation of the probe. During the delay period the context information should be maintained, and previous studies using physiological and neurophysiological measures suggest different patterns of neural processing for the different cue types (A, non-A). We recorded the pupillary changes in a sample of 170 participants during performance of the AXCP task. We hypothesized that individual differences in the processing of the cues, and therefore of context information, would be reflected in different patterns of pupil dilations, and that these would be correlated with behavioral performance. The results suggest that individual behavioral differences can be tracked by physiological signatures. The results are explored within the framework of theories of behavioral performance and cognitive control.

Title: Neural correlates of perceptual grouping during a visual illusion

Authors: *T. A. CARTHER-KRONE[1], J. LAWRENCE-DEWAR[2], S. SHOMSTEIN[3], J. J. MAROTTA[1];
[1]Perception and Action Lab, Dept. of Psychology, Univ. of Manitoba, Winnipeg, MB, Canada; [2]Thunder Bay Regional Res. Inst., Thunder Bay, ON, Canada; [3]Dept. of Psychology, George Washington Univ., Washington, DC

Abstract: Grouping local elements of our visual environment together is crucial for meaningful perception. Since perceptual grouping is generally thought to occur before attentional selection, the neural mechanisms involved have been mainly studied at early and mid-levels of the visual processing stream. However, less is known about how higher-level brain regions may contribute to these responses. While one previous study found involvement of the parietal cortex in mediating the perception of dynamic illusory Gestalts (Zaretskaya et al., 2013), the neural mechanisms involved in perceptual grouping across the whole brain have been largely unexplored. Here we use functional magnetic resonance imaging (fMRI) to examine the brain networks involved in perceptual grouping using a whole-brain analysis. Healthy human adults completed a line discrimination task in which two horizontal lines were superimposed on a background of black and white dots organized so that, on occasion, the dots induced the Ponzo illusion if perceptually grouped together. This task was completed under conditions of divided-attention, in which participants were asked to complete the line discrimination task while paying attention to the pattern that on some trials would be formed in the background. Results of the behavioural analysis revealed that at the end of the task all participants were able to correctly identify the background pattern and made line judgments consistent with an illusion based response. Group whole-brain analysis clearly revealed increased activation in response to the perception of the illusory Gestalts compared to perception of the ungrouped local elements in early visual areas of the right occipital lobe and the postcentral gyrus of the right parietal lobe. While activation in the occipital and parietal regions is consistent with previous research, we also found activation in the right middle frontal gyrus of the frontal lobe, suggesting that this region

may be driving top-down feedback in perceptual grouping under divided-attention conditions. This is supported by electrophysiological evidence showing that the fronto-parietal network facilitates perceptual grouping processes (Han & Humphreys, 2007), refining these findings to a more specific region of the frontal lobe. A recent case study has also suggested that the right middle frontal gyrus plays an important role in reorienting attention (Japee et al., 2015). These results suggest that while lower and mid-level regions are an important part of perceptual grouping under conditions of divided-attention, activity in the frontal lobe may also function to mediate perceptual grouping.

Title: Variability in performance during perceptual decision making is related to attentional filtering

Authors: *M. D. NUNEZ, A. GOSAI, J. VANDEKERCKHOVE, R. SRINIVASAN;
Univ. of California, Irvine, Irvine, CA

Abstract: The aim of the current study was to determine whether variation in subjects' performance (accuracy and RT) during training could be explained by changes in attentional strategies. The Perceptual Template Model (PTM; Dosher and Lu; 2000) predicts that attentional filtering in perceptual decision making either occurs by 1) reducing internal noise to enhance visual input from the entire visual field or 2) reducing external noise and boosting external signal by tuning neural-population responses. The PTM also predicts that reducing internal noise is optimal in low-noise conditions and reducing external noise is optimal in high-noise conditions. In previous studies (e.g. Nunez et al., 2015), we have made use of the steady-state visual evoked potentials (SSVEPs) to measure attention during perceptual decision making tasks. SSVEPs are narrow band EEG responses evoked at the flicker frequencies of visual stimuli that reflect cortical processing of specific visual stimuli. By assuming a hierarchical cognitive model of the decision making process, the drift-diffusion model (Ratcliff 1978; Nunez et al., 2015), we have shown evidence that individual differences in attention predict differences in perceptual encoding and evidence accumulation. In the present experiment, SSVEPs were used as measures of attention deployment to three different visual noise conditions of low-, medium-, and high-

contrast noise in a two-alternative forced choice task in which subjects had to choose Gabors of high (2.6 degrees visual angle) or low (2.4 degrees visual angle) spatial frequency embedded in a broadband masking noise (bandpass filtered between 2 and 3 degrees visual angle). Each subject repeated the experiment over 7 experimental sessions, in order to measure variability in performance and potential improvements due to training. SSVEP responses to the external visual signal (flickering at 30 Hz) and external visual noise (changing at 40 Hz) were detected on each trial using 128-channel EEG recordings. These SSVEP responses were used to index the attentional filtering applied on each trial. In order to explore the effects of attention on specific components of decision making process (encoding time, decision time, and motor response time) for all conditions and subjects, a hierarchical drift-diffusion model was assumed that accounts for trial-by-trial and session-to-session variability. We found that signal enhancement (internal noise reduction) and external noise reduction both lead to improved accuracy within subjects, and can account for the improvement in performance during repeated experiments, and the variability in performance from trial-to-trial.

Title: cholinergic modulation of eyes-closed to eyes-open alpha reactivity

Authors: *L. WAN, N. LAM, A. RAJAN, H. HUANG, N. SCHWAB, C. PRICE, M. DING; Univ. of Florida, Gainesville, FL

Abstract: Alpha oscillations (8 to 12 Hz) are prominent in the human brain during eyes-closed (EC) resting. Opening of the eyes (EO) significantly attenuates alpha activity. The ratio between EC alpha and EO alpha is referred to alpha reactivity. Alpha reactivity has found applications in both basic and clinical neuroscience. Its neural underpinning, however, remains unclear. Past work has implicated acetylcholine in alpha modulation. To further examine this issue we recorded EEG and fMRI separately from twenty participants undergoing two sessions of resting-

state scanning: eyes-closed resting and eyes-open resting. Treating the BOLD signal from basal nucleus of Meynert (BNM) as a proxy of cholinergic activity, functional connectivity between BNM and the rest of brain were computed separately for EO and EC, and the difference was correlated with alpha reactivity. The following results were found. First, BNM connectivity to the visual cortex increased from EC to EO. Second, BNM connectivity to the anterior cingulate cortex, supplementary motor area and inferior parietal lobule decreased from EC to EO. Third, alpha reactivity was negatively correlated with the EC to EO difference of the BNM-visual cortex connectivity, namely, the stronger the EC to EO BNM-visual cortex functional connectivity increase, the larger the alpha reactivity. These findings support a role of acetylcholine in alpha reactivity.

Title: Illusory conjunctions in visual short-term memory: individual differences in Corpus Callosum connectivity and splitting attention between the two hemifields

Authors: *S. QIN, N. RAY, M. O'CONNELL, C. BASAK;
Univ. of Texas At Dallas, DALLAS, TX

Abstract: Studies on split-brain patients have found independent operations in separated hemispheres during attentional scanning suggesting that the two hemispheres can independently process visual information by splitting attention. Overloading visual attentional capacity would likely result in mistakenly combining the various features of an object, i.e. illusory conjunctions. We hypothesize that connectivity of corpus callosum would predict the degree of illusory conjunctions. In the current study, illusory conjunctions from features presented either at the opposite hemifield or at the same hemifield were assessed using a memory-scanning paradigm. DTI scans were obtained for all participants. This study is the first to investigate the role of corpus callosum in splitting attention between the opposite hemifield vs. within the same

hemifield. Results indicate that successful recollection for illusory conjunctions from opposite hemifield was better than that from same hemifield, lending support to inter-hemispheric independence of two hemispheres in visual short-term memory in healthy adults. Moreover, the individual variations in posterior corpus callosum white matter integrity were more predictive of across hemifield illusory conjunctions than within hemifield illusory conjunctions. That is, individuals with lower posterior corpus callosum white matter integrity had higher recollection when features were recombined from two hemifields than when recombined from the same hemifield.

Title: Top-down adjustment of alpha phase in anticipation of predictable relevant stimuli

Authors: *R. SOLIS-VIVANCO[1], M. BONNEFOND[2], O. JENSEN[2];
[1]Neuropsychology Dept., Inst. Nacional De Neurologia Y Neurocirugia Ma, Mexico City, Mexico; [2]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ., Nijmegen, Netherlands

Abstract: Oscillatory alpha activity (8-12Hz) has been proposed to represent an active mechanism of pulsed, functional inhibition over neural processing, due to the finding that its power is reduced in anticipation of incoming relevant information at sensory regions. In line with this assumption, the alpha cycle includes a phase of inhibition and a phase of excitability.

Whether alpha phase can be top-down adjusted in order to improve information processing under appropriate experimental conditions remains unclear, with evidence for and against that possibility. Also, the source of such top-down control is unknown. We carried out a cross-modal (visual/auditory) attention experiment with magnetoencephalography in thirty-four healthy subjects. In each trial, a somatosensory cue indicated to the participants whether to attend the visual or auditory domain, and ignore the simultaneous information from the other domain. The time onset of all stimuli was predictable across trials. We found that when visual information was attended, anticipatory alpha power was reduced in visual areas, while its phase adjustment was increased. Alpha phase adjustment optimized the processing of relevant stimuli, as assessed by performance speed and stimulus-induced gamma activity. In addition, such adjustment predicted effective inter-sensory interference avoidance across participants. We further found that phase distribution for optimal performance between domains was different in visual areas, indicating specific phases for information processing depending on its relevance. Finally, alpha oscillations in the left prefrontal cortex controlled the adjustment of alpha phase in visual areas. Our results confirm that alpha phase can be adjusted in anticipation of predictable stimuli and improve their processing and related behaviour. Modulation of anticipatory power and phase adds to the computational versatility of the alpha rhythm, since it allows for adjustment of the processing capabilities of the visual system on a fine temporal scale. These findings also call for further research about possible changes of such modulation in attentional disorders.

Title: Inattentional deafness is signified by activity in brain regions involved with attentional bottleneck

Authors: *D. E. CALLAN[1], F. DEHAIS[2], N. GONTHIER[2], G. DURANTIN[2,3];
[1]Ctr. For Information and Neural Networks NICT, Osaka, Japan; [2]ISAE: Inst. Supérieur de l'Aéronautique et de l'Espace, Univ. de Toulouse, Toulouse, France; [3]Sch. of Information Technol. and Electrical Engineering, The Univ. of Queensland, Brisbane, Australia

Abstract: Inattentional deafness is the failure to hear otherwise audible sounds (usually alarms) that may occur under high workload conditions and has been cited as the source of many aviation related accidents. One potential cause for the occurrence of inattentional deafness could be an

attentional bottleneck that occurs when task demands are high, resulting in a lack of resources for processing of additional tasks. In this fMRI experiment we explore the brain regions active during the occurrence of inattentional deafness using a flight simulation task in which the participants (n=15) fly through a Red Bull air race course (using a joystick to control elevator and aileron deflections: pitch and roll) passing through a number of gates and at the same time push a button on the joystick to the presence of audio and visual alarms. A first person view was presented from within the cockpit such that the bottom half of the display was the instrument panel of the plane and the top part of the display was the view of the world through the cockpit canopy. In real flight, pilots must maintain visual attention to both the instruments and to the world outside the plane. In order to simulate these perceptual demands we presented a light on the instrument panel that would inform the orientation (either horizontal or vertical) in which they were to fly through the gates. The auditory alarm was a short beep sound played loud enough to be audible even within the fMRI scanner. The visual alarm was an additional light on the instrument panel. Subjects were instructed to focus on the difficult piloting task and to try not to crash and to press the button on the joystick quickly when they noticed an auditory or visual alarm. The results of the fMRI analyses revealed that auditory misses relative to auditory hits (as well as the interaction of auditory misses relative to hits compared to visual misses relative to hits) had significantly greater activity ($p < 0.05$ cluster level corrected) in the pre-SMA, ACC, the right IFG and right insula. Consistent with our hypotheses these regions have been implicated in several studies as being involved with an attentional bottleneck. Activity in these brain regions could be used as a neural signature of the probability of occurrence of inattentional deafness. Using this information it may be possible to develop neuroadaptive automation that attempts to reduce workload when these regions are highly active and/or present more attention grabbing alarms in these cases.

Title: Gamma band analysis in DLPFC during stroop task : MEG Study

Authors: *S.-J. HWANG[1], W. CHANG, 03722[2], B. KIM[3], J. CHANG[2];
[1]Dept. of Neurosurgery, Yonsei University, Col. of Med., Seodaemun-Gu, Seoul, Korea, Republic of; [2]Dept. of neurosurgery, Yonsei Univ. Col. of Med., Seoul, Korea, Republic of; [3]EIT/LOFUS R&D Ctr. Intl. St. Mary`s hospital, catholic Kwandong Univ., Incheon, Korea, Republic of

Abstract: BackGround & Purpose : Magnetoencephalography is a functional neuroimaging technique for mapping brain activity by recording magnetic fields produced by electrical currents occurring naturally in the brain. MEG is a very effective way of spatial and temporal analysis with the number of nerve activity in the brain. While performing the cognitive task we want to find area of the brain which regions are activated and the reaction by the analysis of neural activity. Stroop task is a cognitive task (When the name and color are matched, we called 'congruent', is not 'incongruent) that we will find the difference between those 2 situation. Methods : Stroop effect is a demonstration interference in the reaction time of a task. When the name of a color (e.g., "blue", "green", or "red") is printed in a color not denoted by the name (e.g., the word "red" printed in blue ink instead of red ink), naming the color of the word takes longer and is more prone to errors than when the color of the ink matches the name of the color. When the name and color are matched we called 'congruent', aren't matched 'incongruent'. 8 people were included in the analysis. Recording the MEG data during the stroop task and make the ERP and apply Fourier transform to analysis time-frequency spectrum . Results : In the behavior response, Congruent and incongruent reaction time showed a difference. Congruent reaction time is more faster than incongruent. Percentage of correct answers in the case of some falling trend seems incongruent. But not the trend seems to be common from all subjects. We focused on dorsolateral prefrontal cortexSpecially in gamma range, we can find significant difference between 'congruent' and 'incongruent'. In 40-50Hz, a 100~250ms before tapped right butten, there is a big difference in ERSP(event-related spectral perturbation). In that case, one of the subjects 'Congruent' tapping ERSP power is -3.8794 dB and 'Incongruent' tapping ERSP power is -.4753. These 2 data analyzed using paried t-test, p-value comes out 0.00. The same result comes out when it applies to all subject. That shows significant different between congruent and incongruent in gamma band activity(40-50Hz). Discussion: According to a popular theory, gamma band waves may be implicated in creating the unity of conscious perception. In cognition task, several research in gamma-bank oscillations may explain the heightened sense of consciousness and its cognitive functions. In this experiment, as the gamma band is more active in a difficult situation, when subject encountered in two different situations to found solving problems.

Title: The effects of task irrelevant information on the dynamics of selective attention

Authors: ***J. KIM**[1], M. KANG[2], S.-H. LEE[1];
[1]Brain and Cognitive Sci., Seoul Natl. Univ., Seoul-City, Korea, Republic of; [2]Dept. of Psychology, Sungkyunkwan Univ., Seoul-City, Korea, Republic of

Abstract: We investigated how task irrelevant information influences target processing using a flanker task. Participants (N = 20) performed a gender discrimination task for a centrally presented face stimulus (target), which was crowded by four distractor faces. We manipulated the information congruency in the *task-relevant* dimension by matching or not matching the gender of the target to that of the flankers. The information in the *task irrelevant* dimension was manipulated by varying the facial expression of the target and flankers independently (happy or fearful). In addition, to probe the dynamics of flanker effects, we varied the stimulus onset asynchrony (SOA) between the target and flankers: the target appeared simultaneously with the flankers or advanced the target (SOA = 0ms, 100ms, or 300ms). In overall, consistent with previous studies, gender discrimination was slower when the gender of the target and flankers was incongruent than when congruent (‘*flanker effect’*). Intriguingly, the temporal dynamics of flanker effects was affected by the task-irrelevant information: the flanker effect increased with an increasing SOA when the emotional expression of the target and flankers were matched; but when not matched, the flanker effect was found only at 100-ms SOA. This implies that selective attention failed to suppress the features in the task irrelevant dimension (emotional expression) to some degrees. Because the task irrelevant features were manipulated both in the target and in the flankers, the suppression could have failed either in the target, or in the flankers, or both. To resolve this issue, we carried out another experiment. Here again participants (N=20) performed the same gender discrimination task with varying SOA but, unlike the first experiment, the features in the task-irrelevant dimension were manipulated either only in the target (‘*target-only’* condition) or only in the flankers (‘*flanker-only*’ condition). In the ‘target-only’ condition, the facial expression was varied over trials in the target (happy, neutral and fearful) but remained neutral in the flankers, and vice versa in the ‘flanker-only’ condition. The influence of the task-irrelevant information on flanker effects was more pronounced in the ‘flanker-only’ condition than in the ‘target-only’ condition. Taken together, our findings indicate that the task-irrelevant

features survive feature-selective suppression in the flankers, where spatial attention gain was weak, producing sustained influence in task-relevant information processing over both the target and flanking regions.

Title: Neural correlates of goal directed attentional capture in the absence of conscious perception

Authors: *S. L. TRAVIS[1], P. E. DUX[2], J. MATTINGLEY[1,2];
[1]The Queensland Brain Inst., Brisbane, Australia; [2]The Sch. of Psychology, Brisbane, Australia

Abstract: An observer's current goals can influence the efficiency with which visual stimuli are processed. This is demonstrated in the 'contingent capture' effect, in which spatial attention is captured to the location of a briefly presented cue that shares its features (e.g., color) with the observer's current task set. Here we combined behavioral testing and electroencephalography (EEG) to test whether a set-matching cue can capture attention to its location even when that cue is masked from conscious awareness. We used a variant of the classic contingent capture paradigm, in which participants searched arrays of four letters for a single target in a specific, cued color (e.g., red). Immediately prior to the letter array, a non-predictive cue display was presented in which one item matched the searched-for color, and appeared either at the location of the subsequent target (valid trials) or at another location (invalid trials). In separate trials, cue displays were either fully visible or were masked from awareness using continuous flash suppression (CFS). Behaviourally, target-colored cues yielded significantly faster and more accurate responses when these were spatially valid (at the same location as the target) than spatially invalid (at another location). Critically, these cueing effects occurred for both conscious and unconscious cue displays, and were roughly equivalent in their magnitude. In line with the

behavioral results, the EEG data showed that target-colored cues produced a robust N2pc response – a well known signature of spatial orienting – for both conscious and unconscious cues, although the amplitude was somewhat reduced for the latter. Our findings suggest that top-down control settings for relevant features elicit attentional orienting even in the absence of conscious perception.

Title: Exploring the neural signatures of multimodal inhibition of return

Authors: *R. M. KLEIN[1], G. D'ENTREMONT[1], A. JONES[2], M. A. LAWRENCE[1]; [1]Psychology & Neurosci., Dalhousie Univ., Halifax, NS, Canada; [2]Psychology, Middlesex Univ., London, United Kingdom

Abstract: When the interval between a spatially uninformative cue and subsequent spatial target is long enough response times to targets presented in the vicinity of the cue are delayed. This behavioral effect, called Inhibition of Return (IOR), has been been observed cross-modally between all pairs of vision, audition and touch. It has also been subjected to electroencephalographic examination using event-related potentials (ERPs). Here we use ERPs to explore, for the first time, cross-modal IOR. Early work looking at sensory-related ERP components (e.g., P1 in visual studies) suggested that P1 reductions might be an electrophysiological marker of IOR. This suggestion is challenged, however, by the observation of P1 reductions with and without IOR, and vice versa. Based on recent behavioral and electrophysiological evidence, we hypothesized that early sensory-related ERP component reductions, are the result of repetitive sensory stimulation and not IOR. We tested this hypothesis by exploring cross-modal IOR using ERPs. We found behavioral IOR between all four possible pairings of touch and vision as cues and targets. Cue-related sensory ERP (P1) reductions were not observed with visual targets. Supporting our hypothesis, a cue-related sensory ERP reduction was observed for tactile targets, but only when preceded by a tactile cue.

Title: The difficulty of response pattern-dependent tasks to affect attention

Authors: *M. TAKAYOSE[1], R. KOSHIZAWA[2], K. OKI[3];
[1]Nihon Univ. Col. of Industrial Technol., Chiba, Japan; [2]Nihon Univ. Col. of Commerce, Tokyo, Japan; [3]Nihon Univ. Col. of Sci. and Technol., Chiba, Japan

Abstract: Depending on changes in the environment, it is important to inhibit and/or change responses to produce an appropriate behavior. Attention during the preparatory period affects the inhibition and change to an accurate response. To elucidate the relationship between attention and performance of an accurate response, contingent negative variation (CNV) was examined in tasks with different response patterns.
In the tasks, participants were required to press a switch when a go-signal was presented. However, participants were occasionally required to withhold the response when the go-signal was followed by a stop-signal during a stop-signal task (SST), and were occasionally required to change the response when the go-signal was followed by a change-signal during a stop-change task (SCT). In the multi-SCT (m-SCT), the participants were occasionally required to withhold and/or change the response when the go-signal was followed by a stop- or change-signal. To obtain the CNV, EEG data were recorded from the scalp during the tasks.
The reaction time (RT) increased in the order SST < SCT < m-SCT which suggests the relative degree of difficulty of these tasks. The late CNV amplitude was larger during SCT than during the other tasks. There was no difference in the late CNV amplitudes during SST and m-SCT. The results of CNV were not completely in accord with RT. In the m-SCT, the motivation of the participant might be decreased because of the difficulty of the task. These findings suggest that with the degree of difficulty of the task, the attention of the preparatory period, but attention decreases when the degree of difficulty is too high.

Title: The N2pc and localization of visual information

Authors: A. DREW[1], J. BERGER[2], K. BOWE[2], R. TIMMINS[2], *A. T. KARST[2]; [1]Psychology, Miami Univ., Oxford, OH; [2]Psychology, Univ. of Wisconsin, Oshkosh, Oshkosh, WI

Abstract: Traditional conceptualizations of the N2pc component have characterized this event related potential as reflecting the deployment of visual attention to task relevant stimuli appearing in lateral portions of ones visual field (Luck & Hillyard, 1994a, Luck & Hillyard, 1994b). However, more recent work has begun to suggest that this component may instead reflect the localization of, or orientation to, target information (Tan & Wyble, 2015; Drew, Koch, Chrobak & Karst, 2015). Specifically, Tan & Wyble (2015) demonstrated that when two targets were sequentially presented in the same lateralized location, no prolonged N2pc component was observed. Further, Drew, Koch, Chrobak, & Karst (2015) demonstrated that when a non-target spatial cue preceded a target, the cue elicited an N2pc, and not the target. This suggests that the localization process initiated by the cue, a stimulus that did not require selection, was sufficient to elicit the N2pc. However, the aforementioned study used a red cue and target stimulus among black distractors. The color properties of the cue in this case may have inadvertently caused attentional selection to occur because of its contextually salient nature. The current study seeks to address this concern by using black distractor, cue, and target stimuli. These stimuli were used to further disambiguate the distinction between attentional processes of localization and selection, as they eliminated the confounding nature of overly salient cue features. Trials consisted of two rapidly presented stimulus streams comprised of black distractors and the potential for task relevant stimuli that were presented laterally of a fixation point. Each trial had an equal probability of containing no cue or target, only a cue, only a target, or a cue immediately followed by a target in the same location. Preliminary data suggests that when a cue and target were presented successively, the cue elicited an N2pc whereas the target did not. Further, a cue presented alone elicited an N2pc as well. These data further support the hypothesis that the N2pc may reflect the localization of target information in visual space, rather than attentional selection.

Title: Improving dorsal stream functioning remediates visual timing deficits, improving figure-ground discrimination, reading fluency, attention, and memory

Authors: *T. A. LAWTON[1], J. SHELLEY-TREMBLAY[2];
[1]Perception Dynamics Inst., Del Mar, CA; [2]Psychology, Univ. of South Alabama, Mobile, AL

Abstract: The current investigation explores whether deficits in magnocellular-parvocellular integration, causing both selective and sustained attention deficits, underlies processing problems in dyslexia. Two interventions were compared, one targeting the temporal dynamics (timing) of the visual pathways, visual movement direction-discrimination, with a second reading intervention (control group) using a computer-based guided reading program. This randomized controlled-validation study, balanced on student's reading ability, was conducted by training the entire 2nd and 3rd grade classrooms (42 students) at a local elementary school for 30 minutes twice a week at the beginning of the school day. Standardized tests were administered at the beginning and end of 12 weeks of intervention training to evaluate improvements in academic skills. The direction-discrimination training group significantly improved both the dyslexic and typically developing (TD) students' selective and sustained attention, visual motion timing and sensitivity, reading fluency, working memory, as well as improving figure-ground discrimination. These improvements were not found for the computer-based guided reading group. This study suggests that improving visual dorsal stream function by training on figure-ground discrimination of a test pattern moving left or right relative to a stationary background pattern is the key for reading acquisition to happen at an efficient speed for dyslexic and at-risk TD students. We suggest this occurred because the direction-discrimination training acted to increase the temporal precision and neuronal sensitivity of magnocellular neurons in the dorsal stream relative to linked parvocellular neurons, increasing the activity of inhibitory circuits. Remediating visual timing deficits in the dorsal stream revealed the causal role of visual motion discrimination and attention in reading acquisition. This study supports the hypothesis that faulty timing in synchronizing the activity of magnocellular with parvocellular visual pathways is a fundamental cause of dyslexia. Moreover, this study suggests that visual movement direction discrimination can be used to not only diagnose dyslexia early, but also for its successful treatment, so that reading problems do not prevent children from readily learning. Furthermore, this study provides more evidence that a short amount of visual movement direction-discrimination training improved attention, thereby improving sequential processing, reading fluency, memory, and multitasking, enabling reading and learning to be much easier.

Title: Neurogenetically altered norepinephrine availability affects behavioral and electrocortical indices of affect-biased attention

Authors: ***M. R. EHLERS**[1], K. H. ROBERTS[1], M. G. M. MANALIGOD[1], D. J. MUELLER[2], L. J. FÜRST[3], M. J. WIESER[3], R. M. TODD[1];
[1]Psychology, Univ. of British Columbia, Vancouver, BC, Canada; [2]Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada; [3]Psychology, Univ. Würzburg, Würzburg, Germany

Abstract: It is well known that we continually filter incoming information allocating attentional resources to what is emotionally or motivationally salient or relevant to our current goals. Depending on the context, when emotionally salient and task relevant stimuli are both present, the salient stimuli can either enhance or distract from task performance (Wieser, McTeague & Keil, 2012, Schmitz, De Rosa & Anderson, 2009). In humans, the influence of neuromodulators on cortical processes underlying competition and facilitation of biased attention remains poorly understood. A common genetic variation in the ADRA2b gene coding for α2b adrenoceptors has been observed in over 50% of the populations studied. This variation, which inhibits autoreceptor activity, has been related to increased extracellular norepinephrine (NE) levels, providing a naturally occurring means of probing the influence of NE activity on brain and behavior. The goal of the current study was to employ genotyping with use of EEG steady state visual evoked potentials (ssVEPs) to examine the role of norepinephrine in allocation of cortical resources to competing emotionally salient and task relevant stimuli.
209 East Asian and Caucasian participants (mean age = 21 ± 3 yrs, 128 female) were genotyped

for the ADRA2b polymorphism. EEG was recorded while participants performed a change-detection task. In each trial participants were asked to detect phase shifts in a target Gabor patch that was overlaid over an emotionally expressive face (happy, angry, neutral). Faces and targets were flickered at competing driving frequencies of 15 and 20 Hz (counterbalanced within the task). The amplitudes of the steady state potentials over visual cortex linked to the frequency of faces and targets were examined to measure allocation of cortical resources to distinct stimuli occupying the same area of space.
Results revealed an interaction between genotype and facial expression. The presence of angry faces improved accuracy on the change-detection task and evoked larger ssVEP amplitudes for targets overlaid over angry faces, indicating biased facilitation by negative stimuli only for those who did not carry the deletion variant. These results remained robust after controlling for ethnic group and similar patterns were observed in Caucasians and East Asians. Consistent with previous research showing that high levels of tonic norepinephrine lead to reduced task performance, the current study suggests that putatively lower levels of norepinephrine present in carriers of the ADRA2b wild type are associated with the often-reported "weapon focus," whereby attention is sharpened in the presence of negative affect.

Title: Does spatial attention modulate afferent activity in primary visual cortex?

Authors: *M. A. PITTS, H. BAUMGARTNER;
Psychology, Reed Col., Portland, OR

Abstract: Whether visual spatial attention can modulate feedforward input to human primary visual cortex (V1) is debated. In a recent book entitled "Controversies in Cognitive Neuroscience", Slotnick (2013) designates the nature of attentional modulation in V1 as one of the top seven controversies in the field. One prominent and long-standing hypothesis is that visual spatial attention can influence processing in V1, but only at delayed latencies suggesting a feedback-mediated mechanism and a lack of modulation during the initial afferent volley

(Mangun, 1995; Clark & Hillyard 1996; Martinez et al., 1999; Di Russo et al. 2003; Ding et al. 2014). The most promising challenge to this hypothesis comes from an event-related potential (ERP) study that showed an amplitude enhancement of the earliest visual ERP, called the "C1" component, for spatially-attended relative to spatially-unattended stimuli (Kelly et al., 2008). In the Kelly et al. (2008) study, several potentially important experimental design modifications were introduced, including tailoring the stimulus locations and recording electrodes to each individual subject, cueing endogenous attention on a trial-by-trial basis, and flexibly adapting the difficulty of the target detection task. In the current study, we employed all of these methodological procedures, and tested for attentional enhancements of the C1 component for left and right upper visual field stimuli and left and right lower visual field stimuli, separately. The comparison between ERPs to stimuli in the upper and lower visual fields capitalizes on the polarity inversion property of the C1 component. Using the same analysis strategies as Kelly et al. (2008), we found no evidence for an attention-based modulation of the C1 (50-80ms). In other words, C1 amplitudes were statistically identical for stimuli that were attended versus unattended. Attention-based amplitude enhancements were clear and robust for the subsequent P1 (90-140ms) and N1 (150-180ms) components, which were localized to extrastriate neural generators. Thus, despite using methods specifically designed to reveal C1 attention effects, the current study provided no confirmatory evidence that such effects exist.

Title: Distractor expectation modulates proactive control mechanisms in visual search

Authors: *M. A. PETILLI[1], F. MARINI[2], R. DAINI[1];
[1]Psychology, Univ. of Milano-Bicocca, Milano, Italy; [2]Dept. of Psychology, UCSD, San Diego, CA

Abstract: Visual search literature has long investigated the contributions of top-down and bottom-up processes in guiding search behavior. It is well-established that top-down attentional processes support the efficient discrimination of a target stimulus presented among distractors in serial search tasks. However, whether any proactive control mechanisms guide visual selection during parallel pop-out search remains unresolved. Here, we combined two attention paradigms: Covert Visual Search and Distraction Context Manipulation. While the former has been widely

used to study serial and parallel attention displacement, the latter was recently introduced to investigate proactive and reactive control mechanisms that minimize visual distraction (Marini et al., 2016, *Journal of Neuroscience*). We hypothesized that top-down processes intervene in parallel search and leveraged on the Distraction Context Manipulation to help characterizing the recruitment of top-down control processes in serial and parallel search. Accordingly, blocks of trials were of three types: Pure blocks, Parallel Search Mixed blocks, and Serial Search Mixed blocks. Pure blocks included 100% distractor-absent trials while Mixed blocks (Parallel and Serial Search) included 33% distractor-absent and 66% distractor-present trials each. Moreover, in Parallel Search Mixed blocks the target differed from distractors along a single feature (local contrast), while in Serial Search Mixed blocks the target differed from distractors based on the conjunction of two features (local contrast and orientation). Participants' task was to detect the target's presence or absence on each trial. The comparison of distractor-absent trials of Mixed versus Pure blocks allows detecting proactive control mechanisms. Results showed an enhancement of detection sensitivity and a slowing-down of reaction time (RT) when distractors were expected, yet not presented (distractor-absent trials of Mixed versus Pure blocks). This RT slowing-down was larger in Serial versus Parallel Search Mixed blocks. Thus, the expectation of distractors recruited a proactive process that improved detection sensitivity and entailed a RT cost in both types of search tasks, although its magnitude was modulated by the type of search. Finally, the magnitudes of RT-costs in Parallel and Serial Search Mixed blocks were positively correlated across-subjects (after controlling for other individual differences), thus suggesting a common underlying process. In conclusion, proactive control mechanisms appear to be recruited in both serial and parallel visual search and to be modulated by the type of search demanded by the task.

Title: Amphetamine effects on a traditional and a cross-species variant of the continuous performance task

Authors: *D. A. MACQUEEN[1,2], J. W. YOUNG[1,2], M. A. GEYER[1,2], B. L. HENRY[2], A. MINASSIAN[2], W. PERRY[2];
[1]VA San Diego Healthcare Syst., San Diego, CA; [2]Dept. of Psychiatry, Univ. of California San Diego, San Diego, CA

Abstract: Introduction: Cognitive impairment is a core component of numerous psychiatric conditions and is associated with poor functional outcome. At present, non-human studies are required to fully evaluate the neurobiological underpinnings of impaired cognitive processing. Yet, such efforts are hampered by a discontinuity of testing methods across species. The 5-choice Continuous Performance Task (5C-CPT) has been developed to allow for analogous assessment of attention in both rodents and humans. As with alternative CPT variants, impairments in 5C-CPT performance have been detected in psychiatric populations. To provide additional validation, the present study sought to evaluate the consistency of amphetamine (AMP) effects on 5C-CPT and Conner's CPT (CPT-II) performance.
Methods: Separate samples of healthy participants aged 18-35 were randomized to receive placebo, 10, or 20 mg of AMP before completing either the 5C-CPT (n = 54) or the CPT-II (n = 73).
Results: On the 5C-CPT, AMP impacted hit rate [$F(2,51) = 4.0$, $p < .05$] with both doses improving accuracy relative to placebo ($p < .05$). AMP also tended to improve D' on the 5C-CPT [$F(2,51) = 2.8$, $p = 0.072$], with 10 mg significantly improving performance compared to placebo ($p < .05$) and marginal improvements observed after 20 mg ($p < .1$). AMP did not impact hit rate on the CPT-II ($p > .05$) but, produced an effect on the ADHD confidence index [$F(2,51) = 4.0$, $p < .05$] with significant reductions observed at the 20 mg dose ($p < .05$). A significant interaction of dose x trial block was detected on D' for the CPT-II [$F(4,140) = 4.0$, $p < .05$]. After placebo, D' was significantly lower on the third and final block relative to the first ($p < .05$). However, this effect was not observed after either dose of AMP ($p > .05$) suggesting that the drug protected participants from vigilance deficits which emerge over time. Although no interaction between AMP and trial block was observed in the 5C-CPT for D' ($F < 1.1$, ns), only the placebo-treated subjects exhibited reduced D' in the third trial block compared with the first ($p < .05$).
Conclusion: The general consistency of amphetamine effects across these two tasks support the utility of the 5C-CPT for translational research. Critically, use of the 5C-CPT will facilitate identification of neural substrates for conditions characterized by impaired attention as captured by earlier CPT variants.

Title: Dissociable suppression of salient distractors during perception and goal-directed action

Authors: *J. D. MCCARTHY[1], J.-H. SONG[1,2];
[1]Dept. of Cognitive, Linguistic & Psychological Sci., [2]Brown Inst. for Brain Sci., Brown Univ., Providence, RI

Abstract: In a complex and continually changing environment, humans face the challenge of performing actions toward desired goals while ignoring other salient irrelevant stimuli. For instance, a successful hit in a baseball game requires attending the ball while tuning out the various sights and sounds on the field. While it is generally held that highly salient stimuli (e.g., camera flashes, the bright scoreboard) cause more perceptual interference than weaker ones, our lab recently demonstrated this is not the case for action. Specifically, the presence of a weakly salient singleton distractor was more detrimental to performance during goal-directed reaching compared to when a highly salient distractor was present (Moher, Anderson, & Song, 2015). The authors concluded that highly salient distractors are rapidly suppressed when action is required, leading to more efficient movements toward the target. Here, we used EEG to investigate the time course of attentional allocation during target search in the presence of highly and weakly salient distractors for perception and goal-directed action. Interestingly, we found that the amplitude of the N2pc—an ERP component in which greater negativity is observed at posterior electrode sites contralateral to the attended visual hemifield—was reduced on trials containing a high, compared to a low salient distractor during a perceptual task, suggesting increased competition in attentional selection. In contrast, the opposite pattern was observed when participants reached to the target: the presence of a highly salient distractor was associated with a larger N2pc amplitude relative to displays containing a weakly salient distractor when goal-directed action was required. These results suggest that consistent with the behavioral pattern of data, the efficiency of attentional selection is enhanced when highly salient distractions are present during action, but reduced during perceptual discrimination. Our results suggest that while high salience strongly interferes with perceptual processing, increased salience facilitates target selection during goal-directed action.

Title: Effects of mindfulness training on behavior and electrophysiology in the Psychomotor Vigilance Test

Authors: *J. Z. LIM[1], K. WONG[2], J. TENG[2], M. W. CHEE[2], K. DOSHI[3];
[1]Neurosciences and Behavioral Disorders, Duke-Nus Med. Sch., Singapore, Singapore; [2]Duke-NUS Med. Sch., Singapore, Singapore; [3]Singapore Gen. Hosp., Singapore, Singapore

Abstract: Mindfulness, defined broadly as the awareness and non-judging acceptance of moment-to-moment thoughts and feelings, is gaining popularity as a method to improve general wellbeing and cognition. While a number of studies have shown benefits of mindfulness training on executive attention, studies of its effects on sustained attention have produced mixed results, motivating us to test the effects of an 8-week mindfulness training course on a robust and widely used assay of vigilance. 30 nurses from the Singapore General Hospital (28 female; mean (SD) age = 28.77 (7.74)) fully or partially completed an 8-week (1.5 hours/session) mindfulness-based training protocol (MBSR) based on the program created by Jon Kabat-Zinn. Participants came for 2 EEG recording sessions, before and after the program (S1 and S2 respectively). As most participants were not able to attend the entire program (mean sessions (SD) = 4.16 (2.42); range = 0-8), we used attendance as a moderator for the behavioral and EEG analysis. During EEG recording, participants performed the Psychomotor Vigilance Test (PVT), a 20-minute test of sustained attention, and rated their energy and mood before and after this test. As a manipulation check, trait mindfulness showed a marginally significant increase from S1 to S2 (t_{22} = -2.06. p = .052). Median response speed and slope of response speed on the PVT were compared between S1 and S2. Using attendance as a moderator, we found that median response speed was significantly altered post-program ($F_{1,28}$ = 25.07 ,p = 0.00003), with higher attendance associated with more improvement. No effects were found on slope of response speed. For subjective variables, we found a significant effect of session ($F_{1,28}$= 4.59, p = 0.04), as well as a marginally significant time-by-session interaction ($F_{1,28}$= 4.13, p = 0.052) on subjective sensations of energy. No effects on mood were found. P300 amplitude in response to PVT targets was calculated and compared across task (first 4 vs. last 4 minutes of the PVT) and session. There was a significant reduction in P300 amplitude with time ($F_{1,28}$= 8.32, p = 0.007), and a significant time-by-session interaction ($F_{1,28}$= 6.70, p = 0.02). Similar results were found for event-related desynchronization (ERD) to PVT events in the alpha band, with a significant

reduction in ERD over time ($F_{1,28}$= 6.27, p = 0.02), and a time-by-session interaction ($F_{1,28}$= 4.67, p = 0.04). Overall, these results suggest that mindfulness training benefited sustained attention by sharpening attention to relevant stimuli via suppression of background neural noise, particularly for participants who attended a majority of the training program.

Title: Intrusive effects of task-irrelevant semantic relationships between real-world objects

Authors: *J. C. NAH[1], G. L. MALCOLM[2], S. SHOMSTEIN[1];
[1]The George Washington Univ., Washington, DC; [2]Univ. of East Anglia, Norwich, United Kingdom

Abstract: Every object encountered in the environment consists of a combination of low-level properties (e.g., colors and shapes) as well as high-level semantic relationships. Past research has provided evidence emphasizing the importance of semantic information when it benefits the current goal (Moores, Laiti, & Chelazzi, 2003). However, the pervasive nature of semantic information suggests a continuous semantic bias of attentional allocation independent of task relevance. Accordingly, recent data from our lab provides evidence that task-irrelevant semantic properties influence attentional allocation (Malcolm & Shomstein, 2016). Here, we utilized univariate and multivariate methods (pattern classification) to assess the degree to which semantic relatedness influences sensory responses in the early visual cortex (EVC: V1-V3), object-sensitive lateral occipital complex (LOC), and the inferior parietal sulcus (IPS0-2). If task-irrelevant semantic relationships modulate neural activity via object selective regions, then semantic-based modulation should be observed not only in spatially selective IPS0-2, but also in LOC. If, on the other hand, semantic relationships influence spatial allocation of attention exclusively, then modulatory effects will be observed only in IPS0-2. For the multivariate analyses, decoding of object identity in the EVC, LOC and IPS was examined with a hypothesis that increased attentional allocation leads to an increased pattern classification accuracy. Participants viewed three objects, with one just above the central fixation and one in each

periphery, below the midline. In one condition, one of the peripheral objects was semantically related to the central object. In the control condition, all three objects were semantically unrelated. After the objects were presented, a target and two distractors were superimposed on top of each object. Most importantly, the target appeared on all three objects equally, rendering semantic relatedness task-irrelevant. Behavioral performance supported the conclusion that task-irrelevant semantic relatedness influenced attentional allocation represented by faster RTs and greater accuracy for targets positioned on the semantically related objects. A semantic-based modulation throughout the EVC as well as IPS was observed. EVC and IPS also showed significantly higher decoding accuracy of object identity when objects were semantically related than when semantically non-related, while no difference was seen in the LOC. Combined, these results demonstrate that semantic relationships between objects modulate visual cortical activity via the parietal cortex.

Title: Decrease in the visual search & spatial working memory function accompanying Long-term Consecutive Visual Search

Authors: *K. OKI[1], R. KOSHIZAWA[2], M. TAKAYOSE[3];
[1]Nihon Univ., Funabashi, Chiba, Japan; [2]Col. of Commerce, Nihon Univ., Setagaya, Tokyo, Japan; [3]Col. of Industrial Technol., Nihon Univ., Narashino, Chiba, Japan

Abstract: We investigated the influence of a long-term consecutive visual search (LTCVS) on a cerebral activity during visual search and spatial working memory (VSSWM). 10 subjects performed VSSWM tasks before and after LTCVS tasks. As for the LTCVS and VSSWM, the Advanced Trail Making Test Random Task (ATMT Task R) and the Advanced Trail Making Test Fixed Task (ATMT Task F) was introduced respectively, in which a subject, using a computer mouse, clicked a circle with the numbers from 11 to 40 in serial order. Once a numbered target was clicked, it was to disappear and another circle with the clicked number plus 30 showed up at the same time. In the Task R all the circles were rearranged at random, while the circles were not rearranged in the Task F; 30 circles were on the screen at any time in both tasks. Each subject performed Task R 40 times and Task F 10 times. The performance time, the error frequency and the electroencephalogram power values of the 13-30 Hz (beta power) before

and after the LTCVS are compared. It was clarified that the performance of the Task F impaired and the beta power of F3 and F7 electrodes more significantly increased after the LTCVS than before the LTVS. These results suggested that the LTCVS increased the activities of distraction and impaired the activities of the area.

Title: Removing the curse of dimensionality: a trade-off between adaptability and precision

Authors: *S. GHAANIFARASHAHI, K. ROWE, Z. ASLAMI, A. SOLTANI;
Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Learning from reward feedback is essential for survival but can become very challenging in naturalistic conditions where choice options have many features (e.g. color, shape, texture) and each feature can take many values, resulting in a large number of options whose reward values have to be learned. This challenge is referred to as the "curse of dimensionality," since many value-based learning models (e.g. reinforcement learning) do not scale up as the dimensionality of the environment and thus the number of possible options increase. We hypothesize that humans tackle this problem by adopting models of the environments that reduce the dimensionality and allow faster learning (model-based approach). We therefore designed a series of experiments to identify factors that influence such model adoption over the slower, but more precise model-free approach, which learns individual values for options. Moreover, we constructed different computational models and tested alternative learning architectures for solving the curse of dimensionality. During these experiments, subjects selected between pairs of options that had different features and would yield reward with different probabilities. We found that when faced with a volatile environment in which reward contingencies changed frequently, most subjects adopted a model-based approach, enabling them to learn quickly. However, when we introduced inconsistencies that prevented reward probabilities for all options to be determined based on their feature values, subjects adopted a model-free approach. The presence of inconsistencies prompted a model-free approach even when we increased the dimensionality of the environment. Finally, we found that these results are compatible with a hierarchical decision-making and learning process where the best sources of information (in alternative models of the environment) were used to make decisions and successively updated according to

the reward outcome. Overall, our results reveal that a novel trade-off between adaptability (dealing with the volatility in the environment) and precision (dealing with inconsistencies in the reward structure) determines how humans adopt a model of the environment to reverse the curse of dimensionality.

Title: Timing the onset of the decision to move in arbitrary and deliberate decisions

Authors: *N. ZIARI[1], S. WONG[2], M. SAMAD[2], U. MAOZ[2];
[1]UCLA, Los Angeles, CA; [2]UCLA, LOS ANGELES, CA

Abstract: In its most general form, the Libet paradigm instructs subjects to arbitrarily move their left or their right hand, at a time of their choice, and report the time of the onset of their decision to move--henceforth W time--using a clock. It was shown that predictive information about upcoming action exists in the brain before W time. This led some to assert that conscious intentions play no part in the causal chain leading to action, rendering free will and moral responsibility illusory. However, free will and moral responsibility focus on deliberate decisions. So it is crucial to understand to what extent the Libet results extend to deliberate decisions. This was the focus of our investigation.
In the first part of the experiment, subjects tasted drinks and rated their favorability. In the second part of the experiment, subjects were presented with two randomly selected drinks and a rapidly changing stream of letters. The subjects then select a drink using the keyboard and reported the letter that was on the screen at the moment they decided which drink to select. The experiment included 3 types of decisions, in a randomly counterbalanced blocked design, with 10 trials per block. Subjects were informed that one trial per block would be selected and they would have to drink from the drinks presented in that trial, depending on the trial type. In deliberate-decision blocks, subjects were instructed to select the drink they preferred. To motivate them to deliberate, they were informed that they would only need to drink from the drink they chose on the selected trial at the end of the block. In arbitrary-different subjects were told that, regardless of their selection, they would have to drink both drinks in the selected trial, at the end of the block. In the arbitrary-same blocks, subjects were presented with the same drink twice, again motivating arbitrary selection. To ensure that subjects were paying attention

throughout the experiment, we randomly introduced catch trials after some trials. There, subjects were required to identify which of the presented drinks was presented in the previous trial. If they answered incorrectly, they had to taste one of their least favorite drinks.
We observed clear and notable differences among the W time distributions for the 3 types of decisions, where the deliberate-decision block consistently resulted in earlier W time values compared to the other 2 arbitrary block types. This challenges the generalizability of the Libet results for arbitrary and deliberate decisions and, with that, the validity of the claims that free will and moral responsibility are illusory.

Title: Modality specific neural signals of evidence accumulation for spatial decisions

Authors: *A. NAZZAL[1], C. SCHMIDT-SAMOA[1], M. HOLZGRAEFE[2], M. BÄHR[1], J. ERLICH[3], M. WILKE[1];
[1]Cognitive Neurol., Univ. Med. Ctr. Göttingen, Goettingen, Germany; [2]ASKLEPIOS Hosp. Schildautal, Seesen, Germany; [3]Inst. of Brain and Cognitive Sci., Shanghai, China

Abstract: To successfully navigate through the environment, organisms need to be able to receive, accumulate, and integrate spatial information. It is proposed that sensory information is processed in modality-specific sensory regions under the influence of fronto-parietal cortices leading to the formation of spatial decisions. However, since most decision studies in humans have been performed in a single sensory modality and with speeded motor responses, it remains unclear whether brain regions accumulate modality-specific sensory evidence and/or evidence for an action. The goal of the study was to 1) identify brain regions that are involved in modality-specific accumulation of sensory evidence and 2) test the causal contribution of parietal cortices to evidence accumulation in the visual and auditory modality. To this end, we performed an event-related fMRI study in 17 healthy human subjects and tested patients with lesions in parietal cortices using a spatial perceptual accumulation task in both sensory modalities. Stimuli were

presented discretely over time and space and we asked subjects to respond with a button press, deciding whether a trial had more stimuli on the right or on the left side. The discreetness of the stimuli allowed us to fit a quantitative model that captures the dynamics of evidence accumulation during the decision formation (Brunton et al., 2013). For fMRI analysis, for each trial we used the predicted signed evidence to create a parametric regressor representing the decision variable of interest and the absolute of predicted evidence to create a parametric regressor representing the task difficulty regardless of space. In patients' behavioral analysis, we estimated spatial bias and slope by fitting a sigmoidal curve to the patients' ipsilesional choices. Regions correlating with the signed evidence were occipital cortex for the visual task, and superior temporal gyrus for the auditory task. In contrast fronto-parietal cortices did not correlate with the signed evidence but with the absolute evidence in both modalities, i.e. increased activity as the decision became harder irrespective of spatial location in both modalities. Consistent with our fMRI predictions, patients with unilateral lesions in parietal cortices exhibited a slope (i.e. performance) decrease in the visual and auditory tasks. Patients exhibited a spatial bias towards deciding that there were more stimuli presented on the ipsilesional side, which was not predicted by the fMRI data. Our data suggests that sensory evidence accumulates in modality-specific sensory cortices, while supramodal activity in parietal cortices might reflect evidence for action choice.

Title: Wide-eyed and wrong? Pupil dilation correlates with imperfect evidence accumulation in auditory perceptual decisions

Authors: *T. HAGEN, R. C. WILSON;
Psychology, Univ. of Arizona, Tucson, AZ

Abstract: The temporal integration of evidence is crucial for effective decision making. For simple perceptual decisions, a large body of work suggests that humans and animals are able to perform such temporal integration in a near-optimal manner (e.g. Brunton et al., 2013). Yet other work suggests that such evidence integration is subject to neuromodulation (Cavanagh et al.,

2014). In this work we set out to investigate this modulation in more detail by measuring pupil dilation (a putative correlate of norepinephrine) in 68 humans making perceptual decisions.
In particular, we used a modified version of the Poisson Clicks Task in which participants hear a sequence of clicks in their left and right ears and must decide which ear received the most clicks. Optimal decision making in this task requires the temporal integration of evidence and prior work has shown that both humans and rats can perform this task remarkably well (Brunton et al., 2013).
Using a simple regression analysis we were able to compute the relative contribution of each click to the decision and show how this contribution was modulated by pupil diameter from trial to trial.
Our results show that, on average, people did not perfectly integrate information in this task. We found that participants showed a pronounced primacy effect, with earlier clicks receiving about 50% more weight than later clicks. Moreover, the weights of later clicks were negatively correlated with pupil diameter: high pupil diameter was associated with lower weights and greater primacy effect, while low pupil diameter was associated with higher weights and a weaker primacy effect. These findings suggest a role for norepinephrine in modulating the temporal integration of information, with near-perfect integration only possible when norepinephrine levels are low.

Title: Humans represent visuo-spatial probability distribution as k-means clusters

Authors: *J. SUN[1], J. LI[1,2], H. ZHANG[1,2,3];
[1]Dept. of Psychology, Peking Univ., Beijing City, China; [2]PKU-IDG/McGovern Inst. for Brain Research, Peking Univ., Beijing, China; [3]Peking-Tsinghua Ctr. for Life Science, Peking Univ., Beijing, China

Abstract: The reward for a real-world choice is often randomly distributed on a continuum (e.g. the future price of a stock). Many behavioral and neuroimaging studies have shown that human decisions are sensitive to the statistical moments (mean, variance, etc.) of reward distributions. However, little is known about how reward distributions—or, probability distributions in general—are represented in the human brain. When the possible values of a probability distribution is numerous (infinite for a continuous distribution), it would be unrealistic or at least cognitively costly to maintain the probability for each possible value. Here we explored potential heuristic representations of probability distributions and tested them on human subjects. In particular, we tested a recently developed hypothesis that human representations of probability distributions are mixtures of a small number of non-overlapping basis distributions, which can potentially reduce the computational load of probabilistic calculations as well as alleviate the cognitive load.
Methods: In two experiments, we constructed a variety of multimodal distributions of spatial positions. On each trial, 70 vertical lines—the horizontal coordinates of which were samples independently drawn from the distributions—were briefly presented, one at a time on the computer screen. Human subjects were asked to locate (on the axis where stimuli were presented) the mean and the mode of the samples. A total of 19 naïve subjects participated and completed 144-162 trials each.
Results: All subjects' mean and mode responses were highly correlated with the true means and modes of the samples. Interestingly, all subjects' mean and mode responses had systematic deviations from the true means and modes. The deviation patterns could be well predicted by computational models that assume a division of samples into a small number of clusters following the k-means clustering algorithm. Only the centroid and the relative weight of each cluster were necessary for the further calculation of mean and mode responses.

Title: Discrimination of brightness biased by flicker rate in alpha frequency range

Authors: *J. K. BERTRAND[1], N. J. WISPINSKI[2], D. L. CORMIER[2], A. SINGHAL[2], K. E. MATHEWSON[2], C. S. CHAPMAN[1];
[1]Fac. of Physical Educ. and Recreation, [2]Dept. of Psychology, Univ. of Alberta, Edmonton, AB, Canada

Abstract: Work from over a hundred years ago (Brücke, 1867) showed that a single light flickering at certain frequencies was perceived as brighter than a constant light despite having only half the actual intensity. Notably, the single light frequencies with the greatest difference between perceived and actual luminance occurred within the alpha frequency range (8 to 12 Hz). Recently, entrainment of the alpha frequency has been shown to modulate attention and bias detection of stimuli. We believe the previously reported brightness advantage for flickering stimuli may therefore be causally related to alpha oscillations. To test this, we employed electroencephalography (EEG) and behavioural analysis to investigate how the discrimination of brightness difference across two flickering stimulus may be influenced by their relative frequencies and how oscillatory activity in the alpha frequency may play a part in this biased perception.
Participants were shown two circular stimuli, flashing on either side of a fixation cross. Both stimuli could flicker at either 9.23 or 12 Hz, and both could be either lighter or darker. Before the experiment, light and dark brightness levels were established through a staircase procedure to approximate when a participant perceived one target as brighter 75% of the time. During the experiment, an arrow at fixation cued participants to make a yes/no keyboard response if the cued stimulus was brighter (or darker, counterbalanced) than the other stimulus. Based on the Brücke-effect, we hypothesized that stimuli at 9.23 Hz would appear brighter than those at 12 Hz.
Behaviorally we found a main effect of brightness and, most importantly, a main effect of frequency, with no interaction. As predicted, the slower oscillating target was perceived as brighter than the faster oscillating target more than 70% of the time, even when its true luminance was equivalent. Overall, we were able to powerfully bias brightness discrimination solely by manipulating relative stimulus frequency.
We predict EEG analysis will reveal a third main effect of alpha power where a difference in alpha power between hemispheres will correlate with biased brightness discrimination. Specifically, we predict that greater alpha power in one hemisphere will correspond to a decrease

in attention and subsequently decrease the perceived brightness of the contralateral stimulus. We believe that by uncovering how these neural oscillations affect perceptual judgements, we may be able to extend our understanding of, and ability to bias, value-based judgments.

Title: The tuning of reflexes to environmental risk

Authors: *A. DUNNING, M. BERTUCCO, T. SANGER;
USC, Los Angeles, CA

Abstract: In order to characterize and emphasize the influence of risk in the environment on human movement, we have designed a series of experiments. In previous work, we have shown that humans continuously adapt their movement trajectory to compensate for perceived environmental risk. Here we test whether they also adapt long and short-latency stretch reflexes to minimize the effect of perturbations in a risky environment. Many studies have demonstrated that humans have the ability to modulate the long latency stretch reflex based on the goal of a task, such as in a go-don't-go paradigm. It is our hypothesis that awareness to risk is so fundamental, that humans also maintain reflexes tuned specifically to the risk of the environment, even when the goal of the task remains constant.
In the experiment, subjects were positioned in front of a monitor with their arm strapped to a manipulandum designed to apply torque at the elbow joint while maintaining all other arm joints immobile. The subject's hand gripped a rigid joystick attached to the arm of the manipulandum that controlled a cursor horizontally on the screen. The monitor displayed three equidistant rectangles, two cost regions on either side of a center reward region. Subjects were instructed to maximize points by keeping the cursor within the center reward region while avoiding the cost regions. Nine cost functions were evaluated, all combinations of no penalty, low penalty, and high penalty, in order to evaluate the effect of both symmetric and asymmetric risk. Thus the goal of the task was always to remain in the center target, but the risk of hitting the penalty regions was varied. The robot generated a constant 1 N force (activating the bicep) and randomized 3 N perturbations in both directions (in addition to baseline force) at a mean rate of 5 seconds. Surface electromyography from the bicep and triceps were recorded and filtered. Only

trials in the direction that provoked the bicep stretch reflex were analyzed. Reflex response was categorized into standard epochs for baseline, short latency, long latency, and voluntary response. The filtered EMG within each epoch was averaged to a single value per trial for analysis.
Results demonstrate a difference in the long latency stretch reflex dependent on the risk of the environment. However, results were only clear for the symmetric cost conditions; subjects did not demonstrate a consistent ability to set separate reflex responses for different directions when the direction of perturbation was unplanned. Therefore, results suggest that humans do plan for error by tuning reflexes to the risk of the environment and that they do this independent of the goal of the task.

Title: Comparing visual and tactile Simon effects: a model-based analysis

Authors: *Y. SALZER[1,2], G. DE HOLLANDER[1], L. VAN MAANEN[1], M. SALTI[2], B. U. FORSTMANN[1];
[1]Univ. of Amsterdam, Amsterdam, Netherlands; [2]Ben-Gurion Univ. of the Negev, Beer-Sheva, Israel

Abstract: Quickly adapting to a changing environment is crucial for everyday behaviours. Conflict tasks such as the Simon task have been extensively used to study the temporal dynamics of conflict resolution between relevant and irrelevant stimulus-response mappings. In this task, participants discriminate between a stimuli's relevant feature (e.g., shape), by responding with the left or right hand. The Simon effect finds that response times (RTs) decrease when a stimulus' location is congruent with the response hand. RT distribution analyses have shown that the Simon effect fades over time, i.e., the differences in RTs between congruent and incongruent stimuli decrease as RT increases. The aim of the present study was to examine the neural substrates underlying latent cognitive processes involved in the resolution of spatial stimulus-

response conflict in visual and tactile domains using a model-based approach. The results are in line with the spontaneous decay account of the fading Simon effect and shed light on the modal specificity of processing conflict.
Nineteen participants undertook functional magnetic resonance imaging (fMRI) while performing a tactile and visual Simon task. In the visual task, participants were asked to discriminate between a rectangle and triangle, presented either on the left or right side of a centrally-presented fixation cross. In the tactile task, participants were instructed to discriminate between a pulse or continuous vibration presented on the left or right of the torso, delivered with a vibrotactile belt.
The fMRI data was subjected to a multivariate pattern analysis (MVPA) in regions-of-interest in the visual and somatosensory cortex. For unseen data, the MVPA predicted every trial as having a right or left stimulus presentation with a degree of similarity to seen right and left data classes. We found that trials in which MVPA classified the stimulus location to a higher degree also showed a larger Simon effect. This suggests that the sensory representation of the irrelevant stimulus feature is what drives, at least in part, the magnitude of the Simon effect. The irrelevant stimulus feature could not be decoded in tactile trials. In an ongoing study we aim to extract more distinct neural patterns in the visual and somatosensory sensory areas by using optimised stimulus presentations.
Our results show that the processing of irrelevant stimulus information in visual areas predicts the temporal dynamics of resolving response-conflict in the visual Simon task. This finding is in line with the spontaneous decay account, which stresses the influence of sensory processing on the difference between congruent and incongruent trials.

Title: Perceptual confidence: a true reflection of objective human visual discrimination?

Authors: *L. ZIZLSPERGER[1], L. MEISSAUER[2], T. HAARMEIER[3];
[1]Div. of Vascular Neurol. and Neurorehabilitation, Univ. Hosp. and Univ. of Zürich, Cham, Switzerland; [2]Dept. of Neurosurg. RWTH, Aachen, Germany; [3]Dept. of Neurology, HELIOS Clin. Krefeld, Krefeld, Germany

Abstract: Visual perception has been described as a process of probabilistic inference in which decision confidence contributes to successful choice formation and enactment[1]. Recently we demonstrated that while perceptual sensitivity and confidence in it increased with training, bias-free metacognitive sensitivity (the „precision“ of the metacognitive evaluation) did not[2]. For visual perception in healthy human subjects here we investigated how these three descriptions of perceptual performance vary under more difficult perceptual conditions. 26 emmetropic subjects performed two visual paradigms while presentation time was varied and / or visual acuity was diminished by the temporary inroduction of +2 dpt refraction lenses. In order to allow for comparisons between different stimulus modalities[3], we presented a random dot kinematogram (RDK) in the first and a Landolt C in the second task.
For the experimental myopia we found perceptual performance and the confidence in it to decrease significantly with the introduction of the refraction manipulation in the Landolt, but not in the RDK paradigm. The reduction of the presentation time significantly impaired objective and subjective performance for both visual stimuli. Metacognitive sensitivity evolved in parallel with the two other behavioral measures in both tasks.
In summary, we did not observe a dissociation of these three different performance measures - even for the combination of artificial myopia and short stimulus presentation - but in all experimental variations subjective and objective performance measures went in parallel. We were not surprised to see the changes in type-1 (perceptual) sensitivity differ between the two visual submodalities. But within each experimental condition, combining two presentation times with two different tasks, perceptual confidence and type-2 (metacognitive) sensitivity was observed to be a true reflection of the perceptual performance. In other words, experimental visual impairment by incorrect refraction not only changed objective behavioral performance for the worse, but also the metacognitive evaluation of one own’s perceptual efficiency. The findings suggest that type-1 and type-2 processes operate on the same input, possibly even sharing their neuronal implementation.

Title: How does the brain infer the shape of an object based on hand pose and skin contacts?

Authors: *F. MEHRABAN POUR BEHBAHANI, G. SINGLA-BUXARRAIS, A. FAISAL; Imperial Col. London, London, United Kingdom

Abstract: A hallmark of human cognition is the ability to rapidly and accurately assign meaning to sensory stimuli. Even without visual feedback, humans can determine the shape of objects solely on the basis of haptic feedback. This feat is achieved despite large variability in sensory and motor estimation of hand pose and object location. The human hand can take advantage of rich dynamics in object interaction, but capturing the data and interpreting it with regards to well-defined physics models is challenging and has not been done in a systematic way. A principled way to understand the underlying neural computations is through first-principle Bayesian ideal observer models which have been very successful in explaining human visual, auditory and multi-sensory perception, yet have rarely been applied in the haptic domain. We propose a Bayesian perceptual model for recursive integration of noisy proprioceptive hand pose with noisy contact point information on the surface of the skin. The model simultaneously forms an optimal representation of a haptically explored object and estimates the true hand pose within that space. We present a proof-of-principle reconstruction of object shape from multi-finger tactile exploration with contact points reconstructed using a physics engine. The algorithm presented allows us to predict in real-time, from motion capture data in human experiments, an optimal Bayesian estimate of the object shape, given the same sensory information. Therefore, our work provides a framework for a principled study of human haptic exploration of complex objects in a similar principled manner that transformed vision research.

Title: The role of time in perceptual decision-making

Authors: *D. M. ZOLTOWSKI[1], Á. KOBLINGER[2], J. FISER[2], M. LENGYEL[1];
[1]Dept. of Engin., Univ. of Cambridge, Cambridge, United Kingdom; [2]Dept. of Cognitive Sci., Central European Univ., Budapest, Hungary

Abstract: In perceptual decision-making, neural representations of environmental stimuli and uncertainty must be computed on short time scales. Here, we formulate two opposing probabilistic models in which stimulus time presentation is used for either evidence integration or probabilistic sampling. In evidence integration, time is used to iteratively collect evidence and update a posterior distribution over an environmental variable given the stimulus. Crucially, we assume that the posterior distribution is changing as evidence is integrated and it is represented exactly at each time point. Alternatively, under the sampling hypothesis time is used to approximately represent the posterior distribution by sequentially sampling from a static distribution. We devised a novel orientation-estimation task in which subjects reported their estimate of the orientation of a line segment as well as their uncertainty associated with their estimate, and we developed intuitive as well as formal theoretical predictions of how humans should behave in this task under the two models. On each trial of the task, we obtained a subjective measure of uncertainty along with a true measure of error. Both the evidence integration model and probabilistic sampling model predicted the error and uncertainty to decrease as a function of stimulus presentation time. The factor that distinguished the two models was the relationship between error and uncertainty. As a function of stimulus presentation time, under evidence integration we predicted the across-trial correlation between error and uncertainty to remain constant while under probabilistic sampling we predicted the across-trial correlation to increase for longer presentation times. The key insight is that under probabilistic sampling the representation of uncertainty becomes increasingly accurate through time as the number of samples increases. Finally, we collected data from human subjects completing our orientation-estimation task and obtained initial evidence supporting the probabilistic sampling model.

Title: Perceptual decoupling is not the same as mind-wandering: Using experience sampling to measure the dynamics of thought

Authors: *Q. RAFFAELLI[1], A. C. HERRERA-BENNETT[2], K. CHRISTOFF[2];
[1]Psychology, [2]Univ. of British Columbia, Vancouver, BC, Canada

Abstract: A prominent view of mind wandering defines it is a "shift in the contents of thoughts away from an ongoing task and/or from events in the external environment to self-generated thoughts and feelings" (Smallwood & Schooler, 2016, p488). This definition, however, fails to capture a crucial phenomenological characteristic of the wandering mind: its dynamic quality, including the tendency of the wandering mind to move in an unconstrained fashion (free movement) and to cover a broad conceptual scope (conceptual variability). Here we developed novel experience sampling items aiming to capture these so far neglected dynamic aspects of mind wandering. Participants answered several thoughts probes sent at random times within regular time intervals throughout the days during the course of several days. We were specifically interested in how freedom of thought's movement relates to the extent to which thoughts are perceptually coupled with the environment. Results suggest that being decoupled from (or unaware of) the external environment is not a significant predictor of the felt spontaneity of thoughts' movement. In addition, having one's thoughts related to the immediate surrounding was only marginally predictive of the spontaneity of thoughts' movement. Finally the predictive power of attending to something in the immediate surrounding disappeared when task relatedness was added as a predictive variable. Therefore, the degree of perceptual coupling with the environment appears relatively independent of the felt spontaneity of thought's movement, suggesting that freedom of movement captures something about the wandering mind that perceptual decoupling does not.

Title: Age effects on visual perceptual decisions of ambiguous stimuli

Authors: *E. ARANI[1], R. VAN EE[1,2], R. VAN WEZEL[1,3];
[1]Biophysics, Donders Institute, Radboud Univ., Nijmegen, Netherlands; [2]Lab. of Exptl. Psychology, Univ. of Leuven, Leuven, Belgium; [3]Biomed. Signals and Systems, MIRA, Twente Univ., Enschede, Netherlands

Abstract: The brain is constantly making choices while interpreting the environment. To understand how age affects visual decision-making, we investigated age-related changes in spontaneous percept switches and percept choices during intermittent presentations of ambiguous stimuli. Spontaneous switches can be triggered by different visual stimuli, such as monocular ambiguous visual stimuli or binocular rivalry images. An ambiguous visual stimulus has multiple and equally plausible interpretations, such as the bi-stable rotating sphere. In such a sphere two transparently moving dots are moving in opposite directions and due to structure-from-motion the stimulus is perceived as a 3-dimensional rotating sphere moving in one or the opposite direction. During binocular rivalry experiments, the left and the right eye receive different input simultaneously. During stimulus-presentation only one of the two presented images is perceived, and the other image is suppressed. Dominance durations (the time a percept remains dominant) are typically in the order of several seconds. In this study, 52 observers ranging from 17 to 72 years old, viewed bi-stable rotating spheres and binocular rivalry stimuli and were forced to make a choice between two percepts. Stimuli were presented continuously for 2 minutes or intermittently for 1 second, with a range of inter-stimulus intervals (0.125 - 2 seconds). The results show that dominance durations during continuous viewing are longer for older subjects for the binocular rivalry stimulus but not for the bi-stable rotating spheres. For the intermittent stimulus presentation, perceptual alternations decrease at an older age in binocular rivalry, while for the bi-stable rotating sphere there are only differences in perceptual alternations among different age groups at a short off-duration. Based on these results, we conclude that the effect of age is not a general phenomenon for ambiguous stimuli. Visual decisions are more stimulus dependent, rather than experience dependent.

Title: Contributions of neural adaptation to value-based and perceptual choice

Authors: *O. HORNO[1], M. SPITMAAN[2], A. SOLTANI[2];
[2]Dept. of Psychological and Brain Sci., [1]Dartmouth Col., Hanover, NH

Abstract: Despite the prevalent use of two-alternative choice paradigms to study different types of decision making, real-life decisions often involve selection among a set of options. The set of options, including the irrelevant options, can alter decision-making processes and result in preference reversal between the relevant options. This set of phenomena, referred to as context or decoy effects, has been extensively studied in value-based choice and has revealed important aspects of valuation and decision processes. Recently, we have proposed that trial-by-trial adjustments of neural representations to the set of presented options can account for some context effects (Soltani et al., 2012). Interestingly, a new study has shown that context effects can also arise in perceptual decision making (Trueblood et al., 2013). Considering the prevalence of neural adaptation in most brain areas, we hypothesized that neural adaptation could contribute to both value-based and perceptual context effects. To test this hypothesis, we conducted an experiment to measure context effects in two different tasks using a within-subject design. In one task, human subjects selected between monetary gambles with different reward probabilities and magnitudes in order to maximize payoff (value-based task). In another task, subjects chose the line with the longest shadow out of a set of slanted lines, and were rewarded based on the size of the shadow (perceptual task). In both tasks, however, subjects were shown three options at the beginning of each trial, and one was removed at the time of choice (phantom decoys). Finally, in order to test the effects of neural adaptation on longer timescales, we measured context effects after increasing the range of option values in another value-based task (high-range manipulation). Firstly, we found within-subject decoy effects for both value-based and perceptual decision-making tasks. However, in the perceptual task, the decoys were effective only when presented next to the more horizontal line. Secondly, we found a significant correlation between the overall decoy effects in the two tasks, indicating that similar trial-by-trial adaptation could underlie context effects in two different types of decision making. Finally, we did not find any difference between decoy effects during the main experiment and high-range manipulation, illustrating that adaptation on longer timescales may not contribute to context effects. Overall, our results extend previous findings on the role of neural adaptation in sensory processing to the realm of irrational choice behavior, and further indicate that adaptation contributes to different types of decision making.

Univ. of Ireland, Galway, Galway, Ireland; [3]Ulster Univ., Derry-Londonderry, United Kingdom; [4]Sch. of Psychology, and Complex Systems Res. Ctr., Natl. Univ. Ireland, Galway, Galway, Ireland

Abstract: Tracking eye movements during decision making has provided numerous insights into possible mechanisms of attention and evidence accumulation preceding the actual choice. In a parallel stream of research, mouse/hand trajectories during choice execution are analysed under the assumption that cognition can “leak” into motor output, thereby leaving traces of decision maker’s thought process. At the same time, possible interactions between eye and hand dynamics during decision making remain largely unexplored. This study is the first one to report joint analysis of synchronized eye-tracking, pupilometry, and mouse-tracking data during decision making. We employ a well-known motion discrimination task (“random dots” paradigm) to investigate: (1) the basic patterns of eye-hand coordination during decision making; (2) how these patterns change with task difficulty (that is, motion coherence); and (3) individual differences in dynamics of such simple decision making, and possible relation of these differences to subjects’ personality (as assessed by BIS/BAS, PANAS, and Jackson-5 scales).

Title: EEG-based classification of intended responses in a multi-modal crewstation simulation

Authors: *P. M. CONNOLLY, S. SIMONS, K. ZACHERY, D. KRNAVEK;
Teledyne Scientific and Imaging, LLC, Durham, NC

Abstract: Brain-Computer Interfaces (BCIs) show great promise in augmenting people's abilities. Non-invasive approaches such as EEG, have two fundamental control signals. The first is direct control which uses scalp potentials to decode the details of motor execution (position, velocity, angle, etc.) measured in primary motor cortical areas. The alternative control approach is goal selection. In a goal-directed BMI, goals are selected by detecting neural signals associated with the user's behavioral goals, while the machine enacts the details normally controlled by fine-grain motor commands. To develop our novel goal-directed BMI, we tested the ability to decode the intent of subjects performing identification tasks in a simulated crewstation of a military vehicle. Since crewstations (and many other applications) are inherently multi-modal, we constructed the task to have both auditory and visual stimuli. Therefore, we defined intent as the selection of a response having both an attentional context (visual or auditory) and a target goal (stimulus category). Within each attentional context, subjects had to select among three intended responses in response to the identified stimulus category. Importantly, the specific motor response (button press) was randomized on each trial, and a delay period was inserted between the stimulus presentation and the presentation of the randomized response mapping.Data were collected with a 32-channel active electrode EEG system and an eye tracker operating at 250Hz from n=15 subjects performing the identification tasks in the crewstation environment. In the visual context, subjects had to generate intended responses to stimuli that fell into the threat, friendly, or neutral category. In the auditory context, subjects heard range callouts and generated intended responses to identified ranges in the near, middle, or far categories. From these data we extracted spectral features, including phase coherence, for classification. Classification performance for determining the attentional context averaged 83.63% (chance = 50%) across subjects. Classification performance in selecting the target goal to auditory stimuli averaged 69.1% (chance = 33%), and 60.14% (chance = 33%) in the visual modality. These results show promise for the use of EEG in goal-directed BCIs for military applications. Funding for this research was provided by the Institute of Collaborative Biotechnologies, a University Affiliated Research Center (UARC) based at UCSB and sponsored by the Army Research Office.

Title: Overimitation in a virtual environment

Authors: *M. LILJEHOLM, E. CASTILLO;
Neurosci., Univ. of California, Irvine, Irvine, CA

Abstract: Overimitation - the faithful copying of redundant, causally irrelevant, actions - has been demonstrated cross-culturally in human children as well as adults. To date, human overimitation has been studied using physical boxes, containers or contraptions, from which the observee, and subsequently the observer, extracts some object using a tool. A major limitation of this method is that it is difficult to combine with neuroscientific techniques, such as fMRI, thus impeding assessment of underlying neural computations. Another notable feature of previous demonstrations of human overimitation is that they involve observation of actual limb movements by a conspecific, raising the question of whether such observations are necessary for the phenomenon to occur. Here, we demonstrate overimitation using a computerized maze-learning task, in which participants were required to move an abstract avatar from a start location to a goal location in a 2D maze. Our methods and results pave the way for future assessment of the neural bases of overimitation.

Title: Pre-movement stretch responses predict changes-of-mind.

Authors: *L. P. SELEN, J. MARESCH;
Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ., Nijmegen, Netherlands

Abstract: Tasks change continuously and are often ambiguous in everyday life. In order to act appropriately, our brain has to monitor the task goals and adapt our motor responses in real time. Signs of this real-time adaptation of responses have been shown in the form of changes-of-mind in reach paradigms where subjects evaluate additional information after having initiated their reach (Resulaj et al, 2009; Burk et al., 2014) and in the form of rapid motor response muscle activity that tracks the accumulated evidence in a random-dot-motion (RDM) discrimination task (Selen et al., 2009). Here we investigate whether stretch induced rapid motor responses prior to movement initiation only represent the accumulated evidence or also contain information about an upcoming change-of-mind. Human subjects held the handle of a robotic manipulandum (vBOT) and indicated the direction of a random-dot stimulus by a full arm movement to one of two targets, 30 cm away from the start position and separated by 40 degrees. Subjects were instructed to rapidly indicate the perceived direction once the RDM stimulus disappeared. At this moment the the robot displaced their hand (1cm in 60ms), extending the shoulder and eliciting rapid motor responses in the shoulder muscles (especially Pectoralis Major). We maximized the occurrence of change-of-mind by only presenting intermediate coherence levels of the dots (6.4%, 12.6%, 25,6%) and a limited range of viewing durations (range 0.2-0.6s, mean 0.40s). In order to control and shorten the reaction times, we used a beep paradigm to indicate the offset of the RDM. We recorded muscle activity from Pectoralis Major and quantified the magnitude of the rapid motor response in the first 100 ms after perturbation onset. For each change-of-mind trial we selected a normal trial with the same coherence level, but opposite direction, and the closest viewing duration. If the rapid motor responses reflect the likelihood of a change-of-mind, one would expect increased activity for right-to-left changes-of-mind compared to straight right choices. However, if the rapid motor responses just reflect accumulated evidence, the activity should be lower in change-of-mind trials because there is less evidence for the right target. In all 6 subjects rapid motor responses were lower in change-of-mind trials compared to their matched normal trial. These results confirm that the CNS continuously provides information from the ongoing decision process to the motor system, but that rapid motor responses do not, yet, reflect activity that is related to the upcoming change-of-mind.

Title: An attack-and-defend competition as a redundant cognitive-motor system

Authors: *K. FUJII, Y. YOSHIHARA, Y. YAMAMOTO;
Nagoya Univ., Nagoya, Japan

Abstract: Humans interact by perceiving relevant information, deciding on and then executing suitable actions. Computational neuroscience has revealed the cognition and motor control of individual agents. However, competitive mutual anticipation and action in multiagent systems have no specific solution and exhibit a great diversity in their behavioral forms. To describe the interactive movements, researchers used a non-linear oscillator and revealed that the skirmish and deadlock states in sports emerged from the competitive interaction. However, these studies cannot explain the manner in which the cognition and motor systems function. Here we adopt a hybrid approach to solve the inverse (from measured data to model) and forward (model simulation) problems using previous measurement results and modeling an attack-and-defend competition. Three-layered redundant systems were constructed: two-agents, an individual agent, and cognitive-motor systems. We implemented two non-linear characteristics: one is the attacker's decision to move forward and attempt to pass the defender by observing oneself and the opponent. Second is the transferability, i.e., movement initiation delay, confirmed by our previous study. At the intra-agent level, in the determination phase of the outcome, the model replicated actual state transitions, wherein the defender's higher transferability led to a more successful defense and vice versa. Furthermore, the attacker's model of observing the defender's transferability revealed a higher probability of a successful attack than the non-observed model. At the inter-agent level, the measured and simulated behaviors were similar. In particular, the determination state of order in a successful attack was abruptly changed rather than gradually, from the skirmish state similar to oscillators. We revealed the overall processes in the two-agent competition and suggest the importance of always defending in high transferability and attacking when the defender's less transferability. In our further expanded model, we biomechanically defined transferability by implementing a redundant actuator system in this model. We anticipate developments in the scientific field of complex movement, which adapt to such uncontrolled environments.

Title: Motor affordance biases subjective value

Authors: *C. C. ROMERO[1], M. A. GOMEZ[1], M. WEBSTER[1], J. T. MCGUIRE[2], T. SCHONBERG[3], J. C. SNOW[1];
[1]Univ. of Nevada, Reno, Reno, NV; [2]Boston Univ., Boston, MA; [3]Tel Aviv Univ., Tel Aviv, Israel

Abstract: In everyday life food choices are most often made when consumers are confronted with real foods, yet our understanding of human decision-making is based almost exclusively on studies that have relied on computerized images. Although image interaction is common in the modern world, humans have presumably evolved to perceive, grasp, and consume real foods, not images. Here, we used a 'cue-approach training' procedure described by Schonberg et al., (Nature Neuroscience, 2014) to test whether or not the value of common snack foods can be modulated by passive exposure to real foods that have the potential for (but do not require) a physical motor approach response. We found that 2-AFC choices between 'high-value' (preferred) items were biased significantly in favor of snacks that were viewed as real objects, versus images. Importantly, display format did not influence decisions between low-value (non-preferred) food pairs, indicating that the biasing effect of the real foods was not attributable to factors other than preference. Our results suggest that subjective value is enhanced for items with a definite motor association or affordance.

Title: Optimized functional MRI in the subthalamic nucleus at 7 Tesla and 3 Tesla

Authors: *G. DE HOLLANDER[1], M. C. KEUKEN[1], W. VAN DER ZWAAG[2], R. TRAMPEL[3], B. U. FORSTMANN[1];
[1]Univ. of Amsterdam, Amsterdam, Netherlands; [2]Spinoza Ctr. for Neuroimaging, Amsterdam, Netherlands; [3]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: The basal ganglia (BG) form a group of nuclei in the midbrain that are important for cognitive processes, such as motor control and response inhibition. These nuclei also play a role in the pathogenesis of Parkinson's Disease (PD), where dopaminergic cell loss in the substantia nigra leads to severe (motor) symptoms. Deep brain stimulation (DBS) of the basal ganglia, specifically the subthalamic nucleus (STN), has been a successful therapy in alleviating motor symptoms of PD. However, the precise mechanisms underlying DBS and its side effects are not well-understood. An important hypothesis is that the subthalamic nucleus contains multiple subdivisions, related to different cortical networks, such as the 'limbic', 'cognitive', and 'motor' network, and that they are crucial to optimal DBS electrode positioning (Temel et al., 2005; but see Keuken et al., 2012).
In vivo functional magnetic resonance imaging (fMRI) of the basal ganglia, and specifically the STN, could help to elucidate its role in cognition, as well as those of its putative subdivisions. However, fMRI in the STN remains challenging, even with ultra-high field MRI (7 Tesla [T] and above), because of its small size, as well as its complicating magnetic properties, mainly due to its its high concentration of iron (de Hollander et al. 2015).
In this project we aimed to 1) optimize 7T fMRI sequences to be able to robustly show functional activation in the STN, as well as other basal ganglia nuclei, 2) compare fMRI data obtained at 7T to fMRI data obtained at 3T with identical resolution, 3) run a speeded decision-making task while collecting 7T fMRI data that was designed to tap into putative STN subdivisions. In the speeded decision-making paradigm, subjects were cued about the reward payoff structure of the coming trial, as well as a perceptual difficulty manipulation.
Our results show that care needs to be taken in optimizing fMRI sequences at 7T such that both robust BOLD contrast as well as an acceptable spatial and temporal resolution in the STN can be obtained. More concretely this means that "off-the-shelf" 7T fMRI sequences (usually optimized for cortex) are not suitable and that the impressive submillimeter functional MRI resolutions obtained in some parts of cortex, are currently not feasible in the STN. Our 3T fMRI data show that lower-field fMRI is not capable of delivering both acceptable BOLD contrast, as well as the spatial resolution that is needed to answer questions about putative subdivisions in the STN. Preliminary results from the factorial speeded decision-making task suggest that the STN is involved in adjusting decision strategies related to both reward payoff, as well as stimulus quality.

Title: Dynamics of perceptual decision-making and choice confidence

Authors: *K. LIM[1,2], D. M. MERFELD[1,2,3];
[1]Massachusetts Eye and Ear Infirmary, Boston, MA; [2]Speech and Hearing Biosci. and Technol., Harvard-MIT Div. of Hlth. Sci. and Technol., Cambridge, MA; [3]Harvard Med. Sch., Boston, MA

Abstract: Recent vestibular psychophysical studies have consistently shown that humans discriminate high frequency motions (with short duration) better than low frequency motions (with long duration) when performing binary direction-recognition forced-choice tasks. This behavior has been modeled with a high-pass filter (HPF) having a time constant (circa 0.5s) that is much shorter than all other behaviorally relevant time constants found in vestibular pathways [1,2]. Here, we hypothesize that an HPF with such a short time constant is part of the decision-making process. In other words, we propose that the brain may utilize an HPF to selectively weigh recent information that is more relevant for current state when making a perceptual decision. In order to investigate the dynamics of perceptual decision-making in a forced-choice paradigm, we quantitatively analyzed human choice behaviors and developed a computational model. Specifically, choice accuracy and confidence were concurrently measured as a function of observation duration in 12 normal human subjects while performing a direction-recognition forced-choice task using a tilted subjective visual vertical (SVV) display. Observation duration was varied between 105ms and 1600ms, during which a stationary Gabor patch with a 7° viewing angle was displayed. Both choice accuracy and confidence were consistent with response dynamics that included an HPF having average time constants of 134ms and 225ms, respectively. For our computational model, we incorporated an HPF into a preexisting decision-making model [3] of a sensory evidence accumulator. The proposed model predicted that both choice accuracy and confidence reach a plateau below 100% when given moderate sensory stimulus. This prediction matched the human behavioral data. The veracity of this model's predictions was also compared to predictions made by other published models of decision-making. The other three preexisting models were (a) a pure accumulator model [3], (b) a collapsing bound accumulator model [4], and (c) an urgency signal accumulator model [5]. The simulations showed that only our new accumulator model with an HPF matched choice accuracy,

discrimination thresholds, confidence histograms, and median confidence as functions of observation duration. These results show that (1) binary choice and confidence share a neural representation of the same noisy decision variable(s), and that (2) the dynamics of the shared processing can be captured by an HPF (or other equivalent leaky mechanism) combined with an accumulator.

Abstract: Intact perception of bodily non-verbal signals on intentions, dispositions and emotions of others is of fundamental value in our daily life. However, the architecture of the brain networks for social cognition remains largely unknown. We studied visual perception of emotional (angry and happy) and neutral body language in healthy participants, using a combination of functional magnetic resonance imaging (fMRI) and diffusion tensor imaging (DTI). Data processing was conducted with Statistical Parametric Mapping (SPM12) and FMRIB Software Library (FSL). The right superior temporal sulcus (STS) and caudate nucleus exhibit higher activation for happy body language, and the left inferior insula, perigenual anterior cingulate cortex (ACC) and posterior midcingulate cortex (MCC) for angry as compared to neutral body language. The cerebellar vermis (lobule IX) and right amygdala appear to signal an absence of emotional content in body movements. DTI tractography and effective connectivity analysis reveal the structural and functional architecture within this network for processing of

emotional body language. In summary, higher-order fronto-temporal regions, the cerebellum and basal ganglia are mainly involved in recognition of emotions conveyed by body motion, with a lateralization depending on emotional content. Better understanding of structure and function within the social cognition networks may contribute to further advance in research and management of neuropsychiatric disorders.

Abstract: Over the last decades neurophysiological, neuropsychological, neuroimaging and brain stimulation studies have identified a network of occipital, temporal, parietal, and frontal brain areas that support the visual processing of others' actions. The neural computations and representational properties in each area however need to be better specified. Here, we investigated the representational content of human brain areas involved in action processing using fMRI, representational similarity analyses (RSA), and computational modeling. Participants viewed video clips of 8 different actions performed by 3 different agents (both human and robot) during fMRI scanning. We derived two indices from the representational similarity matrices for each region of interest (ROI): Agent decoding index and action decoding index, reflecting the degree to which significant agent and action information can be

distinguished, respectively. We found significant Agent decoding in earlier visual areas and face and body sensitive visual areas (e.g., FFA, EBA), as well as the core nodes of the action observation network (posterior superior temporal sulcus (pSTS), inferior parietal and ventral premotor cortex). However, agent decoding index varied across ROIs. Notably, the right pSTS agent decoding index was significantly greater than those for the parietal and frontal ROIs ($p<0.05$). For actions, we found significant decoding in all visual ROIs as well as pSTS, parietal and ventral premotor regions. The overall action decoding index did not differ significantly across ROIs, but hierarchical clustering indicated the structure of action-related information representation differs between the levels of the cortical hierarchy. We next applied modeling to the experimental stimuli themselves (i.e., the action videos), characterising both the sensory information in the stimuli (using approaches from computer vision), and higher-level/semantic aspects (e.g., action type, target of the action, intention), and considering these model similarity matrices with those constructed from the brain responses. Based on these analyses, we were able to reveal differences in representational properties in the regions studied. We suggest pSTS pools information from earlier visual areas regarding the visual features of the actor/agent, and works with parietal and frontal regions that code higher-level aspects of actions. These results are consistent with existing computational models of action recognition, and can contribute to their extension with further analyses and modeling of representational properties of each region, as well as the network dynamics.

Title: Cortical processing of emotion: an electroencephalogram study

Authors: *E. H. ZHANG, O. WANG;
Univ. of Shanghai For Sci. & Technol., Shanghai, China

Abstract: Emotion is a fundamental function of human brain, and has been widely studied by using traditional psychology paradigm like self-report rating or experimental method such as

electroencephalogram(EEG) and fMRI(functional Magnetic Resonance Imaging). Using affective movie to elicit subject's emotion state is a widely used method in traditional experiment taking advantage of ability of eliciting stable emotion for longer periods, while have not been broadly used in EEG experiment because of unreliable movie database or insufficient movie amount. The present study implemented 49 affective film clips from proved dependable emotion movie database(Emotional Movie Database, Carvalho et al. 2012) as stimulus and recorded EEG signal from 12 subjects(12 male, 20-21 years old) performing passive viewing task. These stimulus were estimated to induce five emotion states(horror, erotic, social negative, social positive and neutral) in the affective space. Various analysis methods included event-related potentials(ERP), Time-Frequency Analysis and low-resolution electromagnetic tomography (LORETA) were conducted to investigate the emotion process.
The ERP result confirms that previous findings, the early components such as P1,N1,P2 and slow components such as LPP,N450 ,can also be elicited by emotion movie stimulus. Also, amplitude of N1,LPP and N450 show significant differences among each emotion state. To further investigate how these differences were modified by cortex current potentials, we utilised LORETA to map the current density distribution during each component occurred. These results deduced that these motivated areas may relate with different emotion processing mechanism. Although ERP analysis revealed early-stage cortical information process of emotion, we also interested in which stable cortical network can be built during different affective state. We extracted band energy of each channel as frequency characteristic and conducted Analysis of Variance(ANOVA) to each characteristic between horror(negative) and erotic(positive) emotion. This statistic analysis shows there are significant differences in gamma band spatial pattern between two affective conditions. Furthermore, time-frequency analysis were operated to describe related gamma oscillation within and between different functional areas.

Title: Body motion presented upright and upside-down: Human ultra high field 9.4T fMRI

Authors: *M. PAVLOVA[1], M. ERB[2], G. HAGBERG[3], K. SCHEFFLER[4];
[1]Univ. of Tübingen Med. Sch., Tübingen, Germany; [2]Biomed. Magnetic Resonance, [3]Univ. of

Tübingen Med. Sch., Tuebingen, Germany; [4]High-field Magnetic Resonance, Max Planck Inst. for Biol. Cybernetics and Univ. of Tuebingen Med. Sch., Tuebingen, Germany

Abstract: Body motion is an indispensable source of information for social cognition and interaction. Yet display inversion severely impedes biological motion (BM) processing. The primary advantage of upside-down presentation is that an inverted display retains the same relational structure and absolute motion as an upright one, thereby keeping the same amount of sensory information available. This is why display inversion often serves as a control for proper BM processing in patients with neurodevelopmental, neurological and psychiatric disorders. It is still unclear how brain networks underpinning body motion processing are affected by display inversion. To address this issue, we used ultra-high field fMRI at 9.4T providing for highest spatial resolution and sensitivity in humans. Typically developing adults performed a two-alternative-forced-choice (2AFC) task, indicating whether an upright point-light walker or control displays (the same movies inverted 180 deg) were presented. An upright walker elicited most pronounced clusters of fMRI activity in the bilateral superior occipital cortices and the right middle temporal cortex, whereas the inverted display results in bilateral activity of lower occipital cortices, primarily, the lingual cortices and the left fusiform gyrus. Activation in these areas exhibited specific temporal dynamics: a decrease in activation in the second 5 s of stimulus duration, with a recurrent increase afterwards that presumably reflects back propagating influence. Most importantly, we uncovered pivots of activity in the distributed network driven by cognitive processing of the similar visual input: Perceivers who did not recognize upside-down displays as a walker exhibit several clusters of activity in the right hemisphere including the lingual, postcentral cortices, and the pars operculum. The outcome provides novel insights on the brain networks underlying BM processing and its functional neuroanatomy.

Title: Event-related synchronization-desynchronization features of social altruistic and selfish decision

Authors: *I. P. KUZNIETSOV, O. RAKOVETS, N. IEVPAK, T. KACHYNSKA, O. ABRAMCHUK;
Human and Animal Physiol., Lesya Ukrainka Eastern European Natl. Universit, Luts'K, Ukraine

Abstract: Human brain is higly specialized on conducting social cognitive functions, which results in specifics of brain cortex structural and biochemical organization. This, in turn, should lead to differences in brain electrical activity in persons, who have different types of social-oriented activity. While different types of social activity, either altruistic or selfish, based on different types and estimation mechanisms of social reward, we expected to find more expressed differences in activity of executive systems under conditions of making a social interactions specific decision. Since the activity of executive systems can be in general described by interplay of dopamine and norepinephrine mediator systems, which activity is characterised by specific reactions in alpha and beta EEG bands, we supposed, that persons with more expressed prosocial behavior should have more reactive EEG responses in the alpha-2 and beta-bands. Our study was conducted on 45 volunteers, which were classified as altruistic-oriented (24 persons) or selfish-oriented (21 person), based on the results of Leary test and relations of altruistic and selfish decisions they made during the experiment. To obtain altruistic-oriented and selfish-oriented decisions we used two experimental probes: "Stag hunt" game (choosing a stag was considered as an altruistic decision, choosing a rabbit was considered as a selfish decision) and an original game, which mimicked the decision making during a basketball game (a pass is considered as an altruistic decision, a throw as a selfish decision). ERD/ERS reaction was analyzed in P3 and P4 electrode sites. It was shown, that the major difference in EEG reaction between altruistic-oriented and selfish-oriented persons is observed in 15-18 Hz frequency range between 1000 and 2000 ms after a stimulus presentation independently on the stimulus type. The origin of this difference are the sychnronization processes in persons of selfish-oriented type and desynchronization processes in persons of altruistic-oriented type. We consider this effect to be the evidence of a more thorough estimation of stimuli importance by altruistic-oriented persons.

Title: Brain structure and social belonging: expectations of social pleasure and pain are reflected in regional brain volumes

Authors: *B. CRAWFORD[1,2], N. MUHLERT[2,3], G. MACDONALD[3], A. D. LAWRENCE[1]; [1]Sch. of Psychology, Cardiff Univ., Cardiff, United Kingdom; [2]Sch. of Psychological Sci., Univ. of Manchester, Manchester, United Kingdom; [3]Univ. of Toronto, Toronto, ON, Canada

Abstract: Human beings have a fundamental need to form and maintain social connections (a "need to belong"). Satisfaction of this leads to social pleasure, while failure to satisfy these needs results in social pain. Previous research has focused on the neural correlates of reactions to social rejection and acceptance. However, much of the pleasure and pain of social life occurs in *anticipation* of things that have yet to come. To measure individual differences in such anticipatory processes, we have developed a novel self-report measure, the levels of dispositional expectancies for social threat and reward scale (LODESTARS). The LODESTARS is a 10-item inventory examining the extent to which participants expect to experience social reward and social punishment during an imminent vividly imagined social encounter with previously unknown individuals. Data from 848 participants demonstrate that the LODESTARS has a clear two-factor structure and excellent psychometric properties. The brain-structural correlates of dispositional social threat and reward expectancies were examined using voxel-based morphometry (VBM). Regional grey matter volume (GMvol) of 100 healthy participants (mean age 24 years; 26 males) was assessed. High-contrast T1-weighted anatomical images were acquired using a 3-Tesla MRI scanner and analysed using SPM12. To correct for multiple comparisons across the whole brain, non-stationary cluster extent correction was implemented. Age, gender and total brain volumes were accounted for. Higher social threat expectancies were associated with greater GMvol in brain regions involved in social attention and perception, including the right superior temporal sulcus (pSTS). This may reflect attentional bias and hypervigilance directed towards potential social threat signals in the environment. Supporting this interpretation, pSTS GMvol correlated *positively* with amygdala GMvol in our sample (Pearson's $r = .23$; $p = .021$). Higher expectancies of social reward and lower expectancies of social threat were associated with greater GMvol in brain regions implicated in emotion regulation, particularly right ventromedial PFC (vmPFC). Previous findings suggest that this region may function as a hub that modulates negative affective responses (perceived fear and aversiveness) across a broad range of paradigms. Corroborating this, vmPFC GMvol was *negatively* correlated with amygdala GMvol in our sample (Pearson's $r = -.27$; $p = .008$). Our findings may have implications for understanding the consequences of social connection on brain structure, as well as brain structural dispositions to mood disorder risk, including social anxiety and social anhedonia.

Abstract: Neuroaesthetics is a new field of research that combines multiple disciplines to elucidate the neurobiological foundations of the cognitive and affective processes involved in aesthetic and artistic experiences. One important method that can be applied for gaining an understanding of the underpinning of aesthetics in the brain is that of electrophysiology. Electroencephalography (EEG), allows the recording and identification of brain rhythms in a mental processing. We presented a Mexican short film named “MUSA” while simultaneously evaluated the EEG activity and the ocular movements, in order to explore the possible differences in cognitive processing between people with and without aesthetical education (dance, theater, painting, sculpture, architecture and movie making). Our results showed significant differences between the groups in Alpha (8-12 Hz) and Beta (13-30 Hz) components between the two groups studied, suggesting that the previous educational experience, could shape the brain rhythms implicated in an aesthetic and artistic experiences.

Title: Effects of repetitive transcranial magnetic stimulation (rTMS) on human movement responses to the Rorschach test and its electrophysiological correlates

Authors: *G. Z. SOGHOYAN[1], A. ANDO[2], Y. QUN[3], L. GIROMINI[2], A. ZENNARO[2], M. BOHM[1], D. MARYANOVSKY[1], J. A. PINEDA[1];
[1]Cognitive Sci., UC San Diego, La Jolla, CA; [2]Psychology, Univ. of Turin, Turin, Italy; [3]Med. Psychology, Fourth Military Med. Univ., Xi'an, China

Abstract: According to the Rorschach literature, human movement responses (M) demonstrate higher cognitive functioning because of the implied ability to empathize with a human being [1]. Using EEG mu suppression as a proxy biomarker for mirror neuron activation, Giromini, and colleagues [2] suggested that strong internal representation of the "feeling of movement" may be sufficient to trigger MNS activity even when minimal external cues are present. Specifically, by conducting an EEG study with the Rorschach stimuli, these authors have shown that attributing M responses yields greater EEG mu suppression. These findings were replicated by a second study [3] and then further confirmed by additional analyses on the same data [4]. Furthermore, Ando' and colleagues [5], by using Transcranial Magnetic Stimulation (TMS) showed that temporary disruption of left inferior frontal gyrus (LIFG; presumably implicated in mirroring activity), but not Vertex, yielded a statistically significant reduction in the attribution of M responses to the Rorschach. The goal of the current study was to use rTMS to determine the role that prefrontal cortex plays in M production and characterize its electrophysiological correlates. All participants were exposed to the Rorschach stimuli during a baseline (without rTMS but with EEG data recording) and during the experimental condition (with rTMS and with EEG). For the control group, 1 Hz rTMS at 90% of rMT was applied for fifteen minutes over the Vertex (this site was chosen as control site since it is often used to test for non specific rTMS effects); for the experimental group, 1 Hz rTMS at 90% of rMT was applied for fifteen minutes over the LIFG. Mu suppression over sensorimotor cortex (including scalp locations C3, Cz and C4) was calculated: the first 500ms were used as reference point, and the ongoing mu power computed relative to that baseline. We expected that mu suppression would not occur when the stimulation was applied over LIFG. By testing a mixed, 2 (between-subject: vertex vs. LIFG) by 2 (within-subject: baseline vs. rTMS) ANOVA, we observed that disrupting LIFG, but not vertex, decreased the number of M responses produced by the participants, with a highly significant interaction effect, $F(1, 26) = 24.60$, $p = .000$, *Partial* $\eta^2 = .486$. Within the LIGF group, we noted a relative reduction of Mu suppression from baseline (EEG data recording without rTMS

condition) to experimental condition. These findings further suggest an intimate link between action simulation and action perception, provide support for the use of EEG to measure MNS activity, and support the role of IFG in mirroring.

Title: Attachment styles and their relation to respiratory sinus arrhythmia and mu suppression

Authors: *N. C. CASTRO[1], M. WIDDOWSON[1], M. BOHM[1], D. MARYANOVSKY[1], A. MINICHINO[1,2], J. PINEDA[1];
[1]Cognitive Sci., Univ. of California San Diego, La Jolla, CA; [2]Sapieniza Univ. of Rome, Roma, Italy

Abstract: Little is known about the neurobiological underpinnings of attachment orientations and their impact on social and affective behaviors. Theories of adult attachment emphasize two dimensions of attachment insecurity: anxious attachment, associated with exaggerated appraisal of threat in social contexts and hyper-activation of coping strategies, and avoidant attachment, characterized by deactivating coping strategies in emotionally relevant situations. We hypothesized: 1) anxious attachment to be associated with amplified autonomic and mirror neuron system activity; and 2) avoidant attachment to be associated with reduced autonomic and mirror neuron system activity, both in response to video clips of others' painful facial expressions.
Forty-eight participants (secure, anxious, and avoidant attachment style groups) underwent EEG and respiratory sinus arrhythmia (RSA) recording while watching videos of painful, neutral, and blurred facial expressions. To assess attachment styles, participants completed the Experiences in Close Relationships Revised questionnaire (ECR-R). Scalp electrode EEG recordings of mu rhythm (8–13 Hz) over the sensorimotor cortex during the session were used to calculate mu wave suppression, a biological marker of empathic resonance. A comprehensive battery of social cognitive, empathic, and personality measures was also administered to each participant. Preliminary correlation analyses on RSA data (22 subjects) and EEG data (16 subjects) were consistent with our hypotheses: 1) the anxious attachment subscale of the ECR-R was significantly associated with both RSA-indices ($r = -.47$, $p = 0.039$) and increased mu suppression

(r= -.54, p= <0.05), such that subjects with higher scores on this ECR-R subscale had lower RSA indices and greater mu suppression; and 2) the avoidant attachment subscale of the ECR-R was significantly associated with RSA indices (r= .60; p= 0.003), such that subjects with higher scores on this ECR-R subscale had higher RSA indices.
These results suggest that the tendency of individuals with anxious attachment to exaggerate appraisal of threat could be explained by an increased activation of the autonomic (lower RSA indices) and mirror neuron system. On the other hand, the deactivation of coping strategies typically showed by individuals with an avoidant attachment could be associated with a lower activation of the autonomic system (higher RSA indices). Our results provide insights on psychopathological conditions where attachment dysregulation is likely to play an important (causal) role.

Title: Understanding the moral brain: a meta-analysis of regions involved in sociomoral processing using multilevel kernel density analysis and activation likelihood estimation

Authors: *S. J. FEDE[1,2], C. L. HARENSKI[2], K. A. KIEHL[1,2];
[1]Psychology, Univ. of New Mexico, Albuquerque, NM; [2]Mind Res. Network and Lovelace Biomed. and Envrn. Reserch Inst., Albuquerque, NM

Abstract: The neurobiology of moral cognition is a relatively young field. However, the literature has expanded considerably with more than 100 related publications on the topic. Although previous meta-analysis was conducted (Bzdok et al., 2012), the rapidly expanding body of literature merits follow-up to consider recent findings. Additionally, understanding differences in the meta-analytic procedures involved in Multilevel Kernel Density Analysis (MKDA) and Activation Likelihood Estimation (ALE) can inform not only the field of socioemotional decision making but cognitive neuroscience meta-analysis in general. Here, ALE and MKDA were used to conduct neuroimaging meta-analyses of the moral cognitive neuroscience literature. This meta-analysis included 1542 participants across 36 experiments. MKDA, but not ALE, replicated previous main effect findings of the neural correlates of moral cognition: the left amygdala, medial prefrontal cortex (mPFC), bilateral temporoparietal junction

(TPJ), and posterior cingulate (PCC). On the other hand ALE, but not MKDA, replicated findings in the temporal gyrus. These results provide support for the network of brain regions proposed in theories of moral emotion and cognition, but also indicate that the meta-analytical techniques of ALE and MKDA may not individually provide a complete picture of neuroimaging literature and should be interpreted cautiously on their own.

Title: Effect of cheering on functional connectivity between the player's and the observer's brain activity during a competitive game

Authors: *T. KOIDE, S. SHIMADA;
Meiji Univ., Kawasaki-Shi, Japan

Abstract: Mirror neuron system (MNS) is the brain region that is activated not only when performing an action by themselves, but also when observing the same action performed by others. In this study, we utilized functional near-infrared spectroscopy (fNIRS) hyperscanning technique to examine the functional connectivity between the player's and the observer's brain activity during a competitive game. Thirty-two pairs of male subjects participated in the experiment (aged 21.3 ± 1.6 years, mean ± SD). One of the subjects (the player) performed the rock-paper-scissors (RPS) game against the experimenter, and another (the observer) observed the player performing playing RPS game. We assigned half of the pairs to the cheering group in which the observer was instructed to cheer for the player during the RPS game and the other half to the control group in which the observer was instructed to judge whether the player performed RPS game with or without cheating. The experiment was repeated until more than 10 trials were obtained for each condition of outcome (WIN, LOSS and DRAW). The hemodynamic responses were assessed by using 48-ch fNIRS (OMM-3000, Shimadzu, Japan). The channels were divided to 24-ch each for the left hemisphere of each subjects (ch_p1 - ch_p24 for the player, ch_o1 - ch_o24 for the observer) which were placed on the left sensorimotor area (near C3 of international 10-20 system), a main component of the MNS. First, we employed general linear model (GLM) analysis on fNIRS data and found that the observer's MNS was located over the

premotor, the primary motor and the parietal cortices. We then applied the psychophysiological interaction (PPI) analysis and found that the functional connectivity between the player's premotor cortex and the observer's MNS was stronger in the cheering group than in the control group (ch_p2-ch_o7: $t(30) = 2.49$, $p < 0.05$, corrected; ch_p2-ch_o12: $t(30) = 2.19$, $p < 0.1$, corrected). Furthermore, functional connectivity between the player's premotor cortex (-20 -14 76) and the observer's parietal cortex (-32 -62 65) was correlated with the observer's feeling of the sense of unity with the player ($r = 0.590$, $p < 0.05$). These results suggest that cheering enhances the assimilation of the observer's internal motor state with that of the player during observation of a competitive game.

Title: Task and stimulus representation in face responsive cortex in autism spectrum disorder

Authors: *D. KLIEMANN, S. ANZELLOTTI, D. AYYASH, J. GABRIELI, R. SAXE; MIT, Cambridge, MA

Abstract: Understanding the neural basis of the social difficulties in Autism Spectrum Disorder (ASD) is essential to develop effective interventions, test their efficacy and predict individual treatment outcome. Cognitive neuroscience offers a key level of analysis towards this endeavor by bridging the gap between molecular and cellular mechanisms to the behavioral phenotype. One hallmark symptom in Autism Spectrum Disorder (ASD) is disproportionate social impairments, including difficulty processing information from emotional faces. Despite an enormous body of research on this matter, the neural basis for the affected behavior remains unclear with weak and conflicting results. Here, we present a new approach focusing on naturalistic dynamic social contexts with the goal of finding robust, replicable neural correlates of difficulties in social information processing in ASD that generalize across individuals and stimuli. We investigated whether information in patterns of neural responses to emotional faces

represent i) the valence of emotional facial expressions, ii) task of the subject and iii) the flexibility of neural patterns to task demands. In a pilot study, we measured blood-oxygen-level-dependent signal (BOLD) responses while neurotypical subjects watched short naturalistic movie clips of dynamic positive and negative facial expressions. For each movie clip, subjects were instructed to judge either the person's age or the valence of their emotional expression. Split-half multivoxel pattern analyses (MVPA) suggest that the task of the subject (attending to age vs emotion) could be robustly decoded from patterns in face-responsive regions (bilateral anterior and posterior superior temporal sulcus (STS), fusiform face area (FFA) and medial prefrontal cortex (MPFC)), independent of the stimulus. The property of the stimulus (valence of the facial emotion) was represented in STS and MPFC (replicating prior reports), however weaker than the task representation. Next, we compared patterns of neural responses in ASD (n = 17) versus neurotypical participants (n = 20) in a follow up study, and found evidence suggesting aberrant task representation in MPFC in ASD. Additionally, a region in right STS showed reduced flexibility in neural activity to task demands: while neurotypical participants showed increased valence decoding when judging emotion versus age of facial expressions, this modulation was absent in ASD. Our results suggest that atypical cortical representation of social information in ASD might reflect reduced neural flexibility of response patterns to optimally integrate task demands and perceptual input.

Title: Neural control strategies underlying human-human physical joint interaction for object manipulation

Authors: *K. MOJTAHEDI, J. FINE, M. SANTELLO;
Arizona State Univ., Tempe, AZ

Abstract: Research into the behavioral and neural foundations of social coordination have typically employed tasks, such as finger tapping, that focuses on visual or auditory coupling between actors. However, a large component of non-verbal social coordination involves physical

interaction. Furthermore, most studies have yielded mixed results when examining the distribution of roles, i.e., leader and follower, as there are no clear task manipulations that consistently result in individuals taking on particular roles. The current study aimed to further investigate how people self-organize into roles during physical interactions, and how these roles are reflected in each actor's neural dynamics. We examined how the EEG dynamics of leaders (or followers) differed when they are assigned that role or when it emerges naturally. The experiment involved two participants lifting and balancing a U-shaped object, using one hand each. Dyads of participants were either assigned to a group with either no a-priori role assignment (Human-Human; H-H group), or with one person being assigned a role (Leader-Follower; L-F group). Cortical activity was assessed using electroencephalography (EEG) recorded from both subjects. EEG activity was examined using time-frequency (wavelet) analyses to determine complementary patterns of brain activity in the H-H and L-F groups. Behavioral results revealed subjects naturally took on leader-follower roles in the H-H group. EEG results in frontal alpha band activity (11-14 Hz) showed a significant discrimination between leader and follower in both the H-H and L-F groups. These differences in frontal activity are likely driven by a tendency for leaders to exert more active control in action planning and corrective processes during coordination. We also found group differences in the low gamma band (30-35 Hz). Gamma band modulation was more pronounced over central areas for H-H dyads, whereas it was larger over frontal areas for L-F dyads. This result implies that being assigned a role versus taking it on naturally can have differential consequences in terms of what cortical areas are recruited. Overall, our results indicate that certain brain areas are commonly recruited in leaders and followers, whereas different areas are recruited pending how this role distribution was determined, i.e., assigned or emergent. *Key words: social coordination; physical interaction; leader and follower; object manipulation; sensorimotor control.*

Title: The role of the orbitofrontal cortex in regulation of interpersonal space: Evidence from lesions and intracranial recordings

Authors: *A. PERRY[1], J. STISO[1], C. DEWAR[1], J. LIN[2], R. T. KNIGHT[1];
[1]Univ. of California, Berkeley, Berkeley, CA; [2]Univ. of California, Irvine, Irvine, CA

Abstract: Interpersonal distance is central to communication and complex social behaviors but the neural correlates of interpersonal distance preferences are not defined. Previous studies suggest that damage to the orbitofrontal cortex (OFC) is associated with impaired interpersonal behavior. To examine whether the OFC is critical for maintaining appropriate interpersonal distance (IPD), we tested 8 patients with OFC damage in a real-world behavioral interpersonal distance task and compared them to healthy controls and to patients with lesions restricted to the lateral prefrontal cortex. Only patients with OFC damage showed abnormal interpersonal distance preferences. The comfortable distances these patients chose with strangers were closer than controls ($p < 0.005$) and resembled distances normally used only with close others. We then utilized the spatial and temporal advantages of intracranial cortical recordings to test when neuronal populations in the OFC are activated during an interpersonal distance computerized task. We tested 6 patients with intractable epilepsy, who had been implanted with electrode grids or depth electrodes over or in OFC for pre-operative monitoring using a computerized IPD task. Some patients had depth electrodes in additional regions of interest, such as the amygdala and insula. Increases in spectral power in the high frequency band range (HFB: 70-150 Hz) were used to index neuronal activation. Our results show complex patterns of HFB activation in the OFC, as well as in other limbic regions during the interpersonal distance task. Together, these studies provide evidence for a key role of the orbitofrontal cortex in regulating interpersonal behavior.

Title: Facial affect recognition in schizotypy using the n170 and n250 of the event-related potential

Authors: *J. MORALES, S. SARKISSIANS, J. ABARA, M. SERGI;
Psychology, California State Univ. Northridge, Northridge, CA

Abstract: Deficits in social cognition are consistently found in persons with schizophrenia. Neurocognitive studies of persons with schizophrenia and schizotypy suggest a wide range of deficits, including attention, working memory, emotion recognition, and response inhibition. Facial emotion recognition is a key aspect of social cognition. Schizophrenia is associated with impaired facial processing as observed in the N170 and N250. The N170 and N250 are two event-related potentials (ERPs) that have been studied in relation to face processing in schizophrenia. The N170 component relates to facial features encoding. Whereas, the N250 component relates to affect decoding.

There has been little research on facial affect recognition in psychosis-prone or persons with schizotypy. Schizotypy is conceptualized as a subclinical manifestation of the same biological factors that give rise to schizophrenia and other schizophrenia spectrum disorders. Examining emotion recognition in schizotypy eliminates many confounds associated with schizophrenia research such as medication effects, social isolation, chronic hospitalization, and generalized cognitive deficits. This grants the examination of whether emotion recognition deficits reflect susceptibility to schizophrenia.

Electroencephalography studies of schizophrenia and schizotypy have yielded varied results on the N170 and N250. The aim of this study was to examine affect decoding and encoding in controls (low) and psychometric schizotypes (high) using the N170 and N250 components. For the present study, participants were screened utilizing the Schizotypal Personality Questionnaire-Brief and given an emotion recognition continuous performance task (CPT) utilizing Ekman's emotional facial expressions. ERPs were recorded while participants performed a computer-administered visual Happy-Happy CPT. The ERP waveform for fear emotion was evaluated, in which the N170 and N250 were identified.

This study hypothesized differences between controls and schizotypes on the amplitude of the N170 and of the N250. Repeated measures analysis of the amplitude for the N170 and for the N250 yielded no significant difference between controls and schizotypes, $F(1,12) = .79$, $p = .391$. Controls and schizotypes do not differ in early stages of facial affect recognition. This finding suggests that schizotypes produced similar neural activation patterns for facial features encoding and affect decoding as those produced in controls.

Title: Cortical activity during others' preference estimation

Authors: ***J. PARK**[1], S.-P. KIM[1], J.-W. SOHN[2];
[1]UNIST, Ulsan, Korea, Republic of; [2]Daegu-Gyeongbuk Med. Innovation Fndn., Daegu, Korea, Republic of

Abstract: Humans often attempt to predict what others prefer in social interactions. As one of the theoretical bases for how humans can predict the preference of others, perspective taking highlights the human ability of inhibiting one's own preference while estimating emotions or thoughts of others from their point of view. Previous neuroimaging studies have revealed that the network of dorsal medial prefrontal cortex (dmPFC) and right temporoparietal junction (rTPJ) is related to the ability of predicting others' preference. However, it remains unknown whether cortical brain oscillations also play a role in prediction of others' preference. In particular, brain oscillations that are modulated differently when people report their own preference and predict the preference of others would suggest a neural basis for the perspective taking process. To investigate the role of the brain oscillations in perspective taking process, we carried out human experiments in which information of other's preference is minimally available while measuring subject's electroencephalography (EEG). Twenty participants (all female, average age: 21.86) conducted the task of predicting the preference of others while only a facial picture of other's is given. In each trial of the task, participants were shown a picture of others or self for three seconds, followed by the presentation of a movie poster at which participants estimated preference as liking or disliking. A time-frequency analysis was used to analyze temporal changes of the power of brain oscillations. Participants could predict others' preference for movies with accuracy of 56.89 ± 3.16 % and ten out of twenty participants exhibited prediction accuracy higher than a chance level (95% interval, permutation test). There was a significant difference in the power of the right parietal alpha (9~14Hz) oscillation when participants reported self preference and predicted others' preference ($p < 0.05$). The power of the left temporal beta (18~25Hz) oscillation (0~0.5 s after the onset of poster presentation) for all the trials was significantly but marginally correlated with individual prediction accuracy of participants ($r^2 = 0.2903$). In contrast, beta power ratios between the trials of predicting other's preference and reporting self preference showed a much higher correlation with individual accuracy ($r^2 = 0.7857$), indicating that left temporal beta oscillations may reflect the ability of taking other's perspective while suppressing self preference. Our results suggest that right parietal alpha and left temporal beta oscillations may be correlated with one's perspective taking ability to predict what others prefer.

Title: Disruptions in connectivity to frontal theory of mind networks underlies deficits in naturalistic social cognition in schizophrenia

Authors: *G. H. PATEL[1], S. ARKIN[1], N. STRAUSS[1], H. M. DE BAUN[1], C. C. KLIM[1], R. BERMAN[2], D. LEOPOLD[2], D. C. JAVITT[1];
[1]Columbia Univ., New York, NY; [2]Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Introduction: Deficits in social cognition are a major cause of psychosocial disability in schizophrenia patients (SzP). Major components of social cognition include the detection and use of facial affect information to understand the intentions of others. Underlying these operations are visual processing areas, face processing areas, attention networks, and theory of mind networks. SzP have been shown to be impaired in potentially all three networks, especially in dynamic situations. This study investigates the neural and cognitive bases of poor social cognition by tracking eye-movements during a naturalistic social cognition task along with resting-state functional connectivity in SzP vs. healthy controls (HC).
Methods: 18 SzP and 18 HC both performed The Awareness of Social Inference Test (TASIT) with eye-tracking, which involves answering questions about short video clips of social situations, and also underwent both resting-state and task functional magnetic resonance imaging (fMRI). For each subject, the distance of eye-position from the mean position of the HC on each video frame was averaged across frames (HC eye-position was compared to mean of all other HC). Task fMRI data were used to localize the visual, face-processing, attention network, and theory of mind areas, which were then used to calculate interareal connectivity at rest. Connectivity was then correlated with performance on TASIT.
Results: SzP performed worse in answering questions about TASIT videos involving sarcasm vs. lies. Sarcasm performance also correlated with the percentage of time spent within 2 standard deviations of the mean eye-position of HC (r=.35). In HC, performance on TASIT sarcasm

videos was significantly correlated with the connectivity within and between visual and attention areas, whereas in SzP performance significantly correlated with connectivity of visual, face-processing, and attention areas with frontal theory of mind areas.
Conclusions: This study demonstrates the utility of using naturalistic stimuli to study social cognition deficits in Sz and related psychiatric disorders. The difference in eye-tracking patterns may reflect impaired orientation to socially relevant features of the environment and/or impaired interpretation of these features. The functional connectivity-performance correlations indicate that connectivity to theory of mind areas underlies these deficits.

Title: Naturalistic viewing and neuronal signatures in a ketamine model of schizophrenia

Authors: *R. A. BERMAN[1], G. H. PATEL[2,3], D. C. JAVITT[2,4], D. A. LEOPOLD[1];
[1]Lab. of Neuropsychology, Natl. Inst. of Mental Hlth., Bethesda, MD; [2]Columbia Univ., New York City, NY; [3]New York State Psychiatric Hosp., New York City, NY; [4]Nathan Kline Inst. for Psychiatric Res., Orangeburg, NY

Abstract: To navigate the social world successfully, primates rely on dynamic visual cues that convey critical information about actions, intentions, and emotions. Studies of schizophrenic patients suggest that impairments in dynamic perception may contribute to the cognitive and social deficits that are central to the disease (Butler et al. 2009, Martinez et al 2012). In the present study, we investigated the neural mechanisms of dynamic visual perception in the macaque, using a free-viewing paradigm and naturalistic videos to measure gaze behavior and accompanying neuronal activity in a ketamine model of schizophrenia. Monkeys freely viewed a series of five-minute nature videos, which were either "social movies" featuring macaque monkeys engaged in social interactions, or "non-social movies" featuring natural scenes with no animals present (Russ et al. 2015). Monkeys viewed the same set of social and non-social movies

multiple times, both under control conditions and after systemic administration of subanesthetic doses of the NMDA antagonist ketamine (0.25-1.0mg/kg). We measured eye movement behavior and additionally recorded the activity of neurons in the anterior fundus face patch (AF) using specialized chronic microwire bundles that permit longitudinal recording from single cells. As recently reported by our laboratory (McMahon et al. 2015), neurons in AF are reliably driven during free-viewing of the movie stimuli, with each cell exhibiting a unique, signature response across repeated viewings of given movie. This property allowed us to monitor neuronal responses to the dynamic movies across many days and across conditions (control and ketamine). Behavioral analysis of eye movement data showed an increase in fixational drift after ketamine injection, but monkeys nonetheless continued to direct gaze to the content of the movies, suggesting that ketamine did not strongly affect the overall pattern of movie viewing. By contrast, the responses of single AF neurons were often altered by ketamine administration, with an effect that depended on the type of movie stimulus (social or non-social). Specifically, we found that ketamine caused a decrease in neuronal responses during the social movies, whereas responses to non-social movie stimuli were slightly increased under ketamine conditions. These results indicate that the encoding of biological stimuli may be particularly affected by ketamine administration, and suggest that dynamic paradigms will be an important tool for delineating the neural bases of perceptual deficits in schizophrenia.

Title: Engagement of visual, face,, attention, and theory of mind areas in schizophrenia during naturalistic viewing

Authors: *S. ARKIN[1], C. C. KLIM[2], R. BERMAN[3], D. LEOPOLD[3], D. C. JAVITT[2], G. H. PATEL[2];

Abstract: Introduction: Deficits in social cognition are a major cause of psychosocial disability in schizophrenia patients (SzP). A major component of social cognition is social communication, which requires the engagement of multiple networks, including those underlying visual processing, face processing, control of attention, and theory of mind operations. Separate studies of SzP have demonstrated potential deficits in all four networks, but it remains unclear whether a deficit in one network propagates to the other networks or the functioning of all four networks is deficient. To study this, we recorded brain activity evoked by the watching of a cinematic movie in SzP vs. healthy controls (HC) to determine which networks were deficient.
Methods: 11 SzP and 6 HC underwent functional magnetic resonance imaging (fMRI) while watching 15 minutes of a cinematic movie ("The Good, the Bad, and the Ugly"), as well as resting state and task fMRI. Task fMRI data were used to localize the visual, face-processing, attention network, and theory of mind areas. The timecourse for each voxel of BOLD activity evoked in each subject by the movie was correlated with the average timecourse of the HC (inter-subject synchronization; each HC correlated with average all other HC). Resting state data was used to calculate interareal correlation of activity at rest, which was then compared to the resting state data from 500 subjects collected in the Human Connectome Project.
Results: Visual, ventral-stream face-processing, and attention areas were strongly synchronized in both groups. Contrasting the SzP and HC maps revealed that HC demonstrated significantly more synchronization of middle and posterior superior temporal sulcus (STS) and both dorsomedial and lateral frontal areas, overlapping with face-processing networks and frontal theory of mind areas. SzP had more synchronization of posterior cingulate, angular gyrus, and parts of ventromedial frontal cortex, corresponding to the default mode network. Resting state functional connectivity analyses found that middle and posterior STS areas are functionally connected with each other and with the frontal areas.
Conclusions: This study demonstrates the utility of naturalistic viewing paradigms to simultaneously evaluate the functioning of multiple networks in Sz and other neuropsychiatric disorders. We find that visual processing and attention areas are equally engaged in SzP and HC in viewing of the movie, while face-processing and theory of mind network areas fail to be engaged in SzP. Pairing these findings with resting state functional connectivity reveals potential connectivity deficits that may underlie this failure.

Title: Characterizing mentalizing processes during cooperative decisions using EEG-hyperscanning

Authors: *T. RUSCH[1], M. SPEZIO[3], J. P. GLÄSCHER[2];
[1]Systems Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [2]Systems Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamurg, Germany; [3]Psychology, Scripps Col., Claremont, CA

Abstract: Theory of Mind and mentalizing capacities are classically examined with the so called "False Belief Task". We transferred this task's basic concept into the realm of social decision making to investigate how people predict other agents' behavior during value guided choices. Two individuals engage in a simple choice task, in which probabilistic outcomes that also depend on the partner's choice have to be learned. Cooperative choices are highly rewarded. After periods of successful cooperation one player's (Learner's) outcome distribution is reversed, but only the other player (Teacher) is informed about the reversal. The Learner thus has a false belief about the state of the world. To maximize the reward, the Teacher must track how the Learner's false belief evolves over time and make choices to "communicate" the contingency switch to the Learner. The Learner on the other hand needs to detect and recognize the Teacher's incentive to react accordingly. On each trial both players make explicit predictions of their partner's choices before making their own. Throughout the course of the task both players need to act as Teacher and Learner an equal number of times. Furthermore, EEG is continuously recorded from both players synchronously while they engage in the interactive task. Continuous choice behavior and low RTs during periods of successful cooperation suggest, that the players rely on in the learning period established beliefs about the state of the world and the partner's belief. However, after a reversal the Teacher initially predicts unchanged behavior for the Learner in line with the Learners' false belief. Nevertheless, he/she switches his/her own choice. On the one hand, the Teacher's choice switch assures a maximal possible outcome for both players given the Learner's false belief, on the other hand, it informs the Learner about the contingency switch. The Learner detects the Teacher-signal and adapt his/her predictions about the Teacher's choices accordingly. After accumulating enough evidence the Learner reacts to the new reward distribution and adjust his/her choice. The Teacher accurately predicts the learning curve and matches his/her own choices. Increased mentalizing processes required when acting as

Teacher or Learner in comparison to periods of stable cooperation are reflected in decreased theta, alpha as well as beta power. The interactive nature of the task, the necessity to track and incorporate the partners beliefs into the own decision making process and continuous EEG Hyperscanning allow the examination of mentalizing processes on a behavioral and neuronal level in an ecologically valid setting.

Title: Food-related symptoms in autism are related to aberrant gustatory cortex intrinsic functional connectivity

Authors: *M. A. COLLINS[1], S. C. MILLEVILLE[1], S. E. WOHLTJEN[1], J. E. INGEHOLM[1], G. L. WALLACE[2], W. K. SIMMONS[3], S. J. GOTTS[1], A. MARTIN[1];
[1]NIMH, NIH, Bethesda, MD; [2]Dept. of Speech and Hearing Sci., George Washington Univ., Washington DC, DC; [3]Laureate Inst. for Brain Res., Tulsa, OK

Abstract: Abnormal sensory processing is a well-established characteristic of autism spectrum disorder (ASD). Aberrant food selectivity and gustatory sensations are clinically relevant features of ASD, yet the neural bases of these phenomena are largely unknown. In a previous report on neural responses to gustatory stimulation and pictures of appetizing food in typically developing (TD) subjects we identified three critical areas in insula cortex; the left and right mid-dorsal insula and the left anterior insula (Simmons et al., 2013). In the current study we used these regions as seeds in an analysis of resting state fMRI scans to look for differences in neurocircuitry between ASD subjects without intellectual disability (N = 50, mean age: 19.2 ± 8.5, IQ: 112±14.7) and TD subjects (N = 45, mean age: 18.2 ± 3.4, IQ: 116 ± 10.7) matched on age, sex, IQ, and head motion. All ASD subjects met standard clinical and research diagnostic criteria and all subjects completed the Adolescent/Adult Sensory Profile, which contains a number of questions addressing food preferences. Each insula seed region was associated with widespread reductions in correlation for the ASD, relative to the TD subjects in regions typically associated with social processing including the right STS, right post-central gyrus, pre-central and superior frontal gyri bilaterally, and right cingulate cortex ($p<0.05$, FDR corrected). Abnormally increased connectivity between the thalamus and all three seed regions was also observed ($p<0.05$, FDR corrected). Preliminary analyses indicate that similar reductions in seed-

based connectivity are significantly related to increased food-related symptoms ($p<0.01$) in ASD. These findings suggest that reduced connectivity between the insula and other brain regions may underpin food-related symptomatology in ASD.

Title: Discriminating between sarcasm and lying using neural correlates from the amygdala and cingulate cortex

Authors: *Y. PATHAK[1], E. H. SMITH[1], S. SINHA[2], G. M. MCKHANN, II[1], S. A. SHETH[1]; [1]Neurolog. Surgery, Columbia Univ., New York, NY; [2]Neurosurg., Rutgers Robert Wood Johnson Med. Sch., New Brunswick, NJ

Abstract: Emotional recognition is an important aspect of social cognition and allows us to cultivate interpersonal relationships and navigate social contexts. Complex semantic constructs communicated through language such as sarcasm are uniquely human. Deficits in identifying these stimuli are associated with neurological and psychiatric disorders, including autism and psychosis. The socio-emotional network, delineated through lesion studies and neuroimaging, includes the limbic system, facial processing system and mirror-neuron network. Major nodes of these systems include amygdala, anterior cingulate cortex (ACC), prefrontal cortices and hippocampus. The role of the amygdala in identifying faces and emotional valence is well established. The ACC has known involvement in cognitive control and conflict. In this study, we propose that sarcasm represents a level of semantic conflict since the verbal and non-verbal communication is incongruent. Therefore, we hypothesize that neural data from the amygdala and the ACC can be used to classify between sarcastic cues and lying.
We analyzed local field potentials (LFPs) recorded from depth electrodes implanted to monitor epilepsy patients. Specifically, we recorded from the amygdala and the ACC while 4 subjects were engaged in The Awareness of Social Interference Test (TASIT), a task designed to examine social perception and emotional recognition. Power spectral density (PSD) was computed based on subject-perceived condition using the multi-taper method. We also implemented a linear discriminant analysis (LDA) to classify between the perception of lying and sarcasm. Data from all four subjects were combined to increase the power of our analysis. We trained on 74% (68

trials) of the dataset and used z-scored spectrograms from the last 10 seconds of each trial as our classification feature. The remaining 26% (24 trials) of the data was used as the test set.
For both trial types, we observed an increase in theta power (4-7 Hz) at the amygdalar contacts and an increase in theta and alpha power (8-12 Hz) at the ACC contacts compared to baseline. The maximum prediction accuracy of identifying sarcasm versus lying from the LDA classification was 67% for the amygdala and 63% for the ACC.
The results confirm that the amygdala and the ACC play a significant role in discerning complex semantic constructs in human language. Classification features tested in this study could serve as potential inputs for closed-loop systems designed to treat conditions such as autism. Further work will examine other emotional conditions, as well as field-field and spike-field coherence within and between amygdala and ACC.

Title: Common neural substrates of initiator and responder in spatial and feature-based joint attention: a hyperscanning fMRI study

Authors: A. YOSHIOKA[1], T. KOIKE[2], E. NAKAGAWA[2], M. SUMIYA[2], S. OKAZAKI[2], N. SADATO[2], *H. C. TANABE[1];
[1]Nagoya Univ. Grad. Sch. of Envrn. Studies, Nagoya, Aichi, Japan; [2]Natl. Inst. for Physiological Sci., Okazaki, Aichi, Japan

Abstract: Joint attention (JA) is the ability to coordinate and share attention between two persons regarding objects. In a dyad, one person initiates JA (IJA) while the other respond to a JA bid (RJA). It seems important issue to underpin the core neural substrate of initiative and responding to JA bid. In the previous studies, however, the gaze-related brain activity was contaminated because the task has to use spatial attention. To overcome this problem, we

developed a feature-based JA task. Here, we explore the core neural substrates of initiative and responding to JA using spatial-based and feature-based JA task during a real interactive hyperscanning functional magnetic resonance imaging (fMRI). Twenty-two pairs (44 volunteers) were participated in the fMRI study. In the feature-based JA task, stimuli were constructed with 4 DIMENSIONS such as number, shape, color, and pattern. Each stimulus has one of 4 CHARACTERS in each dimension. The initiator freely chose one of 4 DIMENSIONS of the stimulus and informed it by utterance (IJA) during 2 sec silent period. Immediately after the initiator's direction, the responder attended the same dimension of the object and identified a CHARACTER of this dimension (RJA). In the next scan period, the responder answered the character of this designated dimension during the 2 sec silent period. The initiator judged whether the answer is correct or not immediately and feedback verbally in the same period. The results showed that common IJA regions in both feature-based and spatial JA were anterior cingulate cortex (ACC) expanding to caudal medial prefrontal cortex (MPFC), striatum, right cerebellar hemisphere Crus II, whereas common RJA regions were bilateral superior temporal sulcus/gyrus, rostro-medial MPFC, posterior MPFC, and bilateral anterior cerebellum IX. As for the response and feedback period, the anterior to middle cingulate cortex, bilateral putamen, amygdala, superior temporal region, supramarginal gyrus, premotor cortex, and right inferior frontal gyrus were commonly activated in all four conditions. To take our previous results into account, ACC and superior temporal region seems to be the important region in IJA and RJA, respectively.

Albuquerque, NM; [5]MGH/MIT AA Martinos Ctr. Biomed. Imaging, Massachusetts Gen. Hosp., Boston, MA

Abstract: Introduction: Children with autism spectrum disorders (ASD) and their unaffected siblings (US) are frequent targets of social bullying, which leads to severe cognitive, emotional and social consequences. Understanding the risk factors is essential for developing preventative measures. Discriminating different biological body movements (BBM) requires fast and flexible processing and interpretation of visual cues. As previously reported, children with ASD show difficulties in tasks with BBM. Since US show an autism trait endophenotype we expect that they will also display BBM deficits. We investigate whether their deficits relate to simple visual-spatial perception, interpretation of social intentions expressed in BBM, or selection/execution of behavioral responses. **Methods**: *Participants*: 8 US, 8 matched TD children age 7-14; *Tasks/Measurements*: Blue Man Test (BMT, Ciesielski, 2007), visual-spatial N-Back stop-response task (accuracy, RTs, ERPs); Social BMT for Narrative Interpretation of social cues and intentions expressed by BBM of BMT; analysis of narratives with a latent Dirichlet allocation [LDA]); Neuropsychological Test Battery; Social Experience Questionnaires with children and parents. **Results**: As compared to TD the US displayed: (i) Prolonged RTs in visual identification of complex figures and BBM stimuli, but not in simple visual-spatial perception; (ii) Low self-awareness of social bullying in contrast to high parental reports; (iii) Lower quality and repetitious words in social interaction narratives (LDA); (iv) Abnormally reduced amplitude of ERPs P300, a physiological marker of decision making/memory update, despite high accuracy of performance on the visual-spatial BMT. **Conclusions**: The abnormally prolonged visual information processing of complex visual information in US group may be at the foundation of difficulty in interpretation of fast social cues from peers leading to poor awareness that a bullying act has occurred and to less flexibility of words to describe it. The ERP P300 component may elucidate the neural basis of the prolonged complex visual processing and suggest novel preventative measures.

Title: Neural integration of costs and outcomes in evaluations of prosocial actions

Authors: *N. VELEZ, H. GWEON;
Stanford Dept. of Psychology, Stanford, CA

Abstract: The ability to evaluate other people's actions is critical for deciding whom to trust, befriend, or ask for help. Such evaluations rely on the benefits accrued from others' actions, but this is not the only relevant factor; for example, if a stranger holds a door open for you, you might think that they are being helpful, even if they were mistaken and don't provide any real benefit. Thus, evaluations of others' actions are driven not only by the external outcomes (value) of the action, but also by the intentions behind it, which can often be gleaned from the cost incurred by the actor.

The present work investigates neural signals involved in evaluation of prosocial actions within two networks of brain regions. First, we explored brain regions that are recruited when reasoning about other people's mental states, including medial prefrontal cortex (MPFC) and the temporoparietal junction (TPJ). Second, we examined neural populations involved in the anticipation and evaluation of rewards—including social rewards—such as the striatum and subregions in the MPFC. We asked whether distinct neural populations encode the *cost* and *outcome* of others' actions, and what neural populations might be involved in integrating cost and outcome to form social evaluations.

In an fMRI study, we presented 18 participants with 48 stories in which one character gave a gift to another character. In each story, we orthogonally varied the *cost* of the gift (i.e., the difficulty of obtaining the gift), and the *outcome* (i.e., whether the recipient liked it). After each story, participants were asked how much *praise* the giver deserved.

We found separable neural signals that reflected the *cost* and *outcome* of the giver's actions: activity in a subregion of the striatum reflected cost, while patterns of activation within dorsal MPFC distinguished between positive and negative outcomes. Critically, neural activity in ventral MPFC showed a positive correlation with participants' ratings of praiseworthiness. Our results suggest that brain regions that have been traditionally implicated in mentalizing and reward processing contribute to forming evaluations of other people's actions. Further work will systematically examine how neural representations of outcomes and costs are integrated in vMPFC.

Title: Socially anxious tendency affects discrimination of emotions in other's gaze

Authors: *Y. TSUJI, S. SHIMADA;
Meiji Univ., Kawasaki Kanagawa, Japan

Abstract: Socially anxious tendency is considered as a potential for social anxiety disorder (SAD), which is characterized by excessive fear to a social situation associated with being evaluated or embarrassed by others. Especially, gaze of others is known to frequently induce social anxiety. Here we employed an other's gaze emotion discrimination task to examine the effect of socially anxious tendencies on social cognition. We generated emotionally ambiguous gazes by employing a morphing technique (neutral, disgust 10-100% in 10% steps, and happy 10-100% gazes). Subjects were required to judge whether the stimulus was positive or negative. Seventeen male adult subjects (aged 21.2 ± 1.35, mean ± SD) participated in the study. Two subjects were excluded from analysis because they did not correctly perform the experiment. The participant's level of social anxiety was examined by means of the Japanese version of the Social Phobia Inventory (SPIN-J). The SPIN-J is a 17-item questionnaire, each rated on a 5-point Likert-type scale. The total score of SPIN-J ranges from 0 to 68, and the clinical cut-off point is at 30. The SPIN-J is designed to measure three symptom dimensions: fear, avoidance, and physiological arousal. The subjects were assigned to the high (HSA: n = 9) or low socially anxious tendency groups (LSA: n = 6) on the basis of clinical cut-off point. To examine the differences in judgment between the LSA and HSA groups, logistic curves were fitted to the subject's response function in the emotion discrimination task. We estimated the point of subjective equality (PSE) from the logistic curve where positive and negative judgment probabilities are equal (50%). The mean PSE in the HSA group (disgust = 14 ± 8.3%, mean ± SE) was significantly smaller than that in the LSA group (disgust = 30 ± 11%) (Wilcoxon's Rank Sum Test: $Z = 1.77$, $p < 0.05$). We also found a negative correlation between the score of the avoidance, which is a subscale of SPIN-J, and PSE (correlation coefficient $\rho = -0.64$, $p < 0.01$). These results suggest that highly socially anxious subjects have a tendency to recognize ambiguous emotional gazes as negative.

Title: An fNIRS study of cooperativeness during synchronized tapping task

Authors: *A. MURAKAMI, H. YOKOUCHI, S. HIWA, T. HIROYASU;
Doshisha Univ., Kyotanabe-shi, Japan

Abstract: [Introduction] Communication is an important process for our human beings. Especially, the ability to behave in adapting to others' feelings and willingness is referred to as cooperativeness. Higher cooperativeness allows us to communicate with others better and understand each other easier. Cooperativeness varies between different people, and the brain activities when we have an interaction with others have not been investigated well. If the relation between cooperativeness and the brain activities would be revealed, it may help diagnosis and treatment of communication disorders. Our goal of this study is to examine human brain activity during cooperative work. In this paper, we investigated the brain activity during human-machine cooperative work as a preliminary study for human-human cooperative work. We discussed how human processed the information from others and determined their behaviors. [Method] Cooperativeness is often associated with synchronization with others. Therefore, a synchronized tapping task between a subject and a machine has been applied to investigate a mechanism of human predictive behavior for synchronization. In this task, the subject attempted to synchronize a button press with an auditory stimulus. The stimulus intervals were periodically changed. Sixteen healthy male subjects participated in this experiment, and their cerebral blood flow changes were measured using functional near-infrared spectroscopy (Hitachi ETG-7100). Furthermore, social skills of the subjects were evaluated using a questionnaire called KiSS-18. [Result & Discussion] We analyzed their task performances using synchronization error (SE) calculated by a time difference between auditory stimulus and tap interval. The average of time-course SE of all subjects indicated that they could adapt to the change of rhythm within a few times of tapping. From the data of blood flow changes, regions which were activated among over 80 percent of subject were the DLPFC in frontal region and the angular gyrus in left temporal region. The subjects were divided into high-performance (3 subjects) and low-performance (3 subjects) groups based on KiSS-18 scores, and the activated regions differed between the groups. When the rhythm of a stimulus is changed, people attempt to adjust timing to the changed rhythm. It is reported that the angular gyrus has the function of recognition and the DLPFC have the function of behavior control. Our results suggest that the subjects recognized the change of rhythm and controlled behavior of tapping to adjust timing to the changed rhythm. [Conclusion] It was suggested that cooperativeness could be associated with DLPFC and angular gyrus.

Title: Visual erotic stimulation: different cerebral responses in homosexual and heterosexual men

Authors: *C. GÓMEZ[1], C. AMEZCUA-GUTIÉRREZ[1], M. HERNÁNDEZ-GONZÁLEZ[2], M. A. GUEVARA[2];
[1]Inst. De Neurociencias, Guadalajara, Mexico; [2]Inst. de Neurociencias, Guadalajara, Mexico

Abstract: Visual stimuli with sexual content have been widely-used to induce a state of sexual arousal that is associated with psycho-physiological reactions and the activation of different brain areas, including the prefrontal and parietal cortex, which are involved in detecting and processing stimuli. In humans, a whole range of individual, social and cultural factors -for example, sexual preference- affect the perception of, and responses to, sexual or erotic stimulation. Given this background, the aim of this work was to determine the functioning of these cortical areas in homosexual and heterosexual men during observation of visual stimuli with sexual content. The study included 20 healthy men, 10 homosexual and 10 heterosexual, aged 18-30 years. Their electroencephalographic activity (EEG) was recorded for 3 minutes at rest and then while observing a video with erotic content (5 min) or a neutral video (5 min). Absolute power (AP) was analyzed in the frontopolar (Fp1, Fp2), frontal (F3, F4) and parietal (P3, P4) cortices for the following EEG bands: delta (1-3.5 Hz), theta (4-7.75 Hz), alpha1 (8-10.5 Hz), alpha2 (11-13.5 Hz), beta1 (14-19.5 Hz), beta2 (20-30 Hz), and gamma (31-50 Hz). A sexual arousal scale was applied to measure the responses of all subjects after each video. Although all subjects, heterosexual and homosexual, reported only mild subjective sexual arousal, it was sufficient to induce changes in cerebral functionality. During both videos, the heterosexual group presented a lower theta AP in parietal areas and, like the homosexual men, a decrease of alpha in almost all derivations. While watching both videos, the homosexual men presented a higher theta AP at F2, whereas viewing the erotic video generated higher AP in beta2 and gamma at F3. These data show that during a state of moderate sexual arousal, the functionality of frontopolar, frontal and parietal areas varied depending on sexual preference. The results of this study can contribute to a better understanding of the cortical functionality that

underlies differential processing and assigning of incentive value to stimuli in homosexual and heterosexual men during sexual arousal.

Title: Preclinical characterization of SUVN-1507035 with multimodal activity alleviating psychosis and depression in preclinical models

Authors: ***N. MUDDANA**, R. SUBRAMANIAN, S. EDULA, S. PETLU, S. YATHAVAKILLA, R. ABRAHAM, P. JAYARAJAN, R. PALACHARLA, J. THENTU, R. DYAVARASHETTY, H. KALYANI, A. MOHAMMED, S. RAVELLA, R. NIROGI; Suven Life Sci., Hyderabad, India

Abstract: Psychosis such as schizophrenia is a debilitating disease. Most patients undergoing treatment for psychosis are often not socially productive. The currently marketed atypical as well as typical antipsychotics drugs (APD) have a number of draw backs with respect to efficacy and safety profile. APD are not successful in addressing the various domains of schizophrenia. SUVN-1507035 is one of our multimodal molecules having affinity for 5-HT/dopamine receptors. SUVN-1507035 was assessed in the conditioned avoidance response for efficacy. SUVN-1507035 was also assessed in the open field using two different classes of psychomimetics, MK-801 (NMDA antagonist) and amphetamine (Dopaminergic agonist). The antidepressant like activity of SUVN-1507035 was assessed using the differential rReinforcement at low rate 72s (DRL-72s). SUVN-1507035 was tested for its effect on dopamine synthesis rate in reserpinized rats. The safety profile of SUVN-1507035 was investigated using rotarod and the catalepsy assay. SUVN-1507035 was found to have the characteristic response of antipsychotics in the conditioned avoidance response. It reversed hyperlocomotor activity induced by both MK-801 and amphetamine. It also showed antidepressant like activity in the DRL-72s. SUVN-1507035 decreased the dopamine synthesis rate indicating agonistic activity at dopamine receptor in vivo. The efficacy doses were devoid of motor impairment as observed from the rotarod and catalepsy assays, i.e., a separation between the doses which produced efficacy and side effects. SUVN-1507035 is a promising new molecule for the treatment of schizophrenia and associated comorbid disorders.

Title: Pharmacologic augmentation of cognitive training (PACT): Amphetamine enhances gains in auditory discrimination training in adult schizophrenia patients

Authors: ***N. R. SWERDLOW**[1], M. TARASENKO[1], S. G. BHAKTA[1], J. A. TALLEDO[1], A. I. ALVAREZ[1], E. L. HUGHES[1], B. K. RANA[1], S. VINOGRADOV[2], G. A. LIGHT[1]; [1]UCSD Sch. of Medicine, Dept of Psychiatry, LA Jolla, CA; [2]UC San Francisco, Dept of Psychiatry, San Francisco, CA

Abstract: Background: Targeted cognitive training (TCT) of auditory processing drives improvements in higher-order cognition in schizophrenia (SZ) patients. Gains in TCT

performance can be detected after one session of training. We assessed a pharmacological augmentation of cognitive training (PACT) strategy by testing if the psychostimulant, amphetamine, augments TCT gains in auditory processing speed (APS) in SZ patients and healthy subjects (HS).
Methods: Carefully characterized HS and SZ patients were tested in a screening session (test 1: no pill), followed by a double-blind balanced crossover design (tests 2-3), comparing placebo (PBO) vs. 10 mg of AMPH (1 week between tests). On each test day, 1-h of Posit Science "Sound Sweeps" training was bracketed by 2-4 min pre- and post-training assessments of APS. Training consisted of a speeded auditory time-order judgment task of two successive frequency modulation (FM) sweeps. Screen day testing also included measures of acoustic startle prepulse inhibition (PPI), and event-related potentials (ERPs).
Results: Baseline performance (APS, trials completed) was impaired in patients vs. HS. Auditory system "learning" (APS post- vs. pre-training) was enhanced by AMPH, and this effect tended to be more robust in patients than in HS. Greater sensitivity to AMPH-enhanced learning was associated with higher screening levels of PPI and shorter P3a latency, but not with ERP measures of mismatch negativity or P3a amplitude, or with a list of clinical, demographic or physiological variables, including the rs4680 polymorphism of catechol O-methyl transferase. AMPH-enhanced APS learning in patients was not "state-dependent".
Discussion: AMPH enhances auditory discrimination learning in SZ patients, most likely via an enhancement of intact brain mechanisms in the service of the attentional demands of training. Sensitivity to these effects of AMPH was associated with higher screening levels of PPI and faster P3a latency, potentially reflecting more intact forebrain circuitry; these measures might serve as biomarkers to identify sensitive clinical populations. We do not know whether gains in APS observed in patients after 1-h of TCT predict clinical benefits after a full course of 30-50 h of auditory system exercises. If AMPH can enhance or accelerate the therapeutic effects of TCT, this "PACT" approach could represent a transformative treatment paradigm for SZ.

Sch. of Med., Matsumoto, Japan; [8]United Centers for Advanced Res. and Translational Med. (ART), Tohoku Univ. Grad. Sch. of Med., Sendai, Japan

Abstract: Objective: The aim of this clinical trial was to obtain a proof of concept whether high dose pyridoxamine, one of the three forms of vitamin B6, would be a novel treatment for schizophrenia with enhanced carbonyl stress. Method: 10 Japanese schizophrenic patients with high plasma pentosidine that is representative biomarker of enhanced carbonyl stress were recruited in a 24 week, open trial. High dose pyridoxamine ranging from 1200mg to 2400 mg per a day was administered on the present anti-psychotic regimen. Positive and Negative Syndrome Scale (PANSS) and Brief Psychiatric Rating Scale (BPRS) were conducted as efficacy assessments. We also performed Drug Induced Extra-Pyramidal Symptoms Scale (DIEPSS) and Columbia Suicide Severity Rating Scale (C-SSRS) as safety assessment, respectively. Result: As one patient dropped out of the trial due to physical exacerbation, 9 patients completed the trial. Mean decrease rate of plasma pentosidine levels were 26.8% and mean rate of improvement regarding PANSS and BPRS were 8.1% and 10.8%, respectively. Two patients were markedly improved in their psychological symptoms. One patient who harbor frameshift mutation in Glyoxalase 1 (GLO1), which means genetically vulnerable to carbonyl stress, also showed considerable improvement of psychosis accompanied with moderate decrease of plasma pentosidine levels. Additionally, some patients demonstrated improvement of rapport and emotional expression. More than 20% reduction in the assessment scale of drug induced Parkinsonism were found in four patients. Although there are no severe suicide related idea or

behavior, Wernicke's encephalopathy-like adverse drug reactions occurred in two patients followed with completely recovery by thiamine supplementation. Conclusion: High dose pyridoxamine add-on treatment was, at least in part, effective for subpopulation of schizophrenic patients with enhanced carbonyl stress. However it also caused Wernicke's encephalopathy-like adverse drug reactions. Further placebo controlled, randomized trial with careful monitoring will be required to validate the efficacy of pyridoxamine for these patients.

Title: Juvenile treatment with mGluR2 3 agonist LY379268 ameliorates learning deficits via enhancing NMDAR GluN2B function in a developmental model of schizophrenia

Authors: ***B. XING**, M.-J. WANG, M. A. SNYDER, W.-J. GAO;
Neurobio. & Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Cognitive deficits are early symptoms of schizophrenia (SZ) with glutamatergic dysfunction during early neurodevelopment contributing to the pathological process. Group II mGluR2/3 agonist has been proposed to be a therapeutic target, but a recent clinical trial failed. However, early intervention targeting mGluR2/3 remains to be an attractive strategy. Indeed, a recent study has shown that mGluR2/3 agonist treatment confers benefits for the early course of SZ but not for the patients with long-standing illness. We hypothesize that early intervention with the mGluR2/3 agonist LY379268 (LY37) will ameliorate cognitive deficits of SZ by targeting NMDA receptors. We tested this hypothesis by using a neurodevelopmental model of SZ based on prenatal administration of methylazoxymethanol (MAM) at embryonic day 17. We found that learning deficits in juvenile MAM rats can be rescued by repeated LY37 treatment in

the early stage. The improved behavioral performance was associated with an increased protein expression of GluN2B and an increased phosphorylated glycogen synthase kinase-3β ser9 level in the PFC. Furthermore, we found that bath application of LY37 induced significant increases in amplitude and decay time of NMDAR-mediated miniature and evoked EPSCs in PFC neurons, indicating an improved function of GluN2B-containing NMDARs. To determine the potential side effect of LY37 treatment during the juvenile period, we examined neuronal excitability and synaptic transmission of developing prefrontal neurons from rats treated with LY37 versus saline (SAL). One hour after the last injection of the 1-week LY37 treatment during P21-P28, decreased excitability of pyramidal neurons but increased amplitude of spontaneous EPSCs were observed. However, there were no apparent differences in neuronal excitability and synaptic transmission between LY37 treatment and SAL control groups after 1, 5 and 10 weeks following drug cessation, indicating that juvenile LY37 exposure and withdrawal did not alter the electrophysiological properties of prefrontal neurons. These results suggest that early treatment with mGluR2/3 agonist improved the learning deficits in a developmental model of SZ by enhancing GluN2B-mediated NMDA receptor function without clear side effects in the PFC neurons. Thus, early intervention has therapeutic value for SZ treatment.

Title: The role of P2X7 receptors in a rodent PCP-induced schizophrenia model

Authors: *B. SPERLAGH[1], B. KOVÁNYI[1], C. CSÖLLE[1], S. CALOVI[1], E. KATÓ[2], L. KÖLES[2], A. BHATTACHARYA[3], J. HALLER[1];
[1]Inst. of Exptl. Med., Budapest, Hungary; [2]Fac. of Medicine, Semmelweis Univ., Budapest, Hungary; [3]Janssen Res. & Develop., San Diego, CA

Abstract: In this study the expression and function of central P2X7 receptors (P2rx7) were examined in a phencyclidine (PCP)-induced schizophrenia model in mice. In P2rx7+/+ mice,

PCP (2 and 5 mg/kg i.p.) induced hyperlocomotion, stereotype behavior, ataxia and decreased social interactions. In mice, genetically deficient in P2X7 receptors (P2rx7-/-), the social interactions were increased, whereas the PCP induced hyperlocomotion and stereotype behavior were alleviated. The selective P2X7 receptor antagonist JNJ47965567 (30 mg/kg i.p.) partly replicated the effect of gene deficiency on PCP-induced behavioral changes and counteracted PCP-induced social withdrawal. mRNA encoding P2X7 receptors were upregulated in response to PCP in the prefrontal cortex and the hippocampus, respectively. P2rx7 activation released [^{3}H]glutamate from acute prefrontal cortex slices, which was enhanced by preceding in vivo PCP treatment. The amplitude of NMDA evoked currents recorded from layer V pyramidal neurons of cortical slices were slightly decreased by both genetic deletion of P2rx7 and by JNJ47965567 (100 nM). PCP increased mRNA expression encoding NR2A, NR2B and neuregulin 1 and decreased mRNA expression of NR1 and, GABA α1 subunits in the prefrontal cortex of young adult (56 days) P2rx7+/+ mice, but not in juvenile (18 days) or P2rx7-/- animals. In summary, we report here for the first time the alleviation of PCP induced behavioral changes by the inhibition of P2X7 receptors. Functional alterations of glutamatergic transmission in the prefrontal cortex and subsequent changes in the expression of glutamate receptor subunits and other pre- and postsynaptic proteins might underlie these changes.

Abstract: Deficits in early auditory processing contribute to higher-level cognitive functioning in schizophrenia. The current researchers have previously shown that MMN and P3a are reliable EEG measures of auditory processing, and that they are related to cognition and functioning in

clinically stable schizophrenia outpatients. This relationship has never been assessed in highly symptomatic patients with protracted illness requiring public guardianship and longer-term inpatient care. Moreover, the feasibility of administering these EEG measures to chronically ill patients with severe attentional and motivational deficits has been not yet been demonstrated. The current study aims to determine whether measures of early auditory processing are associated with cognitive functioning in an inpatient schizophrenia sample.
Twenty-five schizophrenia patients under public conservatorship were recruited from a transitional care facility and tested following a minimum of one month of acute stabilization with the approval of the Public Conservator's offices in San Diego and Los Angeles County. All participants' conservators were provided with informed consent and each participant assented to being part of the study. MMN and P3a ERPs were measured with a passive oddball paradigm utilizing a 1000Hz, 50msec standard tone and five duration- and/or frequency-modulated deviant tones. Global cognitive functioning was assessed with The MATRICS Consensus Cognitive Battery (MCCB). Total testing time was approximately two-and-a-half hours.
All patients completed the testing battery and provided usable data. Larger frontocentral amplitudes of MMN and P3a were significantly associated with MCCB Working Memory (MMN: $r=0.45$, $p=.02$; P3a: $r=0.62$, $p=0.001$). Moreover, shorter P3a latencies were significantly associated (all $r's>0.40$, $p's < 0.05$) with better performance in Neuropsychological Assessment Battery Mazes (NAB Mazes) and Hopkins Verbal Learning Test-Revised (HVLT-R), MCCB tests that respectively assess problem solving and verbal learning.
The present study demonstrates that EEG measures of early auditory processing - MMN and P3a - are robust correlates of cognitive functioning accounting for substantial variance in schizophrenia inpatients undergoing longer-term hospitalization. These measures require little attention or motivation and are therefore ideal for incorporation into a clinical testing battery, even within intensive inpatient treatment settings. Future longitudinal follow up will evaluate MMN and P3a for use as biomarkers for predicting and monitoring treatment response in this inpatient cohort.

Title: Effect of deficiency of vitamin B6 on mouse behavior and monoaminergic system

Authors: *K. TORIUMI[1,2], M. MIYASHITA[1], A. KOBORI[1], Y. HORIUCHI[1], I. NOHARA[1], N. OBATA[1], M. ITOKAWA[1], G. KONOPKA[2], M. ARAI[1];

Abstract: Schizophrenia is a heterogeneous psychiatric disorder characterized by positive and negative symptoms and cognitive impairment. Recently, we have reported that about 20% of schizophrenia patients show accumulation of pentosidine, one of advanced glycogen end products (AGEs), and lower level of vitamin B6 (VB6), which works as a scavenger against AGEs, in the peripheral blood. Furthermore, our clinical study found that the VB6 level is inversely proportional to the score of PANSS, suggesting that the loss of VB6 might contribute to development of the symptom in schizophrenia. In order to uncover the relationship between VB6 level and schizophrenia, we developed VB6-deficient mice by feeding C57BL/6J male mice with a VB6-lacking diet containing low VB6 at 5μg/100g pellets from 8 to 12 weeks of age, while control mice were fed with a normal diet in which VB6 is contained at 1.4mg/100 g pellets. After the feeding for 4 weeks, the plasma VB6 level in VB6-deficient mice decreased to about 3% of that in control mice. Moreover, the body weight of VB6-deficient mice did not increase during the feeding of VB6-lacking diet, leading to significant difference in the body weight between VB6-deficient and control mice. Next, to evaluate the effect of the low VB6 on mouse behavior, we performed behavioral tests using VB6-deficient mice. In the social interaction test, VB6-deficient mice showed less interaction compared with the control mice, corresponding to an increased negative symptom-like behavior. These behavioral data suggest that the VB6 deficiency might be associated with the negative symptoms. Finally, to investigate whether the VB6-deficiency affected the function of monoaminergic neuronal systems, the tissue contents of monoamines and their metabolites in various regions of the brains were measured. A marked increase in 3-Methoxy-4-hydroxyphenylglycol (MHPG) was shown in all brain regions compared to that in the control, which is consistent with many clinical reports that increased MHPG level was shown in schizophrenia patients. Furthermore, because of the increased MHPG, the ratio of MHPG to noradrenaline significantly increased in VB6-deficient mice, suggesting that the activities of noradrenergic neuronal systems were increased in VB6-deficient mice. These results suggest that VB6-deficiency might be involved in schizophrenia symptoms via the enhancement of noradrenergic system.

Title: Tolcapone improvement of cortical information processing in patients with schizophrenia is modulated by COMT val158met genotype

Authors: *J. A. APUD[1], Y. TONG[2], T. VARGAS[3], J. H. CALLICOTT[3], B. KOLACHANA[4], D. R. WEINBERGER[5], V. S. MATTAY[5], K. F. BERMAN[3];
[1]Office of the Clin. Director, [2]CTNB-NIMH-NIH, NIH, Natl. Inst. of Mental Hlth., Bethesda, MD; [3]CTNB-NIMH-NIH, Bethesda, MD; [4]HBCC-NIMH-NIH, Bethesda, MD; [5]Lieber Inst. for Brain Develop., Baltimore, MD

Abstract: Dopamine (DA) dysregulation is thought to underlay deficits in working memory and prefrontal cortical (PFC) physiology seen in patients with schizophrenia. Converging evidence indicates that DA focuses and stabilizes the prefrontal cortical network by modulating NMDA, non-NMDA and GABAergic currents. In this context, catechol-O-methyl transferase (COMT) may play a unique role in regulating dopamine flux in the prefrontal cortex. COMT has a common functional polymorphism (Val[158]Met) that affects prefrontal function and working memory capacity (Weinberger et al, 2001) and has been associated with cognitive deficits in schizophrenia (Egan et al, 2001). Early studies showed that tolcapone, a COMT inhibitor that penetrates the blood brain barrier, improves working memory and PFC efficiency as measured by BOLD fMRI in normal volunteers. We also previously found that tolcapone's effect on neuropsychological tasks was modulated by COMT val-met genotype, such that Val/Val homozygotes benefited from the drug treatment more than Met/Met homozygotes (Apud et al., 2007). In the current study, we sought to determine whether tolcapone (100 mg three times a day on the first day and 200 mg three times a day for the next 6 days) or placebo would have an effect on prefrontal recruitment of neuronal resources in patients with schizophrenia. We randomized subjects following a within-subjects, counter-balanced study design and enrolled them to participate in a double-blinded, cross-over, placebo-controlled trial. Subjects underwent BOLD fMRI on the seventh day of each arm while performing the N-Back working memory task with three levels of difficulty (1Back, 2Back, 3Back). Comparing the three COMT genotypes, the thirty-three subjects (six women) are not different in age, gender, IQ, race and day of tocapone administration (day 1 vs. day 2). We performed a 3-way ANCOVA analysis with Drug, Load, and Genotype as factors in SPM12. Pulled across all genotype groups and load conditions, the drug effect was not significant. However, post-hoc ROI analysis showed that greater working

memory load yielded greater activation in bilateral dorsolateral prefrontal cortex ($p<0.001$). Post-hoc analyses showed that, compared to the placebo condition, only Val/Val homozygotes on tolcapone showed less activation ($p<0.045$). Our results are consistent with previous findings in healthy volunteers of Val/Val homozygotes benefiting from tolcapone's COMT inhibitory effect by improving information processing. These findings suggest that the effect of tolcapone on prefrontal efficiency is modulated by COMT Val-Met genotype.

Title: Cortisol levels in schizophrenic patients treated with typical and atypical antipsychotic drugs

Authors: *C. VEGA MICHEL[1], M. ROJAS[2], S. MENESES-ORTEGA[2];
[1]ITESO, A. C., Tlaquepaque, Mexico; [2]Inst. de Neurociencias, Univ. de Guadalajara, Guadalajara, Mexico

Abstract: The objective of the study was to analyze salivary cortisol levels in a sample of patients with paranoid schizophrenia, treated with typical and atypical antipsychotic drugs, compared with the data obtained in a control group of healthy participants. Participated two groups of 15 paranoid schizophrenics patients (diagnosed under the ICD-10 criteria). One was treated with typical and other atypical antipsychotic drugs (average 11.6 years of evolution of disease); 15 healthy subjects as a control group. The age range was 24 to 38 years. To measure cortisol levels were collected over 3 sessions saliva samples and analyzed with the method enzyme immunoassay (EIA). The results showed higher salivary cortisol levels in patients treated with atypical antipsychotics compared to patients treated with typical antipsychotic drugs, in the control group lower cortisol levels found. Statistically significant differences between groups ($F_{[2,42]}$=4.81; p=0.02) were found. The analysis of multiple comparisons of Tukey-Kramer showed that the group of patients treated with atypical antipsychotics had higher salivary cortisol levels than the control group ($p < 0.05$). No statistically significant differences between groups of schizophrenic patients treated with typical and atypical antipsychotics, neither among patients treated with typical antipsychotic drugs and control groups were found. For their condition, schizophrenic patients show higher vulnerability to stressful events. The increase in stress levels are associated with enhanced secretion of cortisol, which can activate apoptotic processes in the central nervous system and negatively impact on their cognitive performance. Future research would be directed at determining the effect of these two types of antipsychotics drugs on cortisol secretion and its possible influence on the cognitive impairment shown by patients with schizophrenia. Taking into account variables such as the chronicity of psychiatric symptoms, adherence treatment, age of onset of symptoms and duration of illness.

Title: N-acetyl-cysteine and environmental enrichment reversed the long-lasting effect of oxidative stress on PVI circuitry: relevance for schizophrenia

Authors: *D. DWIR, J.-H. CABUNGCAL, P. STEULLET, M. SCHNIDER, M. CUÉNOD, K. DO;
Ctr. For Psychiatric Neurosci. (CNP), Prilly-Lausanne, Switzerland

Abstract: A hallmark of the pathophysiology of schizophrenia is a dysfunction of parvalbumin-expressing fast-spiking interneurons (PVI), which are essential for neuronal synchrony during sensory and cognitive processing. Oxidative stress and inflammation, as observed in schizophrenia, affects the highly metabolically active PVI. Some schizophrenia patients have decreased brain glutathione (GSH) levels due to genetic and functional origin. GSH dysregulation, by increasing vulnerability to oxidative stress and inflammation during early development leads to impaired cortical circuitry, specifically the PVI and the perineuronal nets (PNN) that surround them. We tested whether a combined treatment of N-acetyl-cysteine (NAC) and enriched environment (EE), during adolescent, prevents the deleterious effect of oxidative insult on PVI and PNN. We used a transgenic mouse model with GSH deficit (GCLM KO) that shows SZ related phenotype, increased oxidative stress and microglia activation. Here, we confirmed previous findings that an additional oxidative stress, using a dopamine reuptake inhibitor (GBR), in early postnatal days (P10-20) led to long-lasting effects in adult GCLM KO: increase in oxidative stress, activation of microglia, increase in MMP9-IR, and PVI and PNN impairment These effects were completely reversed by the combination of NAC treatment (given between P21-35) and EE (during P35-56). Interestingly, MMP9-IR was also reversed by NAC treatment alone. The fast rhythmic oscillations reflecting neuronal synchronization of PVI was decreased in the GBR-treated GCLM KO, and recovered by NAC/EE. Thus, an early oxidative insult induces long-lasting effects on PVI and PNN which can be reversed by a combined NAC and EE, even after the challenge. In analogy, individuals carrying genetic risks to redox dysregulation potentially vulnerable to early-life insults could benefit from a combined pharmacological and psycho-social therapy.

Title: Targeting an upstream neuromodulator of dopamine release rectifies a propsychotic response in a DREADD induced hyperdopaminergic state.

Authors: *T. COOMER, E. E. RENN, R. DAS, E. B. OLESON;
Univ. of Colorado Denver, Littleton, CO

Abstract: Conditioned avoidance is a classical animal model of the antipsychotic response in which a warning signal prompts an animal to press a lever to avoid electrical foot shock. All known antipsychotics disrupt the ability of an animal to show a conditioned avoidance response, an effect our recent data suggest is due to their ability to block dopaminergic encoding of the warning signal. A sensitized dopamine response to cues predicting drug availability is also theorized to cause craving and motivate drug seeking. As such, a hyperdopaminergic neuropathology that facilitates conditioned avoidance may also increase motivation for drugs of abuse through enhanced attribution of incentive salience to drug predictive cues. Due to recent technical advances, we can now directly test this theory by assessing the causal role of heightened dopamine release in behaviors relevant to the co-morbid expression of schizophrenia and addiction. Here, we use designer-receptor exclusively activated by designer drug (DREADD) technology to assess the effects of producing a transient hyperdopaminergic state in conditioned operant avoidance and in a behavioral-economics based cocaine self-administration task. Our data reveal that a DREADD-induced transient hyperdopaminergic state is sufficient to produce a pro-psychotic response and increase motivation for cocaine. We then attempt to counteract that response pharmacologically. Historically, both typical and atypical antipsychotics target the dopamine D2 receptor, but a number of issues exist with these pharmacotherapies that result in poor compliance. We propose an alternative method of treatment that targets upstream modulators of dopaminergic neurons in the mesocorticolimbic pathway that will potentially ameliorate both the schizophrenic symptoms, and drug-seeking behaviors. To achieve this, our group artificially induces a hyper dopaminergic state in transgenic rats by utilizing Gq-coupled DREADD virus technology. We then systemically administer an orexin OX1 receptor antagonist, which was previously demonstrated to modulate dopamine neural activity. Our data demonstrate that an orexin antagonist dose-dependently decreases conditioned avoidance, exclusively when tested in a DREADD-induced hyperdopaminergic state. The implication of this latter observation suggests upstream modulators of dopamine release may offer pharmacotherapeutic utility for schizophrenia.

Title: Impact of exercise training on prefrontal gray matter volume in schizophrenia

Authors: J. W. CHO[1], T. TESLOVICH[2], X. YOU[3], L. C. KORSHAK[1], J. P. POWELL[1], C. J. VAIDYA[4], P. KOKKINOS[1], *B. L. SCHWARTZ[1];

Abstract: Schizophrenia is associated with structural and functional abnormalities in the prefrontal cortex (PFC). Specifically, gray matter (GM) volume reduction has been reported in the dorsolateral PFC, a region linked to performance on cognitive tasks designed to measure executive functioning and working memory. The benefits of exercise and physical fitness, including increases in GM and cognitive performance, have been observed in healthy adults. Brain-derived neurotrophic factor (BDNF) is proposed to play a role in mediating such exercise-induced neuroplasticity. Here, we investigated the effects of exercise on BDNF levels and the middle frontal gyrus (MFG), a region that includes the dorsolateral PFC, using magnetic resonance imaging, in patients with schizophrenia. Participants were 10 veterans, ages 30 to 67 years (M = 54.3 years), who met DSM 5 criteria for schizophrenia or schizoaffective disorder. Participants were enrolled in a 12-week exercise program (3 times a week) tailored to each participant's level of fitness at baseline. Each 1 hour session comprised 30 minutes of aerobic activity and 30 minutes of strength training. Structural images were acquired on a 3.0 T Siemens Trio at baseline and endpoint. Cortical parcellation and volumetric measures were generated via FreeSurfer's automated processing stream. Serum BDNF levels were measured at baseline and endpoint. Nine of the 10 participants successfully completed the exercise intervention. Aerobic fitness, as measured by metabolic equivalent level, increased significantly from baseline (9.3± 2.4) to endpoint (10.9± 1.9) ($t(7) = -3.06$, $p < 0.05$). While average serum BDNF levels did not significantly increase, baseline levels were predictive of change in BDNF following the intervention. Specifically, lower initial levels were associated with greater change ($r(8)= -.64$, $p < 0.05$). Structurally, a significant increase in volume was seen in the right rostral MFG following the intervention (baseline=0.91±.09, endpoint=0.93±.09), $t(8) = -2.36$, $p < .05$),

independent of age. Significant increases in both physical fitness and PFC volume were seen following a 12-week exercise intervention for schizophrenia patients. As greater GM volume in the PFC has been linked to increased cognitive performance, the inclusion of physical fitness training in the treatment of schizophrenia may be an efficient and cost-effective tool to improve aspects of cognition, such as executive functioning and working memory. These preliminary data provide support for a future controlled study to explore and elucidate the mechanisms of exercise-induced improvements in cognition and brain function in schizophrenia.

Title: Mutlicolor two-photon excitation for increasing fluorescence excitation depth

Authors: M.-H. YANG[1], *C. G. FERRI[2], P. A. SAISAN[2], M. ABASHIN[2], P. TIAN[2,4], A. DEVOR[3,5], Y. FAINMAN[1];
[1]Electrical and Computer Engin., [2]Neurosciences, [3]Neurosciences and Radiology, Univ. of California San Diego, La Jolla, CA; [4]Physics, John Carroll Univ., University Heights, OH; [5]Martinos Ctr. for Biomed. Imaging, MGH/HMS, Charlestown, MA

Abstract: The advent of 2-photon microscopy has enabled *in vivo* imaging of cerebrocortical structure and function with micron resolution. Yet, penetrating deep into the cortex remains a challenge due to the scattering and absorption of light by cerebral tissue. The combined unwanted effect of scattering and absorption can be reduced by employing longer illumination wavelengths in the range of 1300-1700 nm. This range, however, is not suitable for conventional,

a.k.a. “degenerate” 2-photon excitation (D-2PE) of visible probes (e.g., with red or green emission). Here, we address this problem by multicolor 2PE, a.k.a. non-degenerate 2PE (ND-2PE). The principle of multicolor 2-photon imaging has been demonstrated *in vivo* for simultaneous excitation of multiple chromophores [1]. We are adapting this technology for deep imaging.

We excite the fluorophores via the simultaneous absorption of two photons of different energy (i.e., wavelength) using two different pulsed lasers sources. The lasers are spatially aligned and temporally synchronized. One laser is tuned to the near infrared (NIR, 700-900 nm), the second laser is tuned to the infrared (IR, 1300-1700nm) to match the energy needed for excitation of the fluorophore. The IR laser is used to compensate for NIR power loss due to tissue scattering. Furthermore, IR wavelengths are scattered less by tissue than NIR, allowing for deeper penetration into the cortex.

We excited fluorescein (FITC) submerged within an intralipid suspension of varying concentration. Excitation was provided by a pulsed Ti:Sapphire laser tuned to 825nm and an optical parametric oscillator tuned to 1315nm. Under these conditions, we can compare the D-2PE and ND-2PE fluorescence. We find that ND-2PE fluorescence decreases over a longer distance within the intralipid as compared to D-2PE fluorescence for all concentrations. These results are summarized in the attached figure. Thus, we have demonstrated a proof-of-principle for increased fluorescence excitation depth using non-degenerate excitation.

Title: Mesoscale mapping of cortical neuron activity

Authors: ***N. J. SOFRONIEW**, D. FLICKINGER, J. FREEMAN, K. SVOBODA;
Janelia Farm Res. Campus / HHMI, Ashburn, VA

Abstract: Cellular imaging is widely used to link neural activity in populations of neurons with behavior. Neural activity related to particular animal behaviors is distributed across multiple brain areas, often separated by millimeters. Most microscopes with subcellular resolution have small fields-of-view and therefore cannot image neurons in multiple brain areas at the same time. Large field-of-view microscopes do not resolve single cells, especially in the axial dimension. To overcome this limitation we designed and built a 2-photon random access mesoscope (2p-RAM) that provides rapid access for fast raster scanning anywhere within a large tissue volume. The 2p-RAM has subcellular resolution (lateral, 0.66 μm, axial 4.09 μm at the center) across a large imaging volume (diameter 5 mm x 1 mm cylinder). A fast three-dimensional scanning system allows efficient sampling of neural activity in arbitrary regions of interest across the entire imaging volume. We used the 2p-RAM to map neural activity in transgenic mice expressing protein calcium sensors as they navigated in tactile virtual reality. We first performed low frame rate (1.9 Hz) imaging of a large (4.2 mm x 4.2 mm) area overlapping somatosensory and parietal cortex, containing more than 2500 active neurons. We then used high frame rate (9.6 Hz) imaging to characterize four smaller (600 um x 600 um) patches in more detail. We describe mesoscale cortical organization of neuronal tuning to tactile input and locomotion.

Title: Two-photon imaging of neurons using stereoscopy (TwINS)

Authors: *A. SONG[1], A. S. CHARLES[2], S. Y. THIBERGE[3], J. L. GAUTHIER[2], S. KOAY[2], J. W. PILLOW[2], D. W. TANK[2,3,4];

Abstract: Two photon laser scanning microscopy of calcium dynamics is a widely used imaging method for large scale recording of neural activity *in vivo*. Here we demonstrate a volumetric calcium imaging method—Two-photon Imaging of Neurons using Stereoscopy (TwINS) —that increases the number of recorded neurons without the sacrifice of frame rate in sequential multi-plane volume imaging. TwINS exploits sparsity of neural activity by creating a single 2D projection image of the volume and relying on demixing algorithms to extract signals from individual neurons. A projection along a single axis, however, both loses depth information and creates significant spatial overlap of signals from axially-aligned neurons, compromising demixing. Thus, to both preserve depth information and produce a spatially distinct image profile for each neuron, TwINS raster-scans a V-shaped point spread function (PSF; 30-50μm axial FWHM) to illuminate neurons across a volume. When an active neuron in the volume is scanned, each arm of the V shaped PSF makes a neuron-shaped contribution to the 2D projection, but the contributions from each arm are spatially shifted by the distance between the two arms at that depth in the volume. Thus neurons that might overlap on the image with a single excitation beam will have spatially distinct depth-encoding "image pairs" on the projection, facilitating demixing. The TwINS microscope consists of a beam-shaping module and a conventional two-photon microscope. In the beam shaping module, two parallel beams,

displaced lateral to each other, are created with a birefringent block. The two beams (either low NA Gaussian beams, or Bessel beams created with an axicon) are directed into a custom two-photon microscope. Volume imaging at 30Hz is performed using conventional resonant scanners and a PMT. For analysis, neural activity is first separated from background activity using a denoising algorithm that estimates pixel activity above a background level and uses a Laplacian Scale Mixture prior to incorporate sparsity and spatial cohesion. The denoised data is then fed into a somatic pair finding algorithm using orthogonal matching pursuit, which exploits the fact that neurons appear as image pairs. This process returns demixed activity traces for individual neurons and their inferred 3D position. We demonstrate the use of TwINS to image activity both in layer 2/3 neurons in primary visual cortex under a visual stimulus in an awake mouse and from populations of CA1 neurons in mouse hippocampus during behavior. Our results demonstrate that TwINS is a relatively simple to implement approach for volumetric two-photon imaging while maintaining a high volume frame-rate.

Title: Characterisation of spontaneous hippocampal circuit dynamics by two-photon minimal inertia scanning

Authors: *R. SCHUCK[1], P. QUICKE[2], A. FOUST[2], L. A. ANNECCHINO[2], C. COPELAND[2], S. GARASTO[2], S. R. SCHULTZ[2];
[1]Bioengineering, [2]Imperial Col. London, London, United Kingdom

Abstract: Understanding how the dynamics of activity in neural circuits relates to information processing is a key problem in understanding perception, memory and brain disorders. To characterise the dynamics of large and dense neural populations, we employ two photon (2P) calcium imaging. Standard raster scanning of a 2P spot scales extremely poorly with population size, limiting acquisition rates and/or signal to noise ratio. Improvements to cellular sampling rate can be achieved by scanning directly from soma to soma. While such algorithms markedly increasing sampling rates over raster scanning, their trajectories require the beam to execute

sharp turns, necessitating slowdowns to overcome galvanometric scanner (GS) inertia. Our recently developed Adaptive Spiral Scanning (SSA) algorithm (Schuck et al. 2014, IEEE EMBS) quickly samples all cells in the field of view while avoiding inertia-imposed slowdowns. Here, we apply this algorithm to achieve fast cellular-resolution sampling of granule cell activity in the dentate gyrus of the hippocampus. 400µm horizontal hippocampal slices were taken from wild type mice (P14-P17) in 1-4°C ventilated (95%O2, 5% CO2) ACSF. Slices were recovered at 37°C for 30min before being placed in 2.5mL of rACSF at 37°C and "painted" with 10µL of a solution (50µg Cal520 dissolved in 2µL of Pluronic and 48µL of DMSO), then incubated and washed for 30 minutes. We compared the scanning efficiency of the SSA with a “shortest-path” algorithm (Travelling Salesman Algorithm, TSA), characterizing performance as a function of the number, density, and geometry of sampled targets. Calcium transient acquisition rates of around 200Hz to 300Hz for 25 targets were achievable with SSA. Both TSA and SSA substantially outperformed raster scanning for simultaneous acquisition of signals from many cells, with high signal to noise ratio and temporal fidelity. We analysed the dynamics of spontaneous activity in the dentate gyrus using two approaches: (i) computation of an information distance metric between all signals, followed by dimensionality reduction using multi-dimensional scaling. This allowed us to visualise the similarity of the information conveyed by each cell. (ii) embedding of the entire spatial pattern dynamics into a space constructed using the cosine distance, followed by multidimensional scaling. This approach allows us to characterise how patterns of activity traverse response space during spontaneous activity, and to study the dynamics following electrical perturbation. We hypothesize that these dynamics may be disturbed during neurodegenerative disorders which affect learning and memory.

Title: Miniaturized two-photon microscopy enabled single-spine resolution brain imaging in freely-behaving mice

Authors: *W. ZONG, R. WU, M. LI, H. JIA, Y. HU, Y. LI, H. RONG, Y. ZHANG, A. WANG, Z. ZHOU, L. CHEN, H. CHENG;
Inst. of Mol. Med., Beijing City, China

Abstract: An ultimate goal of neuroscience is to decipher the principles underlying neuronal information processing in freely-behaving animals at the subcellular, cellular, circuit, and even higher levels. Recently, a flurry of effort has been dedicated to the development of light-weight and compact optical imaging systems that can be carried by awake and mobile animals. A major unmet challenge, however, is to image individual synaptic activity (of sub-micron sizes, operate at the millisecond scale, and are often buried deep within the brain) in freely-behaving animals. Owing to its intrinsic optical sectioning and deep tissue penetration, multi-photon microscopy has been the technique of choice for the *in vivo* three-dimensional (3D) imaging of dendrite spine structures and activities. However, to date, none of current miniaturized 2PMs has been able to achieve sub-micron imaging of synaptic activity in a freely-moving animal. Here we report the design, optimization, and construction of a miniaturized imaging device that can be head-mounted to a freely-behaving mouse and enables fast-scanning, high-resolution, two-photon fluorescent or second-harmonic generation (SHG) imaging. We have named it the "video-rate high-resolution dual-detection-mode miniaturized two-photon microscope" (VIHID-m2PM). The headpiece consists of a fast two-axis microelectromechanical-systems (MEMS) raster scanner, a miniature compound objective lens with an NA of 0.8, and a Z-scanning micromotor of 4-mm travel. Emission photons are detected either by a micro-photomultiplier tube (μPMT) directly attached to the headpiece (3.25 g) or gallium arsenide phosphide (GaAsP) photodetectors remotely connected to the headpiece (2.1 g) *via* a custom-made super-supple fiber bundle (SSFB). Overall, the VIHID-m2PM provides 0.65-μm lateral and 3.75-μm axial resolution at a 40-Hz (256 × 512 pixels) frame rate or 10 kHz linescan rate. Moreover, we demonstrate its superb performance for resolving Ca^{2+} signals in cell bodies, dendritic shafts, and single spines in the primary visual cortex of mice as they freely explore and interact with the surrounding environment.

Title: An implantable two-photon fiber-coupled microscope with electrically-tunable focus for applications to awake behaving mouse brain imaging

Authors: ***B. OZBAY**[1], G. L. FUTIA[1], M. MA[2], J. T. LOSACCO[2], D. RESTREPO[2], E. A. GIBSON[1];

Abstract: We demonstrate a miniature fiber-coupled microscope (FCM) with a variable focus lens for two-photon brain tissue imaging of GFP and tdTomato fluorescent markers. The FCM is coupled to a laser-scanning microscope with pulsed excitation light centered at 950 nm. The pulse duration is 130 fs out of the fiber, as characterized using frequency resolved optical gating. The fluorescence emission passes through a bandpass filter (450 - 700 nm) and is detected on a non-descanned photon counting PMT. The FCM is coupled through a coherent fiber-bundle for lateral scanning with ~2 μm resolution. Axial-scanning is achieved using a small electrically-tunable lens distal to the fiber-bundle and allows for a z-scan range of ~500 μm. We achieved a total image volume of 250 μm diameter x 500 μm in depth.
Our FCM demonstrates a mechanically simple and lightweight 3D imaging system for rodent brain imaging. The FCM plastic enclosure is manufactured using 3D printing with a resolution of 0.04 mm and uses commercial optical components, which allows for greater accessibility and customization. The assembled device is lightweight (< 4 g) and is designed for mounting onto the skull of a mouse for brain imaging during behavior. We also show that the FCM can be chronically implanted on a mouse skull for recurrent imaging.

Abstract: Over recent years, increased access to affordable, high quality, low volume manufacturing and online collaborative platforms has led to a transformative open-source movement in the neuroscience community. A goal of this movement is to accelerate neuroscience research through the open sharing and collaborative advancement of research tools. Here we present the current status of our open-source Miniscope project which aims to advance miniature wide-field fluorescence microscopy through the open sharing of design files, parts lists, and tutorials on a collaborative, online resource, miniscope.org.
The Miniscope system consists of all necessary hardware, software, and firmware to image large-scale neural activity in awake, freely behaving animals. The head mounted scope (3 grams) connects to a custom designed Data Acquisition (DAQ) box through a single, commutator compatible, coaxial cable (down to 0.3mm in diameter, over 3m in length) carrying power, imaging data, and control signals. The DAQ box communicates to a computer over USB3.0 and can be controlled with our own DAQ software or through any third party DAQ software capable of connecting to a webcam. The electronics support the vast majority of commercial CMOS imaging sensors, giving access to the full range of resolutions/framerates available among commercial imaging sensors while requiring minimal circuit redesign. The optical elements in the scope are modular, allowing for the use of different filter sets, excitation sources, and imaging lenses.
To share this system we have built miniscope.org, an online resource constructed on a Wiki backbone. Miniscope.org contains part procurement and system assembly tutorials/videos for labs interested in using the system as well as detailed schematics and source code for labs to customize and innovate the Miniscope. The site also supports collaborative tools such as discussion boards, member pages, and the ability for members to create their own project pages around new developments.

Abstract: Neurons and neural networks often extend hundreds to thousands of micrometers in three dimensions. To capture all the calcium transients associated with their activity, we need volume imaging methods with sub-second temporal resolution. Such speed is challenging for conventional two-photon laser scanning microscopy (2PLSM) to achieve, because of its dependence on serial focal scanning in 3D and the limited brightness of calcium indicators. Here we present an optical module that can be easily integrated into standard 2PLSMs to generate an elongated focus approximating a Bessel beam. Scanning the Bessel focus in 2D turns frame rate into volume rate and enables video-rate volumetric imaging. Using Bessel beams optimized to maintain synaptic-level lateral resolution *in vivo*, we demonstrated the power of this approach in contributing discoveries for neurobiology by studying the activity of volumes of neurons and synapses in intact brains of fruit flies, zebrafish larvae, mice, and ferrets.

Title: Optimized volumetric live imaging with light field microscopy and selective volume illumination.

Authors: *T. V. TRUONG[1], A. ANDREEV[2], S. MADAAN[2], D. HOLLAND[1], S. E. FRASER[1]; [1]Translational Imaging Ctr., [2]BME, USC, Los Angeles, CA

Abstract: Recent efforts to carry out cellular functional imaging across large areas of the brain could greatly benefit from a volumetric live imaging modality, where a single snapshot could capture spatial information over a tissue-scale axially-extended volume, while maintaining single- or few-cell resolution. Such capability has been recently demonstrated with Light Field Microscopy (LFM), where the light field coming from the sample space is recorded in a single 2D image, capturing information from the 3D volume extended above and below the native focal plane, albeit at reduced spatial resolution due to the diffraction limit. Computational reconstruction is used to generate the 3D images of the sample from the 2D light field images.

Up until now, LFM has been done with widefield illumination, essentially lighting up the entirety of the sample, even though only a part of the sample is meaningfully captured in the reconstruction. Thus, widefield illumination introduces extraneous background and noise, degrading the contrast and accuracy of the final reconstructed images. Here, we implement Selective Volume Illumination (SVI) to LFM, illuminating only the volume of interest, thus significantly reducing the background and providing higher contrast and accuracy for the light field image reconstruction. We demonstrate SVI-LFM with both 1-photon and 2-photon excitation, the latter providing higher penetration depth in scattering tissue. Additionally, our implementation allows recording a high resolution, optically-sectioned 3D image of the same sample, in addition to the light-field-reconstructed volumetric, but low-resolution, image. Having both the high-resolution/low-speed, and low-resolution/high-speed image data of the same sample facilitates optimized observation of dynamical processes, and provides the potential for using the high-resolution image data to help speed up and constrain the reconstruction of the light field data.

Title: Optical monitoring of behavior-related calcium dynamics in 12 brain regions using a novel multi-fiber array

Authors: *Y. SYCH, F. HELMCHEN;
Lab. of Neural Circuit Dynamics, Brain Res. Institute, Univ. of Zurich, Zuerich, Switzerland

Abstract: Methods for a brain-wide monitoring of neural activity in subcortical areas are scarce. Here, we present an implantable multi-fibre array and an optical system for a brain-wide monitoring of calcium signalling. The lightweight (0.3 g) multi-fibre implant consists of a ferrule, fixation pins and 12 fibres (100 micron core diameter) fitted into a guiding structure. Implanted fibres are bevelled to 45 degrees, facilitating smooth penetration into deep brain areas. Thereby, the far-field illumination profile of each fibre is modified such that fluorescence is mainly excited in the tissue volume normal to the bevelled surface. The multi-fibre implant is connected via a linear 12-fiber bundle to an imaging system. The fibre-optic signal was cross-validated with two-photon scanning microscopy and electrophysiological recording of multi-unit

spike activity. We applied the novel multi-fibre array to simultaneously measure population calcium signals (GCaMP6 s/m virally delivered) in 12 brain areas during multiple behavioural sessions. Mice were trained in a whisker-based texture discrimination task. Preliminary data of the mesoscale brain network activity indicate that multiple cortical regions (S1BF, M1 L5/6) and subcortical brain areas *e.g.* striatum (CPu), thalamus (VPM, VPL, Po) and hippocampus (CA1, CA2, CA3) are recruited during sensorimotor processing in the task. Moreover, we observed temporal reorganization of a network activity during learning from naive to expert level mice. The multi-fibre array thus is a versatile tool to chronically study large-scale dynamics of the network of interacting brain regions.

Title: Swept confocally aligned planar excitation (SCAPE) microscopy for the identification of neural circuits in adult *Drosophila*

Authors: *W. LI[1], N. MISHRA[2], E. S. SCHAFFER[2], V. VOLETI[1], E. M. C. HILLMAN[1,3]; [1]Biomed. Engin., [2]Neurosci., [3]Radiology, Columbia Univ., New York, NY

Abstract: The identification of functional neuronal circuits in the brain is an important step towards developing predictive models of behavior. Although our neurogenetic understanding of the fly allows us to identify and label different neuronal subsets, there is still a huge gap between structural information provided by, for example, a connectome map and inferred functionality. To this end, one of the largest challenges is an inability to observe whole-scale brain activity within a normal, behaving animal.

Here, we use Swept Confocally Aligned Planar Excitation (SCAPE) microscopy to image whole-brain activity of adult behaving Drosophila at speeds of 10 brain volumes per second. SCAPE is a form of light-sheet imaging which uses a single objective lens, and a novel sheet scanning-descanning approach that enables translationless volumetric imaging at very high speeds. This imaging geometry is ideally suited to head-fixed imaging the fly brain, without requiring body restraint or immersion of the fly that would otherwise interfere with behavior. During *in vivo* imaging, the fly can be subjected to an odor stimulus controlled via an olfactometer while performing tracked walking behavior on an air-suspended ball.
To test the efficacy of SCAPE whole brain imaging as a tool for the functional identification of neural circuits, we express GCaMP6f pan-neuronally and ask whether known olfactory circuits can be identified from brain-wide calcium signals. Our latest results will be presented.

Title: Design of a modular microscope for flexible, high-resolution imaging of neural activity in the non-human primate

Authors: *J. CHOI[1], V. GONCHAROV[2], J. KLEINBART[1], A. ORSBORN[1], B. PESARAN[1]; [1]New York Univ., New York, NY; [2]Janelia Res. Campus, Ashburn, VA

Abstract: Recent advances in genetically encoded neural activity indicators, in vivo two-photon imaging, and optical stimulation have enabled cellular-resolution recording and stimulation of cortical activity with high signal quality and population specificity. These technologies need to be deployed in awake primate models to elucidate pathologies and phenomena most relevant to the human brain. Unfortunately, no existing microscope can be used for work in non-human primates without significant customization due to the size and shape of the primate brain. The large size of the primate cortex presents numerous technical challenges for studying large-scale distributed functions, which potentially involve many brain regions in concert. Areas of interest

span centimeters, imposing stringent demands for optical access across curved, expansive surfaces and suppression of large movement artifacts from cardiac, respiratory, and behavioral sources. These problems underscore the need for flexible and repeatable positioning of the objective lens relative to the cortical surface. At least five degrees of freedom are required to achieve parallel alignment of the focal plane and cortex. While some non-primate studies have achieved this by rotating the subject's body along two axes and moving the microscope in position alone, this method does not extend well to the large angles required for primate cortex. Therefore, a rotating optical assembly is required. Axial brain movement produces artifacts that are difficult to correct, and methods are needed for applying and maintaining pressure to a transparent artificial dura. To achieve and maintain optical access to multiple brain areas, an annular skull implant is designed that provides hygienic isolation and adequate space for placing multiple low-profile imaging chambers. Each chamber is designed to fit the curvature of the skull and provides optical access through an artificial dura. The low profile accommodates large, high numerical-aperture objectives with small working distances and would allow multiple non-overlapping imaging fields to be serially scanned over the course of an experiment. Over long-term implantation, a common failure mode of optical chambers is growth of a translucent neomembrane---a problem that must be addressed to allow recording over the months or years typical of primate experiments. Here we present a novel microscope and surgically-implanted chamber system designed to provide solutions to these issues. We propose that novel instrumentation will pave the way for comprehensive neuronal recording from primate cortex to study large-scale distributed networks.

Abstract: Light-based neuroimaging techniques are suitable to functionally image neural tissue elements from the area range down to the synaptic elements, thereby being an indispensable tool to understand brain function. A common drawback of optical imaging is the depth limit due to light scattering in live tissues. The usual working depth of these systems do not exceed a few hundred micrometers, hardly the width of the rodent cortex. There are engineering approaches to solve this problem, since deeper neural tissue elements also play crucial role in shaping cognition and behavior. So far these solutions all suffer from one or several constraints of being highly invasive, not precise, or of limited scope. Here we describe a possible solution along with *in vivo* test measurements to use with 2 photon laser scanning imaging of genetically encoded calcium indicators allowing to image deep tissue functions in considerable volumes.

Title: Highly sensitive implantable imaging device for flavoprotein fluorescence imaging

Authors: *Y. SUNAGA, M. HARUTA, T. YAMAGUCHI, H. TAKEHARA, T. NODA, K. SASAGAWA, T. TOKUDA, J. OHTA;
Nara Inst. of Sci. and Technol., Ikoma-Shi, Nara, Japan

Abstract: To observe neural activities in the brain of an animal, fluorescence imaging technology is very useful. Especially, Green Fluorescent Protein (GFP) or autofluorescence of mitochondrial flavoprotein is very useful because its intensity is changed by neural activities without any treatment to an animal [1]. In usual, fluorescence reactions of a tethered animal is observed by a fluorescent microscope. However, it is difficult to observe the brain of an animal under freely moving condition with a fluorescent microscope. In order to observe fluorescence reaction associated with animal behavior, we have developed a miniaturized fluorescence imaging device based on a CMOS image sensor. Its dimensions are $1 \times 2.7 \times 0.15$ mm^3, and its

weight is less than 0.05 g. Furthermore, the device and its LEDs can be driven using only six wires. By implanting the imaging device into an animal brain such as a mouse or a rat, fluorescence reactions can be observed even under freely-moving conditions with minimal invasiveness. The imaging device was set on the brain surface and was fixed with the skull by a dental cement. To avoid interfering daily behavior of an animal, wires are connected only while imaging experiments are performed. In our previous works, we have developed an implantable imaging device for green fluorescence imaging at brain surface [2], and achieved to observe flavoprotein fluorescence reaction associated with visual stimulation [3]-[4]. However, the previous device needed many trials to reduce influence of noise by averaging the obtained data. To solve this problem, we have tried to develop a new implantable imaging devices for highly sensitive imaging. In this work, we introduced a new image sensor to improve flavoprotein fluorescence imaging quality. In flavoprotein fluorescence imaging, light detection sensitivity of the image sensor is more important than its spatial resolution, because flavoprotein fluorescence changes very weakly in wide range. To improve detection sensitivity, we designed a new image sensor that has 4 times larger pixels than that of the previous sensor. This new sensor enables us to observe weaker fluorescence with high signal-to-noise ratio compared with previous devices. We are now working to confirm the performance of the improved imaging device in *in vivo* experiments. [1] K. Shibuki *et al*. J. Physiol.. 549(3), 919927, 2003. [2] Y. Title: Deep brain fluorescence imaging using an ultra-thin optical fiber

Authors: *S. OHAYON[1], A. M. C. AGUIRRE[2], R. PIESTUN[2], J. DICARLO[1];
[1]MIT, Cambridge, MA; [2]Boulder, Colorado, CO

Abstract: A major challenge in studying the brain is to image neural activity in deep structures that lie beyond the depth range of two-photon microscopes (500-1000um). Existing methods for imaging deep structures either use bulky objectives or GRIN lens (gradient refractive index) that are rigid, short, suffer from various optical aberrations, have large diameters (500-100um) and cause considerable damage upon insertion into tissue. We present a minimally invasive technique to image in-vivo fluorescence using standard multi-mode fibers (50-100um in diameter) that can be lowered to target structures at any arbitrary depth. In contrast to fiber-photometry, where all spatial information is lost and the recovered signal is averaged across the fiber core, our technique maintains full spatial information and can reconstruct the full 3D volume beneath the fiber. The system has reasonable optical properties (in plane FWHM 1um, optical sectioning: ~6um) sufficient to image cell bodies (neurons). To demonstrate the capabilities of this technique and to validate it we present results from a series of experiments. We show that fluorescence beads (15um) can be imaged in-vivo in mice. We also show that calcium dynamics can be recorded in-vitro (full frame acquisition speeds range between 0.5-15Hz, depending on spatial resolution). The technique has the potential to be used as an all-optical tool for both monitoring and perturbing neural activity. On-going efforts are now taking place to achieve in-vivo functional imaging. We hope this would pave the path for calcium imaging in deep brain structures in genetically intractable animals (e.g non-human primates).

Title: High-fidelity functional and structural whole-brain imaging with Bessel-beam light-sheet microscopy

Authors: *C. MUELLENBROICH, L. SILVESTRI, L. TURRINI, A. P. DI GIOVANNA, T. ALTERINI, A. GHEISARI, P. RICCI, L. SACCONI, F. VANZI, F. S. PAVONE;
LENS, Univ. of Florence, Sesto Fiorentino, Italy

Abstract: Light-sheet microscopy (LSM) has proven a useful and versatile tool in neuroscience and is particularly well suited to image the entire brain with high frame rates at single cell resolution. On the one hand, LSM is often employed in combination with tissue clearing methods like CLARITY which allows for the reconstruction of the neuronal or vascular anatomy over cm-sized samples like the entire mouse brain. On the other hand, LSM has been paired with intrinsically transparent samples for the real-time recording of neuronal activity with single cell resolution across the entire brain, using calcium indicators like GCaMP6. Despite its intrinsic advantages in terms of high imaging speed and reduced photobleaching, LSM is very sensitive to residual opaque objects present in the sample, which cause dark horizontal stripes in the collected images. In the best case, these artefacts obscure the features of interest in structural imaging; in the worst case, dynamic shadowing introduced by red blood cells significantly alters the fluorescence signal variations related to neuronal activity. We show how the use of Bessel beams in LSM can dramatically reduce such artefacts even in conventional one-sided illumination schemes, thanks to their non-diffractive and "self-healing" properties. On the functional side, Bessel-beam LSM allows recording neuronal activity traces without any disturbing flickering caused by the movement of red blood cells. Furthermore, using this approach it is possible to extend high-resolution calcium imaging in less transparent samples or regions, like older or slightly pigmented Zebrafish larvae. On the structural side, our proposed method is capable of obtaining anatomical information across the entire volume of whole mouse brains - without the selection of 'nice regions' - allowing tracing blood vessels and neuronal projections also in poorly cleared specimens.

Title: Towards two-photon SCAPE microscopy for extended depth, fast volumetric imaging of brain function.

Authors: *H. YU[1], P. T. GALWADUGE[1], W. LI[1], V. VOLETI[1], K. PATEL[1], E. M. C. HILLMAN[1,2,3];
[1]Biomed. Engin., [2]Radiology, [3]Mortimer B. Zuckerman Mind Brain Behavior Inst., Columbia Univ., New York, NY

Abstract: Reduced scattering at near-infrared wavelengths enables two-photon laser scanning microscopy (2PLSM) to image deeper into scattering biological tissue. However, conventional point-scanning implementations of 2PLSM are limited by slow volumetric imaging rates, preventing the capture of fast, 3D dynamics. Swept confocally-aligned planar illumination (SCAPE) microscopy is a recently developed new technique capable of very high speed 3D microscopy in living targets including the awake behaving mouse brain. SCAPE achieves high speed 3D imaging by using light-sheet illumination instead of point scanning. SCAPE's unique single-objective geometry and scan-descan approach enables rapid movement of the illuminated plane through the sample without needing physical translation of the objective or sample. However, current implementations of SCAPE utilize a 488 nm laser source for single-photon excitation, limiting the imaging depth of SCAPE to less than ~ 300 μm in in-vivo mouse brain.Implementing SCAPE with two-photon excitation would provide several benefits including deeper imaging and improved background rejection and contrast. However, it is challenging to combine two-photon excitation with light-sheet illumination owing to the need for much more laser power, particularly in the context of acquiring data at very high speeds. Here, we will describe our latest progress towards two-photon implementations of SCAPE.

Title: Non-invasive functional neuroimaging in mice using structured illumination diffuse optical tomography

Authors: *M. REISMAN, Z. MARKOW, A. Q. BAUER, J. P. CULVER;
Washington Univ. In St. Louis, Saint Louis, MO

Abstract: The study of correlated spontaneous activity in functionally-related brain regions using functional connectivity MRI (fcMRI) has allowed comprehensive mapping of distributed brain networks in humans. Although studies utilizing fMRI in mice have recently seen an increased application towards mapping resting state networks, the difficulty of obtaining high resolution images with sufficient signal to noise in mice using fMRI has led to optical intrinsic signal (OIS) techniques providing most of the observations of fc in the mouse brain. While effective, OIS requires scalp retraction and is limited to superficial cortical tissues. Diffuse Optical Tomography (DOT) provides non-invasive imaging, but current DOT systems are either too sparsely sampling to match the cortical resolution of OIS or are too slow for capturing spontaneous hemodynamics in the mouse brain. Here we develop a DOT system that combines the spatial sampling of camera-based systems with the rapid-imaging of structured illumination (SI) to non-invasively map activity in the mouse cortex. The non-invasive mouse SI-DOT system is comprised of a sCMOS camera and a digital micromirror device (DMD) that allow for rapid illumination and detection with high spatial resolution (Fig 1A). Custom data quality assessment metrics allow for measurement optimization and improved accuracy of an input light model (Fig 1B). The sensitivity between each measurement and brain voxel is used to reconstruct hemodynamic activity. Evoked responses in the somatosensory cortex of the mouse upon electrical stimulation of the forepaw are observed non-invasively, through the intact scalp (Fig 1C). Establishing analogous functional imaging in both mouse and man is one of the most promising strategies for providing clinical translation. SI-DOT addresses many of the problems limiting other techniques from full 3D mouse brain imaging. Evoked responses are seen non-invasively, and the system's complete flexibility of wavelengths, illumination patterns, and detector binning provide a powerful framework for 3D mapping of mouse brain networks.

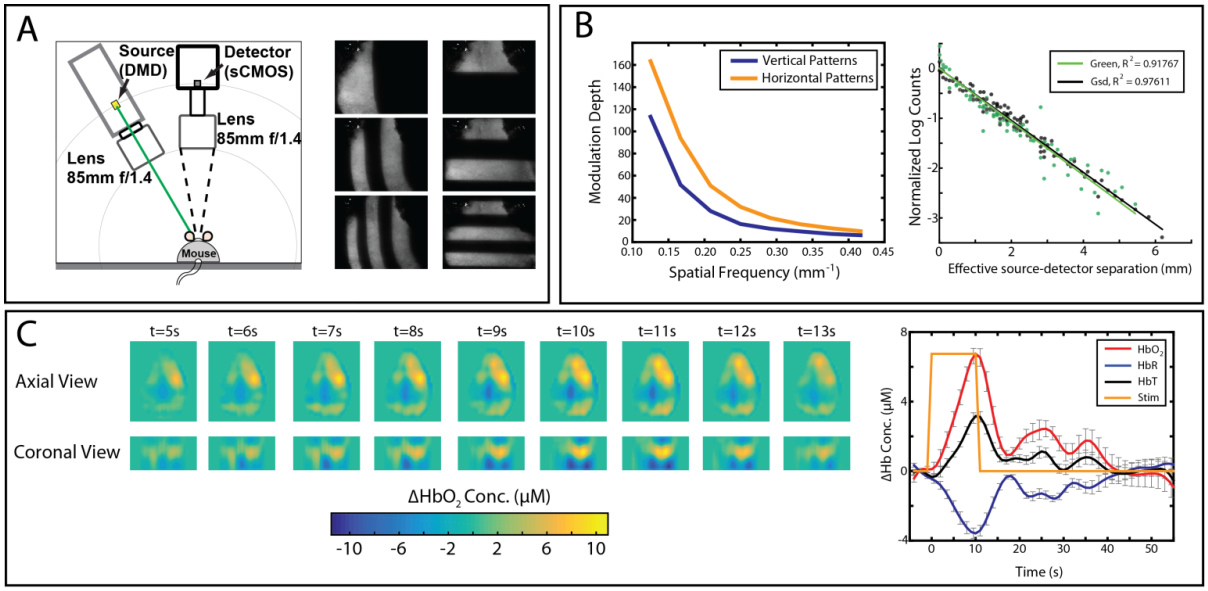

Fig 1. (A) System drawing showing spatial orientation of DMD source projection and Andor Zyla sCMOS detector. Six sample patterns show the illumination on the head of a mouse with the scalp intact and the sCMOS FOV. (B) Modulation depth shows the dynamic range of each illumination pattern as a function of spatial frequency, and allows optimization of illumination patterns by removing those with too low of a modulation depth. A comparison of the light falloff between the raw data and the modeled data show good agreement, confirming the accuracy of the light model and sensitivity matrix. (C) Reconstructions non-invasively show the evoked response in the somatosensory cortex of a mouse following an electrical stimulus of the left forepaw. The coronal slice through the maximum activation in the axial view provides previously unattainable depth information, up to 2mm beneath the surface of the scalp. A time trace of the signal in voxels >50% of the max response shows the expected increase in oxy- and total hemoglobin and decrease in deoxy-hemoglobin.

Title: Super-field two-photon microscopy for simultaneous imaging of multiple cortical areas at cellular resolution

Authors: *S.-I. TERADA[1,2], M. OHKURA[3], J. NAKAI[3], M. MATSUZAKI[1];
[1]Dept. of Cell. and Mol. Physiol., The Univ. of Tokyo, Tokyo, Japan; [2]Grad. Sch. of Biostudies, Kyoto Univ., Kyoto, Japan; [3]Grad. Sch. of Sci. and Engin., Saitama Univ., Saitama, Japan

Abstract: Understanding the dynamics of cortico-cortical communications is essential because information processing in the brain is not only performed in intra-areal circuits but also through inter-areal interactions. Recent advances in two-photon microscopy have allowed us to simultaneously image multiple brain areas at cellular resolution. However, it is still difficult to image a continuous large field (>2 mm) and two distant (>3 mm) brain areas at cellular resolution using a single two-photon microscope. Here, we introduce super-field two-photon microscopy through a single objective, which allows the imaging of two distant (up to 6 mm apart) cortical areas and a large continuous area (up to 3 mm) at cellular resolution. The method depends on placing a novel optical device under a high-NA objective with a long working distance in a standard two-photon microscope. The device is composed of a pair of mirrors and a holder to rotate the mirrors perpendicular to the optical axis. By controlling the rotation timing and angle using custom-made software, the field of view can be rapidly switched without moving either the objective or the sample. By rotating the mirror pair back and forth between two angles, we conducted sequential two-photon calcium imaging of neuronal activities in two distant areas up to 6 mm apart and at a depth of up to 800 μm from the cortical surface. Furthermore, by stitching the fields of view, we succeeded in imaging a 3 mm × 1 mm continuous area. To prove that this optical system is effective for the study of the dynamics of cortico-cortical communications, we applied it to concurrent calcium imaging of layer 2/3 and layer 5 neurons in rostral and caudal motor cortical areas while the mice performed a lever-pull task (Hira et al., J. Neurosci 33, 2013). We will discuss how the neural activities in these fields are coordinated during motor execution. Importantly, the optical device together with the controller can be easily installed on a standard two-photon microscope. Its adaptation by neuroscientists should open the door to the study of information processing in brain networks at cellular resolution.

Title: 3D functional brain activity recording in zebrafish with compressive light field microscopy

Authors: *D. P. MOSSING[1], N. PEGARD[2], L. WALLER[3], H. ADESNIK[4];
[1]Grad. Program in Biophysics, [3]Electrical Engin. and Computer Sci., [4]Mol. and Cell Biol., [2]Univ. of California, Berkeley, Berkeley, CA

Abstract: Understanding the neural code requires minimally invasive instruments that are capable of monitoring brain activity in large volumes with cellular resolution and millisecond precision. Although genetically encoded dyes can report neural activity in the behaving animal, strong optical scattering in brain tissue generally limits performance. Most functional imaging devices attempt to overcome scattering using point scanning, non-linear two-photon excitation, or adaptive optics. These are complex and expensive, and suffer from either poor temporal or low spatial resolution. Here, we present a new microscopy technique for 3D functional imaging in live brain tissue aiming to maximize the number of neurons that can be reliably observed, while minimally perturbing animal behavior. The device is a simple light field fluorescence microscope allowing full volume acquisition in a single shot. Our computational methods first rely on the spatial and temporal sparsity of fluorescence signals to identify and precisely localize neurons and/or dendrites. For each neuron, we compute a unique pattern called the light-field signature that accounts for the effects of optical scattering and aberrations. The technique then yields precise localization of active neurons as well as a quantitative measurement of activity in all identified neurons within the 3D field of view. A single shot frame enables acquisition with single neuron spatial resolution and at high speeds, without ever reconstructing a volume image. This strategy is computationally efficient and compatible with strong optical scattering conditions. Experimental results are shown on live 5-day old zebrafish.

Title: 48-channel hyperspectral multiphoton microscopy in live mouse cortex

Authors: ***A. J. BARES**, M. A. PENDER, M. A. MEJOOLI, S. TILLEY, K. E. CHEN, J. DONG, P. C. DOERSCHUK, C. B. SCHAFFER;
Meinig Sch. of Biomed. Engin., Cornell Univ., Ithaca, NY

Abstract: Studies of normal and disease state physiological processes in the brain would benefit from direct imaging of the dynamics and interactions of multiple cell types in live animal models. Nonlinear microscopy enables sufficient depth penetration and spatial resolution for such studies, but is typically limited to imaging only a few cell types at a time because of the inability to cleanly separate the emission from multiple, spectrally-overlapping fluorescent labels. We developed a hyperspectral multiphoton microscope (HMM) that provides 48 channels of excitation/emission information to enable clean separation of labels, while retaining the imaging depth and resolution of standard nonlinear imaging.

Emitted fluorescence is separated by dichroics into four broad color channels, each with an angle-tuned bandpass filter (ATBF). A four-channel image is collected for four successive angles of the ATBFs (**Fig.1A**), producing a 16-channel image that spans the visible spectrum. To leverage differences in excitation cross-section of different fluorophores, this is repeated across three excitation lasers (800 - 1035 nm) producing a 48-channel image for every plane in an image stack (**Fig. 1B**). These data are linearly unmixed to yield an image for each fluorescent label (**Fig. 1C**).

We imaged the cortex of a live mouse that had pyramidal neurons labeled with yellow fluorescent protein (YFP), microglia labeled with green fluorescent protein (GFP), nuclei and astrocytes labeled with topically applied Hoechst and Sulforhodamine 101 (SR101), respectively, and blood vessels labeled by intravenously-injected FITC and Cascade Blue (**Fig. 1B**). After unmixing, **Fig. 1C** shows from left to right: Hoechst nuclei (blue; colors refer to composite image in **Fig. 1D**), GFP microglia (green), FITC/Cascade Blue vasculature (cyan), YFP neurons (yellow), and SR101 astrocytes (red).

The HMM enables in vivo imaging of the dynamics and interactions of many cell types simultaneously, despite overlapping fluorescent labels.

Title: Remote z-scanning with a macroscopic voice coil motor for fast 3D calcium imaging in the zebrafish olfactory system

Authors: *P. RUPPRECHT[1], R. W. FRIEDRICH[1], C. WYART[2], A. PRENDERGAST[2]; [1]Rainer Friedrich Lab., Friedrich Miescher Inst., Basel, Switzerland; [2]Inst. du Cerveau et de la Moelle Épinière (ICM), Paris, France

Abstract: We developed a focusing technique for fast axial scanning based on a remote movable mirror that is conjugate to the specimen plane and translated by a voice coil motor. We constructed cost-effective z-scanning modules (<2500 $) from off-the-shelf components that can be mounted onto standard multiphoton laser scanning microscopes to extend scan patterns from 2D to 3D. These systems were designed for large objectives and provide high resolution, high speed and a large z-scan range (>300 μm). We used these systems in adult zebrafish for 3D multiphoton calcium imaging in the olfactory bulb (OB) and telencephalic area Dp, the homolog of olfactory cortex. We measured activity patterns across up to >1500 neurons with single-neuron resolution and high signal-to-noise ratio in response to slowly changing odor stimuli. The results revealed neuronal dynamics in mitral cells of the OB and in somata in Dp that evolved both on short (<1 sec) and long (>10 sec) timescales.

Abstract: As advances in multiphoton imaging techniques continue to push neuronal imaging deeper into the brain *in vivo*, correcting for sample-induced aberrations become vital in recovering diffraction-limited imaging performance at depth. As such, a plethora of adaptive optics (AO) techniques have emerged for biological imaging. However, these methods are often difficult to integrate into existing systems, only correct the aberration within a small field of view, or requires multiple specialized hardware to measure and correct the wavefront aberration. Here, we describe a simple AO module using a multiplexed aberration measurement method and apply it to *in vivo* two-photon imaging of the brain. We compare two different modulation techniques used for multiplexed measurement of aberration, characterize the effects of feature size on their performance, and apply them to in vivo imaging of zebrafish larvae and mouse brain. Because of its simplicity and independent software control, we expect our AO module to be easily integrated into existing custom or commercial laser scanning microscopes.

Title: A modular system for transcranial optical imaging in behaving mice

Authors: *B. R. MULLEN[1], J. D. MAYO[2], S. L. HILL[1], A. FONG[1], J. B. ACKMAN[1]; [2]Molecular, Cell, Developmental Biol., [1]UC Santa Cruz, Santa Cruz, CA

Abstract: Brain waves are spontaneous or sensory evoked patterns of neural activity that signal collective action within and across groups of neurons. Understanding the flow of cerebral waves across circuits during resting or active behavior is crucial for gaining insight into the mechanisms underlying self-organization in the developing brain. To this end, we've developed a relatively low cost and modular system for imaging genetically encoded calcium indicators expressed throughout the cerebral cortex. Our system allows for simultaneous imaging of neural activity across cortical regions with mesoscale spatial and temporal resolutions (less than 100s of μm and 100s of ms) and provides flexibility when integrating multiple functional signals together with experimental manipulations and tests of behavioral function. The system allows for wide field, single sensor monitoring of brain activity and motor behavior not typically available with conventional microscopes and the acquired signals are suitable for testing the organization of large-scale brain networks during behavior. We show how dynamical wave patterns in developing mouse neocortex are structured both in an areal and behavior dependent fashion and illustrate how assessments of distributed functional architecture may be used to better understand the nature of neurodevelopmental disease.

Abstract: Intrinsic signal imaging (ISI) is a well-established methodology for delineating stimulus-evoked functional areas of the brain. The method leverages differential absorption of red light by oxy- vs. deoxy-hemoglobin to distinguish active centers of brain activity. Broader use of intrinsic imaging is hindered by the lack of viable, commercial products capable of generating high-quality ISI maps with sufficient flexibility, standardization, and precision to meet the needs of a broad range of experimental paradigms. Here we describe how application of industrial product development principles enabled the adaptation of a highly-customized, academic research tool into a generalized, robust, standardized, and highly-automated intrinsic signal imaging platform.

Abstract: Fluorescence microscopy is increasingly used for measuring neural activity *in vivo*. Arrival of miniaturized microscopes has opened for deep imaging of brain tissue in freely moving animals. The power of these experiments is the possibility of simultaneous recordings of the activity from a large number of neurons. However, this makes it hard to maintain image quality and resolution for each individual neuron, which complicates data analysis.

Although many software tools for data analysis exist, it is challenging to evaluate their accuracy because the ground truth of the data is mostly unknown. Using simulated microscopy, however, the ground truth is known and could be used to test the accuracy and weakness of analysis software and also guide experiments.
Here we present Photonflow, an open-source fluorescence microscopy simulator made to test the performance of analysis software and identify the limits of experimental configurations. Photonflow simulates photon transport to create realistic microscopy images of brain tissue. Typically, the quality of microscopy analysis software is determined by comparing it to manual inspection. For instance, software that identifies neurons from a series of images can be compared with manual outlining of regions of interest. While this is useful, it may be inaccurate because the analysis is idiosyncratic and the ground truth remains unknown. This is overcome in Photonflow by generating a set of simulated microscopy images based on a tailored ground truth. These can then be used to test the analysis tools.
Photonflow may also be useful in pilot experiments and make it possible to understand the potential and limitations of the planned experimental setup. For instance, Photonflow can be used to determine the optimal level of fluorescence to avoid excessive contamination by light from surrounding tissue.
Photonflow is intended to be easy to use. It provides a graphical user interface for exploring the imaged neurons. The simulator is written in C++ and is based on open-source libraries and methods that are in common use both to simulate photon transport and for creating realistic photography. Photon transport simulation can produce realistic images similar to those found in experiments. Our simulator tracks a large number of photon packets that are emitted from light sources, such as fluorescent cells, and are scattered throughout the tissue before they reach the camera sensor. The simulator registers where on the sensor the photon packets arrive and uses this to render the final image.
With Photonflow, we aim to further improve the confidence in fluorescence microscopy and the corresponding data analysis.

Title: Crowdsourced label learning for independent components of EEG data

Authors: *L. PION-TONACHINI[1,2], R. MARTINEZ-CANCINO[1], K. KREUTZ-DELGADO[2], S. MAKEIG[1];
[1]Swartz Ctr. For Computat. Neurosci., La Jolla, CA; [2]Electrical and Computer Engin., UC San Diego, La Jolla, CA

Abstract: Independent component analysis (ICA) has already been shown to be a powerful tool for analyzing electroencephalographic (EEG) data, but there are two inherent difficulties in its usage. The first is data preprocessing, as ICA can be sensitive to spatially non-stereotyped noise/artifact in the data. But while data aggregation, normalization, and feature extraction needed to select data for decomposition are non-trivial and time consuming, they do not present a barrier to working with ICA. The first real obstacle encountered by researchers is the absence of component labels to assist in interpreting the results. As ICA is a form of blind source separation, the estimated independent components (ICs) are not labeled as to their origin (brain or non-brain; if non-brain, ECG, EOG, EMG, line noise, or other). While, given expert knowledge, this ambiguity is not an unresolvable obstacle to using ICA in data analysis, expert knowledge may not be available to beginners nor to automated procedures nor when dealing with large datasets where the time required to obtain detailed expert evaluation is a bottleneck. To address the IC classification problem, we are creating an automated EEG IC classifier to label, probabilistically, the nature of the source processes producing the IC scalp maps and time courses returned by ICA decomposition. Although some IC classifiers are currently available, each has drawbacks we plan to overcome, primarily by using an IC data set that is orders of magnitude larger than those used previously, as well as by employing more complex learning algorithms to make best use of the data. With upwards of half a million ICs in our dataset, seeding the classifier learning process by labeling even a small subset would be difficult to perform individually. Therefore we have turned to crowdsourcing, creating a website and asking researchers on the EEGLAB mailing list to contribute their time to the effort. Others with experience in using ICA decomposition of EEG data are welcome to contribute as well -- visit http://reaching.ucsd.edu:8000/tutorial for details. The major motivation for those contributing is the eventual value to them of such a classifier, as well as gaining some tutorial experience in making these classifications. To date, we have amassed more than 12,000 submitted component labels from more than 50 contributors and are now beginning to process the contributed labels to prepare them for use in the final classifier learning process. The collected labels will be used to generate the most reliable estimated label for each IC shown on the website by comparing which contributors labeled which ICs as what type by using a family of algorithms known as crowdlabeling.

Title: Adjusting permutation tests for multivariate analysis of neuroimaging data with subclasses

Authors: *H. JAMALABADI[1,2], S. ALIZADEH[1,2], M. SCHÖNAUER[1], S. GAIS[1];
[1]Med. Psychology and Behavioral Neurobio., Univ. of Tuebingen, Tuebingen, Germany;
[2]IMPRS for Cognitive and Systems Neurosci., Tübingen, Germany

Abstract: When multivariate pattern analysis (MVPA) is used for hypothesis testing, a classifier is trained on a portion of a data set to separate data belonging to different classes (e.g. different experimental conditions, different groups of patients, etc.). Then, the classifier is tested on new data, determining the correct classification rate (CCR) using a cross-validation procedure. If this accuracy lies significantly above the level expected by chance (e.g. 50% for a two-class problem), the classifier is able to detect generalizable class-related information in the data, i.e., classes differ significantly.
However, we show that in neuroimaging data with nested subclasses, above chance classification accuracy is possible even when no class-related effect exists. This happens because MVPA is sensitive to any kinds of structure in the data and thus, in such data sets, subclass-specific differences increase classification accuracy beyond what is expected. Subclasses are formed in data if stimuli can be further categorized with respect to a secondary attribute (e.g. physical properties, familiarity, etc.), if stimuli or types of stimuli are presented repeatedly, or if multiple subjects and experimental sessions are included into one analysis. Importantly, however, this subclass-specific information which contributes to the classification is not related to the effect under investigation and their effect should be discarded from analysis. The unexpected above chance classification of data with subclasses has implications when using MVPA for hypothesis testing. In particular, binomial tests as well as trial-wise randomization tests will lead to false positive results. To circumvent this problem, we propose a permutation algorithm that provides exact control of false positives in such data sets. We show if permutation tests are correctly adjusted, false positive rates can be controlled.

Title: Neural oscillatory power is not Gaussian distributed across time

Authors: *L. IZHIKEVICH, E. PETERSON, B. VOYTEK;
Cognitive Sci., UCSD, San Diego, CA

Abstract: Neural oscillations are important in organizing activity across the human brain in healthy cognition, while oscillatory disruptions are linked to numerous disease states. Oscillations are known to vary by frequency and amplitude across time and between different brain regions; however, this variability has never been well characterized. We examined human and animal EEG, LFP, MEG, and ECoG data from over 100 subjects to analyze the distribution of power and frequency across time, space and species. We report that between data types, subjects, frequencies, electrodes, and time, an inverse power law, or negative exponential distribution, is present in all recordings. This is contrary to, and not compatible with, the Gaussian noise assumption made in many digital signal processing techniques. The statistical assumptions underlying common algorithms for power spectral estimation, such as Welch's method, are being violated resulting in non-trivial misestimates of oscillatory power. Different statistical approaches are warranted.

Title: Improving detection and localization of spontaneous oscillatory dynamics in simultaneous EEG-fMRI

Authors: *L. D. LEWIS[1], G. BONMASSAR[2], K. SETSOMPOP[2], J. R. POLIMENI[2], B. R. ROSEN[2];

Abstract: Simultaneous recordings of electroencephalography (EEG) and functional magnetic resonance imaging (fMRI) provide complementary measures of brain function, enabling high spatial and temporal resolution studies of human brain activity. EEG acquired inside the magnet is heavily contaminated by ballistocardiogram artifacts induced by each cycle of the subject's heartbeat. Several cleaning methods have been developed that work well for reducing EEG artifacts in high (>10 Hz) frequency bands, and studies of evoked potentials can further reduce the effects of these artifacts by averaging across trials. However, the effects of these cleaning methods have not been evaluated for a broader range of frequencies. In particular, dynamics in the low (<10 Hz) frequency band can be difficult to recover, especially when studying spontaneous activity that cannot benefit from averaging multiple trials. We sought to identify whether low-frequency activity could be recovered from the EEG without averaging, and test how these signal processing approaches influence the networks identified in EEG-fMRI data. We acquired 256-channel EEG data from three subjects with simultaneous fMRI at 3 Tesla. To induce an ongoing EEG oscillation of known frequency, we presented a radial checkerboard with contrast inverting at a frequency of interest (0.5, 1, 2, 4, 8, 12, or 20 Hz). Subjects wore a custom-constructed reference layer cap to isolate the majority of the channels from the scalp (Chowdhury et al., 2014; Luo et al, 2014). We compared a set of different cleaning methods to determine how each affected EEG content: average artifact subtraction (AAS, Allen et al., 2000), optimal basis sets (OBS, Niazy et al., 2005), reference layer artifact subtraction (RLAS, Chowdhury et al., 2014; Luo et al, 2014), and removal of a subset of independent components (Abreu et al., 2016). We found that while all methods performed well at high frequencies, combined RLAS-AAS achieved the best recovery of the induced EEG oscillations across the full range of frequencies studied, suggesting that experiments seeking to measure lower frequencies would benefit from using an isolated reference layer to directly sample the ballistocardiogram noise. Finally, we applied these methods to resting state datasets from the same subjects to determine how they influenced calculated relationships with the fMRI BOLD signal, and found alterations in measured fMRI correlations depending on the method used. We conclude that commonly used EEG cleaning methods differentially affect signal strength across different frequency bands, and suggest specific ways in which this may influence the results and inferences in EEG-fMRI studies

Title: Stability of representational similarity analysis across a large range of overall activation levels

Authors: ***S. ARBUCKLE**, A. YOKOI, J. DIEDRICHSEN;
Univ. of Western Ontario, London, ON, Canada

Abstract: Representational similarity analysis (RSA) characterizes the relationship between the complex patterns of activity recorded using functional magnetic resonance imaging (fMRI), to infer how the brain encodes different classes of information. While the fine spatial organization of the patterns elicited from specific stimuli or tasks can vary widely across individuals, the ratios of relative dissimilarities between patterns (here referred to as representational structure) is often stable across individuals. We recently demonstrated this stability for individual finger movements in primary motor cortex (M1, Ejaz et al., 2015). The great strength of RSA is that the measured representational structure can be compared to predictions derived from theoretical models, allowing inferences about neural processes in different cortical areas.
However, a major concern is that the non-linearity between neural activity and fMRI signal may distort the local pattern of activities, such that the representational structure would depend strongly on activity in the respective region - making the ratios between distances uninterpretable. Here we report the results of a control experiment with 9 participants, in which we increased the overall level of activity in M1 over a large dynamic range by increasing the movement frequency of single finger presses from 0.3Hz to close to performance limit. Average activity in M1 increased approximately linearly with the log of the tapping frequency. We then calculated the crossvalidated Mahalanobis distance as a dissimilarity measure between the 5 fingers for each of the 4 speeds. While the distances between the different fingers increased with increasing activation, the representational structure (i.e. ratio of these distances) remained stable.
We then analyzed all data in a single representational space to determine the relationship between the activity differences between fingers and between speeds. We show that overall

structure is well explained by a linear scaling of the patterns associated with each finger relative to rest plus an additive speed-dependent pattern, which is independent from the individual finger patterns. Importantly, this relatively simple model (20 parameters) can fully describe the representational structure (210 parameters).
These results suggest that RSA using crossvalidated Mahalanobis distances yields a description of the representational structure of activity patterns that remains stable over a large dynamic range of activation levels, and that we can characterize the scaling response of these patterns using a relatively simple model.

Title: Multivariate pattern connectivity

Authors: *S. ANZELLOTTI[1], A. CARAMAZZA[2,3], R. SAXE[1];
[1]Dept. of Brain and Cognitive Sci., MIT, Cambridge, MA; [2]Harvard Univ., Cambridge, MA;
[3]Ctr. for Mind/Brain Sci., Trento, Italy

Abstract: When we perform a cognitive task, multiple brain regions are engaged. Studying how these regions interact is a fundamental step to understand the neural mechanisms at the basis of behavior. Most investigations of interactions between brain regions have focused on the overall univariate responses in the regions. However, in the context of 'static' analyses, important advantages have derived from the application of multivariate techniques considering the fine-grained spatial structure of responses within each region (multivariate pattern analysis - MVPA). In this poster, we introduce and apply a technique to study connectivity in terms of the multivariate relations between patterns of responses within brain regions: multivariate pattern connectivity (MVPC). MVPC characterizes the responses in each brain region as trajectories in region-specific multidimensional representational spaces, and uses multivariate techniques to model the relationship between these trajectories. Considering the fusiform face area (FFA) as a

seed region, we show that MVPC provides novel information about the interactions between regions that goes beyond univariate functional connectivity analyses.

Title: Identification of "hot" local brain networks during motor sequence learning

Authors: Y. ZHAO[1], X. LUO[1], E. UPFAL[2], P. BÉDARD[3], *J. N. SANES[3];
[1]Biostatistics, [2]Computer Sci., [3]Neurosci., Brown Univ., Providence, RI

Abstract: Functional magnetic resonance imaging (fMRI) is used to infer brain network activation and interactions, and graph theory methods can identify how networks may mediate behavior. However, current approaches have not focused on identifying local (sub) networks that likely underlie components of behavior, such as the perceptual, cognitive, mnemonic, and motor subprocesses needed to learning new skills. We developed a statistical method to discover significant, task-related subnetworks while participants learned a motor sequence (Sanchez et al. 2010) during continuous acquisition of fMRI signals. We developed an integrated method that addresses three interwoven aims: (1) activation detection, (2) network estimation, and (3) subnetwork identification. In addition, we aimed to develop a method that could scale to large dimensions without incurring substantial computational costs. To achieve these aims, we extended existing frameworks, including general linear models (GLM), sparse inverse

covariance estimation, and "HotNet", a subnetwork identification method originally developed to identify cancer mutation subnetworks (Vandin et al. 2011; 2012). Building on the GLM analysis for activation for each node, we compared existing approaches (e.g., community partition, Rubinov and Sporns 2010) to infer the connectivity network using correlations, inverse covariance estimation, and a recently developed machine learning method for sparse graphical models (Friedman et al. 2008; Liu and Luo 2015). We then applied the HotNet algorithm to identify “hot” subnetworks based on these inferred activations and connectivities using different approaches, and the performance was evaluated using several metrics for subnetwork identification accuracy. We compared the approaches via realistic large scale fMRI simulations and with fMRI data sets obtained during motor sequence learning. Our method identified hot subnetworks with higher accuracy than the community partition algorithms in graph theoretical analysis. Further, the HotNet approach yielded task-related networks in brain regions engaged in visual and motor processing and areas previously identified as becoming activated during motor learning. We anticipate that these methods will become a tool widely used for subnetworks discovery that shifts dynamically during performance of adaptive behavior. References: Friedman et al. Title: Cortical current source estimation improves detection of sensorimotor rhythm in resting-state: Validation through simultaneous EEG-fMRI recording in humans

Authors: *S. SHIBUSAWA[1], S. TSUCHIMOTO[1], S. KASUGA[1], K. KATO[3], E. YAMADA[4], H. EBATA[4], M. LIU[3], J. USHIBA[2];

Abstract: Electroencephalogram (EEG) is often used for cortical activity recording in humans because of its advantages of noninvasiveness, low movement constraints, and high temporal resolution. However, EEG spatial resolution is low, and signal contaminations from cortical regions are often observed. Cortical current source estimation, a numerical method for solving ill-posed inverse problems on EEG electrophysiology, has been therefore widely used to overcome these issues, but yet its methodological efficacy is not sufficiently tested using physiological data. The present study used simultaneously recorded EEG and functional magnetic resonance imaging (fMRI), and tested the goodness-of-fit of estimated cortical current source signals to fMRI blood oxygen level-dependent (BOLD) signals. Resting-state EEG and fMRI were simultaneously recorded for continuous 10 minutes in 14 neurologically normal participants. To construct individual brain models, T1 weighted structural MR images and EEG electrode positions were acquired from each participant. Cortical current source was estimated by solving the inverse problem using Variational Bayesian Multimodal Encephalography (VBMEG) in this study. Correlation of the estimated cortical current source signals to fMRI BOLD signals of Somatomotor Network (SN) was calculated to see its estimation quality. For quantitative assessment of signal localization, a binary classification test was involved as follows. First, SN in the fMRI space was defined as 'TRUE' region where SMR signal comes from. Other cortical regions except SN in the fMRI space were defined as 'FALSE' regions. Second, the classification performance of the estimated cortical current signal from EEG sensorimotor rhythm (EEG-SMR) recorded over the left sensorimotor cortex was assessed using Receiver Operating Characteristic (ROC) curve analysis. Third, the same classification test was performed with EEG-SMR as a reference, and calculated improvement of signal localization by current source estimation. Area Under the Curve with the current source estimates was significantly larger than that obtained with EEG signals (Wilcoxon signed-rank test, $p<0.001$). The optimal cutoff-value with the current source estimates was also significantly larger than that calculated with EEG signals (Wilcoxon signed-rank test, $p<0.001$). We considered that the estimated current source can successfully segregate cortical signals from EEG. These results suggest that current source estimation successfully segregate cortical signals from EEG, resulting in the improvement of spatiotemporal detection of the sensorimotor cortical activity.

Title: Optimal resolution for searchlight classification of BOLD fMRI data?

Authors: H. MANDELKOW[1], J. DE ZWART[2], *D. PICCHIONI[1], J. DUYN[2];
[1]Intramural Res. Program, [2]Advanced MRI / LFMI / NINDS, NIH, Bethesda, MD

Abstract: Conventional univariate BOLD fMRI analysis relies on a fixed a-priori model of the spatio-temporal hemodynamic response to predefined stimuli. An alternative, the Searchlight (SL) method [1] makes less assumptions by inferring local information content from multivariate BOLD signal statistics. It has been hypothesised that higher spatial fMRI resolution would increase SL sensitivity allowing better discrimination between different stimuli. Here we investigate the effect of fMRI resolution on the sensitivity of SL analysis using several machine-learning (ML) classifiers.

Four healthy volunteers underwent fMRI and simultaneous eye tracking while watching one 5-minute scene from a popular action movie repeatedly. For each experimental run fMRI data were acquired either at a high (1.2mm) or a low (2mm) fMRI resolution on a 7T MRI scanner. ML classifiers known as Nearest Neighbour (NN), Gaussian Naïve Bayes (GNB) and Linear Discriminant Analysis (LDA) were used to determine the classification accuracy (CA) in identifying each of the 150 time points (300s/TR) in the movie. A searchlight map was formed by computing this classification analysis separately for each voxel location using a neighbourhood of 1-5 voxels in each direction as input features. SL maps computed separately from high-resolution (HR) and low-resolution (LR) data in each subject were compared by taking the difference HR-LR (Figure 2). The SL analysis was repeated for different classifiers and with different levels of Gaussian smoothing (3-9mm FWHM).

As expected, searchlight CA decreased with decreasing SL volume yielding mostly insignificant CA for SL radii <(6mm)3 for both HR and LR data. For SL volumes >(1cm)3 CA in most cortical locations along the ventral visual stream increased with increasing voxel size. Gaussian smoothing had a similar effect. These findings are consistent with previous results, which showed a maximum in CA for classifiers operating on 25% of all visually activated voxels across the entire ventral visual stream and at a moderate fMRI resolution of 2-3mm [2]. For intermediate SL volumes (6-9mm)3 CA and fMRI resolution effects varied systematically between brain regions, subjects and experimental runs:

a) Searchlight CA maps showed hotspots in early visual areas V1-4 and V5/hMT.

b) Positive resolution effects CA(HR)-CA(LR) were mostly observed in primary visual cortex V1-4.

c) Positive resolution effects were more widespread in subjects with more consistent (correlated) eye gaze patterns.

The aforementioned differential effects were independent of the choice of classifier, even though absolute CA levels differed substantially.

Title: Improving predictive models using non-spherical Gaussian priors

Authors: *A. O. NUNEZ-ELIZALDE, A. G. HUTH, J. GALLANT;
Helen Wills Neurosci. Inst., UC Berkeley, Berkeley, CA

Abstract: Predictive models for neural or fMRI data are often fit using regression methods that employ priors on the model parameters. One widely used method is ridge regression, which employs a Gaussian prior that has equal and independent variance for all parameters (i.e. a spherical multivariate Gaussian). However, a spherical prior is not always appropriate: there are many cases where expert knowledge or hypotheses about the structure of the model parameters could be used to construct a better prior. Non-spherical Gaussian priors can be employed using a generalized form of ridge known as Tikhonov regression. Yet Tikhonov regression is not (explicitly) used very often in neuroscience. Here we show that Tikhonov regression with non-spherical Gaussian priors can improve several predictive models for fMRI data. We also show that linearized ridge regression (i.e., linearly transforming the regressors before regression) can be formulated as Tikhonov regression.
Our first result is based on an fMRI language experiment in which subjects listened to several hours of natural stories. A predictive model in which the features were indicator variables for each unique word (a spherical prior) provided poor predictions of held-out data. However, performance improved by using a non-spherical Gaussian prior in which words that have similar meanings are likely to be assigned similar weights. Our second result comes from an fMRI vision experiment in which subjects watched several hours of natural movies. A predictive model in which low-level structural and high-level categorical features were combined (a spherical prior) provided poor predictions. However, performance improved by using a non-spherical Gaussian prior in which the two feature spaces have unequal variance. We also show that non-spherical priors can improve the estimation of temporal kernels. Finally, we demonstrate a computationally efficient method for incorporating non-spherical priors into regression models.

Title: Correlations between myelin water fraction, ratio of T1- and T2-weighted images, and diffusion tensor imaging measures in human brain white matter

Authors: *M. UDDIN[1], K. G. SOLAR[2], A. SHATIL[3], S. YOUNAS[3], S. M. COURTNEY[4], C. R. FIGLEY[1];
[1]Dept. of Radiology, [2]Physiol. and Pathology, [3]Biomed. Engin., Univ. of Manitoba, Winnipeg, MB, Canada; [4]Psychological and Brain Sci., Johns Hopkins University, , MD, USA, Baltimore, MD

Abstract: Microstructural changes in human brain tissue can be measured noninvasively using myelin water imaging (MWI), diffusion tensor imaging (DTI), and other quantitative MRI methods. These measures can provide novel insights into demyelinating diseases, such as multiple sclerosis. Myelin water fraction (MWF) obtained from MWI (multicomponent T2-relaxation) has excellent specificity for myelin content. Although not a pure measure of myelin, signal intensity ration maps of T1- to T2-weighted (T1w/T2w) images appear to show increased sensitivity and lower variability to myelin content compared to magnetization transfer ratio. On the other hand, DTI metrics such as fractional anisotropy (FA) and mean diffusivity (MD) are considered to be indicators of white matter (WM) microstructure owing to their sensitivities to cellular density, axon diameter, and myelin content. In this study we examined the relationships between MWF, T1w/T2w ratio, FA, and MD in several WM structures using 3 T MRI data from 32 neurologically healthy human subjects. Image analyses were performed using MRIStudio and SPM12, and each subject's images were normalised to ICBM space using non-linear warping to facilitate group comparisons. To assess correlations between the MRI metrics in well defined regions-of-interest (ROIs), we extracted data from 25 WM ROIs listed in the JHU_MNI_SS ("Eve") atlas. Significant correlations were found between MWF and T1w/T2w for several ROIs, including the cerebellum, splenium of the corpus callosum (CC), fornix, inferior fronto-occipital fasciculus, posterior thalamic radiation, cerebral peduncle, anterior internal capsule and external capsule. T1w/T2w correlated significantly with FA in both the genu and splenium of CC, the external capsule, and the fornix, while MD showed negative correlations (as expected) with T1w/T2w as well as with FA for several other WM structures. Perhaps surprisingly, MWF did not show any significant correlations with either FA or MD in any single ROI; however, linear regression of the data combined across structures revealed a highly significant correlation

between MWF and FA ($r = 0.75$; $p < 0.001$), as did T1w/T2w vs. FA ($r = 0.49$; $p < 0.001$). Furthermore, MWF vs. FA and T1w/T2w vs. FA had slopes 3.05 and 2.31 respectively, suggesting that these measures might be more sensitive than FA to microstructural differences between ROIs and subjects. Overall, however, our results indicate that MWF, T1w/T2w, and DTI measures are all correlated, and that findings from one modality can be interpreted, to some extent, within the context of the others (e.g., using previous DTI findings to support novel results based on T1w/T2w or MWF, etc.).

Title: Combining fMRI and ECoG using common naturalistic stimulus

Authors: *A. C. CONNOLLY[1], J. HAXBY[2], B. C. JOBST[3];
[1]Dartmouth Col. Geisel Sch. of Med., Lebanon, NH; [2]Dartmouth, Hanover, NH; [3]Geisel Sch. of Med. at Dartmouth, Hanover, NH

Abstract: fMRI measures the blood-oxygen level dependent (BOLD) signal, which follows the hemodynamic response to local neural activation, which is orders of magnitude slower than the underlying neural fluctuations which occur in milliseconds. Electrocorticography (ECoG) affords superior temporal resolution; however, while the spatial resolution for ECoG may be better than scalp for EEG, the increase in temporal resolution comes at a cost of decreased ability to localize activation compared to fMRI. Because of volume conduction, the voltage changes measured with ECoG contain mixtures of signals from multiple sources whose locations cannot be easily determined. We address these temporal shortcomings of fMRI and the spatial shortcomings of ECoG through a novel a cross-subject/cross-modality functional connectivity paradigm that integrate brain recordings across subjects and across modalities. Based on brain activity recorded while subjects (5 ECoG patients, and 10 healthy fMRI subjects) watched four 15 minute segments of a nature documentary, we report results of a cross-subject/cross-modality functional connectivity analysis. The “seed” signals were derived from electrophysiological recordings from electrodes in epilepsy patients undergoing monitoring for epilepsy surgery. These signals were preprocessed and transformed into spectral power time-courses and then convolved with a canonical hemodynamic response function and down sampled to the sampling frequency of

fMRI (0.4Hz). Our results show that the ECoG signal can be decomposed and related to functional activity recorded using fMRI in other subjects. Furthermore, different frequency bands from the same electrode are correlated with different, but logical anatomical sources: low-frequency bands correlated best with primary sensory regions both auditory and visual depending on the location of the electrode, and high frequency bands recorded in the occipital lobe correlated with high-level vision. We predict that repeating these analyses with a larger sample of subjects and a large number of electrodes will result in a functional mapping of ECoG electrodes to brain regions that will be very useful for all researchers conducting brain mapping using ECoG. It will also provide a means to test the time-courses of activity and causal processes for interconnected functional regions for which the temporal resolution has been lacking in fMRI.

Title: Association of gray matter imaging markers with alcoholism incorporating structural connectivity information: a regularized statistical approach

Authors: *J. HAREZLAK[1,2], M. KARAS[1], M. DZEMIDZIC[2], J. GONI[3], B. G. OBERLIN[2], D. A. KAREKEN[2];
[1]Biostatistics, Indiana Univ. RM Fairbanks Sch. of Publ. H, Indianapolis, IN; [2]Indiana Univ. Sch. of Med., Indianapolis, IN; [3]Purdue Univ., West Lafayette, IN

Abstract: The majority of multimodal neuroimaging studies are analyzed separately for each modality. Importantly, statistical methods that simultaneously assess multimodal data provide a more integrative and comprehensive understanding of the brain. Here we model associations between alcohol abuse phenotypes and regional grey matter measures while incorporating a priori structural connectivity (SC) information. We utilize cortical thickness and integrated rectified mean curvature obtained from FreeSurfer, to predict alcoholism-related phenotypes while incorporating the SC density of connections between 66 Desikan-Killiany atlas regions.

The analyzed sample included 148 young (21-35 years) social-to-heavy drinking male subjects from several alcoholism risk studies. A functional linear model with a penalty operator quantified the relative contributions of cortical thickness and curvature as predictors of drinking frequency, with age and number of years since regular drinking started as covariates. Model parameters were estimated by a unified approach directly incorporating SC information into the estimation by exploiting the joint eigenproperties of the predictors and the penalty operator. The best predictive imaging markers of drinking (number of drinks per week) were the average thickness of the left lateral orbitofrontal cortex, majority of the cingulate gyrus subdivisions (left anterior rostral and caudal, bilateral posterior and isthmus), bilateral paracentral gyrus, and the left inferior temporal gyrus. These regions all showed significant negative associations with the outcome, with no significant positive associations present. Introducing a priori information minimized spurious findings by assigning penalty weights in such a way that highly connected regions associated with the outcome were less penalized than other regions that had no association with the outcome. Future work will incorporate functional connectivity and finer cortical parcellation to discover even more subtle associations.

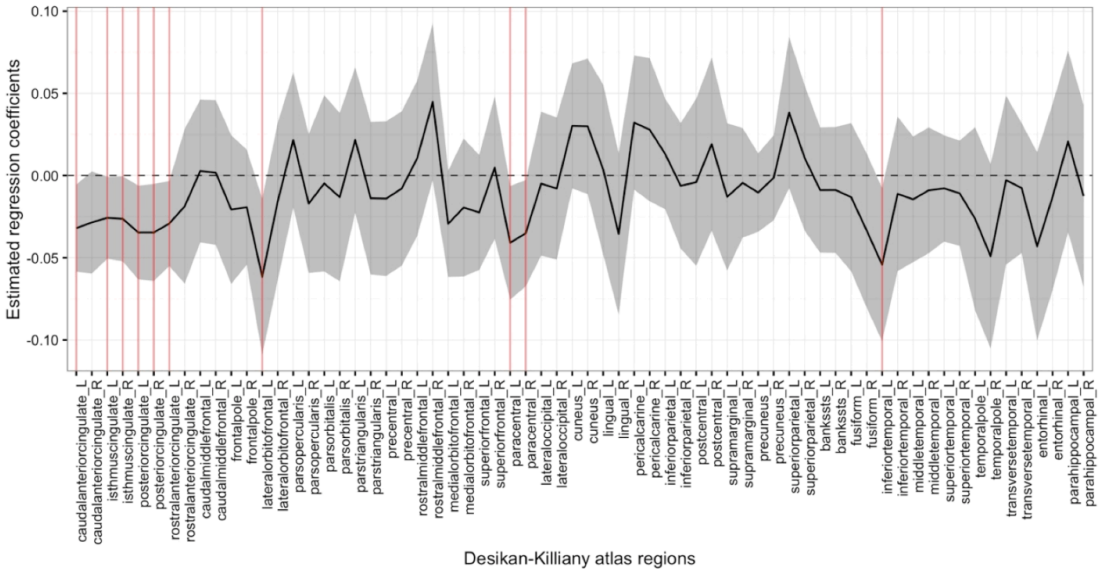

Figure 1: Estimated regression coefficients (black line) and their respective 95% confidence intervals (grey shaded area) based on the structural-connectivity-informed regularization. Vertical red lines indicate coefficients of average cortical area thickness which are significantly different from zero.

Title: Supervised and blind voxel-based state space methods recover task-related states from fMRI responses

Authors: *T. ZHANG[1], J. GAO[2], J. GALLANT[3,2,1];
[1]Joint Grad. Group in Bioengineering, [2]Vision Sci. Program, [3]Dept. of Psychology, Univ. of California, Berkeley, Berkeley, CA

Abstract: Purpose: Task-dependent brain responses are complex and difficult to understand. The problem can sometimes be simplified by modeling population responses as a dynamical process that reflects the task. Here we adapt a recent dynamical systems modeling approach developed in neurophysiology (Mante et al., Nature, 2013) and apply it to fMRI data recorded from subjects who performed an attention task and an open-ended video game task. **Methods:** In the attention task, five subjects viewed 1,800 s of natural movies repeated across cue conditions. Subjects fixated on a central point, and were cued to attend to either humans or vehicles in a balanced, randomized order. Humans, vehicles, both, or neither category were equally likely. Attentional state was defined as the cued category. In the open-ended task, one subject played a computer game for 90 minutes. States were labeled using nine categories defined by two people familiar with the game. In both experiments, whole brain MRI data with a 2.24x2.24x4.1mm voxel size was acquired on a 3 T Siemens scanner at UC Berkeley. We tested both supervised and blind voxel-based state space recovery methods. We first used principal component analysis to denoise responses. In the supervised method, we interpreted the weight vector of each state variable across voxels as the state direction and constructed a task state space from these vectors. We projected responses into this space to recover state. In the blind method, we applied independent component (IC) analysis to the responses and projected them into the space spanned by the ICs. The ICs were interpreted retroactively. **Results:** In the attention task, the supervised method recovered axes for attentional state and for the presence of each category in the movie. In the open-ended task, the supervised method found significant shifts for each state along the corresponding axis. State classification accuracy on separate validation data was above chance in both tasks (attention accuracy = 0.58 ± 0.09, chance = 0.25; open-ended accuracy = 0.56 ± 0.03, chance = 0.40). The blind method recovered two axes from the open-ended task. One axis reflects degree of physiological arousal, and the other distinguishes between opposing state

categories of "engage target" and "explore." **Conclusions:** We developed both supervised and blind voxel-based state space recovery methods for fMRI data. The supervised method recovers dimensions for all labeled states. The blind method recovers physiological arousal and a continuum from target engagement to exploration.

Title: Anatomical evaluation of Colin 27 against a database of labeled brain scans

Authors: *A. J. WORTH[1], J. A. TOURVILLE[2];
[1]Neuromorphometrics, Inc., Somerville, MA; [2]Speech, Language, and Hearing Sci., Boston Univ., Boston, MA

Abstract: The Colin 27 average brain is a stereotaxic registration model from the Montreal Neurological Institute (see Holmes et al. 1998). This T1 weighted MRI scan has very high signal-to-noise ratio and as a result shows fine anatomical details. Because it is of such high quality and is readily available, it is often used in research (e.g. Strangman et al. 2013). While this is a very valuable resource, it is a representation of the anatomy of a single individual. It may be tempting to use this model as a template to represent a generic brain, but before doing that it is important to understand how it compares with other brains. Following Ono et al. 1990, we present a quantitative comparison of both topology and topography of the cortical anatomy of the Colin 27 scan against our database of labeled MRI brain scans. The famous Colin 27 scan was obtained from a 27 year old individual who was scanned 27 times over a period of 3 months. Individual MRI brain scans were automatically registered to a common space in which they were subsampled and intensity averaged. To understand the anatomy in detail, every voxel of the brain was given a neuroanatomical label: 72 regions comprehensively covered the brain including: cerebral and cerebellar gray and white matter, ventricles, brain stem, accumbens, amygdala, caudate, hippocampus, pallidum, putamen, and thalamus according to the "General

Segmentation" protocol defined by the MGH Center for Morphometric Analysis, and the cortex was parcellated into 51 units based on 36 sulci according to the BrainColor protocol. After the initial labeling, an anatomist with years of labeling experience checked all results and the technician made corrections as necessary.
We compared the Colin 27 scan with similarly labeled scans of 113 subjects using methods described in the Ono atlas, which gives common topographic variants of cortical anatomy and reports the incidence rate of each variant. Quantitative measures include sulcus position, replication, interruptions, side branching, and connections to other sulci. Position with respect to other sulci is used to identify common patterns of local sulcal topography.
The resulting images, plots, and statistics show which regions in the Colin 27 template are anatomically similar to their counterparts in the larger group and those regions that are not. In particular, we noted atypical sulcal topography in, and around, Broca's area in Colin 27 relative to the larger population. Our results demonstrate a high degree of local variability in cortical anatomy. We conclude that templates derived from individual subjects are insufficient for accurately identifying and/or localizing a specific brain region.

Title: LesionWarp: An automated approach to lesion mapping through the use of nonlinear registration techniques from popular neuroimaging pipelines

Authors: J. BRUSS[1], M. SUTTERER[1], D. WARREN[2], J. HESKJE[1], *D. TRANEL[1];
[1]Dept Neurol, Univ. Iowa, Iowa City, IA; [2]Neurolog. Sci., Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: Neuropsychological studies of patients with focal brain injuries often draw conclusions about structure-function relationships based on the common anatomical components of patients' lesions. A key challenge for the human "lesion method" is the registration of each patient's brain and brain lesion to a common atlas space. The importance of valid registration of individual patient lesion territory to common atlas space has only increased in recent years due to the development of mass univariate and multivariate statistical approaches to interpreting structure-function relationships. Common automated brain registration techniques assume healthy brain tissue and normal T1-weighted image intensities, but the MRI signal obtained from patients with focal brain injury is often distorted or missing in the lesioned area. One traditional approach to lesion transfer relied on precise manual lesion transfer to an atlas brain by an expert in neuroanatomy, but this approach was time-consuming and difficult to standardize. Recent advances in automated nonlinear registration algorithms may provide an opportunity for automated registration of a patient's native space lesion mask into common anatomical space while improving replicability and standardization of the lesion transfer. In order to validate the application of automated registration techniques for purposes of lesion mapping, we performed a comprehensive evaluation of nonlinear registration packages applied to patients with focal lesion damage. In the present study, we compared 50 atlas-space lesion masks created using a manual lesion transfer method (MAP-3) to the masks representing the same lesions created by 1) tracing the lesions in native space and 2) warping those masks to atlas space using a non-linear algorithm; we call this novel approach LesionWarp. Notably, automated non-linear registration has been implemented in several unique software distributions, each of which employs a somewhat different algorithmic approach. In order to sample the accuracy of these different approaches, we compared the results of automated non-linear warping produced by several widely-cited neuroimaging software packages including AFNI, ANTs, Freesurfer, FSL and SPM. We found high spatial similarity (as measured by Dice's coefficient) between the nonlinear registration and manual lesion transfer approaches. Nonlinear registration outcomes between software packages were highly similar. These findings indicate that native space lesion-mapping followed by nonlinear registration to atlas space provides an empirically supported alternative to traditional, manual lesion-mapping approaches.

Title: Method to account for spatial bias in multimodal neuroimaging

Authors: ***N. J. HEUGEL**[1], S. BEARDSLEY[2,3,5], E. LIEBENTHAL[2,4,6];
[2]Biomed. Engin., [1]Marquette Univ., Milwaukee, WI; [3]Clin. and Translational science Inst., [4]Neurol., Med. college of Wisconsin, Milwaukee, WI; [5]Biomed. Engin., Boston Univ., Boston, MA; [6]Bringham Women's Hosp. and Harvard Univ., Boston, MA

Abstract: Fusing functional magnetic resonance imaging (fMRI) and electroencephalography (EEG) brain maps offers the potential for reconstructing neural networks with high spatial and temporal resolution. One approach for fusing the neuroimaging maps is to use fMRI activation foci as priors for EEG source localization, however with the caveat that activity across neuroimaging modalities may not be fully coupled. We propose a technique to fuse fMRI and EEG brain maps that allows for spatial biases and does not rely on a priori assumptions of coupling between the modalities. This is done by projecting the volumetric fMRI maps onto an inflated cortical surface, and modeling the projected map as an EEG signal by passing it through the forward and inverse matrices constructed for EEG source localization. In this way, the spatial bias of the EEG analysis is applied to the fMRI. Preliminary results in 13 subjects tested with simultaneous fMRI/EEG in an auditory oddball task suggest that fMRI activity directly accounts for approximately 73% of the EEG activity, and the EEG activity accounts for approximately 71% of the fMRI activity. Furthermore, much of the non-overlapping fMRI activity is in areas adjacent to the areas of overlap. Furthermore, areas of overlap across subjects are consistent with those implicated in the auditory oddball task. The proposed method for fusing fMRI and EEG maps has important implications for interpreting multimodal neuroimaging data and revealing substrates and dynamics of sensory and cognitive neural networks.

Title: Cortical parcellation for functional brain "fingerprinting"

Authors: L. NIE[1], *P. M. MATTHEWS[2], Y. GUO[1];
[1]Data Sci. Inst., Imperial Col. London, London, United Kingdom; [2]Div. of Brain Sciences, Dept of Medicine, Imperial Col. London, London, United Kingdom

Abstract: Recent studies show that cortical functional parcellations vary between individuals [1-2]. We tested whether cortical functional parcellations can be used to "fingerprint" [3] and identify individuals.
We analysed resting-state fMRI scans from 832 subjects provided by the Human Connectome Project [4]. Each of the subjects completed two resting-state fMRI sessions on separate days. The sessions on the first and second days are denoted as the Day1 and Day2, respectively. An individual cortical parcellation was generated for each subject using the Day1 data and the group-wise K-means algorithm, designed for simultaneously parcellating the full cortices across a large group. The group-wise regularisation in the algorithm ensures the parcellations across the group are similar, but allows for individual variability. A distribution of parcellations was calculated from the Day1 data and used as a prior for a second, identification step using the Day2 data. For this, the regularised K-means algorithm was used to generate parcellations based on the prior distribution. Parcellations were then compared quantitatively between Day1 and Day2 results in a blinded fashion to identify the strongest correspondences. Depending on the choice of adjustable regularisation parameter, 828-830 of the Day2 brains could be matched correctly (identified). Our studies suggest that functionally defined patterns of fMRI activity at rest are highly unique and may be able to be used to explore elements contributing to human variation.

Title: Using PLSC method to detect hyperacusis condition based on audiogram and fMRI data of tinnitus patients.

Authors: *N. GHAZALEH[1], W. VAN DER ZWAAG[2], R. MAIRE[3], M. SAENZ[4,1], D. VAN DE VILLE[5,1];
[1]École Polytechnique Fédérale De Lausanne (EPFL), Lausanne, Switzerland; [2]Spinoza Ctr. for Neuroimaging, Royal Netherlands Acad. for Arts and Sci., Amsterdam, Netherlands; [3]Dept. of Otorhinolaryngology, Head and Neck Surgery, Lausanne Univ. Hosp., Lausanne, Switzerland; [4]Dept. of Clin. Neurosciences, Lausanne Univ. Hosp., Lausanne, Switzerland; [5]Dept. of Radiology and Med. Informatics, Univ. of Geneva, Geneva, Switzerland

Abstract: Intro
Tinnitus is the chronic perception of ringing or other phantom sounds. Some tinnitus patients additionally suffer from loudness hyperacusis. We used audiogram measurement and fMRI data of auditory activity for detecting hyperacusis patients using partial least square correlation method.
Method
We recruited ten patients with unilateral hearing loss and tinnitus, among which five also have loudness hyperacusis. For every patient, the audiogram was acquired by measuring the audible thresholds for 9 frequency presentations in the range 125Hz-8kHz. The fMRI data was recorded on a 7T MRI. The experimental paradigm was according to the tonotopic mapping experiment by (Dacosta et al., 2011) which consists in presenting a sequence of 15 pure frequency tones in 14 cycles (88Hz- 11340Hz). Voxels from the auditory cortex are then extracted and then amplitudes of voxels with the similar preferred frequency are averaged resulting into 15 fMRI features/subject. We then use partial least-squares correlation (Kirshnan et al, 2011) to establish the link between the audiogram measures and the fMRI tonotopy responses. We make PLSC model in two different forms to find out which set of these data can discriminate better the other set of data. In the 1st form we take audiogram measurement as the behavioral data and in the 2nd form, the fMRI data is taken as behavioral data. By maximizing correlation in a multivariate way, PLSC identifies a set of latent variables that each contain a saliency vector for the main data and two saliency vectors for the behavioral data (one for each group; i.e., hyperacusis and

non-hyperacusis).
Result
In each form of applying PLSC method, every subject has three features. In form1, the measurements for the three frequency tones (4,6 and 8 kHz) can discriminate fMRI data of the two groups. In form 2 it is just the first fMRI saliency (voxels with the frequency label of 88Hz) that can discriminate the audiogram data of the two groups.
Conclusion
This is the 1st study that clearly establishes a link between audiogram and fMRI tonotopy responses. We see that taking audiogram measurement as behavioral data, its salience reveals the differences between two groups for more measurements than taking fMRI response as behavioral data the reason could be that the functional changes of hyperacusis in respond to different frequency tones in the cortex level is more general than in the ear because of the homeostatic plasticity and lateral inhibition that maintains the overall level of activity. Our
results do not only show that it is possible to detect hyperacusis patients, but it might also open new avenues to study the neural mechanisms that underlie this condition.

Title: Classification of visual stimuli from electrocorticographic recordings using stacked autoencoders

Authors: *S. CANCINO, J. F. DELGADO SAA;
Electrical and Electronics Engin., Univ. Del Norte, BARRANQUILLA, Colombia

Abstract: In this work, we propose a deep-learning-based algorithm for classification of visual stimuli from Electrocorticographic (ECoG) signals. In the experiment performed, a random sequence of grayscale images from houses and faces are presented to 7 subjects, and the electrical potentials from their ventral temporal cortical surface are recorded. The proposed approach makes use of stacked auto-encoders and a soft-max layer to perform classification of the two types of visual stimulation. Our experimental results show the advantages of the proposed method over state of the art techniques based in spectral decomposition, achieving an average accuracy of 97% (+/- 0.02%) across subjects. Contrary to traditional approaches, the

proposed method has the advantage of requiring minimum prior information about which features need to be used. Furthermore, the analysis of the final structure of the network can provide insight about common patterns generated by the brain during the visual stimulation presented to the subjects.

Title: Exploring conductive materials for low-cost EEG phantom devices

Authors: *W. HAIRSTON[1], A. B. YU[2], B. BURKE[2], G. A. SLIPHER[3];
[1]Real World Neuroimaging, [2]Human Res. and Engin. Directorate, [3]Vehicle Technol. Directorate, US Army Res. Lab., Aberdeen Proving Ground, MD

Abstract: Despite electroencephalography (EEG) being commonly used for decades in medicine and as the basis for a myriad of neuroimaging research, the EEG community as a whole has yet to adopt a single device or approach for calibrating and validating EEG data acquisition equipment or related algorithms. While so-called "phantom" devices are used in MRI, CT, PET, and other imaging devices for testing and calibration, to date no such device has been widely adopted for EEG. To be useful, such a device would need to be (1) electrically conductive in a manner roughly analogous to the human head (brain, skull, scalp), (2) consistent and predictable, and (3) relatively cost-effective in order to be accessible across the community. A major challenge to all three of these has been finding a suitable material which can satisfy all of these needs. Here, we discuss exploring the electrical conductive properties of potential materials for use in creating a cost-effective, easily producible EEG phantom. In particular we characterize the conductive properties of ballistic gelatin, which can be easily formed and mixed with additional solutes to change its conductance across the frequency spectrum typically used for electrophysiology, including both the real and imaginary components. Ballistic gelatin samples were formed at a range of concentrations (10-20%) relative to water, and salt (NaCl) was added at up to 10% by mass to improve conductance. A custom U-shaped frame including removable sides of sheet acrylic was fabricated to allow forming of disc-shaped samples with flat contact surfaces. Impedance magnitude and phase angle were collected for the gelatin samples using a network analyzer, and interrogated between 5Hz and 1500Hz using a parallel plate electrode configuration with the gelatin samples sandwiched in the middle. Results support viability and tenability for use as a phantom, with a dramatic (>100x) nonlinear reduction in impedance magnitude with increased NaCl, with a functional maximum around 10% NaCl by mass; beyond this point the material does not consistently solidify. Critically, the response is also non-linear across frequency, similar to biological tissue Significant phase shifts as well as non-linear trends in phase are also observed. The similarity to biological tissue and tunability allows a wide range of scalp conditions to be simulated on a phantom EEG device in an inexpensive and repeatable manner. A remaining challenge however is the limited lifespan of gelatin due to its organic nature. Ongoing work focuses on alternative, stable materials such as carbon nanofibers within elastomeric substrates in order to fabricate devices with greater long-term stability.

Title: Getting ahead of ourselves: Fabricating an inexpensive EEG phantom

Authors: *A. B. YU[1], G. A. SLIPHER[2], W. D. HAIRSTON[3];
[1]Integrated Capability Enhancement Br., [2]Autonomous Systems Div., [3]Real-world Soldier Quantification Br., United States Army Res. Lab., Aberdeen Proving Ground, MD

Abstract: Phantoms are tools for testing and calibrating imaging devices to specific standards over time and across installation sites. Electroencephalography (EEG) is an imaging approach that has excellent temporal resolution but lacks spatial precision due to volume conduction effects. It is also highly susceptible to artifacts in the form of environmental and non-neural electrical noise. Despite their potential usefulness, phantoms do not widely exist for EEG. We describe a simple approach to EEG phantom head fabrication that is inexpensive and easily reproduced across individual laboratories. A three-part mold was designed using a scalp surface extraction from the T1-weighted MRI scan of a volunteer. The mold was 3-D printed and made watertight using silicone-based sealing material. The phantom head was formed within the mold using ballistic gelatin mixed with NaCl serving as an ionic source in aqueous solution. Dipole sources were placed within the phantom head volume using tubular guides and terminated in leads for signal input via function generator. Standard waveforms (sine wave, square wave, colored noise, etc.) can serve as input, or pre-recorded EEG can be played back. This degree of control provides a rare opportunity within EEG to know the ground truth of the source signal. Both the phase angle and impedance vector magnitude were characterized over a range of frequencies relevant to EEG in order to derive the full complex electrical impedance profile for a range of NaCl loadings. Current-voltage phase angle is an important parameter directly influencing localization accuracy that is often neglected. We show that NaCl loading in ballistic gelatin can be used to broadly match the electrical properties of human tissue, including both impedance magnitude and phase angle. Due to its inexpensive and highly reproducible nature this approach has the potential to achieve widespread adoption within the EEG community.

Title: Graph models and recursive feature elimination identify biomarkers of schizophrenia

Authors: *D. MASTROVITO[1], S. HANSON[2], C. HANSON[2];
[1]Rutgers Univ., Newark, NJ; [2]Psychology, Rutgers Unviersity, Newark, NJ

Abstract: Differences in resting-state functional connectivity between schizophrenics and healthy controls have been found across the brain as well as in specific functional networks. We have characterized these differences in brain dynamics associated with schizophrenia by creating graph theoretic models of unconstrained brain activity measured from schizophrenic patient populations. Using standard machine learning algorithms, we are able to classify patients from healthy controls with 99% accuracy. Furthermore, we have evidence that the scale-free properties of the connectivity profiles of these patient populations diverge from those of healthy subjects and of theoretically efficient network configurations. Finally we identify the specific changes in brain organization that underly this disorder, by means of recurrent feature elimination.

Title: Development of a targeted proteomics approach to unravel the molecular etiologies of synaptic pathologies

Authors: *T. W. BRADSHAW[1], A. UEZU[2], E. J. SODERBLOM[3], S. H. SODERLING[4];
[1]Cell Biol. and Neurobio., [2]Cell Biol., [4]Neurobio., [3]Duke Univ., Durham, NC

Abstract: Synapses are the most abundant and distinguishing feature of the brain, providing enormous functional diversity and plasticity to neural circuits. Human genetics has recently unveiled mutations associated with a large number of brain disorders. These mutations are highly prevalent in genes that encode synaptic proteins, leading to the emerging realization that many complex neurodevelopmental and psychiatric disorders are synaptopathies. It is estimated the synapse carries the greatest disease burden of all subcellular structures in the brain. Thus, it is increasingly apparent that novel methods are needed to analyze the molecular alterations of synapses associated with neuronal dysfunction. Here we describe the development of a high-throughput targeted proteomic assay enabling the quantitative analysis of hundreds of synaptic proteins associated with brain disorders from any mouse model. This novel approach is expected to significantly advance our understanding of synaptic abnormalities associated with multiple neurological disorders.

Title: Sophion Analyzer as a tool for biophysical and pharmacological characterization of eight Na_v subtypes evaluated in parallel on Qube

Authors: A. LINDQVIST[1], *P. CHRISTOPHERSEN[2], M. P. G. KORSGAARD[1], H. L. OLSEN[1], L. D. LØJKNER[1], T. BINZER[1];
[1]Sophion A/S, Ballerup, Denmark; [2]Saniona, Ballerup, Denmark

Abstract: Drug discovery on ion channels is a slow and complicated process and demands a high throughput system with high data quality, but also with a flexible design and easy-to-analyze data. Sophion Qube is a next-generation giga-seal automated patch clamp (APC) screening instrument, capable of testing thousands of compounds with a single click on a button.

Data analysis is as important as data acquisition. In HTS the need for powerful analysis with efficient quality filtering is evident in order to handle the vast amount of data generated on an electrophysiological platform.. Qube is capable of testing up to 16 different cell lines or cell clones in one experiment. This can be utilized to test a different panel of cell lines or for selecting the best suited cell clone before embarking on a HTS campaign. The integrated analysis software, Sophion Analyzer, ensures analysis to keep track of all the results and whenever another QChip is assayed the analysis is done with the same set of user defined criteria. Here we demonstrate the power of automated analysis by exploring three types of experiments executed on eight different Nav channel subtypes; 1) TTX sensitivity, 2) IV-relationship for activation and inactivation and 3) pulse train suitable for screening for use dependent sodium channels blockers. For every run Nav1.1, 1.2, 1.3, 1.4, 1.5, 1.6, 1.7 and 1.8 were tested in parallel on a QChip. Recorded ion channel whole-cell currents were automatically analyzed for IV-relationships for activation and inactivation (V½ and Boltzmann fit and time constants) and concentration-dependent drug effects (Hill fit and IC50) were analyzed using the Sophion Analyzer. If preferred, data can by a click be exported and calculated by other programs as Spotfire, Genedata screener or implemented in in-house software. For each subtype, the experiments identified the expected pharmacology for use- and state-dependent drugs as well as biophysical properties. The findings determined the differences between the different subtypes as expected and also that post experiment analysis can be performed with minimum of effort when using integrated, automated analysis software.

Applied Physics and Instrumentation Group, HHMI - Janelia Res. Campus, Ashburn, VA

Abstract: Extracellular recording technologies such as silicon probes provide means to simultaneously record from ever increasing number of neurons, and one of the latest exemplary

advancements is the Neuropixels probe containing hundreds of sites (up to 966) on a single shank. Such large-scale extracellular recordings bring a unique set of computational challenges to assign spikes correctly to individual units. In-vivo experimental conditions such as probe drift can necessitate time-consuming manual curation. To address this bottleneck, we engineered a spike sorting pipeline (JRCLUST) to achieve high accuracy, speed and usability by taking advantage of the latest clustering algorithm and GPU computing. Our analysis pipeline involves an initial automated sorting followed by a manual stage that offers efficient means of verifications and corrections. This algorithm scales linearly to the number of channels by spatially dividing the detected spikes according to their center positions. Event timing is assigned at the peak-amplitude site for each spiking event, and low dimensional features are extracted from a fixed-size spatiotemporal window surrounding each event center. Clustering is then performed for the spikes centered at each sites, and including spikes from adjacent sites for spatial merging. We employed a recently developed method of clustering by "fast search and find of density peaks" [Rodriguez and Laio, 2014] that can deal with non-Gaussian cluster shapes often-observed in real recordings. Although this algorithm scales quadratically to the number of spikes due to pairwise distance calculation, we perform this in GPU by running massively parallel threads to minimized its relative impact on the total run-time (~10 min. to sort 83 min. 120-channel recording containing 4.7M spikes). We quantified accuracy of our automated and manual sorting using three types ground-truth datasets obtained from manual-curation [Steinmetz et al, 2016], paired-juxtacellular recordings [Neto et al, 2016] and biophysical simulations [Mitelut et al, 2015]. Our automated sorting achieved 85-95% accuracy in terms of the percentage of correctly assigned spikes depending on the signal-to-noise ratio, spike amplitude and firing rate. The sorting accuracy further improved after efficient manual corrections guided by an intuitive graphic user interface and semi-automated merging and splitting. A probe drift compensation step also significantly improved the clustering performance for the datasets with noticeable drifts. We conclude that JRCLUST offers an accurate and fast means to sort spikes from large-scale extracellular recordings containing hundreds of channels.

Title: The methodology of developing interleaved transcranial magnetic stimulation (TMS) with functional magnetic resonance imaging (fMRI) at UBC

Authors: ***R. GE**[1], A. DIPINTO[1], L. BARLOW[1], E. MACMILLAN[1], A. MACKAY[1], M. ALFONSO[2], F. VILA-RODRGUEZ[1];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]PLC Electronic Solutions Ltd., Vancouver, BC, Canada

Abstract: Transcranial Magnetic Stimulation (TMS) is a non-invasive neurostimulation tool, and in combination with fMRI, we can assess cortical excitability while monitoring intra-cerebral functional connectivity. Through new techniques we can apply these tools simultaneously (interleaved). The present study aimed to develop a TMS/fMRI system at UBC for applying the technique to clinical populations, to gain insight into the underlying mechanisms of the neural response to TMS treatment.
Phase one aimed to implement a standardized setup for interleaved TMS/fMRI at UBC with strategic placement of: MR-compatible TMS coil, high current filter box, and TMS stimulator outside of the MR room. Custom-written software (controlled by the trigger signals from the scanner) was used for interleaving the TMS pulse with the echo planar imaging (EPI) acquisition, thus preventing the TMS pulses interfering with the EPI images.Phase two was acquiring measurements to determine image quality. Using the fBIRN phantom, we determined if the EPI data quality was being affected by the interleaved TMS pulses by measuring with the TMS coil off, and the following stimulation intensities: 0%, 30%, and 90%.
To check for static signal dropout, the following measures were: 1) Signal to Fluctuation Noise Ratio (SFNR), 2) Temporal Fluctuation Noise Images (TFNI), 3) Signal to Noise Ratio (SNR) summary value. For possible dynamic artefacts, we selected the first volume as a benchmark and computed the percent signal change rate (SCR) of the consecutive volumes relative to the benchmark.Phase one was successfully completed. For phase two, 1) the SFNR calculations showed that the EPI data's temporal stability was not affected by the stimulation; 2) TFNI showed that the stimulation conditions with 30% and 90% intensity are very similar to that of free-stimulation condition, and 3) SNR summary value decreased with stimulation intensity increased. However, there was a static signal dropout observed due to the coil being inside the scanner. For possible dynamic artefacts, SCR values showed that although consecutive volumes showed fluctuations relative to the benchmark, these fluctuations were sufficiently small, which indicated that there were no significant dynamic artefacts produced by the stimulation.
With the foundation of interleaved TMS/fMRI completed, future testing experiments will determine whether the system could be applied to human participants safely and noise-freely.

Title: DeepNeuron: applying convolutional networks as a web service for neuroscientists

Authors: J. WU, 08540[1], I. TARTAVULL[1], *H. SEUNG[2];
[1]Princeton Neurosci. Institite, Princeton Univ., Princeton, NJ; [2]Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ

Abstract: Convolutional networks (ConvNets) have become a popular technique for diverse computer vision tasks like object recognition and image segmentation. ConvNets are being applied to brain images generated by MRI and microscopy. Training often involves datasets of limited size, due to the requirement of ground truth obtained via human annotation. After training, a ConvNet may be applied to extremely large datasets. Here, we report a web service that performs this function, called DeepNeuron. Given 3D image stacks and the ConvNet architecture and parameters as inputs; the service returns the ConvNet output. Computations are performed by Amazon Web Service (AWS) EC2 instances, which can scale with the amount of data elastically. A dataset that is too large to be processed in the RAM available to a single EC2 instance is divided into chunks, each of which is processed on a separate instance. We have tested DeepNeuron to process over 7 billion voxels in 3 days using 5 AWS instances. We illustrate DeepNeuron by applying it to the segmentation of serial section electron microscopy image stacks.

Title: Hierarchical general-linear modeling of EEG data in EEGLAB and LIMO extension

Authors: *R. MARTINEZ-CANCINO[1], S. MAKEIG[1], C. PERNET[2], A. DELORME[1]; [1]Swartz Ctr. for Computat. Neurosciences, La Jolla, CA; [2]Div. of Clin. Neurosciences, Univ. of Edinburgh. Brain Res. Imaging Ctr., Edinburgh, United Kingdom

Abstract: Here we present results of integrating into EEGLAB (sccn.ucsd.edu/eeglab) functionality for computing general linear model (GLM) statistics leveraging functionality in the LIMO EEG Toolbox (Pernet et al., 2011), and validating their efficacy using a publicly available data set (Wakeman and Henson, 2015). In the near future, statistical analysis based on hierarchical general linear models (within subjects, between subjects) will be the default approach supported by EEGLAB. In this approach, model parameters are estimated for any selected data measures (ERP, ERSP, power spectra, etc.) independently at each time (or time/frequency) point for each subject and each source process (or other spatial channel combination). Parameters estimated in these first-level (within-subject) analyses are then integrated across subjects into a second-level GLM, similar to the approach used to analyze fMRI data. Analysis of data following decomposition into independent component source processes (or other decomposition) is supported. To effect this integration and the consequent extension of statistical analysis available in EEGLAB, we have developed functions to define and test statistical contrasts, to visualize their results, and to interact with the user via intuitive graphic user interfaces (GUIs). EEGLAB internal data and file structures have been modified to improve computation speed while bearing the burden of increased data storage required for more complete single trial-based data analysis. Existing EEGLAB statistical analysis methods will also continue to be supported. Here we validate the results of the new development using a publicly available EEG data set by qualitatively comparing the results to those returned by the existing EEGLAB statistical analysis. The integration into EEGLAB of hierarchical GLM statistics will allow users to process data collected in more complex statistical designs and to report more robust results.

Abstract: Epilepsy is a neurological alteration characterized by the recurrent appearance of spontaneous seizures due to neuronal hyperactivity in the brain. Approximately 10% of the general population experience at least one seizure during their lifetime and 1% have epilepsy. [1-2-3]. There are different techniques to identify active substances that are present before, during and after a seizure. HPLC is the preferred method for quantification of biologically compounds concentrations, both in normal and pathological conditions. However, these techniques require a long time and a high level of complexity. Here we describe an alternative method to measure of biologically active compounds. [1-2-3]. Raman spectroscopy is an established and increasingly utilized technique for the rapid and effective discrimination among various compounds. Epilepsy is a brain dysfunction syndrome, recurrent character which is characterized by sustained abnormal synchronous group of brain neurons discharge. Typically epilepsy originates in neural networks under normal synchronous oscillations generate local or long distance. It is also considered that the seizure activity is the result of an imbalance between the excitatory activity which leads to neuron depolarization by increased neurotransmitter Glu, and inhibitory hyperpolarization generated due to a decrease of γ-aminobutyric acid (GABA) (4-5-6). The pathogenesis of epilepsy is associated with abnormal stimulation occurring in a certain region of the brain, causing depolarization of the membrane and which expands to the surrounding cells. Characteristic electroencephalographic (EEG) Epilepsy is the interictal spike-wave discharge which reflects abnormal depolarization events and membrane hyperpolarization, which occur synchronously in many neurons of the epileptogenic region; EEG spike is formed by the sum of paroxysmal depolarization, while the slow wave is formed by the sum of potential inhibitors (7).Microdialysis coupled to HPLC is the preferred method for quantification of neurotransmitter concentrations, both in normal and pathological conditions. However, these techniques require a long time and a high level of complexity Raman spectroscopy is a spectroscopic technique based on inelastic scattering of monochromatic light, usually from a laser source. Inelastic scattering means that the frequency of photons in absorbed by the sample and then reemitted. Frequency of the reemitted photons is shifted up or down in comparison with original monochromatic frequency, which is called the Raman effect.

Title: Advanced perception threshold estimation using neurophysiological and behavioral parameters

Authors: *A. SCHILLING, P. KRAUß, K. TZIRIDIS, H. SCHULZE;
Exptl. Otolaryngology, Erlangen Univ. Hosp., Erlangen, Germany

Abstract: We present a novel, robust and precise method to universally estimate behavioral or physiological thresholds using the example of measurements of acoustic brainstem responses (ABR) and acoustic startle responses (ASR). By definition the threshold defines the smallest possible stimulus strength that evokes a response significantly different from that one of the non-stimulus condition. It is common practice that for estimating thresholds measurements of physiological or behavioral responses to stimulus intensities that are close to the putative threshold are carried out. Unfortunately, the signal-to-noise ratio (S/N) naturally is worst near the threshold, since the intensities of evoked responses are positively correlated with stimulus strength.
Virtually all psychometric and physiological stimulus-response functions resemble sigmoid functions like the logistic function. Here we demonstrate that thresholds may be estimated without any near threshold measurements if data are fitted to a generalized logistic function and an additive term representing the measured response intensity to the non-stimulus condition is added. We demonstrate that the goodness of fit becomes best if the supporting points are located within the area of the logistic function with the highest gradients, also referred to as its dynamic range, i.e. in a range with good S/N. To become independent from the number of measurement repetitions and the absolute noise level we perform stepwise subsampling with increasing sample-size followed by extrapolation and estimation of the asymptote. This method is highly robust against outliers which we proof using bootstrapping of sample data.
We validate our method using extensive numerical simulations and a broad variety of different experimental data. We conclude that our new approach will be beneficial for all purposes aiming to estimate a threshold based on physiological or behavioral parameters.

Abstract: NES (http://neuromat.numec.prp.usp.br/nes) is a web-based system that provides neuroscience experiments data and metadata record facilities in a secure and user-friendly platform. It was designed to provide a single repository for the experimental data of an entire research laboratory, group, or project. NES is a free software tool, developed using open technologies and tools that can be easily installed and used in any research laboratory. Its modular structure and web interface provide an intuitive use of its data management functionalities. NES was developed to combine experimental data with its provenance information. Examples of provenance information maintained by NES are: information about scientists responsible for experiments and data collection; details about recording protocols or behavioral data collection; details of the experimental protocols used in primary data collection; date and time of data collection start and end; experiment aim; conditions to which experimental subject groups were submitted; laboratory where data was collected; and publications or other results which resulted from the study. The system also allows recording of additional data for experimental volunteers, such as information on clinical history and socio-demographic data. NES requires the experimenter to record in detail each step involved in the experimental protocol before storing collected primary data. The experimental protocol is described as a workflow, which can contain both sequential and parallel steps. NES uses a standardized data model in neuroscience, enabling interoperability with other initiatives for data representation standardization. In its current version, NES is able to manage several types of electrophysiological data and metadata used by the neuroscience community, and the neuroimaging module is under development. NES is an initiative of the Research, Innovation and Dissemination Center for Neuromathematics (NeuroMat), hosted at University of São Paulo, Brazil. It is licensed under Mozilla Public License version 2.0 and its source code and documentation are available at https://github.com/neuromat/nes. One of the goals of NeuroMat is

to establish in Brazil a leading research group in Neuroinformatics, specialized in experimental data curation. With the development of free software tools such as NES, we want to encourage and support the collection of high-quality data and metadata and the creation of more open databases in neuroscience.

Title: The real-time experiment interface: a hard real-time closed-loop data acquisition system with sub-millisecond latencies.

Authors: *A. GEORGE[1], Y. PATEL[2], F. ORTEGA[1], D. CHRISTINI[1], A. DORVAL[3], R. BUTERA[2], J. WHITE[4];
[1]Weill Cornell Med. Col., New York, NY; [2]Georgia Inst. of Technol., Atlanta, GA; [3]The Univ. of Utah, Salt Lake City, UT; [4]Boston Univ., Boston, MA

Abstract: To understand causal interactions between neural activity and function, both need to be monitored at the sub-millisecond scale. This requires closed-loop, hard real-time technologies that are capable of controlling stimulation (optogenetic, electrical, thermal, etc.) dependent upon some functional measure (behavior, motor action, etc.) within a deterministic period. While monitoring neural activity at precise time scales is commonplace, there is an important unmet need in a cost-effective sub-millisecond closed-loop real-time framework capable of interacting with neural activity and function. To meet that need, we have developed the Real-Time eXperiment Interface (RTXI) - a versatile interface that enables deterministic closed-loop monitoring, stimulation, and control of single-cell, network, animal, and human electrophysiology experiments.
RTXI is a free and open source platform based on real-time Linux. It runs on standard desktops and contains a built-in driver that uses National Instruments cards for data asquisition. At its core is a plugin framework where users load modules designed to run specific protocols in real-time. RTXI has a set of built-in modules, such as a high-speed oscilloscope, signal generator, and common filters, and it boasts a large library of user-made modules designed to run custom

closed-loop protocols tailored for their experiments. The framework, along with the open-source license, enables users to share resources freely and openly, and it also maximizes reproducibility of experimental setups and results. RTXI is benchmarked to provide deterministic, hard real-time performance for up to 32 16-bit I/O channels and worst-case jitter less than 5 microseconds, and it is currently used in over 65 labs around the world. Addtional information is available on our website (http://rtxi.org), and all source code is available on GitHub (https://github.com/RTXI).

Title: A new method to analyze the synaptic connection between interneuron and pyramidal neuron in 3D mice brain

Authors: *Q. XIA[1], W. CAO[1], Y. DU[1], S. LIN[1], Q. YANG[1], J. LUO[1], J. XU[1], J. XIA[2]; [1]Sch. of Basic Med. Sci., Zhejiang Univ., Zhejiang, China; [2]The Hong Kong Univ. of Sci. and Technol., Hong Kong, Hong Kong

Abstract: Although microscopy offers a method to present the number, location and the chemical nature of synapse in cultured neurons, and gives a way to visualize the spatial information of specific targets in a brain slice, a new method accompanied with microscopy is still in need to accurately analyze the synaptic connections occur in between different neurons of tissue sections in a 3D-way. Here we present a method for quantifying the number, intensity and size of neuronal synapse in the 3D mouse brain sections. We used specific synaptic markers and genetically engineered mice to specifically localize the synapses in inhibitory or excitatory neurons, and analyzed with the Imaris software. Here we show that we are able to analyze the synapses between different neurons as 3D objects from brain section slice which is comparable to the electrophysiological recordings. We also used this method to examine the synapses between interneurons and pyramidal neurons in an autism model mouse, the Neuroligin-3 R451C knock-in mouse, and observed the synaptic formation abnormalities in a 3D-manner. With this method, we can get a better understanding about morphology and anatomy of neurons, which may provide more evidence to the formation, maturation and the activity of synapse *in vivo*.

Title: LabStreamingLayer: a general multi-modal data capture framework

Authors: ***D. E. MEDINE**[1], C. KOTHE[2], M. GRIVICH[3], S. MAKEIG[4];
[1]Swartz Ctr. for Computat. Neurosci., Univ. of California San Diego, La Jolla, CA; [2]Qusp, La Jolla, CA; [3]Nerobehavioral Systems, Berkeley, CA; [4]Swartz Ctr. for Computat. Neurosci., UC San Diego, La Jolla, CA

Abstract: We present the Lab Streaming Layer (LSL) software framework (*github.com/sccn/labstreaminglayer/)*. LSL is a system for the synchronized collection of measurement time series in research experiments. It handles both networking and time synchronization, and allows near-real-time access and centralized control of data collection, data reviewing, and data recording functions. LSL consists of a general and cross-platform transport library (*liblsl*) with several language interfaces (C, C++, Python, Java, C#, MATLAB) as well as a constellation of data acquisition applications built on top of the library that can stream data from a wide range of hardware and software devices attached to a local computer network. LSL data streams can be written to a single (xml based) file for offline analysis. The native file format is XDF (*github.com/sccn/xdf/)*. LSL was written by Christian Köthe at the Swartz Center for Computational Neuroscience, UCSD (*sccn.ucsd.edu*), and is already in wide use to collect and record experimental data from multi-modal EEG experiments. LSL is free, open source software and as such can be modified and improved by anyone. Furthermore, LSL has been incorporated into software suites and development kits of several commercial research tools and EEG hardware devices. The LSL framework offers a solution to the problem of synchronizing multiple data streams collected via devices having different hardware clocks without the need to introduce external triggering signals (although those can also be incorporated into any LSL-based experimental setup). Testing experiments have shown that LSL is capable achieving sub-millisecond synchronization accuracy between different data streams, provided the throughput

latency and jitter of the hardware devices are known. These can be learned by simple experiments using the LSL framework itself as a test bed.

Title: Total conductive flux analysis provides fast and physiologically relevant quantification of amyloid pore toxicity in bilayer recordings

Authors: *A. L. GILLMAN[1], J. PHANEUF[3], J. LEE[1,2], R. LAL[1,2];
[1]Bioengineering, [2]Materials Sci. and Engin. Program, Mechanical and Aerospace Engin., UCSD, La Jolla, CA; [3]Electrical & Computer Engin., Worcester Polytechnic Inst., Worcester, MA

Abstract: Ion channels are membrane protein complexes essential to signaling and communication between cells of living systems. The dysfunction of ion channels has been widely studied and directly related to the pathology and cell death in many disorders, including Alzheimer's disease (AD). The amyloid channel hypothesis of AD theorizes that amyloid β (Aβ) peptides induce ionic leakage of Na^+, K^+, and Ca^{2+}, disrupting membrane potential and cellular homeostasis leading to cell death. Electrophysiological studies of amyloid poration in membranes are typically conducted in model lipid bilayer systems. Unfortunately, traditional analysis of membrane channels is unsuitable for Aβ, and other amyloid peptides. This is due to the variable nature of amyloid activity which introduces challenges for their analysis. Investigation of amyloid toxicity has suffered from the lack of a quantitative analysis tool and technique that directly links changes in ionic conductance to cytotoxicity and provides a benchmark for comparison between peptide species. No current commercial software program is capable of properly analyzing the channel activity of heterogeneous peptides, such as amyloids. While qualitative conclusions can be drawn by observing the traces, without unitary conductance, quantitative assessment is time consuming, labor intensive, and speculative, at best. Comparison of amyloid pore activity is most often accomplished via histograms of the single channel conductance for the ensemble, which could erroneously bias histogram analysis toward prevalent, but short lived, pores that may not hold significance to dysregulation of cellular ionic balance. Instead, we propose that the total ionic flux through the bilayer is the key parameter that should be analyzed with respect to cytotoxicity. To address this issue, we have developed a custom Python analysis program that allows for more accurate understanding of the

characteristics and behavior of amyloid channels. As proof of principle for the program, we analyze our previously published data on pyroglutamate-modified amyloid-β ($A\beta_{pE3-42}$) toxicity. Analysis time was reduced by >90% while demonstrating that $A\beta_{pE3-42}$ exhibits more sustained, less transient, activity and causes cytotoxicity faster than full length $A\beta_{1-42}$. While statistically meaningful bilayer analysis will require many more recording experiments than were previously possible, emerging high throughput technologies provide the means to reach this goal. Proper understanding of amyloid toxicity through this analysis will improve diagnosis, therapeutic development, and ultimately the prevention of amyloid channel diseases and disorders.

Title: Quantification of immunohistochemistry on adjacent sections comparing fluorescent and dab markers

Authors: *J. BAUN, C. ZURHELLEN, T. YORK, B. TIPTON, R. C. SWITZER, III; Neurosci. Associates Inc, Knoxville, TN

Abstract: The location of antibody binding sites in brain tissue sections is commonly detected with fluorescent markers or with colored reaction products such as diaminobenzidine. We sought to answer the question: do both types of detection schemes reveal the antibody binding sites to the same extent as judged by density of staining?
Adjacent sections of tissue were stained with several antibodies including GFAP for astrocytes and Iba1 for microglia from rat brains that were unilaterally rendered ischemic by middle cerebral artery occlusion. Sets of adjacent sections were immunohistochemically stained free floating using standard IHC methods. For one set the antibody binding site was detected using a secondary antibody conjugated with a fluorescent molecule. The second set was stained using the sequence of a secondary antibody conjugated with a biotin molecule, followed by an avidin-HRP complex and then reacting with diaminobenzidine and H_2O_2.
Two areas of interest were digitally captured for each detection scheme/stain: an ischemic area in one hemisphere and an unaffected area in the other hemisphere. The same region of interest for each stain was analyzed on adjacent sections to rule out any random differences in brain areas. Images of both the DAB and fluorescent stains were converted to 8-bit grayscale. The grayscale images of DAB stained tissue were modified to a pseudo-green (fluorescence-like) state by

applying the LUT tool in FIJI. Densitometry was performed to determine any differences between the true fluorescent and pseudo-fluorescent images. The percent area in both the ischemic and normal areas of interest were analyzed.
There were dramatic differences observed between the two staining methods. In both the GFAP and Iba1 stains there were obvious variations in staining intensity in both the affected and normal brain regions. This is not surprising because there is considerably greater amplification of the antibody presence using the DAB multiple stage sequence vs. the 'single' stage fluorophore-secondary antibody sequence. Nonetheless, the degree of hypertrophied astrocytes seen with the fluorescent method is meager compared to the image using the DAB sequence.
Antibody staining using fluorophores is required in some applications, for instance if colocalization in the same structure (e.g. cytoplasm) is expected. For reaction products where colocalization is not expected DAB detection seems to be more sensitive and has the added benefit of not being susceptible to signal loss or fading over time.

Abstract: Thanks to high-throughput and high-resolution imaging technologies such as Knife-Edge Scanning Microscopy (KESM), it is possible to acquire three-dimensional neuronal morphology and microvascular system of whole mouse brains at sub-micrometer resolution. To facilitate group efforts from research communities it is imperative to efficiently share the teravoxel volumes. Yet, due to the immense size of the data sets, sharing and managing them have been a big challenge. There have been efforts to address the issue. Vaa3D-TeraFly can

visualize terabyte-sized volumetric images on common laptops and graphic hardware. But this open-source plug-in can be used only for local data sets. The KESM Brain Atlas (KESMBA) visualizes and analyzes neuronal circuits and vascular networks enabling pseudo 3D visualization through stacking semitransparent image slices. But the KESMBA is far from real-time, not real 3D, and the maximum overlay is only 30 layers.We propose a Web-based and real-time (subsecond) 3D visualization framework for teravoxel volumes. The 3D visualization is completely Web-based so that it is independent of the underlying operating system. The image processing pipelines are as follows. A raw data set of 2D images is in the form of stacks and columns. As a preprocessing step, the tissue area from each of the raw images is automatically cropped and saved. From each of the cropped images, noise is removed and image intensity is normalized. Then the images from across columns are stitched in an image sheet. This process repeats for all images. The dimension of the final volume is about 10K^3. As the next step, multiple resolutions for the stack of the stitched images are generated. From the several different resolutions, unit volumes (256^3) are created. The total number of unit volumes are about 75K. Isosurfaces of each of the unit volumes are found using the Marching Cube algorithm and are saved into a 3D mesh STL file. The result of the image processing pipelines is a set of multi-resolution unit volume meshes. A web application manages visualization and interactions with the 3D models along with selections of region-of-interest and zoom in/out levels.The image pipelines were written in C++ with ITK and VTK along with Qt. We utilized the X toolkit; a lightweight web toolkit for scientific visualization.We expect the proposed Web-based and real-time 3D visualization framework to enhance accessibility of teravoxel volumes and help research communities to use the data sets.

Title: Multiple statistical comparisons. Is it really a problem?

Authors: *V. L. TSIBULSKY;
Pharmacol., Univ. Cincinnati, Cincinnati, OH

Abstract: Every *Statistics* textbook strongly suggests not running multiple statistical tests for significance of the difference between groups. Herein, the validity of this statement is reviewed. Let's assume that we sample from a large pool of a normally distributed parameter. The difference between two groups is then estimated by a t-test. What is the probability finding a *P*-value less than 0.05 or higher than 0.95, for example? Statistical models tell us that both probabilities are equal because the *P* distribution function is flat between 0 and 1. It suggests that *any* result of a single significance test will be insufficient to help us to make a decision about rejecting the null hypothesis because the probability of finding *any P*-value is approximately equal. There are two solutions to this problem. The first one is, contrary to all textbooks, repeating the experiment two or more times. Obtaining $P < 0.05$ again should strongly suggest that sampling was not from the same pool. However, in many cases we cannot repeat the experiment under the same conditions. The second solution is based on using the effect size. There are different approaches to measure the effect size. The idea could be illustrated using ξ (ksi) estimate as a measure of the effect size: $\xi = n^{0.5}\theta/\sigma$ where n = number of observations, θ = difference between means, σ = standard deviation. If we are to measure the probability of finding $P < 0.05$ as a function of ξ we should see that the probability density function is a sigmoid curve. At low $\xi < 1.6$ the probability of a significant difference between groups is very low and grows to 0.2. At $\xi \approx 2.8$, the probability to find $P < 0.05$ after single t-test is about 50%. Then at high $\xi > 4.0$ the probability of a significant difference grows from 0.8 to 1. It could be advisable to repeat the experiment if the effect size is $1.6 < \xi < 4.0$. There is no need to repeat the experiment if $\xi < 1.6$ because the probability of finding $P < 0.05$ again is below 20%. In contrast, there is no need to repeat the experiment if $\xi < 1.6$ because the probability of finding $P < 0.05$ again is above 80% meaning that the effect is highly significant. These ideas are illustrated with statistical analysis of effects of a monoclonal cocaine antibody on the rate of cocaine self-administration in rats. The antibody effect is the strongest on the day of injection. Then it gradually disappears along with the degradation of antibody with a half-life of 5 - 7 days. Multiple t-tests are unavoidable, but still everyday comparison between control and experimental groups is unique because every day the sampling is from different pools. Estimation of the effects size ξ allows determination on what day after antibody injection the effect becomes insignificant.

Title: Automated functional analysis of astrocytes from chronic time-lapse calcium imaging data

Authors: *G. YU[1], Y. WANG[1], G. SHI[2], D. J. MILLER[3], Y. WANG[1], G. BROUSSARD[2], Y. WANG[1], L. TIAN[2];

Abstract: The interest in analyzing astrocyte functional status is greatly evoked by recent discoveries that astrocytes exert proactive regulatory effect on neural information processing and are deeply involved in normal development and disease pathology. The functional analysis is further facilitated by technical advances in modern microscopy and chronic ultra-sensitive genetically encoded Ca^{2+} indicators. However, there is a big gap between the capability of generating huge amount of data and the availability of sophisticated analytical approaches. The current practice relies on eyeballing the time-lapse imaging data and manually picking up regions of interest, which not only limits the analysis throughput but also is at risk of introducing bias and missing important information encoded in the big complex dynamic data. Here, we report a suite of algorithms, called *Functional AStrocyte Phenotyping* (FASP), to automatically analyze and characterize the functional status of astrocytes. Aiming at the complex nature of Ca^{2+} signaling and low signal to noise ratio, FASP is designed to be data-driven and probabilistically principled, to flexibly account for complex patterns and accurately control false discovery rates. We demonstrate the effectiveness of FASP on both synthetic and real data sets. A user-friendly plugin for ImageJ and Fiji was developed and tested. The plugin and its source code are freely available on the internet.

Title: New Data Science tools for analyzing neural data and computational models

Authors: *E. M. MEYERS[1], M. DEAN[2], G. HALE[3];
[1]Brain & Cognitive Sci., [2]Hampshire Col., Amherst, MA; [3]MIT, Cambridge, MA

Abstract: As the amount of data collected by neuroscientists continues to increase (Stevenson et al, 2011), new tools are needed to turn this data into insights into about the algorithms that underlie complex behavior (Brown et al, 2004). Here we present our latest research on computational tools we have developed at Hampshire College and at the Center for Brains, Minds and Machines at MIT. In particular, we describe new tools for neural population decoding including a graphical user interface to the Neural Decoding Toolbox (Meyers 2013), methods for analyzing single neurons, and ongoing work on a parallelized population decoding framework that uses R and Apache Spark™ to greatly increase the speed of population decoding. We also discuss CBaaS, which is a distributed platform that allows one to evaluate the effectiveness of different computational models (such as different versions of deep neural networks). These tools will allow researchers to gain deeper insights from the data they collect, and to better assess whether computational models are acting in similar ways to biological systems.

Abstract: The Cortical Activity Map (CAM) project is a survey of neural activities in different retinotopically mapped areas of visual cortex, cortical layers, and Cre lines during visual stimulation in behaving young adult laboratory mice. It will provide a resource for understanding how the sensory information is processed through the cortical visual pathway at both the single-cell and population levels. The project collects multiple data streams, including intrinsic signal imaging (ISI) data sequence and two photon time-series of neuron responses. A data processing pipeline involving multiple interconnected modules was built to process these data streams. To visualize functional areas and guide the measurement of neuron responses to a targeted retinotopic location, each intrinsic signal imaging (ISI) experiment data was processed to

generate a sign map. The functional areas in the sign map were then automatically segmented and annotated. Each two-photon time-series of neuron responses was processed in multiple steps. First, to remove the fluorescence leakage between nearby pixels in the two-photon time-series, a regularized Wiener deconvolution method was applied by taking the spatially non-uniform leakage into consideration. A motion correction step based on iterative phase correlation algorithm was then applied to reduce the artifactual fluorescence changes that could contaminate actual cell response analysis. After that, fluorescence from individual cells that fire at different intervals in the two-photon time-series were detected using adaptive morphological operations and classification techniques. These segmented cells define the ROIs. To correct for contamination of the ROI calcium traces by surrounding neuropil, a gradient descent method was used to estimate the contamination ratio and true ROI fluorescence signal in a linear model. Mean fluorescence traces were then extracted from ROIs after subtracting signal from the surrounding neuropil. After that a normalized DF/F trace was computed using a sliding windowed low-passed mode operation. A variety of tuning metrics based on evoked and spontaneous activity of individual ROIs was computed for static and drifting gratings and natural scene stimuli. To find the same cells across different optical physiological experiments, an automated registration and cell mapping module was developed. All data was registered to the ALLEN Mouse Brain Common Coordinate Framework (CCF) in order to integrate CAM data with all other Allen Brain Atlas resources. Data product, API, as well as SDK are made publicly available for the global brain research community.

Title: Enabling large scale analysis of calcium imaging data on standalone machines

Authors: *A. GIOVANNUCCI, E. A. PNEVMATIKAKIS;
SCDA, Simons Fndn., New York, NY

Abstract: Calcium imaging methods continue to gain traction among experimental neuroscientists because of their capability to monitor in vivo large population of neurons across weeks with centisecond time and single neuron resolution. Advances in genetically encoded calcium indicators and microscopy techniques facilitate imaging larger brain areas with finer time resolution, producing an ever increasing amount of data. We estimate that a standard two photon rig equipped with resonant scanners today can produce data at a rate of 2 TB per week (40 hrs/week), a number that is even higher for alternative imaging techniques (e.g., one photon and lightsheet imaging, or voltage imaging). This sheer amount of data poses significant challenges in terms of both handling and processing. While large scale solutions for these problems are available[1], their use typically requires dedicated or shared computing clusters, thus hindering their diffusion to the average user.

Here we present a suite of open source tools developed in MATLAB® and Python for the analysis of large scale calcium imaging datasets. Our focus has been threefold: First, apply state of the art methods to the universal pre-processing problems (motion artifact correction, source separation/segmentation[2] of overlapping fluorescence signals, and neural activity deconvolution[2]), in an optimized and automated way that requires minimal user intervention. Second, enable processing of large scale datasets on a single multi-core machine by employing parallelization, memory mapping, and downsampling[3] techniques, that harness the computational resources of standalone machines. Third, equip the user with visualization and interactive processing capabilities for reviewing and modifying (if necessary) the results of the analysis.

We demonstrate the usage of our suite on a wide variety of datasets, with sizes that are comparable or even exceed the amount of available memory, including parietal and visual cortices, hippocampus and cerebellum. Even though the focus has been the analysis on a standalone machine, we note that our software can be readily employed in high performance computing clusters, thus enabling the analysis of even larger datasets.

Title: Bigneuron toolbox for neuron image acquisition, visualization, annotation, reconstruction, analysis, retrieval, and sharing

Authors: *H. PENG[1], Z. ZHOU[1], X. LIU[1], B. LONG[1], H. CHEN[1], Y. LI[1], Y. WAN[2], A. BRIA[3], T. BIGNEURON CONSORTIUM[4];
[1]Allen Inst. For Brain Sci., Seattle, WA; [2]Janelia Res. Campus, Ashburn, VA; [3]Univ. of Cassino, Rome, Italy; [4]Allen Inst., Seattle, WA

Abstract: Digitization of neuron structures is arguably one of the most important steps in current neuroscience studies. How to perform image acquisition of neurons and their connections effectively? How to manage the many different types and vast amount of neuron image data? How to visualize them and compare the neuron structures quantitatively? How to analyze such data comprehensively? How to search the data and how to share with colleagues? All these have become substantial, although technical, challenges that neuroscientists must have good tools so that they could focus on understanding the biology. The BigNeuron project (Peng, Hawrylycz et al. Neuron, 2015, DOI: 10.1016/j.neuron.2015.06.036; Peng, Meijering et al. NeuroInformatics, 2015, DOI: 10.1007/s12021-015-9270-9) is a global effort to standardize the interfaces of neuron tools and neuron image data, and to provide a common platform to facilitate fair, high-throughput bench testing of various neuron reconstruction methods. We have established a Vaa3D (http://vaa3d.org) based Open Source platform for Neuron Image Acquisition, Visualization, Annotation, Reconstruction, Analysis, Retrieval, and Sharing. Currently, the released suite of BigNeuron Toolbox consists of over 130 plugin tools developed by worldwide contributors. We will highlight in this presentation some of the killer applications of the BigNeuron Toolbox, such as how to develop a SmartMicroscope to efficiently acquire sparsely labeled neurons without imaging the background areas, how to freely surf the terabyte of neuron images in three-dimensions freely, how to edit a complicated neuron structure with tens of thousands of compartments quickly, how to blast-search databases with tens of thousands neuron reconstructions, how to visualize hundreds of neurons simultaneously, and even run analysis with them, and how to share and reuse the data with users with cloud-services.

Title: Oculomatic: high speed, reliable, and accurate open-source eye tracking for humans and non-human primates

Authors: Y. VAZQUEZ, J. ZIMMERMANN, P. W. GLIMCHER, B. PESARAN, *K. LOUIE; Ctr. Neural Sci., New York Univ., New York, NY

Abstract: Video-based noninvasive eye trackers are an extremely useful tool for many areas of research. Many open-source eye trackers are available but current open-source systems are not designed to track eye movements with the temporal resolution required to investigate the mechanisms of oculomotor behavior. Commercial systems are available but employ closed source hardware and software and are relatively expensive therefore limiting wide-spread use. Here we present Oculomatic, an open-source software and modular hardware solution to eye tracking for use in humans and non-human primates. Our fully modular hardware implementation relies on machine vision USB3 camera systems paired with affordable lens options from the surveillance sector. Our cross platform software implementation (C++) relies on openFrameworks as well as openCV and uses binary image statistics (following Green's theorem) to compute pupil location and diameter. Oculomatic makes use of data acquisition devices to output eye position as calibrated analog voltages for direct integration into the electrophysiological acquisition chain. Oculomatic features high temporal resolution (up to 600Hz), real-time eye tracking with high spatial accuracy (< 0.5°), and low system latency (< 1.8ms) at a relatively low-cost (< 1000USD). We tested Oculomatic during regular monkey training and task performance in two independent laboratories and compared Oculomatic performance to existing scleral search-coils. While being fully non-invasive, Oculomatic performed favorably to the gold standard of search-coils with only a slight decrease in spatial accuracy. We propose this system can support a range of research into the properties and neural mechanisms of oculomotor behavior as well as provide an affordable tool to scale non-human primate electrophysiology further.
